The recovery of the volatile constituents of coal. — The attention at present paid to the utilization of products heretofore wasted is well illustrated in an account of the Jameson process of coking coal, given before the London society of arts, April 26. The coking-ovens of England are estimated to have a capacity of some 20,000,000 tons a year; and only a slight and inexpensive alteration in the plant would, it is said, recover oil and ammonia to the value of $16,000,000, and good heating-gas to the value of $12,500,000. From the experiments of Sir J. B. Lawes, it has been estimated, that, if all the ammonia from all the raw coal burned in England were utilized in agriculture, 250,000,000 dollars' worth of bread-stuff would be added to the yearly produce. The use of raw coal is characterized as a relic of barbarism. — (*Iron*, May 4.) R. H. R. [220

GEOLOGY.

Stratified drift in Delaware. — F. D. Chester describes the relations of the gneissic rocks of Delaware, with their rolling, hilly, and local soils, to the unconformably overlying cretaceous clays extending to the south-east, with stratified gravels derived from the gneiss. These gravels and similarly derived deposits extend even over the top of Polly Drummond's hill, the highest land in the state, two hundred and fifty feet above the cretaceous plain, and three hundred and thirty feet above the sea. Large dolerite bowlders of undetermined origin, sometimes twenty-five feet in circumference, lie on this hill; and a little farther south there are two hills of unstratified detritus and bowlders, which are thought to have been dropped from ice floating in the sea, that deposited the stratified gravels during the submergence of the Champlain period. As the highest point in Delaware was then covered, this measure gives a minimum value of three hundred and thirty feet for the submergence. — (*Amer. journ. sc.*, xxv. 1883, 436.) W. M. D. [221

Meteorites.

Concretions in meteoric iron. — Professor J. Lawrence Smith gives a connected statement regarding the concretions found from time to time in the interior of various meteoric irons. Six kinds of simple nodules occur, composed respectively of pyrrhotite (troilite), schreibersite, graphite, daubréelite, chromite, and lawrencite. Others consist of several minerals aggregated together. Smith holds, from the study of these concretions, that the containing 'iron was at one time in a plastic state from the effect of heat.' —(*Amer. journ. sc.*, June.) M. E. W. [222

MINERALOGY.

Scovillite. — Under this name, Messrs. G. J. Brush and S. L. Penfield have described a new phosphate from the Scoville ore-bed, Salisbury, Conn. It occurs as a thin crust of a pinkish or brownish color, coating iron and manganese ores. Hardness, 3.5; specific gravity, 4. Before the blowpipe the mineral is infusible, and, with borax and salt of phosphorus, gives beautiful rose-colored beads (didymium) in both oxidizing and reducing flames. It is readily soluble in dilute acids. Chemical analysis yielded P_2O_5 (24.94). $(Y,Er)_2O_3$ (8.51). $(La,Di)_2O_3$ (55.17). Fe_2O_3 (0.25). H_2O (7.37). CO_2 (3.59) = 99.83 %. The presence of carbon di-oxide is regarded as due to an admixture of lanthanite, — $(La,Di)_2$ $(CO_3)_3$ $9H_2O$; and, deducting the constituents corresponding to the above formula, there is left 82.79 % of a phosphate, which, calculated up to 100 %, gives P_2O_5 (30.12). $(Y,Er)_2O_3$ (10.28). $(La.Di)_2O_3$ (55.75). Fe_2O_3 (0.30). H_2O (3.57) = 100 %. This corresponds closely with the formula $R_2(PO_4)_2$ H_2O, where R = (Y, Er, La, and Di). The new mineral is therefore a normal phosphate of the above metals, plus one molecule of water. — (*Amer. journ. sc.*, June.) S. L. P. [223

Ullmannite. — Crystals of this mineral from Montenarba, Sardinia, have been crystallographically investigated by C. Klein. The crystals were embedded in calcite, and were obtained by dissolving the calcite in dilute acetic acid: they were of cubical habit, possessed a perfect cubical cleavage, and showed on the cubic faces the striations so common in pyrite, and characteristic of the parallel or pyritohedral hemihedrons. Besides the cube, the faces of the rhombic dodecahedron and pentagonal dodecahedron, $\pi \infty O_2$, were observed. The chemical analysis was made by P. Jannasch, and yielded S (14.02). Sb (57.43). As (trace). Ni (27.82). Co (0.65). Fe (0.03) = 99.95 %, corresponding closely with the formula Ni Sb S. Gravity, 6.84. The mineral is therefore closely related to pyrite, crystallizing like it in parallel hemihedrons, and having an analogous composition in that the nickel and antimony are isomorphous with iron and sulphur. — (*Jahrb. min.*, 1883, 180.) S. L. P. [224

GEOGRAPHY.

(*Africa.*)

French missionary-work in eastern Africa. — The French missionaries sent from Algeria have successfully established a station at Tabora in charge of Père Hautcoeur. Their missions at Ujiji and Usanzé are progressing favorably. That at Uganda, owing chiefly to the petty persecution experienced from king M'tesa, has been abandoned, and the party have taken refuge on the southern shores of Lake Tanganyika. Six new missionaries have been despatched from Algiers to re-enforce the staff at stations in Central Africa. The station at M'rogoro, less than six months old, already presents the aspect of civilization, stone buildings replacing thatched huts; and the adjacent land, until lately covered with forests and jungle, has been cleared, and planted with coffee-bushes, which appear likely to succeed. Other establishments are equally flourishing. — (*Comptes rendus soc. géogr.*, no. 11.) W. H. D. [225

BOTANY.

Protogyny of grasses. — Bailey gives as an example, Spartina juncea. — (*Bull. Torrey club, July.*) W. T. [226

Pollination of prickly pear. — Dr. Kunzé sees, in the irritable stamens of Opuntia vulgaris, a provision for securing close fertilization by insect aid. In fair weather each flower opens on two successive days. Hive-bees, flies, and humble-bees were seen to visit the flowers for nectar, in obtaining which they grasp clusters of stamens, which, when released, fly up against the pistil, from which they slowly recede to their former position. Although the legs of the insects were covered with masses of pollen after visiting a flower, they were not seen to creep over the stigmas: *ergo*, the pollen grains are supposed to be thrown between the stigmas after the sudden movement following the retreat of an insect. It is hardly necessary to add, however, that crossing is well effected by the insects in question, the motion of the stamens insuring a thorough dusting of their bodies with pollen. — (*Bull. Torrey club, July.*) W. T. [227

Mimicry. — Bailey notes the resemblance of a spider to the involucral scales of the swamp thistle, on which it lies in wait for insects which visit the flowers. — (*Bot. gazette, Aug.*) W. T. [228

ZOÖLOGY.

Mollusks.

Pleurotomidae of Senegambia. — Baron von Maltzan reviews the Pleurotomidae of this region, especially of the Island of Goree. He obtained thirty-six species and varieties, of which about one-third are new. Only four were known to Adanson, who first monographed this fauna. About fifteen per cent are European forms, which are smaller and rarer than those of the same species in the Mediterranean. — (*Jahrb. mal. ges.*, vii. ii.) W. H. D. [229

Mollusca of the Caucasus. — Böttger offers an important paper on the land-shells of the Caucasus, supplementary to others printed in preceding years. Rich material has been brought together by Gen. Komaroff and Hans Leder. The Limacidae afford several new forms: the new section Gigantolamax is proposed under Amalia, and Paralimax under Limax. A new genus of Testacellidae, Selenochlamys, is proposed for a form resembling Daudebardia externally, but without an internal shell, and with the respiratory orifice at the right anterior part of the very small clypeus. No known mollusk closely resembles this remarkable slug, which was found near Kutais. A large number of new species and varieties are described. — (*Jahrb. mal. ges.*, vii. ii.) W. H. D. [230

Monograph of Ringicula. — L. Morlet has published a second supplement to his valuable monograph of Ringicula, in which four new recent and as many new fossil forms are made known, and a synopsis, after Seguenza, of the tertiary Italian species, is added. — (*Journ. de conchyl.*, xxii. 3.) W. H. D. [231

Worms.

New worm with remarkable nervous system. — The Willem Barents on her third voyage captured a worm, which A. A. W. Hubrecht describes under the name of Pseudonematon nervosum. He gives a general account of its structure, and promises a fuller monograph. The animal is about sixty-five millimetres long, one and three-quarters millimetres thick, tapering behind. The digestive tract runs straight through from end to end. On the ventral side, about forty-five millimetres from the head, is a disk, probably a sucker. No traces of sexual, excretory, or sensory organs were found. The epidermis is thin. The muscles form three layers, — a thick external longitudinal, a middle transverse or circular, and an internal longitudinal layer, — variously developed in different parts of the body. The nervous system is very remarkable: it forms a continuous layer completely around the body, and lies immediately inside the layer of circular muscular fibres. It consists, 1°, of a fine network of delicate filaments, appearing as if felted, barely tinged by the staining reagents; and, 2°, of scattered nuclei belonging partly to connective tissue, partly to ganglion-cells. The layer forms a continuous tube from the head, where there is no ganglionic enlargement, back through the body to the caudal region, where the layer is present dorsally only.

Hubrecht further discusses the phylogeny of the nervous system in continuation of his previous paper (*Quart. journ. micr. sc.*, xx. 431). He points out, that, 1°, in its lowest form (Medusae), the nervous system is diffuse, and there are no nerve-fibres properly so called; 2°, in a little more advanced stage it tends to form a layer spread out under and parallel with the ectoderm; the general histological character is the same as under 1°, — a felted network of fine fibrillae, which spring from the ganglion-cells (Actiniae, Psuedonematon); 3°, the diffuse layer is still present, but certain tracts are more developed, making the primitive nerve-cords (Chaetognathi, Chiton, etc.); 4°, the diffuse part is gradually lost, and the cords are retained. These conclusions are confirmed by citations from numerous recent researches. Dr. Hubrecht has, we think, successfully established two very important generalizations, — first, that in the lower animals there prevails a uniform type of nervous tissue, ganglion-cell and nerve-fibre being incompletely differentiated, and the nerve-fibres being in the form of a network; secondly, that the nerves were developed by concentration of the diffuse tissue along certain pathways. His paper is certainly one of much value and originality. Systematically the position of Pseudonematon is uncertain, but it probably belongs somewhere near the nematods and plathelminths. — (*Verh. acad. wetensch. Amst.*, xxii. 3d art.) C. S. M. [232

VERTEBRATES.

Development of the diaphragm and pericardium. — Our knowledge of the changes which lead to the partitioning-off of the anterior end of the body-cavity in vertebrates to form the pericardial and pleural cavities has heretofore remained obscure. Uskow has investigated the subject under Waldeyer's direction, at Strassburg, and publishes an important memoir. The essay opens with a review of the previous literature. The research was carried out principally on rabbits, but also extended to other mammalia, and classes of vertebrates. At nine days (in rabbit embryos) the omphalo-mesaraic veins enter the body from the sides, along the lower wall of the body-cavity, into which they bulge up. The part of the body-cavity in front is cylindrical; behind, fissure-like. The two cylindrical halves meet anteriorly, and unite below the heart, forming the primitive pericardial division of the coelom. The posterior wall of this cavity is pierced by the sinus venosus, and receives the name of septum transversum: it is a thin membrane, which separates the pericardial space from the fore-gut of the embryo. In the next stage, the pericardial space has enlarged, the most important effect of which is to drive the septum transversum backwards until it lies together with the omphalo-mesaraic veins, so producing the membrane which supports the great veins, and divides off the ventral portion of the pericardial space from the dorsal portion and the general body-cavity, or paired coelom. This membrane then forms part of the wall of the pericardial cavity; but it also forms the primitive diaphragm, the dorsal portion of the original pericardial space becoming, in conjunction with the anterior end of the coelom, the pleural cavity.

The pericardial wall consists, according to its development, of three parts: 1°. part of the original wall of the coelom (this includes that portion which remains permanently attached in mammals to the anterior thoracic wall); 2°. the septum transversum, which becomes the pleuro-pericardiac membrane; 3°. the principal part derived from the body-wall, its separation being consequent upon the enlargement of the pleural cavities. The part from the septum is originally continuous with the diaphragm.

The diaphragm is at first a connective tissue structure. The muscle grows in later from the dorsal side, appearing first in embryos (rabbits) of nine millimetres length. It probably is derived from the muscle plates, but that was not determined with certainty. The primitive diaphragm arises in its ventral part from a papillary growth of the septum transversum; in its dorsal part, laterally from the tissue carrying the large omphalo-mesaraic veins; medianly, from the outgrowth of the septum transversum known as the massa transversa.

From the comparative study of other types, the following grades of development of the diaphragm were ascertained. 1. The ventral and dorsal portions of the diaphragm are completely developed: they completely divide the coelom, and have muscles. The pericardium, except two thin lamellae, is entirely separated from the diaphragm (rabbit). 2. Same as 1, save that a part of the diaphragm remains united with the pericardium (man). 3. Same as 2, but the diaphragm contains no muscles, and its ventral part is completely fused with the pericardium (hen). 4. Same as 3, but the dorsal part is not completely developed, remaining in a primitive condition (lizard) or in an early stage (frog). Here might properly be reckoned certain imperfect developments in man. 5. Same as 4, but the diaphragm, or its ventral part, forms a united whole with the pericardium, remaining at the stage of the septum transversum (Myxinoids, — Ammocoetes). 6. The teleosts stand apart, in that, although, as seen in the salmon, there is a certain separation of the diaphragm from the pericardium, even more than in birds, yet the dorsal portion of the diaphragm is completely wanting.

The paper contains numerous details. The author's nomenclature is confusing, and we have found it very difficult to follow his account. — (*Arch. mikr. anat.*, xxii. 143.) C. S. M. [233

ANTHROPOLOGY.

Mutilations of the teeth. — Ethnographers who have minutely described mutilations of the teeth in other parts of the world have said nothing of a similar practice among the natives of the two Americas. The practice is not common in the western world; and it is a little singular that people who deform to an extraordinary degree their lips, noses, cheeks, and ears, respect the integrity of their teeth. The historians of this practice overlook the abrasions noticed by Vancouver among the Indians of Trinidad Bay, and by Petitot among the Tchiglits at the mouth of the Mackenzie and of the Anderson. Finally, no notice is taken of dental mutilations formerly in use in Mexico and Yucatan, upon which Sahagun, Landa, and Mota Padilla have furnished information. M. Hamy has gathered from the last-named writers their allusions to these subjects, and prepared an illustrated monograph. The drawings indicate both filing and perforations. — (*Bull. soc. anthrop. Paris*, v. 879.) J. W. P. [234

Imperial Chinese tombs. — Among the mountains east of Peking are the imperial tombs. The Great Wall forms the northern boundary of an enclosure five miles square. Besides this, a wide tract outside the boundary-wall belongs to the mausolea, and is forbidden ground, wherein man is not permitted to build dwellings or to bury his dead. Shun-chih (1644–62) and four of his successors sleep here, with the heavens, the hills, and the streams around them. The earlier Manchu princes are buried at Movkden. The tombs are all alike in essential features, built on a southern slope, with a stream in front. In approaching the tomb, the explorer passes first two lofty stone pillars, that serve as a gateway to figures of men and animals in pairs, facing one another on opposite sides. An ornamental archway opens upon a curved marble bridge of several arches, with finely carved balustrade. After crossing the stream, the traveller passes guard-houses and the sacrificial hall on the right and left, and comes upon a small building, in the centre of which stands, supported upon the back of a huge marble tortoise, the memorial tablet, on which is written an account of the deeds of the departed. Halls of entertainment flank this building; and farther on in a direct line are the chapel of the dead, the bright pavilion, and, last of all, the earth-palace, or tumulus, within which the coffin lies. When the body is laid in this earth-palace, the door is shut. Behind the door, inside, is a round hole in the stone floor; and, when the door is shut, a large ball of stone follows it, and, falling into the hole, prevents the stone door ever opening again. The emperor is then said 'to be at peace forevermore.' Mr. F. S. A. Bourne, who gives the information above quoted, entered this enclosure with great difficulty. A minute account of the appearance and function of the two rows of sphinx-like figures adds much interest to the author's narrative. The mausoleum prepared for the present empress's regent is just completed, and cost about £1,500,000. — (*Proc. roy. geogr. soc.*, v. 23.) J. W. P. [235

EARLY INSTITUTIONS.

Malagasy place-names. — We have a long article upon local names in Madagascar by the Rev. James Sibree, jun. The object of the writer is to show how the names of places illustrate the mental habits of the people and their powers of observation. Many names of villages include Malagasy equivalents for the Anglo-Saxon words *tun*, *ham*, *burgh*. Personal names are very common. Villages are named after distinguished chiefs The article will interest some of our readers. — (*Journ. roy. Asiat. soc.*, April, 1883.) D. W. R. [236

Chinese laws and customs. — An article upon this subject by E. H. Parker appeared in the *China review*, viii. 67. Now we have another by Christopher Gardner. The two writers are of one mind upon most points. It is only upon a few matters of detail that they differ. Mr. Gardner tells us that the laws and customs of China have been very little changed since the seventh century. Chinese law, we are told, cannot be 'squared' with the theory of Bentham and Austin, which resolves all laws into commands imposed by a lawgiver. It is based upon public sentiment and opinion, and upon previously existing custom. It 'follows the instincts of the people.' Then we are told that the tribe has been derived from the family, not the family from the tribe. Exogamy has in China prevailed over endogamy. As for the land, it is held by single families (house communities), or by groups of families (village communities). It is a pity that the writer does not describe the house community and village community more fully, and in more exact language. The article is interesting. — (*Journ. roy. Asiat. soc.*, April, 1883.) D. W. R. [237

NOTES AND NEWS.

WITH this number our report of the meeting of the American association is completed. No session of section G was held, and no vice-presidential addresses delivered in sections C, D, or G. In our next number we shall print in full the promised papers of Messrs. Carhart and Dana. At some future time we may also take occasion to refer more particularly to the report of the committee upon the removal of duties on imported text-books and the discussion of the same, of which we have a full account. Few other committees besides this, and those already announced, made any reports; and the several committees on weights, measures, and coinage, on standard time, on primary meridian and international standard time, and on the records of science, were discontinued, that on standard time in consequence of the favorable action of the railways of the country in the proper direction. The committee on the introduction of science teaching in the public schools, on the registration of deaths, births, and marriages, on stellar charts, and on an international convention of scientific associations, reported progress, and were continued.

A by-law to the constitution was passed, providing that every member should have the privilege of registering the members of his family at meetings of the association (not including men over twenty-one years of age), by paying three dollars for each registration; the person so registered being entitled to all privileges offered members by the local committee. The standing committee also passed a rule that hereafter no paper will be accepted for reading before any of the sections, unless accompanied by such abstract as the writer deems ready for publication.

Sections H and I had, in some respects, a similar experience at Minneapolis. Both were unable to organize until the week of the meeting was half over. To each there came, almost at the very last moment, a paper of unusual interest. In the anthropological section, Miss Babbitt's paper announced the discovery, in Minnesota, of traces of human labor beneath a deposit of twelve or fifteen feet of the material which forms one of the terraces of an ancient river. This seems to be a confirmation of the theory advanced by Dr. Abbott, respecting his similar discoveries in New Jersey, that man existed on this continent during at least a portion of the glacial epoch. There will, of course, be a lively discussion between experts, as to whether these quartz specimens are actual relics of human industry. Thus far, at best, the glacial workman is known only by his chips.

In the section devoted to statistics, Mr. Dodge announced what may perhaps be accounted a discovery in that dry branch of science. He has found that a singular and quite definite relation exists, in large communities, between an excess of non-agricultural over agricultural workers, and an increase of values in the land, products, and wages of agriculture. The figures may soothe the fears of those political economists who from time to time predict national disaster because so few American youths take kindly to farming pursuits. An obvious inference from the statistics is that prosperity comes where industry is diversified. Weapons of argument may thence be drawn by those who believe in a public policy tending to encourage non-agricultural industries.

— The Royal academy of medicine of Turin has unanimously awarded the Riberi prize of 20,000 francs ($4,000) to Prof. Bizzozero for his researches on the 'Physiopathology of blood,' the subject proposed by the academy. The commissioners of award received several essays: those of Wharton Jones, Norris, Hayem, and Bizzozero were considered to deserve special consideration. The last two were assigned the first rank. The most important matter in both of these is the investigation of the third morphological element of the blood (Hayem's haematoblasts). The commissioners, all well-known *savants*, judged that Hayem did not completely demonstrate that the red globules are derived from the haematoblasts. Bizzozero solves the important problem of the origin of the red globules, determines the relation of the haematoblasts to coagulation, and throws new light on the formation of thrombi. His memoir was therefore deemed the more important, and to Bizzozero accordingly the very valuable award has been made.

— The officers of the Cincinnati society of natural history inaugurated about June 1 a course of free lectures on botany. The first was given on June 9, to a company of forty-seven, many of them teachers in the public schools. The lectures have been continued weekly, and the last was given on Aug. 11. The object of the society in the establishment of this course was to get the public generally interested in scientific pursuits; and the success of this, the first attempt of the kind in this city for many years, has been most gratifying. The average attendance has been over thirty, notwithstanding the hot weather, lateness of the season, and the absence from the city of many who would otherwise have attended. The officers hope, in the autumn, to have courses in other branches of science, so that a general interest may be awakened among the citizens, and attention called to the importance of the study.

— News has been received from the French meteorological station at Orange Harbor, Patagonia: all were in good health, and work progressing favorably. The cattle which had been brought from Montevideo had perished, but those from Punta Arenas were flourishing. The surgeon of the party, Dr. Hyades, had made full anthropological investigations of the Fuegians who were settled near the station. Casts of heads and limbs had been secured, and many photographs taken. A collection of utensils, etc., had been brought together, including a large canoe with its entire outfit. He was engaged in studying the language, which appeared to be somewhat different from the vocabularies collected by Darwin nearly half a century ago.

— Professor W. A. Rogers wishes us to state that the relation between the imperial yard and the *mètre des archives* is wrongly given in our abstract of his paper on p. 250. It should have been stated as follows: Imperial yard + 3.37027 inches = *mètre des archives.*

— Matthew Arnold's ingenious argument for the survival of literature, from its relation to conduct, encounters an objection in the apparent effect of scientific pursuits upon the character of his countrymen. When one affirmed of Clerk Maxwell, that "he was free from every taint of the world, the flesh, and the devil," it seemed no exaggeration to those who knew him. Darwin, Balfour, Sir Rowan Hamilton, and H. J. S. Smith, each in his turn was scarcely less endeared by his genial virtues than admired for his lofty powers. None of these was so largely identified with the world, its business temptations, its social allurements, as William Spottiswoode, the late president of the Royal Society; and none left the memory of a purer life, a heart more "full of exercised humanity."

In his funeral sermon, referring to the text, "The world passeth away, and the lust thereof; but he that doeth the will of the Lord abideth forever," the Dean of Westminster Abbey said, "Apart from general considerations of life and death, the words have special reference to that last one of our own time accounted worthy to rest with the illustrious dead within these walls. . . . To his great talents and his profound knowledge were united such graces of character as the most modest unselfishness and the most spotless integrity. He was ever anxious, earnestly and justly, to place before his fellow-men such knowledge as would conduce to their welfare; and so well did he do this work among his countrymen, that it might be doubted whether his philanthropy did not predominate over his love of science."

— M. Pasteur has proved that the burial of diseased animals does not destroy the germs of disease, or obviate the chance of infection to any animals who may afterwards feed on the ground above where the body of the diseased animal was buried. M. Aimé Girard proposes to destroy the germs in the dead bodies of diseased animals by treating the carcasses with cold concentrated sulphuric acid. The destruction of the germs is proved to be complete. Experiments made at St. Gobain show that three hundred and twenty-one kilograms at 60° proof, dissolved in ten days nine sheep, weighing two hundred and four kilograms. The resulting liquid, mixed with four hundred and forty kilograms of coprolites from Ardennes, produced nine hundred and forty kilograms of superphosphate of lime, containing thirty-six per cent of nitrogen. Thus, by a simple process, most dangerous bodies are destroyed, and a valuable fertilizer obtained.

— *Nature* announces that the Lords of the committee of council on education, of England, have, by a recent minute, decided to withdraw the prizes hitherto given to candidates in the science examinations who obtain a first class in the elementary stage of the various subjects of science, substituting certificates of merit, and retaining only the prizes given in the advanced stage. The money hitherto devoted to prizes will be employed in providing thirty-six national scholarships, — twelve each year, — which will be offered in competition to students of the industrial classes, and awarded at the annual examinations of the department. The National scholarship will be tenable, at the option of the holder, either at the Normal school of science, South Kensington, or at the Royal college of science, Dublin, during the course for the associateship, — about three years. The scholar will receive thirty shillings a week during the session of nearly nine months in the year, second-class railway fare to and from London or Dublin, and free admission to the lectures and laboratories. This is a most important step in advance.

— The Rev. Father Émile Fortuné Stanislas Joseph Petitot, well known for his valuable contributions to American linguistics and his extended journeys over the Hudson Bay territory, has received a medal from the Royal geographical society. He is the first Frenchman thus honored since Francis Garnier. He has now retired from mission-work, and will devote himself to study for some years.

— The Delaland-Guerineau prize has for the second time been bestowed by the French academy upon M. Savorgnan de Brazza, of Congo notoriety. The military medal for 'exceptional services' has been given to the sergeant Malamine, a native of Senegal, for his defence of Brazzaville against all comers during the absence of his superior.

— The last number of the bulletin of Nuttal club contains part of Burrows' list of birds from the lower Uruguay, which is sufficiently full to be of value. The critical list of birds in vicinity of Colorado Springs is of great interest. Mr. Allen's valuable list of minor ornithological publications should also be mentioned.

— Mr. E. H. Miller states, in the *American agriculturist*, that wherever the ornamental shrub commonly called Deutzia scabra grows near grape-vines, the rose-bugs prefer the flowers of the Deutzia, and thus the grapes are protected. Grape-growers may therefore cultivate a charming shrub with a double purpose.

— Rev. W. W. Meech recommends, in the *American agriculturist*, judicious salting to prevent the blight which troubles quinces, and burning affected parts to overcome the ravages of the fungus Roestelia aurantiaca.

— The sixth annual report on the birds of Germany in the *Journal für ornithologie* contains many interesting notes on migrations and breeding-dates.

— At a lecture recently given at Mauch Chunk, Penn., by Mr. Charles A. Ashburner, geologist in charge of the anthracite surveys in that state, the lecturer made some general statements in regard to the amount of coal which has been mined, and which still remains in the region, which we copy from the *Mining herald* of Shenandoah. "The total amount of coal produced from the anthracite fields up to Jan. 1, 1883, was 509,333,695 tons. It is hard to realize this amount. To place it in a popular form, it was stated that it would form a solid compact wall of coal (25 cubic feet = 2,240 pounds = 1 ton) 100 feet wide and 100 feet high for a distance of 241 miles, or it would form a similar wall along the railroad between Philadelphia and New York 100 feet wide and 268 feet high. It was estimated that the region originally contained 25,000,000,000 tons. If it be assumed that in the production of 509,333,695 tons an area has been practically exhausted which originally contained 1,500,000,000 tons, there is 94% of the coal originally contained which still remains untouched. In comparing the anthracite region with the bituminous fields of England, the estimated contents of the former is about one-sixth of what the most recent estimates assign to the latter. About the same proportion exists between the annual production of Pennsylvania anthracite and English bituminous. Mr. Ashburner stated the estimates were based upon very general, but at present the most reliable data. The geological-survey estimates have not yet extended beyond the Panther Creek basin, between Mauch Chunk and Tamaqua. It was stated that this basin originally contained 1,032,000,000 tons of coal, — double the amount which has already been shipped from the entire region. An area had been mined over in this basin, up to last January, which originally contained about 92,000,000 tons, so that 91% of the original coal still remains untouched. About 88% of the coal which has been mined from this basin was taken from the mammoth bed."

In a subsequent communication to the same paper, Mr. Ashburner disclaims having made any statements with regard to the exhaustion of the anthracite coal-fields of Pennsylvania, with which he had been credited by various newspapers. He adds, however, that Mr. P. W. Sheafer, who has probably given this subject more careful consideration than any one else, has made a very general statement that the field still contains about 25,000,000,000 tons of coal. Up to Jan. 1, 1883, he had estimated that the total production amounted to 509,333,695 tons. It has been generally thought that but one-third of the coal contained has been consumed as fuel; so that, up to last January, an area had been exhausted which originally contained about 1,500,000,000 tons, 23,500,000,000 tons remaining untouched. If this same proportion of production to original content be applied to that which still remains, about 8,000,000,000 tons would represent the possible future production. According to the mine-inspector's report, there was produced last year 31,281,066 tons. If this production should remain constant for all future time, the field would be exhausted in a little over 250 years. Such a conclusion is quite untenable, for our yearly production is rapidly increasing. In 1870 there was shipped from the region 16,182,191 tons, and in 1880, 23,437,242 tons. The abrupt exhaustion of the coal-fields is a practical impossibility; nor is it reasonable to suppose, that, if on an average for every ton of coal won there are two lost, this will be the practice in future mining. The geological survey has already in its possession many valuable facts to throw light on this subject; but, as it is hoped that the survey will be completed before this question of ultimate exhaustion will become one of practical concern, it would be folly to make any statement as to how long the coal will last.

— M. Daubrée has been examining an interesting meteorite which fell not far from Nogoga, in the province of Entre Rios, Argentine Republic. Chemical analysis proves that the meteorite contains iron, lime, and magnesia; but its most important feature is, that it is said to contain carbon in an organic form, which is chiefly proved by the action of potash in it. M. Daubrée from this is led to hope that he may yet find organic remains in a meteorite.

— In the September *Atlantic*, Bradford Torrey prints some studies in the temperaments of birds, which will interest ornithologists, as they are made from personal observation. The chickadee, goldfinch, brown thrush, towhee, blue-jay, shrike, white-eyed vireo, and chat, and the New-England species of Hylocichlae, are discussed.

— The Florence newspapers announce the acquisition of a skull of Mastodon arvernensis by the Istituto di studii superiori. Professor d'Ancona writes to *La nazione*, that it was found through excavations that were making in pliocene deposits in the neighborhood of Percussina, situated about two hundred metres above the sea, between Siena and Florence.

— In his recent work on cultivated plants, DeCandolle says, "In the history of cultivated plants I have found no indication of communications between the inhabitants of the old and new world anterior to the discovery of America by Columbus. The Gulf Stream has equally been without effect. Between America and Asia, two transportations may have been effected; one by man (the batatas), the other by man or by the sea (cocoa-nut)." Drs. Gray and Trumbull, in commenting on this in the last number of the *American journal of science*, say, "Perhaps the banana should be ranked with the sweet-potato in this regard. And we may merely conjecture that the purslain came to our eastern coast with the Scandinavians or the Basques."

— Ostrich-chicks are hatching out at the ostrich-farm near Anaheim, Cal., at the rate of one a day. When they first come out of the egg, they are about the size of a half-grown duck. They have good appetites, and grow rapidly.

— Means of transportation are rapidly increasing on the borders of countries not within the recognized bounds of civilization. Thus it is announced that the journey from Paris to Algiers will shortly be reduced to thirty-three hours rail and steamer travel, of which only sixteen will be by boat. Hitherto passengers by the Marseilles line, in the regular routine of travel, have spent forty hours on the water alone, beside the railway journey from Paris.

— At the meeting of the French entomological society, held July 11, Mr. E. Lefèvre showed a large solitary ant allied to Ponera, found about Hong Kong, remarkable for the extraordinary development of its mouth parts, and for its power of leaping; being able, when disturbed, to make bounds of twenty to twenty-five centimetres. The statement was confirmed by the experience of earlier observers. As the legs are in no way developed for springing, Mr. Lefèvre was inclined to think that it was accomplished in some way by its buccal organs.

SCIENCE.

FRIDAY, SEPTEMBER 21, 1883.

THE U. S. SIGNAL SERVICE.

II.

It must be said that the annual report would be vastly improved by being made either one thing or the other, or, better, two separate things. At present it is at once a *résumé* of meteorological work done during the year, and a government blue-book. As the former, it falls far short, not of the ideal, but of the possible: it is probably equally deficient considered as the latter. It is certainly desirable that the summarized results of such great labor, comprehending so vast a field, should be published annually in such a form as to be useful to those who are engaged in meteorological study and research, and it ought to be done with reasonable promptness.

The size of the volume might be reduced to at least one-half of what it is at present, and that without material loss. The report proper of the chief signal officer ought to be rewritten; and it does not seem too much to ask that it be prepared afresh every year, and that it should be confined to a statement and discussion of the actual progress made during the year. Expensive reprinting is a luxury that only government offices can afford to indulge in, and it is sometimes carried to an extent that is not only wasteful, but positively objectionable. A large portion of this annual report is made up of a republication of the monthly weather-reviews for the year. These have already been printed and circulated among those to whom they would be useful. Another large part consists of material already printed and circulated as 'Instructions to observers,' and might well be dispensed with here. The 'annual meteorological summary,' occupying about one-fourth of the volume, is susceptible of considerable condensation without loss of value to the student of meteorology. Many of the appendices are made up entirely of matter which is, of itself, not without value, and which may well be kept on file and accessible at the central office, but which is entirely without interest or value to the majority of those into whose hands this report is intended to fall. A much smaller volume, embodying the real meteorological work of the year, with such discussions thereof as could be given, as everybody knows, by persons in the employ of the government at the central office, would be welcomed everywhere, and would be a real boon to students. As at present issued, the report is unmanageable, uninviting, and unsatisfactory.

As already intimated, the report for 1881 contains evidence of some important changes in the organization of the central office, and in the general policy of the service. It seems now to be recognized, that meteorology is, or will be, a *science*, and that it is wisdom on the part of the government to secure the cooperation of scientific men in the work which it has undertaken, as well as to employ an important portion of its own staff in the investigation of meteorological problems, and the carrying-on of special researches. This is a step which, although tardy, will be highly appreciated.

Among the most tangible results thus far may be mentioned the permanent establishment of a 'scientific and study division.' The wisdom of placing this entirely under the control of Professor Abbé, and of permitting him to select his own assistants, cannot be too highly commended. His selection of Messrs. Upton, Hazen, and Waldo for this important service has been justified by the numerous valuable contributions which they have already made under his direction. The transfer of Professor Ferrel from the coast survey to the meteorological bureau is another step in the same direction, which is likely to materially increase the strength of the division. In many other directions, the chief signal officer has shown his appreciation of the 'eternal fitness of things.' He has sought and obtained the cooperation of the National academy, in the appointment of a permanent committee of that body to which he may refer such questions concerning meteorological science as may seem desirable. He has inaugurated the custom of consulting specialists upon various matters pertaining to the service, and has shown a disposition to aid scientific research in all matters related to meteorology, as instanced in Professor Langley's expedition to Mount Whitney, in the offer to the coast-survey of cooperation in the making of pendulum-observations, and in the interest shown in polar research. The publication of professional papers by members of the staff; the work undertaken in the way of a revision and definitive establishment of standards of pressure and temperature; a promise that after a while something will be attempted in the way of a study of atmospheric electricity; and the proposition to offer prizes for essays upon various meteorological problems, competition to be open to the world, — are all straws that show which way the wind is blowing.

At the same time, the general observation work has been much extended by the wise and hearty interest which the chief signal officer has shown in the establishment of state weather services, which have rapidly increased in number through his encouragement and material aid. This is particularly fortunate just now, when the general service has unfortunately been crippled by the failure on the part of congress to make sufficient appropriations. In short, it is only just to Gen. Hazen, to say that he has greatly enlarged the scope of the service, and that he has materially strengthened it by a broader recognition of the relations which ought to exist between it and the science of the country.

It is difficult, however, to review the past without indulging in speculations concerning the future. It must be admitted, that the work of the meteorological bureau falls far short of the standard which many of its friends have set for it. Many, indeed, believe that it will continue so as long as it remains a military rather than a civil service. Each successive report of the chief signal officer has contained long arguments in defence of its military organization; and, unintentionally no doubt, the same reports have furnished strong arguments against such organization. In order to improve the character of the observing corps, considerable efforts have been made, for two or three years past, to induce well-educated and well-trained men to enlist in the service. Under the present organization, it does not seem that the work could have any great attraction for a college-bred man. In the first place, he must enlist as a private in the army for a period of five years. It is true that the service is special, and that his chance for promotion up to a certain point is fair; but before beginning his work as an observer, he is obliged to go through months of military drill, study, and discipline, the relation of which, to the duties which afterward devolve upon him, it is difficult to see. Proficiency in the 'manual of sabres' or the 'manual of the kit' will not greatly facilitate his making a barometric reduction or a dew-point determination. Even after the service is fairly entered, objections to the military system are not less strong. Permanency of position is very desirable in any occupation, and it goes farther than most other things in securing the best attainable results; but it must be a permanency very different from that which obtains in a military service.

The difference is best seen by a comparison of the relations existing between the service and the two divisions of the staff of the chief signal officer, the civil and the military. The young civilians who have recently become *attachés* of the central office have been led to do so, it is almost certain, by their own fondness and predilection for the study of meteorology. They bring to their work a vigor and enthusiasm resulting from a thorough collegiate training, followed by post-graduate work in which observation and research have played the most important part. The permanency of their positions, and their advancement to more responsible places, will, or at least should, depend solely on the value of their services. With the laudable ambition to establish a reputation among scientific men, they have every incentive to hard work, that success may be achieved, and failure, which would be to them disastrous, avoided.

But by far the greater portion of the work at the central office, and that which is doubtless the most immediately effective, is done by commissioned officers of the army. While it is true that many of them have fairly earned distinction through their conscientious labors in the weather bureau, it cannot be claimed that the relation which they sustain to it, and which is no fault of theirs, is that which would be for the best interests of all concerned. Except the very few who have been promoted from observer sergeants, they have been ordered to the service from other occupations and other branches of the army. As a special training to fit them for the work, they have the year at Fort Meyer, during which the study of meteorology is not allowed to interfere materially with other occupations. They enter the central office at the close of this year, having had an experience of eight days in practical meteorology. When, after further study and practice, they become really useful, they are likely to be transferred to some other post and duty for which this training has in no way fitted them; for the policy of the army seems to be in the direction of frequent changes of location of its officers. But by far the worst feature of the case is that there is no particular incentive to induce them to devote themselves earnestly to the work. If, through interest and industry, one succeeds, he is probably retained in the office longer than he otherwise would be: if, through indifference and neglect, another fails, he is likely to be transferred to some other branch of the general service without loss of rank or reputation. It is also true that the meteorological work of the signal service is looked upon with disfavor by many army officers, as not being a legitimate addition to their duties. Under such conditions, and for many other reasons not necessary to mention, it does not seem possible for the weather service to reach that high degree of efficiency which is believed to be possible under a different organization; and it will require weightier arguments than those annually reprinted in the report of the chief signal officer to prove the contrary.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

ROUEN MEETING, AUG. 16-23, 1883.

This association has just held its twelfth annual session at Rouen, the ancient capital of Normandy, situated on the Seine, between Paris and Havre. It is, I believe, the youngest association of its kind, but is not, for that reason, the less worthy of study. Perhaps, to an American, its most striking feature is its resemblance, in its organization and proceedings, to its sister across the water. It has its permanent secretary to organize its business and give information to members, its daily programmes, its general meetings, its sectional meetings, and its excursions, all fulfilling the same objects as with us. It has even gone through the same process of evolution, and reached the same stage of development, in becoming a representative of popular and applied, rather than of very 'high,' science. Its members already complain, that, when one is elected a member of the Academy of sciences, he no longer affiliates with the association. I have recognized but two academicians at the meeting, and doubt if there are more. But it must not be inferred from this, that the members and their papers are unimportant: on the contrary, the number of eminent teachers, authors, and investigators, who read papers and take part in the proceedings, is decidedly greater than in the American association. If there are fewer academicians than with us, there are also fewer circle-squarers, essayists, and propounders of school-boy problems. On the list of papers presented, there is not one upon atoms, ether, the nebular hypothesis, or the origin of the present form of the universe.

The range and treatment of subjects are much wider than with us, and one is especially struck with the prominence assumed by social science and engineering. It would seem as if the blind passions, which are so apt to stir the laboring population of France and to lead them toward a policy of general social disintegration, had led the thinking and wealthy classes to give especial attention to the question of the welfare and pacification of the workingman. Not only is political economy one of the most prominent subjects, but discussions of plans for improving the condition of the laboring-class form a leading feature of the proceedings. The plan which seems to have met with most success is that of making the workmen in large establishments sharers in the profits. One speaker described, at length, the working of this plan in a great dyeing-establishment, where it would seem to have proved a great success, although coupled with conditions which would hardly have been accepted by an American artisan. I do not know what interest our railway-companies take in the personal welfare of their employees; but the examination of what is done by the Western railway of France, as exhibited and explained to the association, is suggestive of a philanthropic as well as of a business institution. Bedrooms, baths, eating-rooms, medical attendance, savings bank, and life-insurance are among the privileges provided by the company, of which each and every employee may avail himself according to circumstances.

The prominence of engineering questions was due to a cause which shows that human nature is much the same through the civilized world. Rouen is engaged in river improvements, of which the object is to make it a great seaport; in fact, to make it to Paris what Liverpool is to London. Great pains were therefore taken to secure the attendance of distinguished engineers from abroad as well as from home; and harbor improvements, especially those of Rouen, formed the most prominent subjects of discussion in the section of engineering. How far the French association is ready to go beyond its fellows in this direction, is further shown by the fact that one of the prominent papers in the engineering section was devoted to the exposition of a scheme for a metropolitan railway in Paris, similar in its object to those of London and New York, which could be built at a cost of two hundred million francs. No one hinted that the subject was not germane to the objects of the society.

There is at least one custom of the meeting worthy of imitation by the American association; namely, evening lectures by members, on subjects of general scientific interest. These lectures are not gotten up at hap-hazard on the spot, but are arranged by the secretaries, long enough in advance of the meeting to admit of careful preparation. Those of the Rouen meeting were: The transit of Venus, by Mr. Hatt, chief of one of the French expeditions; and on the Transmission of energy, by Professor Comberousse. The general character of these lectures was the same so familiar to us at home; but it was noteworthy, that French science was almost exclusively considered. Occasional references to the works of other nationalities were rather to show that the speaker knew something about them, than to give full information respecting them.

In two points the French association makes a decidedly more favorable showing than our own. One has already been mentioned, — the absence of the respectable gentleman who writes interminable essays on scientific subjects of which he knows nothing except from current literature. In the mathematical section, the papers read were of decidedly greater importance than those to which the American association is accustomed. The other is the financial condition of the society. In few respects does American science show to greater disadvantage, beside that of Europe, than in its power of raising money to promote its objects. The income of the French association for the current year was reported at 85,000 francs. It has already an invested capital of about 450,000 francs. It expended 39,000 francs in printing its proceedings, 20,000 in administrative expenses, and 14,000 in grants for researches of various kinds.

Let us compare this sum total with the income of the American association.

Income of French association	$16,600
" American "	8,943
Difference in favor of France	$7,657

And we must remember that this is not a case in which the excess is due to greater age; for the French society is only one-fourth the age of the American. The comparison will afford us food for profitable reflection.

EVIDENCE FROM SOUTHERN NEW ENGLAND AGAINST THE ICEBERG THEORY OF THE DRIFT.[1]

In presenting to the association evidence from southern New England with regard to the insufficiency of the iceberg theory of the drift, I shall have to say some things that have often been said before, and by various investigators. But I may claim for what is here brought forward, that it is, in my own mind, the fortified conclusion of long-continued investigation.

The arguments on the subject are derived from three sources, —

I. The scratches and groovings over the rocks.

II. The transported bowlders and other material.

III. The facts as to the relative level of the land and sea.

I. The scratches or grooves over the rocks.

Under this head there is, first, the old argument based on the universal distribution of the scratches over the region of all New England. These effects of abrasion are to be

[1] Read at the Minneapolis meeting of the American association for the advancement of science.

found everywhere beneath the soil, each fresh exposure of the rocks bringing them to light. This was said years ago; and the conviction of its truth has been gaining force with every year of additional observation.

a. In view of this fact, it is urged rightly that only an abrading agent that pressed heavily against the broad rocky surface could have produced the effects; and such is not an occasionally grounding iceberg, or a succession of them. Neither is it the still more locally acting shore-ice.

b. Floating ice would have found little bare rock over the sea-bottom to be abraded. Like the bottom of existing seas, and eminently those of the continental borders, the submerged region would have had for the most part a bottom of detritus, its former detritus, and additional detritus from later depositions. The removals would have been local, and relatively of small area. Consequently, the drifting ice would rarely have reached down to the rocks. Shore-ice carried along by the currents would have had a better chance, and yet a poor one, for the work to be done.

c. The character of the groovings and ploughings is, to a great extent, such as floating ice could not have produced. As has been often said, the close uniformity of direction and parallelism over large areas, which so generally prevails, is not a possible result of iceberg action. The needed pressure and steadiness of movement are wanting. Troughs in hard granite even six inches deep are the work of one and the same moving tool for a long period; and one year would be long for the steady action of an iceberg. If grounded, it would do almost nothing; if floating free, absolutely nothing; and a nice adjustment to depth would be required for any steady abrasion, much nicer than would have long continued anywhere over the uneven bottom.

In the triassic sandstone of East Haven, Conn. (just east of New Haven), at a place where the sandstone is a very firm, thick-bedded, gritty rock, the ploughing ice ploughed out a piece of moulding, somewhat like the *ogee* of the carpenter, which was 8 feet deep, 25 feet wide, and over 150 feet long, and perfectly even in surface as well as direction.

d. The currents that would have borne along the icebergs over submerged New England, in case of a submergence sufficient to cover the highest striated surfaces,—3,000 to 5,500 feet,—would have been those of the present ocean, the Labrador current, and Gulf stream; and, with less submergence, the same in part, modified by the courses of the valleys and the tides. It is to be noted, that the New-Haven region, in Connecticut, is the southern extremity of the Connecticut valley. The mean trend of this valley in Connecticut is about S. 15° W., and, in southern Connecticut, S. 18° W. Now, the numerous scratches over the *eastern* portion of the New-Haven region average in direction S. 16° W.; but along its *western* border, where the rapidly rising slopes give the region rather an abrupt limit 150 to 350 feet high, the scratches have an average course of S. 33° W., the extreme being S. 27° W., and S. 55° W.; and S. 33° W. is the almost uniform trend over the undulating surface of the country for six to nine miles west. It is, as far as I can see, impossible that the valley stream should have had on its west side so wide a divergence from the direction of the Connecticut valley: all the features of the region oppose it. The scratches are well exposed over the metamorphic rocks in many places; and large and perfect examples of *roches moutonnées* here occur.

Again: over the higher lands of western Connecticut (and of New England generally, according to the observations of Prof. Edward Hitchcock, Prof. C. H. Hitchcock, and others), the direction of the scratches is south-eastward. To have produced them, if icebergs were the agent, the submergence should have exceeded 2,500 feet, and this would have given a chance for the full play of the oceanic currents; and yet the above direction does not correspond with that of either of the great currents.

II. Distribution of the drift.

Bowlders of trap, from 50 to 1,000 tons in weight, are numerous in the New-Haven region, especially along its western border. All are Connecticut-valley travellers; for the trap ridges of the valley—400 to 1,300 feet in height—are the only possible source. They were gathered up by the ice from these trap ridges, and were carried 15 to 60 miles down the valley. It is mechanically impossible that the larger bowlders should have been taken up, or gathered in any way, by floating ice; either shore-ice, where the water was but 1,000 feet deep and less, or by that of icebergs, where the depth was greater.

It is well known, that the distance of drift transportation is in general less than 20 miles. Hills of but 100 feet often have their long trails. A moving glacier would easily gather and carry along the material from hills, high or low, wherever loose or detachable masses of rock or gravel existed to be gathered; while floating ice would be very poor at gathering, and hence inefficient in distributing.

III. Relative level of the land and sea.

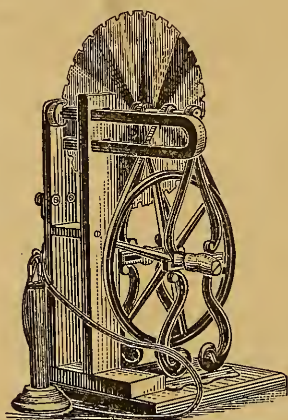
I have examined carefully along southern New England for proofs of the quaternary submergence which the iceberg theory assumes to have existed in the glacial era. I thought at one time that I saw evidence about New Haven of a submergence of 45 to 50 feet. But the terrace that afforded the evidence was situated six miles back from Long Island Sound, adjoining the rivers; and on further examination I found that the deposits had precisely the structure of those along the river-valleys farther north, and that, in fact, they were nothing but fluvial formations. The highest terraces on or near the shores of the sound, in the vicinity of New Haven, have a height above mean tide of 23 to 26 feet; and on Milford bay, nine miles west, a similarly situated terrace has a height of 30 to 33 feet. Along the hills facing the waters, and the southern extremity of the valleys, no traces of any higher level exist. Twenty-five to thirty-five feet is the greatest amount of submergence the facts sustain. Sea-border deposits exist at a higher level on the coast of Maine and on the shores of the St. Lawrence, and show what was the position of the shore-line in those regions. But the level along southern New England is not proved by the facts there gathered, neither is it established by the demands of the iceberg theory.

In conclusion, if icebergs, or floating masses of ice, were not capable of covering with scratches great continuous areas, and would have had a chance for little rock-abrasion on account of the covering of detritus; if they could not have made, in their hitching and swinging way of action, when touching bottom, scratches over great areas, that had the even course and parallelism characterizing those of drift regions, or could not have ploughed out the deep furrows; if they could not have gathered the great bowlders for transportation; and if the sea along the sound did not cover the land, in any part of the era of ice, to a greater depth than 30 or 35 feet, — the iceberg theory of the drift may be reasonably pronounced unsatisfactory for southern New England; and similar facts show that it is equally unsatisfactory for the rest of New England.

James D. Dana.

THE MAGNETOPHONE.[1]

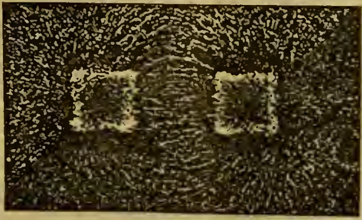
The experiments of Bell,[2] Preece,[3] Mercadier,[4] and others on the radiophone, suggested to me the possibility of interrupting, or at least periodically modifying, the lines of force proceeding from the poles of a magnet, by means of a disc of sheet iron, perforated with a series of equidistant holes, and rotated so that the holes should pass directly in front of the magnetic pole. It is well known that an armature, placed on the poles of a permanent magnet, diminishes the strength of the external field of force by furnishing superior facilities for the formation of polarized chains of particles from pole to pole. This is the case even when the armature does not touch the poles, but is in close proximity to them.



If a piece of sheet iron be placed over the poles of a magnet without touching, and the magnetic curves be developed on paper above the iron, they will be found to exhibit less intense and less sharply defined magnetic action than when the sheet iron is removed. If, however, a small hole be drilled directly over each magnetic pole, the screening action of the sheet iron is modified in much the same way as when a hole is made in a screen opaque to light; for the developed curves show distinctly the outline of the holes. If, therefore, the sheet iron in the form of a circular plate, pierced with a number of holes, be rapidly rotated between the pole of a magnet and a small induction bobbin, the action of the magnet on the core of the bobbin will be periodically modified because of the passing holes; and hence induced currents will flow through a circuit including the bobbin. A disc of sheet iron was pierced with two circles of quarter-

[1] Read at the Minneapolis meeting of the American association for the advancement of science.
[2] Proceedings Amer. assoc. adv. sci., xxix. 115. Smithsonian misc. col., xxv. 143.
[3] Proceedings Royal society, xxxi. 506.
[4] Journ. phys. x. 53.

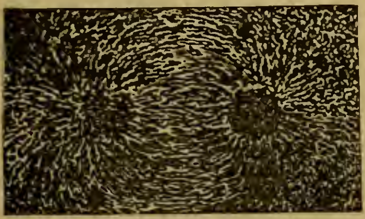
inch holes concentric with the disk, the number of holes in the two circles being thirty-two and sixty-four respectively. On one side of the disk was placed a horse-shoe magnet with its poles very near the rows of holes; on the other side were arranged two corresponding induction bobbins. The circuit was completed through a telephone and either bobbin at pleasure. Upon rotating the disk rapidly, a clear musical sound was produced in the telephone, the pitch rising with the rapidity of rotation. Moreover the bobbin opposite the circle of sixty-four holes gave the octave above the other, and each gave a note of the same pitch as was produced by blowing a stream of air through the corresponding holes. Hence, as a beam of light, focused upon a circle of equi-distant holes in an opaque disk, is rendered periodically intermittent by the rotation of the disk, and produces a musical tone when falling upon the proper receiving-apparatus; so the lines of force proceeding from a magnet may be rendered periodically intermittent in their action on an induction bobbin by a similar metallic disk, set in rapid rotation; and the induced currents, arising from the periodic change of magnetism in the core of the bobbin, produce a musical tone in a telephone, the pitch depending in both cases only upon the number of holes passing in unit time.



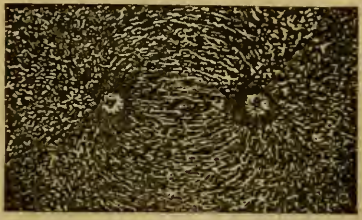
MAGNETIC CURVES OVER HORSE-SHOE MAGNET.

or in opposite directions through the telephone. In the latter case, an almost perfect neutralization of currents took place, so that the sound was scarcely audible.

Non-magnetic metallic disks produce similar musical notes by the periodic modification of the magnetic field by means of the distortion or bending of the lines of force. The solid parts of the conducting disk deflect the lines of force in the direction of the rotation; but upon the passage of a hole, they fall back toward their normal position. A periodic movement of the lines of force will, therefore, take place when the disk rotates. Disks of zinc and copper produce a clear musical sound, somewhat less intense than that given by iron under the same conditions. Any discontinuity in the rotating disk recurring periodically will produce corresponding induction currents in the bobbins. Thus, V-shaped notches round the circumference of the disk are quite as efficient as the holes in effecting the requisite modification of the magnetic field. Moreover, it is not necessary that the holes extend entirely through the disk. Two disks of zinc, of the same diameter and thickness, were placed together on the same rotating spindle, one pierced with a circle of holes, and the other not. The combination proved as efficient in producing the sound as the single perforated disk.



EFFECT OF SCREEN OF SHEET IRON.



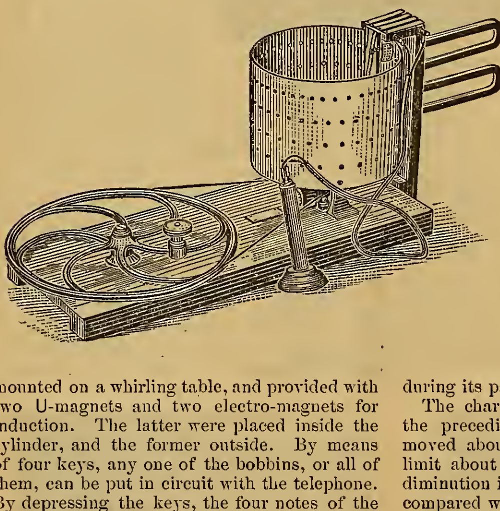
EFFECT OF HOLES THROUGH THE IRON SCREEN.

The experiment was modified by so placing the poles of the magnet that the same circle of holes passed them in succession. By the proper connections, the currents from the two bobbins were made to pass either in the same

A sheet of tinfoil, with a circle of small holes, was pasted on the continuous zinc disk. The perforations, extending only the thickness of the tinfoil into the compound disk, constituted a sufficient discontinuity to produce a clear, though somewhat faint, musical sound. About the same result was given by a disk consisting of the same sheet of tinfoil pasted on cardboard.

Any periodic variation from uniformity in the disk appears to produce corresponding variations in the magnetic field when the disk is rotated. Depressions made with a punch, at regular intervals, in a zinc disk, rendered it a sound-generator when rotated in this apparatus.

Since the pitch of the note obtained depends only on the number of holes passing the pole of the magnet in a second, it is easy to construct a piece of apparatus to illustrate musical intervals. A cylinder of galvanized iron, with four rows of holes in the ratio of 4 : 5 : 6 : 8, was



mounted on a whirling table, and provided with two U-magnets and two electro-magnets for induction. The latter were placed inside the cylinder, and the former outside. By means of four keys, any one of the bobbins, or all of them, can be put in circuit with the telephone. By depressing the keys, the four notes of the common, or major, chord are brought out with great distinctness and clearness. In fact, the intensity of the sounds obtained by the magnetophone is sometimes so great as to be painful to the ear when the telephone is held closely against it.

The above experiment was simplified by employing a disk perforated in four concentric circles with 24, 30, 36, and 48 holes respectively. A telephone with the mouthpiece and diaphragm removed, was presented to the four rows of holes in succession, with the production of the four notes of the major chord as before, clearly defined, but not so loud as with the other apparatus. Further experiments are in progress. H. S. Carhart.

Evanston, Ill.

THE WEATHER IN JULY, 1883.

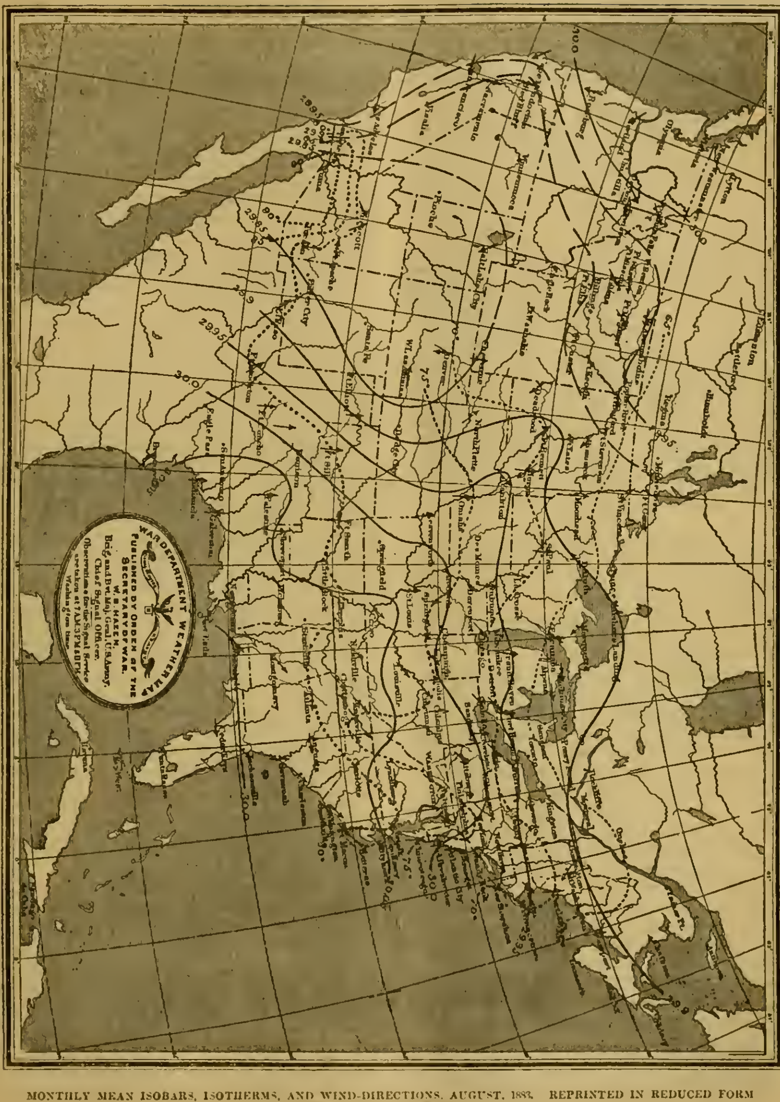
The monthly weather review of the U.S. signal service shows that the most noteworthy characteristics of July were the large deficiencies in rainfall in the southern states and in the north-west, the low mean temperature in nearly the whole country, and the severe local storms, which were frequently accompanied by lightning and hail.

The pressure was nearly normal, the departures in few instances exceeding .05 inch. The progress of eight depressions has been charted. Only one of these passed south of New England, and none visited the southern states. None were traced from the Pacific coast, and four apparently developed in the Rocky-mountain region. One only of these depressions is deserving of the name of a severe storm. This developed in Colorado on the 4th, and reached Nova Scotia on the 7th, accompanied by heavy rains in the lake region, and violent local winds at Hatteras and Sandy Hook. The storm proceeded across the Atlantic, and on the 11th was central off the north-western coast of Ireland, causing heavy squalls and high seas during its passage.

The chart of ocean-ice shows, that, since the preceding month, the eastern limit has moved about 2° westward, and the southern limit about 2° northward. There is a marked diminution in the number of icebergs observed, compared with July, 1882.

The temperature has been below the average, except in the Pacific districts, the northern plateau region, the south Atlantic and east gulf states; but the departures have been small. In New England, the middle Atlantic and west gulf states, the temperature was less than 1° below the normal, while the greatest difference was 3° below in the extreme north-west. A maximum of 112° was recorded at Phœnix, Arizona; and frosts occurred in northern New York, Michigan, Wisconsin, Iowa, New Hampshire, and Pennsylvania.

The special feature in the precipitation record



MONTHLY MEAN ISOBARS, ISOTHERMS, AND WIND-DIRECTIONS, AUGUST, 1883. REPRINTED IN REDUCED FORM BY PERMISSION OF CHIEF SIGNAL-OFFICER.

is the large excess in the upper lake region, New England, and the upper Mississippi valley; and the large deficiency in the southern states, which materially affected the crops in that section. The following table contains the rainfall record: —

Average precipitation for July, 1883.

Districts.	Average for July. Signal-service observations.		Comparison of July, 1883, with the average for several years.
	For several years.	For 1883.	
	Inches.	Inches.	Inches.
New England	3.92	5.76	1.84 excess.
Middle Atlantic states .	4.04	3.28	0.76 deficiency.
South Atlantic states . .	5.65	4.92	0.73 deficiency.
Florida peninsula . . .	5.77	4.49	1.28 deficiency.
East gulf	5.04	2.50	2.54 deficiency.
West gulf	4.16	2.44	1.72 deficiency.
Tennessee	4.06	3.07	0.99 deficiency.
Ohio valley	4.55	5.35	0.80 excess.
Lower lakes	3.84	4.51	0.67 excess.
Upper lakes	3.36	5.42	2.06 excess.
Extreme north-west . .	2.83	2.44	0.39 deficiency.
Upper Mississippi valley,	4.02	5.58	1.56 excess.
Missouri valley	4.44	3 37	1.07 deficiency.
Northern slope	1.94	0.82	1.12 deficiency.
Middle slope	2.77	2.57	0.20 deficiency.
Southern slope	2.50	3.19	0.69 excess.
Northern plateau . . .	1.01	0.00	1.01 deficiency.
Southern plateau . . .	2.35	2.50	0.15 excess.
North Pacific coast. . .	0.58	0.00	0.58 deficiency.
Middle Pacific coast . .	0.01	0.00	0.01 deficiency.
South Pacific coast. . .	0.08	0.15	0.07 excess.

In some portions of the southern states, the deficiencies were even greater than those recorded in the above table: at New Orleans the rainfall was 5 inches less, and at Vicksburg 6.82 inches less, than in July, 1882. Eastport, Me., reports a fall of 5.24 inches in 10 hours, on the 14th inst.

The local storms reported are very numerous, and much damage resulted from rain, lightning, and hail. The greatest damage from rain was at London, Ont., on the 10th, due to the overflowing of the river Thames. Much damage to crops, especially in the west, was caused by hail. A vessel in lake Michigan reports a hail-stone weighing two pounds. The rivers were not high, except at the very beginning of the month; and navigation was suspended in the Savannah and Cumberland rivers on account of low water.

Among miscellaneous phenomena may be noted the brilliant aurora on the nights of the 29th and 30th, which was observed from Dakota eastward to New England, and southward to southern Virginia. Slight earthquake shocks were experienced in Nevada, Illinois, California, and Kentucky; though insignificant in comparison with that on the island of Ischia, of which a condensed account is given. Sunspots were numerous; and an instance is noted in Oregon, of their observation with the naked eye, taking advantage of the smoky state of the atmosphere caused by forest-fires.

The accompanying chart represents the distribution of the mean pressure, temperature, and wind direction for the month.

THE EARTHQUAKE OF JULY 28, 1883, IN THE ISLAND OF ISCHIA.[1]

HAVING visited the island of Ischia by order of the inspector-in-chief of the Royal corps of mining engineers, a few days after the earthquake of the 28th July, I present some observations made during my short tour; and begin with a brief account of the topographical and geological conditions of the island, which last are, without doubt, the chief cause of the terrible disaster.

The formation of the island of Ischia is wholly volcanic, with the exception here and there of some argillaceous elevations, of marine formation, but derived from the disintegration of pre-existing volcanic matter. In connection with the islands of Vivara and Procida, it belongs to the volcanic group of the Campi Flegrei, and forms its western limit.

The aspect of the island as seen from the north is pleasant and delightful, although with deep hollows crowned by the towering and indented crest of Epomeo, rising to an elevation of 792 metres.

The town of Casamicciola, now destroyed by the terrible scourge, was built on the side of Epomeo sloping towards the north, upon two small hills, beside which flow two of the principal streams of the island, one near the mountain, fed chiefly by the waters of thermal springs, the other emptying into the sea near Lacco Ameno, a little farther to the west; these run from south to north; and another more important stream, called the Scarrupato, runs from north to south, flowing through a deep and precipitous valley on the southern slope of the island, having on its banks the villages of Fontana, Serrara, Moropane, and Barano. These last two streams are, in my opinion, very important; being, as we shall see, situated directly in one of the principal gorges of the island.

Forio is on the west coast, upon a plain gently rising towards Epomeo, bordered upon the north by Mount Zale. Eastward of Casamicciola are seen the volcanoes of Monte Rotaro and Montagnone (respectively 215 and 236 metres in height.)

According to Fuchs, the most ancient terrane of the island is composed of the tufa of Epomeo, of a clear green color, containing numerous sanidin, and sometimes pumice and lapilli. On this rest, here and there, strata of pumice and trachytic tufa, and depositions of trachytic lava, with beautiful sanidin from the mountains Rotaro, Montagnone, Tabor, Garofali, etc., which may also be seen on the road from Lacco Ameno to Forio, forming the promontory of Zale.

On the tufa of Epomeo rests a great extension of

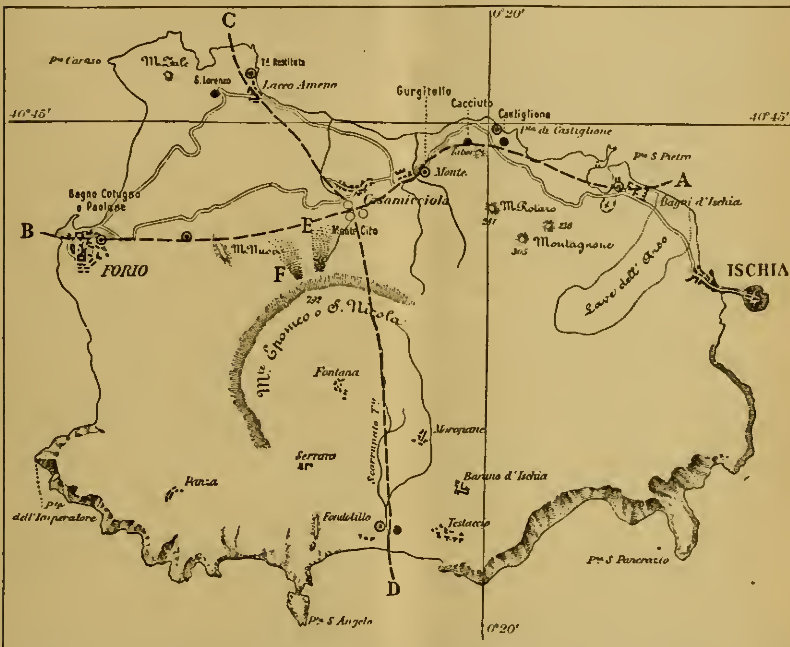
[1] Translated from the Italian of L. Baldacci of the Royal corps of mining engineers (*Boll. R. com. geol.* 1883, nos. 7, 8).

a product of decomposition of this tufa, of submarine origin, which passes occasionally into a plastic argillite well suited for the making of brick. Casamicciola was built upon this disintegrated clayey soil; while Lacco is partly upon trachyte, and partly upon the tufa of Epomeo; and Forio, as also Fontana, Serrara, etc., are built exclusively upon the above-mentioned tufa.

To these formations constituting the island must be added the trachytic lava and scoriae of Arso, the last eruption of which occurred in the year 1301; and, finally, the gravelly or clayey deposits, containing numerous marine fossils of species now living, indicating, that, in an epoch not very remote, a great part of the island was submerged.

For the description and analyses of the rocks forming the soil of Ischia, we must refer to the very important monograph of Fuchs previously cited: what chiefly interests us now is to observe how they are connected with the manifestations of innate activity which are developed in the island. These are of three classes, — hot mineral springs, stufas or jets of aqueous vapor, and fumaroles. These will be easily seen on the accompanying chart. They could not all be given with so small a scale, but I was obliged to limit myself to the most important.

The northern coast contains the chief evidences of volcanic activity. Thus, traversing the coast from east to west, we find the thermal springs of Pontano, Fornello, and Fontana, near Ischia; the stufas and thermal springs of Castiglione, near the point of that name; the stufas of Cacciuto, on the trachytic lava of Tabor; the rich and abundant thermal springs of Gurgitello, near the mountain (il Monte) at Casamicciola, besides others, less important, in that neighborhood; the fumaroles of Monte Cito, to the west of Casamicciola, which on the day of my visit was actively emitting steam and sulphuric acid from different crevices in the tufa of Epomeo; and, finally, trending slightly to the south-west, the thermal springs which are so valuable at the Bagno Cotugno or Paolone of Forio, and which flow from the side of Monte Nuovo



ISLAND OF ISCHIA, EARTHQUAKE OF JULY 28, 1883.

at the east of that town. In these jets of water, steam, and gas, the temperature always ranges from 40° to 100° C.

From these elements, it appears to me, we may reasonably conclude that there exists a large curving line of cleavage from which arise such manifestations, turning its convexity chiefly to the north, running between the baths of Ischia and Forio, and passing exactly through Casamicciola (A B on the chart).

Examining now the other principal manifestations from north to south, we find in Monte Zale and Marecocco, near Lacco Ameno, the thermal springs of Santa Restituta and the stufas of San Lorenzo, the fumaroles of Monte Cito, already mentioned, in the stream which flows into the sea near Lacco; and in the same direction, on the other slope of Epomeo, we have the valley of the Scarrupato, at the southern end of which we find the hot springs of Fondolillo and the stufas of Testaccio. I am assured that on this line will be found other similar but much less important fumaroles, also on the heights of Monte Epomeo; but for want of a guide or exact indications, I cannot verify the assertion. Therefore, also, there is evident to me the existence of another fracture running from north-north-west to south-south-east, which crosses the first exactly at Monte Cito, almost under the town of Casamicciola (C D). These two grand lines of fracture are designated by broken lines drawn upon the annexed chart.

The reason which inclines me to believe that there are two principal fractures, and not an intersection of the fracture C D with the line of superposition of one crater (that of Epomeo) upon another, submarine and more ancient, according to the opinion of the celebrated Prof. de Rossi, is the identity of the manifestations along the two lines, A B and C D; the thermal springs, the stupas, and the fumaroles being identical in the two cases, I believe that they may be more simply attributed to an identical cause, without having recourse to hypotheses hitherto not entirely demonstrable by facts.

As to the phenomena which heralded the terrible disaster, the information collected on the spot is somewhat contradictory. It is certain only, that, for some days previous, slight shocks were felt with faint rumblings; that the springs of Gurgitello, etc., had shown irregularities of quantity and temperature; and that the fumaroles of Monte Cito, hitherto almost inactive, had evinced symptoms of excitement, emitting a peculiar hissing and quick jets of steam and sulphurous acid. It is said that the wells of Casamicciola and Forio were almost dried up, but that assertion does not agree with the facts. There are no spring wells in Casamiccola and Forio, only cisterns; and a scarcity of water observed in some, not all, of these, might perhaps be attributed rather to the drought prevailing for some time in Ischia, than to cracks in the walls of the cisterns. At Forio, I learned from trustworthy persons, that, in the cisterns between San Pietro and the upper part of the town, a remarkable increase of temperature was observed in the water. That seems highly probable, such cisterns being exactly in the direction and neighborhood of the great fracture above described.

The shock which brought desolation upon these lovely regions occurred on the evening of 28th July, at 9.25 P.M. I need not dilate upon its deadly effects, which are already too familiar from numerous accounts. The shock was accompanied by a horrible bellowing, and lasted, apparently, twenty seconds. Casamicciola, Lacco Ameno, and Forio were almost levelled to the ground, with a frightful sacrifice of life; Serrara, Fontana, and other lesser villages suffered terrible injury. The seismic disturbance was felt at Ischia, — where, however, it did but little damage, — and extended to great distances, having been indicated by the seismographs at the geodynamic observatory of Rome.

At Casamicciola and Lacco Ameno, the shock was vertical at first, and then undulatory. Information obtained at the place, and the few observations which I was able to make, indicate that the direction of the wave at Casamicciola was from west to east, then from north to south; at Lacco Ameno, from south-east to north-west; at Forio, the shock was first vertical, then undulatory, and the direction from north-east to south-west. In examining the localities destroyed, I could observe but little in respect to the greater or less resistance offered to the shock by buildings according to their orientation: this idea was advanced by Prof. de Rossi in his account of the earthquake at Casamicciola, in March, 1881, and is certainly based on sound reasoning and also on proved facts. But, in the first place, this shock was so violent and complete that but few walls had been left standing; and secondly, at the time of my visit to Casamicciola, eight days after the catastrophe, the state of the ruins was no longer such as was caused by the earthquake alone: many walls had been torn or thrown down, in order to render less difficult and dangerous the work of rescuing the living, exhuming the dead bodies, and searching among the ruins.

Among other things, I could perceive that some of the walls still standing presented crevices at an angle inclined 30° or 40° from the vertical, with the apex upward, indicating a prevailing upward and downward movement.

On the upper portion of the front wall of the church of the Anime del Purgatorio, in Forio, I observed a clean horizontal crack, showing here, also, the decidedly vertical character of the shock. This character seems confirmed by the condition of a large gate at a short distance to the east of Forio: only the two blocks of stone forming the lower part of the jambs remain in place; the two blocks upon them are thrown towards each other, projecting about six centimetres from those beneath, while the upper parts and the arch have fallen down.

Between Forio and Casamicciola, it seems as if the greatest seismic activity had been manifested along the road joining the two towns, passing by S. M. delle Grazie, and under Fango. The road is, in fact, completely destroyed, and the little cottages that bordered it are ruined. Besides this, the shock has produced two great land-slides, which, descending from the precipitous flanks of Epomeo, have covered a wide extent of chestnut-groves and vineyards; and on the southern slope are great fissures in the earth.

In summing up my observations of all the localities most devastated by the calamity, I am convinced that the buildings standing upon the trachyte at Lacco Ameno and Monte Zale suffered incalculably less than those built upon the tufa of Epomeo and the argillite resulting from its disintegration. Casamicciola was almost entirely built upon this argillite; and it can be said without exaggeration, that not one stone rests upon another. Forio was built upon tufa; and of this town, also, very little remains standing. At Lacco, the houses and walls erected on the trachyte offered, as was stated above, great resistance to the shock, while those built upon the tufa were destroyed.

This agrees completely with the theory of Mallet. Mallet says, that when a seismic or a terrestrial wave passes rapidly from a soil possessing limited elasticity, — as would be the case with our tufas and clays, — to another soil of great elasticity, like the trachytic lavas, it changes not only its velocity, but in some degree also its direction; one part being reflected, the other refracted. The seismic wave, being thus checked, produces a shock in the opposite direction, causing great injury to buildings by the recoil. At the same time the shocks are diminished in force when they reach the more elastic soil, such as granite or trachyte.

This would explain very satisfactorily why Ischia, separated from the cleft AB by the great masses of trachytic lava of Rotaro, Montagnone, and Arso, which would absorb much of the energy of the seismic wave, felt it in so slight a degree.

With respect to the causes of these seismic disturbances, which still continued after the great earthquake of the 28th July, other shocks, accompanied by subterranean rumbling, being felt even when I was on the island and afterwards, it seems to me that they must be attributed to an awakening of the residual volcanic activity of Epomeo. The opinion has been advanced by the illustrious Professor Palmieri, that the violence of the shocks might be especially attributed to the fact of the existence of great subterranean caverns directly beneath Casamicciola, and to the giving-way of the supports which upheld these vaults, caused by seismic action, and facilitated by the weakening of these supports by the underground flow of thermal waters. This opinion does not appear to me to be fully demonstrable. There exist, it is true, in the neighborhood of Casamicciola, caverns of plastic argillite, formed by the lapse of ages; but certainly it is not of these that the illustrious professor of Naples intends to speak: the cause would assuredly be insufficient to produce effects so imposing, and such far-reaching seismic disturbances. I could not enter these caves, for want of persons disposed to serve as guides at such a time; but it is certain that they could be only more or less tortuous galleries of small diameter and but a few metres in height, as is generally the case in such formations. I have been assured also, by persons worthy of trust, and experienced in these caverns, that this is the case. Besides, neither at Casamicciola nor in the vicinity could I see any lowering whatever of the level of the soil: the roads which lead from Guardiola or the shore to Casamicciola, from Casamicciola to Lacco, from Lacco to Forio, have preserved their level perfectly, and show only the longitudinal or transverse fissures inevitable after such a telluric commotion. The only road completely destroyed (but not depressed) is that which leads from Forio to Casamicciola, along the side of Monte Epomeo, which, as we have seen, is directly along the cleft A B.

In any event, when this period of desolation and ruin has passed, when perhaps the time shall have come to decide upon the fittest place to rebuild the shattered dwellings, it would be useful to make a most accurate inspection of all the ancient and modern caverns of the island, and to determine what influence they may have upon the stability of the soil and the superincumbent buildings.

In conclusion, then, it appears to me, 1°. that no other cause need be sought for the shocks which have desolated the island than the volcanic activity which still remains, and awakes at intervals; 2°. that the residual volcanic activity of the island is manifested along two principal fissures, one, A B, a curve with its convexity to the north, from the baths of Ischia to Forio, the other, C D, directed approximately north-north-west and south-south-east, between Lacco Ameno and the stufas of Testaccio; 3°. that the place where Casamicciola stood is upon the intersection of these two lines, and, therefore, at the very focus of seismic activity, and that it has been, and always will be, the locality most liable to be devastated by earthquakes; 4°. finally, that buildings erected upon trachytic lava offer a resistance to the shocks, far superior to that of buildings erected upon tufa or clay, and that this circumstance should be borne in mind when it is proposed to restore the ruined villages.

Rome, Aug. 9, 1883.

JULY REPORTS OF STATE WEATHER SERVICES.

A number of states have organized weather services which are of material benefit to the people. A brief summary of the July reports that have been received is here given.

Georgia. — The July crop report contains meteorological data from fifteen stations. The special feature is the drought, of which it is said, "In northern and middle Georgia, the drought has been almost continuous since April 23, — the date of the last general rain in the state, — broken only by light and ineffective showers at considerable intervals. A few points reported sufficient rain, but the northern half of the state, with these exceptions, has suffered a most prolonged drought, which is yet unrelieved."

Illinois. — Minimum temperatures of 47° were reported, and maximum of 99°. The prevailing wind direction was south-west to south; the highest wind velocity was eight miles per hour.

Indiana. — The special feature of this report is the minimum temperature of 50°; the highest temperature noted was 96°, and the rainfall varied from 2.83 to 7.72 inches.

Iowa. — In this state the weather "was very favorable to the crops, being fair, nearly normal in temperature, with an excess of rainfall, and southerly winds prevailing." The greatest rainfall was that of nearly ten inches in north-eastern Iowa, from the 20th to the 23d inst. A number of severe squalls and local storms were reported, which did much damage. Insolation has been high, because cloudy days were rare; the sun thermometer exceeded 140° on twenty-one days.

Kansas. — The report includes one station only, — Topeka; and the month is reckoned from June 20 to July 20. On fifteen days the temperature exceeded 90°, the maximum being 98°. "On June 23, just after a heavy rainstorm, the air having had a temperature of 65° to 70° all the forenoon, the temperature suddenly rose more than 20°, in consequence of a hot current of air from the south. This lasted but half an hour, when the temperature fell as suddenly as it had risen."

Missouri. — The temperature has been considerably below the normal; there being but five instances since 1837, when lower average temperatures in July have been recorded. A minimum of 52° was observed. On the 13th a destructive wind-storm passed through the north-western and northern portions of the state. A railway train, near Browning, was blown from the track, and many towns suffered much damage. This storm was not a tornado, but 'a steady straight blow for upwards of half an hour.'

New Jersey. — The maximum temperatures range from 91° to 98°, the minimum from 52° to 61°, the rainfall from 2.21 to 4.38 inches.

Ohio. — The mean height of the barometer, 30.025 inches, was higher than that of either of the three months preceding. A minimum temperature of 43° was reported. The rainfall ranged from 1.55 at Lebanon to 7.23 at Quaker City, and was above the July normal. "The railway weather signals were continued during July, and by examination of the reports it is found that eighty-six per cent of the predictions were verified." The predictions are those of the U. S. signal office.

Tennessee. — The temperature ranged from 56° to 98°. A range of 0° was reported from Smithville on the 7th. The rainfall ranged from 1.20 to 7.99 inches. Rain fell on the average on nine and two-thirds days, but the rainfall was rather unevenly distributed. "In some localities the extensive rains have greatly injured the crops of wheat, oats, and hay that had been cut, causing the former to sprout, and rendering much of it unmarketable, while in other localities a continuous drought has materially lessened the chances for the growing crops, which were full of sap, and it will require very favorable conditions during the coming month to even partially restore them." W. U.

THE MEETING OF SWISS NATURALISTS.

The sixty-sixth annual reunion of the *Société helvétique des sciences naturelles* took place this year at Zurich, Aug. 6–9. As at all these Swiss meetings, discussions were happily mingled with daily banquets, at which toasts were offered to fatherland, to guests, and to the older honored names in Swiss science, — Studer, Heer, and Mousson, founders of the society. Sometimes German, and sometimes French, was spoken, and sometimes both by one speaker in the same speech. This year this venerable society gathered men of many countries, and Zurich received them cordially. Daubrée and Hébert of Paris were there; Lory of Grenoble, Credner of Dresden, Fritsch of Halle, Fontannes of Lyons, Hughes and Madame Hughes of Cambridge, Blanford of London, Dewalque of Liège, Kölliker and Fick of Wurzburg, Kundt of Strasburg, Clausius of Bonn, Szabo, Schuler, and Wartha of Budapest, Wislicenus of Wurzburg, Krauss of Stuttgart, von Hauer, Suess, Neumayr, Mojsisovics, and Goldschmidt of Vienna, Vilanova of Madrid, Beyrich and Richthofen of Berlin, Capellini of Bologna, Giordano of Rome, Wiedmann and His of Leipsic, and Seguin of New York.

From communications to the *Journal de Genève*, under initials which we presume to refer to the well-known physicist, Raoul Pictet, we glean the following account of the scientific sessions of the meeting, which began on the morning of Aug. 7.

Mr. Cramer, professor of botany at the university of Zurich, and president of the assembly, opened the meeting with a very noteworthy address before an interested audience of more than three hundred persons. He reviewed the chief progress of the natural sciences, and laid particular stress on the study of those minute organisms which constitute life within life, and whose appearance and development accompany epidemic diseases among men.

Reports on the various commissions (on finance, geology, geodesy, earthquakes, etc.) were followed by two communications from Profs. V. Meyer of Zurich and H. Fol of Geneva.

Mr. Meyer traced the progress of chemistry under the influence of the ideas of Mendelejeff and L. Mayer. He explained how these investigators had been able to classify all simple solids under five distinctly separated families. All these bodies are similar as to their general properties, the gradual increase of their atomic weights, the similarity of their chemical reactions, their atomic volume, etc. These likenesses are so striking, that the memorable discovery of gallium by M. Lecoq de Boisbaudran of Paris was foreseen three years before that simple body was separated. The density and atomic weight of this metal had been determined by calculation before its actual presence was demonstrated beyond doubt by the well-known experiments of the French chemist.

Professor Meyer concluded by showing the indebtedness of science to men who think, to men who found theories on experiments, and then verify the truth of their hypotheses by renewed investigations. It is beyond question, that the labors of Mendelejeff and Meyer are the point of departure of a rational classification of matter, and that they have been a fertile source of useful chemical discoveries.

Professor Hermann Fol of the university of Geneva described his studies on animal individuality. In the lower animals, individuality is a different thing from what it is in the higher, such as the mammifers. But this law of individuality among the vertebrates is not without exception; and we all know the wonder which is excited by the sight of creatures with some member double, such as are often exhibited at shows, or may be seen in museums.

For a long time we have tried to explain the origin of these anomalies. Two theories have been proposed, — that of the creation of two distinct beings, and that of the partial division of one primitive simple. Neither of these theories quite accounts for the phenomena observed. The new and essential fact which Mr. Fol presented comes under the general law, that in these abnormal cases two heads always appear in the egg at the commencement of its development. The body forms immediately behind; and these two trunks, coming together, are so perfectly united that the two primitive heads are very near each other at the outset. In the first place, then, only the higher part of the body is duplicated in these montrosities; yet these two parts may become completely separated, resulting in twins, which so closely resemble each other that even the parents find difficulty in distinguishing them.

Mr. Fol has investigated the causes of the appearance of two embryos in one egg, by a very neat method. He asphyxiated the eggs of Echinus by immersion in Seltzer water (containing pure carbonic acid); and he ascertained that in this unhealthy condition, maintained for a moment, two germs at the instant of passage into life could simultaneously have birth.

Our individuality is one of our most cherished ideas. The great philosophers Descartes, Kant, etc., did not investigate even the possibility of a multiple individuality: it is interesting to observe the flexibility of that idea under the disturbing influence of special conditions of the origin of life.

Mr. Fol exhibited plates representing different kinds of montrosities: two heads and one body, a little body projecting from the eye of a child otherwise relatively well formed, etc.

Professor Herzen of Lausanne, in closing the session, invited all the doctors present to observe an exceedingly interesting case, — that of a man who was on the point of dying from hunger, the results of strangling, when M. de Cérenville of Lausanne began his experiments. This skilful surgeon arranged a stomachic fistula by which the man ate. He was regularly supplied with food, recovered his strength, and rapidly improved. Mr. Herzen took care of this man at his laboratory, and studied the phenomena of digestion according to the process which recalls the well-known Canadian case of M. de Beaumont.

The next morning the association met in sections in different halls. Unfortunately the gift of omnipresence was not given to man, and the members of one section could with difficulty glean here and there any knowledge of what was taking place in the neighboring halls. Besides it would take a volume to contain such a quantity of material, of which a *résumé* will appear in the September number of the *Archives des sciences physiques et naturelles.*

The following account treats only of the subjects taken up in the single section of physics.

Professor Clausius of Berne was elected, by acclamation, president; and Mr. Weber of Neuchâtel, secretary. Mr. F. A. Forel submitted a very interesting paper on the variations of temperature which the Swiss lakes undergo, from summer to winter, and from morning to night. It seems that in an average year the variations of temperature in the year are scarcely noticeable at a greater depth than 60 to 80 metres; above that, the surface of the water is for these lakes between 4° and 5.4°, the highest temperature corresponding to that of Lake Geneva. The variations are felt at a mean depth of ten metres.

After a lively discussion of the manner in which the currents of water influenced by these variations of temperature are set in motion, Prof. Charles Soret of the university of Geneva submitted the results obtained with his new apparatus, the refractometer. This first set of experiments dealt especially with the crystals of the alum-series whose radical is an alkaline metal. This very clear communication was especially remarkable for the skill with which the young professor set forth his subject with a great number of new facts in a comparatively short time. He was followed by his father, Prof. L. Soret, who presented a paper for Mr. L. E. Sarasin, and demonstrated by figures and curves the values of the index of refraction of fluor spar, a crystal, which, since the important works of Cornu and L. Soret, has taken so important a place in the construction of the achromatic lenses of spectroscopes. This paper was marked by extreme precision.

Mr. L. Soret presented a communication to the section of chemistry, belonging in great part to the section of physics. He set forth how the absorption bands seen in the spectra of solutions of albuminoid substances could be used in ascertaining the chemical nature of these solutions. These absorption bands are found especially in the ultra-violet; and, thanks to the fluorescent eye-piece invented by the speaker, their presence renders an analysis very rapid and simple.

Professor Clausius of Bonn gave us a lesson in mechanical electricity: he considered the problem of the production of electric currents by mechanical means. All the knowledge of this scholar, this enthusiastic and ingenious investigator, was necessary to obtain the final solution of so complicated a problem. The paper was heartily applauded.

Mr. Casimir de Candolle repeated, before the members who were present, some experiments to show how sand-ripples at the bottom of our lakes are formed. These facts were applied, in accordance with the ideas of Professor Strasburger of Bonn, to explain certain appearances of envelopes and vegetable cells in fossils.

Mr. Raoul Pictet presented an experimental demonstration of the second law of thermo-dynamics, deduced from the simultaneous working of steam-engines and frigorific apparatus.

Professor Weber of Zurich presented two interesting papers: one, on a dynamic method for the exact measurement of the coefficient of conductibility of heat in liquids; the other paper, on the apparatus for measuring electric units.

Mr. H. Dufour of Lausanne distributed among the audience a set of photographs showing the electric condition of the air, which were obtained by means of a registering electrometer in the new physical laboratory at Lausanne. These curves are so connected with the condition of the heavens, that it is no exaggeration to expect to predict the weather several days in advance, through a careful examination of the variations of electric tension of the air. For fine weather, the electric tension is strong; it sensibly decreases during and before storms; the rapid falling of the curve of the electric potential of the air is always an indication of rain or storm.

The late hour made it impossible to listen to five additional communications which had been announced. The boat for an excursion on the lake awaited its guests; science paled before the beauties of nature. Though continuing to converse on the subjects treated, we all together betook ourselves to the pier. The excursion was delightful. On our return, the streets were illuminated; Bengal and electric lights mingled their dazzling rays. The citizens of Zurich gave us a magnificent reception; and the *fête*, enlivened by an excellent orchestra, was continued to a late hour.

The next morning, Thursday, we listened to three scientific papers which closed the intellectual part of the reunion.

The honors of that morning belong to Professor Suess of Vienna. With consummate skill he set before us the chief points of the modern theory of the upheaval of mountains: he held his audience with great ease, and left a refreshing memory with all who heard him.

This paper, with that of Mr. Heer which followed, will be issued in full in the memoirs of the society.

The afternoon was given up to leave-takings. Seated around the long tables of the hotel L'Uetliberg, thanks and farewell were said again and again. Toasts of gratitude, toasts to the absent, to the present, to Clausius, to Mousson, Oswald Heer, and Studer, founders of the society, were applauded by all, glass in hand.

Appended to this account, appears a list of the principal papers offered in the other sections.

In the botanical section, Professor Heer spoke of the cretaceous and tertiary flora of Greenland; Mr. Schnetzler, of a Chinese primrose in which the sexual organs corresponded to an earlier stage in the evolution of Primulaceae, and on certain relations between an aërial alga and lichen; Mr. Favrat discussed the hybrids of two species of primrose and of other plants, and called attention to the changes in a Cardamines growing in turfy soil. Mr. Andreae spoke of pasturage on the Jura; and Mr. Casimir de Candolle drew attention to a curious Cytisus bearing both red and yellow flowers.

In the chemical section, Professor Krafft read a paper on the preparation of saturated alcohols; Professor Soret, on the absorption of the ultra-viole rays by the albuminoid substances; Professor Schulze, on the composition of cheese; and on phenylamido-propionic acid; Prof. Victor Meyer gave a new method for determining the vapor density of Cl. Br. I. for high temperatures, and reported on a new series of bodies, which he termed *thyophènes*, contained in benzol. Professor Wislicenus of Wurzburg offered a contribution to the theory of Van t'Hoff; and made a communication on the action of chloride of phtalyle and of phtalic anhydride on the ethers of malic acid; Professor Schaer recalled the forgotten works of De Saive (in 1756) on zinc combustion; Dr. Goldschmidt showed the action of hydroxylamine on ketones; Dr. Ceresole spoke of acetacetic acid; Professor Lunge, of the manufacture of sulphuric acid; Dr. Schumacher gave analyses of foods; and Dr. Urech exhibited a laboratory-lamp.

In the geological sections, papers were offered by Messrs. Favre, Neumayr, Schardt, Goll, Mühlberg, Fellenberg, Jaccard, Koch, Chevannes, Mösch, Fratech, and Suess.

LETTERS TO THE EDITOR.

**** Correspondents are requested to be as brief as possible. The writer's name is in all cases required as proof of good faith.*

Geology of Philadelphia.

In Dr. Frazer's notice of my lecture upon the geology of Philadelphia, there is so little of adverse criticism, that it may seem ungracious to reply to the few points regarded as blemishes. Merely in defence of the use made of certain terms called in question, a few words here may not be out of place.

In describing the Philadelphia gneiss as both Huronian and Mont Alban, there is no confusion, if, as is held by many geologists, the former term is generic, the latter specific.

The term 'creep,' as applied to the pulling-over of softened or broken strata downhill, by the action of gravity, frost, etc., is one frequently used in describing such phenomena in regions south of glacial action. It is used repeatedly in this sense, in a report issued by the Geological survey of Pennsylvania, in 1880.

The term 'hydro-mica slates,' objected to, is not only used by Rogers, Lesley, Dana, Hall, and others, but occurs repeatedly in Dr. Frazer's recent geological reports on Lancaster and Chester counties, being used by himself.

The positive statement regarding the absence of glaciation in Pennsylvania south of the terminal moraine (the immediate 'fringe' in the western part of the state excepted) was made because of certain statements to the contrary quite recently made by a distinguished authority. It was made only after a thorough investigation of every locality supposed to be glaciated.

In conclusion, I may be permitted to say that while, owing to the necessarily limited length of a public lecture, the rocks of Philadelphia could not be so fully treated of as the superficial formations, this latter — and in this region more debatable — subject will form the topic of future lectures, which may perhaps be worthy of further comment by my friendly critic.

HENRY CARVILL LEWIS.

Philadelphia, Sept. 7, 1883.

The pre-Cambrian rocks of Wales.

Those who are interested in the questions raised by Dr. Henry Hicks in his criticism of Professor Geikie in SCIENCE for Aug. 10, may find it to their advantage to consult my paper entitled 'History of some pre-Cambrian rocks in Europe and America,' which appeared in the *American journal of science* for April, 1880 (vol. xix. p. 268–283). I had the good fortune, in 1878, to spend several days with Dr. Hicks, in going over the typical localities previously studied by him, not only at and near St. Davids in South Wales, but also those of Carnarvon, Dinorwic, and Anglesea, Messrs. Tosell and Tawney being our companions, in North Wales. As a result of these studies, I am satisfied that the views of Messrs. Hicks and Hughes are correct, and their criticisms of Professor Geikie well founded.

The Dimetian, alike in North and South Wales and in Anglesea, has both the lithological characters and the stratigraphical relations of the Laurentian of North America. The Arvonian corresponds in like manner to the great series of *hälleflintas* or petrosilex rocks, jaspery and porphyritic, whose distribution on the coast of Massachusetts and of New Brunswick, in the Blue Ridge of Pennsylvania, in Missouri, and on Lake Superior, I have studied and elsewhere discussed (*Second geol. surv. Penn.*, rep. E, p. 189–195). Similar rocks have also been described by Irving in the Baraboo river in central Wisconsin, a locality which I have lately had an opportunity of examining. The conglomerates of Arvonian pebbles, which form the basal beds of the Cambrian near Snowdon, are indistinguishable from those found at Marblehead and elsewhere on our eastern coast, lying on or near the Arvonian.

The Pebidian of Hicks is our typical Huronian, as seen in eastern Canada and around the lakes Huron and Superior. Professor Bonney, who has lately received a collection of these, is struck with their complete resemblance to the Welsh Pebidian which I had seen and called Huronian thirteen years since. The succeeding gneisses and mica-schists (upper Pebidian or Grampian of Hicks, and Caledonian of Callaway), which are our Montalban series, are not met with in Wales, but appear not only in Scotland, but, as I have pointed out, across the channel, in the Dublin and Wicklow hills in Ireland.

The similar succession in the Alps, I have described in a late paper, of which an abstract appeared in SCIENCE for Sept. 7 (p. 322). The student who compares the succession of stratified crystalline rocks alike in North America, in the British Islands, and in southern Europe, can scarcely fail to recognize, in their constant stratigraphical and lithological relations, something like a 'universal law.'

T. STERRY HUNT.

Montreal, Sept. 11, 1883.

SERGEANT FINLEY'S TORNADO STUDIES.

Report on the character of six hundred tornadoes. Professional papers of the signal service, No. vii. By J. P. FINLEY, Washington, *Signal service*, 1882. 19 p., 3 maps, 4°.

Tornadoes: Their special characteristics and dangers. By J. P. FINLEY. Kansas City, 1882. 30 p.

So striking a phenomenon as a tornado, and one so destructive in its effects, would naturally receive much attention; yet, curiously enough, the competent treatment which these storms have received is remarkably inadequate. Those omniscient gentlemen, the reporters of the newspapers, have written much about tornadoes, and many columns of our summer dailies are filled with accounts of them; but, aside from the books of Peltier and Reye, the scientific literature is fragmentary. Half a century ago, at the time of the battle between Reid, Redfield, Piddington, Espy, Hare, and others, over the rotatory theory of storms, the tornado-literature took a considerable development; but it soon fell to small dimensions, and here it has remained until quite recently. The present activity in this field is largely due to the signal service, and Sergeant Finley's contributions form an important part of the current literature.

Mr. Finley's specialty is the collection of facts concerning tornadoes. He has accounts of individual tornadoes in many of the annual reports of the chief signal officer. They represent the facts collected by him on the field of destruction itself. They are evidently gotten together with great care; measurements are made when practicable, and explanatory maps and sketches are numerous. His evident object is to put before the reader the accurate representation of what he saw, encumbered as little as possible by explanatory theories. The result is that his reports are interesting reading, and afford a mine of wealth for the future Kepler of tornadoes.

Not quite so important, perhaps, from a scientific point of view, but of far more general interest, is his report. Its principal feature is the tabulation of the tornadoes discussed, with headings for time, dimensions, velocity, clouds, and other meteorological features. These are summed up, and from the results are drawn various interesting conclusions concerning maxima, minima, and averages.

Mr. Finley's search for accounts of tornadoes has been extensive; but as he has unfortunately given no references, we cannot tell how extensive it may have been. Evidently he has not gone through the Proceedings of the American association for the advancement of science, or he would have found the tornado of Aug. 9, 1851, in Connecticut, recorded, and that of May 3, 1868, at Shanghai, Ill. Nor has he searched through the state agricultural reports, where he would have found that of June 3, 1860, in Illinois, and doubtless others. Again, Niles's American register gives one at Keene, N.H., on July 25, 1807, and at Knoxville, Tenn., on May 25, 1808. The Philosophical transactions would have yielded him one in New England, July 10, 1760; and several others could have been picked up in Blodgett, Piddington, and in the *American journal of science*. Even that of May 22, 1873, in Illinois and Iowa, reported in the publications of his service for 1873, seems to have escaped his attention.

As average results like those deduced by Mr. Finley depend for their value on the number of individual cases taken into consideration, would it not have been wise for him to have collated those occurring in other countries, so far as they were accessible without difficulty? Peltier would have yielded him quite a crop, some of which, by the way, come curiously near home. Other text-books would have given other European ones; and Chinese and African ones have been described, the latter frequently. Tornadoes are by no means exclusively American; and by a comparison with those in the other countries their essential features could be more easily sifted out, and the incidental ones given their proper prominence.

In the pamphlet, 'Tornadoes, their special characteristics and dangers,' the author classifies the rotatory storms. It was in the pursuit of a classification of storms, that he first had his attention called to the insufficiency of our knowledge of this species. Tornadoes are here described in some detail, and numerous directions given for the protection of life and property on their occurrence. It is the best description of the storm known to the writer.

Mr. Finley considers the tornado a much better-defined species than is likely to be acknowledged by meteorologists generally. Right names are extremely useful, but we must not permit them to conceal any underlying unity. By his anxiety to get a clear species, the author shuts out the light which he might get from the study of storms of so similar character that one is compelled to believe that their differences are due only to difference in surroundings. Thus water-spouts are only tornadoes on the water, with circumstances remarkably favorable for observation. They occur not infrequently on the Great Lakes, and the change from tornado to water-spout has been observed more than once. Judging from the only description known to me of the riband storms of British North America (*Cosmos*, 2d series, iii. 274, 275), they are also somewhat modified tornadoes. And while the name cloudburst refers rather to a single feature of subordinate meteorological importance, the phenomenon is probably often of tornado character. Indeed, leaving out of account eddies, which it is not, the tornado differs only quantitatively from the other members of that list of storms which begins with the formation of a cumulus cloud, passes on to thunderstorms and hailstorms, and culminates in the 'low-centre,' the hurricane, and the typhoon. They all find their origin in the transformations of water; and to overlook the relations they have to each other, is to refuse assistance in a problem well-nigh insoluble with that assistance.

It is expressly stated (see p. 4 of the last-mentioned pamphlet), that the gyratory motion is always from right to left. The writer would point out the exceeding difficulties which surround the determination of this point. Some of the early observers saw only indications of a radial inpour, and in the descriptions of tornadoes one frequently finds dextral whirls mentioned. In so small a storm, the earth's rotation would surely have no appreciable disturbing effect; and that, in a difference of latitude of only a few rods, it should originate velocities of a hundred or more miles an hour, is so unlikely that it need hardly be considered. Furthermore on p. 7 the author admits variations in the gyration of the tornado's other self, — the water-spout. So, while unwilling to differ from so experienced an observer on such a point, both the records and general considerations lead the writer to think that the direction of gyration may be indifferently dextral or sinistral.

There is one possible feature of tornadoes which has not yet been definitely proven, but of which we ought now to be able to ascertain the truth or falseness by an investigation like that just discussed; viz., Are tornadoes disposed to return on the same path? The writer spent his childhood in northern Illinois, where heavy hail and other tornado-like storms are not rare. He remembers several instances of their following the exact path of their predecessors. Professor Whitfield (*Amer. journ. sc.*, 3d series, ii. 99) says in regard to southern tornadoes, "It is not an established fact, but it is commonly believed, and with some reason, that the tornado does, in the course of years, return along its beaten path, and that it is unsafe to build where one has ever passed. The house in Pickens county stood on a hill from which a log-cabin had been blown away some thirty years before. I witnessed the last of three, which have passed along the same track. Near Hernando, Miss., three have followed an unvarying line." He suggests that some places are more favorable than others for the production of these storms, which would make them of a more local character than Mr. Finley would be willing to admit.

While Mr. Finley's work, like that of all others, is capable of improvement, the writer believes he has done great service to this branch of science, and deserves the sincere gratitude of both the student of science and the resident in tornado districts. In enabling him to pursue his investigations, the signal service deserves the commendation of the scientific and general public.

ZIEGLER'S PATHOLOGICAL ANATOMY.

A text-book of pathological anatomy and pathogenesis. By Ernst Ziegler; translated by Donald McAlister. London, *Macmillan*, 1883. 360 p. 8°.

This book is a translation, from the German, of a portion of Professor Ziegler's work on pathological anatomy, which appeared two years ago. The work is not as yet completed in German, nor does the translation contain all that has yet been published, covering only the ground of general pathological anatomy.

Professor Ziegler is a young man who has already gained distinction in Germany by his original investigations in connection with tuberculosis and certain of the processes involved in inflammation.

The scope of the present work is to afford to students and physicians a text-book which shall give a short and concise statement of what is known upon the subjects treated, including the results of the most recent investigations.

The book opens with a section of three chapters on malformations. This is condensed and dry; and further, as there are no plates to illustrate the monstrosities, the student wishing to acquire a knowledge of this difficult subject will do better to fall back upon the earlier monographs of I. G. St. Hilaire, Foerster, and Ahlfeld.

Then follow four chapters on the pathology of the blood and lymph, which, though short, are very good, containing essentially what is known upon the subject. Very little space is devoted to thrombosis and embolism; but this is not a neglect on Ziegler's part, as he treats of it in detail in that portion of the book which has not yet been translated.

The succeeding chapters on the retrograde disturbances of nutrition are worthy of much praise, giving as they do a very clear, though concise, account of these changes, including also the results of the latest work on coagulation-necrosis.

The chapter on cysts, consisting of but a single page, is incomplete, and does not treat with sufficient fulness this important subject.

The three chapters devoted to hyperplasia, regeneration, and metaplasia of tissues, give a good account of the somewhat meagre knowledge on these points.

In treating of inflammation, the author gives a short historical sketch of the ideas held at various times upon the conditions present in this process, and then devotes considerable space to the ideas now in vogue, as expressed by Cohnheim, Samuel, and others; the exudation from the vessels, due to presumable changes in the vessel-wall, now forming the anatomical basis. The parenchymatous inflammations of Virchow find no place in the category, nor will Ziegler allow that the connective-tissue corpuscles take any part in the process, as advanced by Virchow, and still maintained by von Recklinghausen.

The secondary changes occurring in the products of an inflammation are well treated; a point in regard to which Ziegler has himself contributed some original work.

The infective granulomata are removed from the category of tumors, and are classed with the inflammations. Under this head are considered tubercle, syphilis, leprosy, glanders, lupus, and actinomycosis.

The anatomy of tubercle and its development are fully and well treated, and the relation of the Bacillus tuberculosis to the disease detailed so far as the present knowledge permits.

Virchow's classification of tumors is adopted, with the exception, as already stated, of the omission of the granulation-tumors. In reference to the aetiology of tumors, the author does not regard Cohnheim's embryonic-foci theory as sufficient to explain all cases, though undoubtedly applicable to many.

Of the increasing importance of the subject of parasites in relation to disease, no better proof is to be found than in the greater number of pages devoted to this point in the newer books; and among the parasites the Schizomycetes claim the lion's share of attention.

The author gives Cohn's classification of the latter, together with a description of their general morphological characters. He then devotes considerable space to a consideration of the conditions, such as temperature, nutritive substances, and the like, favoring their growth; their effect in causing the groups of changes included under the terms fermentation and putrefaction; finally, discusses their relation to disease. Of their method of action, he very properly refrains from expressing an opinion.

The list of pathogenic microbia, according to Ziegler, is a larger one than the strictly cautious observer will admit. For, to go beyond as a proven fact that specific organisms have been found in connection with other diseases than anthrax, relapsing fever, septicaemia of mice, and probably with tuberculosis, glanders, malignant oedema, and, under the Hyphomycetes, actinomykosis, is, in the present state of our knowledge, unwarrantable.

In regard to the mutability of bacteria, the views of various writers *pro* and *con* are given, but no definite conclusion is expressed.

To the Hyphomycetes a chapter is devoted; and, while giving a very good account of what is known in regard to their pathogenic qualities, one can but be impressed with the fact of the extreme meagreness of knowledge of the relation which the ever-present mould-fungi bear to disease.

The chapter on animal parasites contains nothing of special interest.

The book as a whole shows evidence of having been written by a young man. All that is new has special stress laid upon it, while the work of the earlier generation receives less attention. The author inclines to state things positively, with but little of the cautious scepticism which marks the writings of the older and more conservative worker who is prepared to weigh every objection, and combat every point.

This latter quality, however, does not in the least detract from the value of the work, for the object for which it was intended; on the contrary, much enhances it. For nothing can be more disheartening to the student beginning a subject, than to be plunged at first into that mire of doubt which is ever present for him who attempts a deeper insight into a science.

The English translation is a remarkably good one. It is certainly as agreeable as it is rare, to read a smooth translation, where one is not constantly reminded of the tongue from which it had its origin.

The letter-press and wood-cuts are much superior to those usually found in text-books; and Macmillan deserves with Dr. McAlister the thanks of the English-reading profession for presenting Professor Ziegler's work in so attractive and readable a form.

As a text-book for students, physicians, and those men of science who are interested in the sciences upon which medicine rests, it fills a gap which has long been felt.

ECONOMIC ENTOMOLOGY IN ENGLAND.

Report of observations of injurious insects during the year 1882, with methods of prevention and remedy, and special report on wire-worms. By ELEANOR A. ORMEROD, F. M. S, etc. London, 1883. 98 p., illustr. 8°.

THIS is the fourth of a series of reports prepared by Miss Ormerod for the use of the farmers of Great Britain. The plan of these reports is peculiar. They consist largely of abstracts from the writer's correspondence; the greater part of which is presumably in reply to circulars issued by her. In thus collecting and publishing the results of the experience of the more observing agriculturists, Miss Ormerod is doing an important work, and the enthusiasm and energy which she has displayed in it are deserving great praise. It is fortunate, however, that she has not confined herself to the work of compilation, but has recorded the results of personal observations. And we venture to suggest that what she states on her own authority will be read with more interest than the quoted portions of her work. For no one but herself can judge of the relative value of the conclusions of her various correspondents. We realize, however, that the publication of the reports of these correspondents is probably a considerable part of the incentive to their co-operation with her; and the system has produced such good results that one should be slow to criticise it.

The report for 1882 contains notes on more than thirty different species of insects infesting fruit, garden-vegetables, field-crops, and forest-trees. The most serious injury recorded for that year is that to hops by Aphides. It is estimated that the loss to the hop-growers of the United Kingdom from this cause was not less than £1,750,000. This injury is the greatest which has been incurred for many years.

Nearly one-half of the report is devoted to an article on wire-worms, or click beetles. This article was compiled from notes contributed in reply to a circular issued by the council of the Royal agricultural society, and it doubtless gives a very good idea of the popular beliefs now held in the British isles respecting these pests. We wish that the above-named society would now afford their entomologist, Miss Ormerod, an opportunity for directing a series of comparative experiments to test the truth of these beliefs.

The report is well illustrated, partially by some of the well-known figures of Curtis, and partially by original figures drawn by the authoress.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

The elliptic differential equation. — M. Rud. Sturm has here given a method of integration for the general elliptic differential equation $\frac{dx}{\sqrt{X}} \pm \frac{dy}{\sqrt{Y}} = 0$, where X and Y are quartic functions of x and y respectively, say, $X = E(x-a)(x-b)(x-c)(x-d)$, and Y a similar function of y. He shows that this equation can be integrated directly by aid of an integrating factor which he determines. Denoting by $X_{ab} \ldots Y_{ab} \ldots$ the products of two of the factors $x-a, x-b \ldots, y-a, y-b \ldots$, then the left-hand side of the equation $\frac{dx}{\sqrt{X}} \pm \frac{dy}{\sqrt{Y}} = 0$ is made the exact differential of

$$\frac{1}{x-y}\left\{\sqrt{X_{ab}Y_{cd}} \mp \sqrt{X_{cd}Y_{ab}}\right\}$$

by multiplying it by the quantity

$$\frac{1}{(x-y)^2}\left\{[\tfrac{1}{2}(x+y)(a+b) - xy - ab]\sqrt{X_{cd}Y_{ab}} \mp [\tfrac{1}{2}(x+y)(c+d) - xy - cd]\sqrt{X_{ab}Y_{cd}}\right\}.$$

— (*Math. ann.*, xxi.) T. C. [238

PHYSICS.

Electricity.

Efficiency of telephones. — K. Vierordt measures the weakening of sound through telephones by diminishing the sound at the transmitter until it just becomes inaudible at the other end. The sound is measured by the mass and height of a small leaden sphere, which is dropped upon a tin plate. Using two Siemens-Halske telephones, of 205 and 208 S. U. resistance respectively, he found that the loss over thirty-four m. of wire was less than seventy-five per cent of the loss in air. — (*Ann. phys. chem.*, xix. 207.) J. T. [239

Electric lighting. — Ganz & Co. of Budapesth find, that, with a continuous current, the carbon filament of an incandescent lamp gives out first at the end where the positive current enters, a spot of carbon being deposited on the neighboring part of the glass. If alternating machines are used, the life of the lamp is almost exactly doubled, and when the deposit forms it is all around the case. — (*Engineering*, June 15.) J. T. [240

ENGINEERING.

A great 'Sound steamer.' — The steamer Pilgrim, of the Old Colony steamship company, was recently added to the fleet now plying through Long Island Sound. The vessel is the largest and the most expensively fitted up of all steamers which have yet been built for those waters. The hull is of iron, double, and built in compartments. The boiler space is so enclosed by iron bulkheads that the danger of fire is wholly avoided. The engines are of the standard beam-engine type, and fitted with the Stevens valve-gear. They were designed by Messrs. Fletcher & Harrison, and built by Messrs. John Roach & Son. The steering is done by means of a Sickles steam steering gear, and the lighting is performed by Edison dynamos. The hull is 390 feet long on deck, 375 on the load line; the beam is 50 feet over the hull and 87.6 feet over the 'guards;' the depth of hold is 18.6 feet; draught of water, 11 feet. The engine has a steam-cylinder 110 inches in diameter and 14 feet stroke of piston. There are 12 boilers of steel, and calculated for a pressure of 50 pounds per square inch. The total power is estimated at 5,500-horse power. The wheels are of the radial type, and are 41 feet in diameter, weighing 85 tons each. The shafts are 26 inches in diameter. The cylinder weighs 30 tons; the bed-plate, 30 tons; the beam, 33 tons; the condenser, 60 tons. The machinery will weigh, altogether, with water in the boilers, 1,365 tons. There are 103 water-tight compartments; and it is considered that it will be impossible to sink the vessel by collision or grounding. There are 912 electric lamps operated by two Edison dynamos of a total of 11,400-candle power. They are driven by an Armington & Sims engine, built at Providence, of 150-horse power. The grand saloon is the largest in the world: it is 350 feet long, and accommodates 1,400 passengers, for whom state-rooms are provided. — (*Sc. Amer.*, June 30.) R. H. T. [241

CHEMISTRY.

(*General, physical, and inorganic.*)

Apatites containing iodine. — In continuing the study of the formation of artificial apatites, A. Ditte fused baric iodide with a mixture of sodic iodide and ammonic phosphate, the latter in small quantity. On slow cooling, the mass crystallized in hexagonal prisms of the composition $BaI_2 . 3 Ba_3(PO_4)_2$. When ammonic arseniate was substituted for the phosphate, the corresponding iodarseniate, $BaI_2 . 3 Ba_3(AsO_4)_2$, was formed. The iodvanadate, $BaI_2 . 3 Ba_3(VO_4)_2$, crystallized in transparent prisms. The strontium compounds, $SrI_2 . 3 Sr_3(PO_4)_2$, and $SrI_2 . 3 Sr_3(AsO_4)_2$, and calcic iodvanadate, $CaI_2 . 3 Ca_3(VO_4)_2$, were obtained. — (*Comptes rendus*, xcvi. 1226.) C. F. M. [242

The spectrum of beryllium. — Mr. H. N. Hadley finds that the spectrum of beryllium shows no marked analogy with the spectrum of calcium, magnesium, or aluminum. It does not resemble the spectrum of carbon, boron, or silicon; but it is more closely allied to that of lithium. The author therefore concludes that it is the first member of a dyad series of elements homologous to calcium, strontium, and barium. — (*Journ. chem. soc.*, June, 1883.) C. F. M. [243

Decomposition of water by the metalloids. — When distilled water is boiled with sulphur, C. Z. Cross and A. F. Higgin find that it is decomposed according to the equation $2\,H_2O + 3\,S = 2\,H_2S + SO_2$. They also noted that sulphur distilled with steam or with the vapor of dilute alcohol. On boiling arsenic with water, it was converted into arsenious acid and hydric arsenide. Arsenious sulphide was changed into a sulfoxy-compound. — (*Berichte deutsch. chem. gesellsch.*, xvi. 1195.) C. F. M. [244

Pyronome. — This is the name given by M. Sandoy to a new explosive, consisting of sixty-nine parts of saltpetre, nine of sulphur, ten of charcoal, eight of metallic antimony, five of potassium chlorate, four of rye-flour, and a very small quantity of potassium chromate. The materials are mixed with an equal quantity of boiling water, and the mass is evaporated to a paste, dried, and powdered as wanted. This mixture is said to be much cheaper than dynamite, but its manufacture and use must be attended with considerable danger. — (*Chem. techn. rep.*, 1883, 154.) C. E. M. [245

METALLURGY.

Gaseous fuel in iron manufacture. — Mr. W. S. Sutherland read a paper before the British iron and steel institute, on the production and utilization of gaseous fuel in iron manufacture, in which he claims that the seams of boilers can be welded instead of riveted, if the heat can be applied uniformly, and of sufficiently high temperature, without excess of air or admission of dirt. This kind of heat he has obtained only by the use of coal-gas, Siemens-producer gas, or water-gas, the preference being given to the latter. To secure the requisite air in constant proportion, the gas being in excess, gas and air are mixed before combustion; probably the first instance of such a utilization of the principles of a Bunsen burner on a large scale. Explosions are prevented by having an outlet lightly covered by india-rubber, at some corner of the main; and when the wave, or disk of flame, which does not readily turn a corner, reaches this cover, it breaks the rubber just as a blow would. The method has been worked some ten years without accident. From all his experience, Mr. Sutherland concludes, that to produce a good, true, wrought iron, Siemens gas with varying proportion of air, instead of air alone, should be blown into the iron in the Bessemer converter. — (*Eng. min. journ.*, July 14, 21.) R. H. R. [246

Nickel extraction. — Prat and Laroche of Bordeaux add powdered nickel ore to a bath of sulphuric acid 56° to 66° Baumé: on stirring the mass it becomes heated, and in half an hour it is nearly solid. The soluble salts of the metals, thus formed, are leached out with boiling water. From this solution, oxalate of nickel is formed by boiling with oxalic acid; the precipitated oxalate of nickel is boiled with caustic soda, yielding oxide of nickel and oxalate of soda. The oxalic acid is recovered from the latter salt. — (*Eng. min. journ.*, June 2.) R. H. R. [247

The Doetsh copper extraction process. — This process has been in use by the Rio Tinto mine for some years. The ore is crushed to .4 inch in size, and piled in heaps forty-five feet wide, with suitable channels at the bottom, and vertical draught-holes. About two per cent of salt is sprinkled over the top. A basin thirty feet square is made on the top of the heap, and the regenerated liquors from the last operation are run into it. The dissolved and leached copper is precipitated by scrap iron, the iron liquors remaining are regenerated by sprinkling them down through a coke tower, while mixed chlorine and hydrochloric acid are forced upward. — (*Eng. min. journ.*, July 14.) R. H. R. [248

MINERALOGY.

Picro-epidote. — MM. Damour and Des Cloizeaux have investigated a gray crystalline mineral from Lake Baikal, and found it closely related to epidote in crystalline form and optical properties. A complete chemical analysis was not made; but qualitative tests proved it to be a silicate of alumina and magnesia, with only a trace of calcium. It is supposed to be a magnesium epidote, and the name 'picro-epidote' is proposed for it. — (*Bull. soc. min.*, vi. 23.) S. L. P. [249

Jeremeieffite. — A new mineral from the Soktoui, south-east of Adun-Tschilon in western Siberia, has been described by M. Damour. It occurs in nearly colorless, transparent, hexagonal prisms, thus resembling some varieties of beryl and apatite. Hardness, 6.5; specific gravity, 3 28. Qualitative analysis proved it to be essentially a borate of alumina. Before the blowpipe it is infusible, loses its transparency, and colors the flame green (boron); with cobalt solution, it assumes a blue color. It is insoluble in acids, except after strong ignition, when sulphuric acid dissolves it. Chemical analysis yielded B_2O_3, by difference (40.19) . Al_2O_3 (55.03) . Fe_2O_3 (4.08) . K_2O (0.70) = 100%, from which the formula $(Al, Fe)_2\,B_2O_6$ is derived. It is named after the Russian mining engineer, Mr. Jeremejew. — (*Bull. soc. min.*, vi. 20.) S. L. P. [250

METEOROLOGY.

Bavarian meteorology. — The quarterly publications of the meteorological stations in Bavaria deserve special mention for the model way in which the observations are recorded, and for the excellent discussions which accompany them. The concluding number of the series for 1882 contains a monograph by Dr. Lang upon the observations at Munich for sixty-seven years. Among the results reached is that the mean pressure for any day can be better obtained by taking the mean of the observations at six A.M., two and ten P.M., than by any other of the eight different combinations tested. The mean of the maximum and minimum for the day gives in general nearly as good a result. Similarly of the temperature, the best combination is the mean of the seven A.M., two and nine P.M. observations, but the mean of the maximum and minimum is nearly as good. — (*Beob. met. stat. in Bayern*, iv. 4.) W. U. [251

Rainfall at Hawaii. — The meteorological conditions of the island of Hawaii are so peculiar, that, though the island is not large, in one portion rain seldom falls, and the land is a desert; while in another the rainfall is so excessive that it is said it should be measured, not in inches, but in feet. In proof of the excessive rainfall, the following figures have been furnished by Dr. C. S. Kittredge of Hilo, Hawaii. The observations were made by Dr. Wetmore at Hilo.

Rainfall at Hilo, Hawaii.

	1880.	1881.	1882.	1883.
	In.	In.	In.	In.
January	–	5.1	36.7	3.1
February	–	3.1	23.6	23.1
March	–	55.2	18 7	2.4
April	14.5	8.3	5.2	12.4
May	6.9	4.2	7.0	–
June	8.1	10 8	7.1	–
July	22.1	9.9	7.9	–
August	7.3	8.8	7.0	–
September	14.5	8 2	8.6	–
October	15.7	4.9	6.9	–
November	3.6	21.7	20.4	–
December	3.1	34.2	15.7	–
Sums.	–	174.4	164.8	–

For the three years April 1, 1880 to April 1, 1883, the total amount is 463.6 inches, averaging 154.5 inches each year. — W. U. [252

GEOGRAPHY.

(*Arctic.*)

North-west America. — Reports from the island of Kadiak, Alaska, state that the spring has been unusually late, and on the 6th of June summer seemed to have just set in. During the preceding three months, the rainfall had averaged eleven inches per month. Salmon-canneries had been established at Karluk, on the island of Kadiak, and at Seal bay, Afognak island. On Cook's inlet, a cannery had been established at the Kassilax river. Exploring parties were examining the shores of the inlet for minerals. One party was ascending the Sushitno river, where Doroschin reported gold many years ago. Another party had sailed for Kamishak bay, Aliaska peninsula. An experiment in sheep-raising has been going on, on the island of Kadiak, for three years. Success seemed certain, as the wool improved in quantity and quality, and was free from burrs and impurities. In adding to the number, an epidemic disease was introduced; and of the flock of three hundred, only about thirty survived. —— Rev. S. Hall Young has been making a study of the religious belief of the T'linkit Indians of the Alexander archipelago, which will shortly be made public. —— The U. S. revenue-steamer *Corwin* left Sitka on her Arctic cruise, June 16. —— At Juneau City, the largest shipment of gold-dust ever made was sent by the June steamer. The troubles among the miners here have caused many to depart. It appears that the rock containing the gold is of a loosely crystalline or granular nature, which weathers to a gravel. The lighter portions of this wash away in the rains; but the gold settles down into the remainder, which becomes much richer than the original rock in equal quantities. This gravel is said to exist on the upper parts of the auriferous mountain-belt. Prospectors claim this gravel as placers, and desire to work it under the law governing placer-mining. The companies who have taken up quartz-claims desire to have it regarded as quartz or vein mineral: hence the conflict, which was to have been settled by the officers of the U. S. S. *Corwin*. The decision has not been made public. —— Prospectors have gone to explore the country about Yakutat bay, where the Indians have hitherto been hostile. Reports as to its richness in gold have long been prevalent; but so many have met their death from the natives, that hitherto no one has dared attempt exploration. The party consists of five men, with six months' provisions, and was transported by the U. S. S. *Adams*. The prestige of the naval vessel, it is hoped, will afford them protection. —— The schooner *Alaska* has sailed from San Francisco, for Golovine sound, Alaska, taking with her a small stern-wheel steamer and a complete mining equipment and some twenty-five miners. The mines are situated on the Fish river, which forms part of the water-communication between Grantley harbor and Golovine sound. It is stated that the ore is a very rich argentiferous galena. The parties engaged in the enterprise have been several years investigating the deposit, and feel sufficiently encouraged to begin a regular prosecution of the business. In this vicinity, graphite is known to occur in a sienitic rock, in considerable quantities. This will be the most northern mine actually worked in the western hemisphere. — W. H. D. [253

(*South America.*)

Bove's new expedition. — Lieut. Bove proposes a new expedition to complete studies begun during his last journey in the southern part of the Argentine republic. He proposes to investigate the present physical and economic condition of the country, with a view to closer commercial relations with Italy. He will take up the exploration of Patagonia and Tierra del Fuego, especially the basin of Santa Cruz, the canals of western Patagonia, and the habitable country extending from the Ona to the Cioniu Chonos. The inhabitants are totally unknown. The explorer has placed himself at the disposition of the Argentine government for the purpose of placing light-houses on Staten island and other points needful for navigation, an arrangement which will facilitate the prosecution of his other investigations. For transportation he will depend partly on the English missionary board, who have promised co-operation, and will afterward equip for exploration one of the small vessels always obtainable for such purposes either at the Falkland islands or Punta Arenas. The journey will occupy a year, and cost about five thousand dollars. — (*Revue géogr.* June, 1883.) W. H. D. [254

BOTANY.

Ellis' North American fungi. — Dr. Farlow, who edited the third and, in part, the eleventh century of this collection, contributes valuable notes on some of the Peronosporeae and Uredineae so far distributed, with some pertinent remarks on the nomenclature of the latter group. Though desirous of retaining the earliest specific names wherever practicable, the writer does not believe, with Winter, in applying the name given to the Aecidium of a Puccinia or other teleutosporic form to the species, when its several stages are grouped under the generic name of the latter form. "For practical reasons, if for no other, the custom of substituting an aecidial specific name, for a name given to a Uredo or teleutosporic form, should by all means be avoided. Of all the Uredineae described by older writers, probably none are more difficult to determine satisfactorily at the present day than the species of Aecidium, so called. Original specimens of that genus are, as a rule, not so well preserved as those of other genera of the order; and, if one usually gets little satisfaction from examination of what is left of the original types, he is scarcely better off on reading the older descriptions. It was not unfrequently the habit of older mycologists, to describe as varieties of one Aecidium forms found on the most diverse plants; and most certainly it is going too far to substitute for the name of a Puccinia, let us say, which has passed current for many years, the name given by an old authority, like Persoon or Link, to what he considered a variety of an ill-defined Aecidium. It cannot be said that any want of respect to the older writers is shown by abandoning their aecidial names in such cases."

With respect to the Uredo name, however, the case is held to be somewhat different. "As a matter of fact, the types of the earlier-described Uredo forms are much better preserved than Aecidia, and examinations of older herbaria frequently enable one to determine with accuracy what form was meant by an older author. Furthermore, the Uredo and teleutosporic forms frequently are found together in the same sorus, or in close proximity; and examinations of authentic specimens often show the relation of an old-described Uredo to a more recently described teleutosporic form. The most important consideration, however, is the following. Many of the forms now recognized as teleutosporic have one-celled spores, and were originally described as forms of Uredo; and, in such cases, one must go back to the original specific names." He adds, however, "If I have advocated retaining the older Uredo name in cases where we know with certainty what was meant by the earlier mycologists, I have by no means intended encouraging the use of names about which there is doubt, either from the absence of typical specimens, or confusion of several species by older writers. Rather than favor that method — if one may say so — of forcing priority, I should prefer to give up the substitution of all old Uredo names, except, possibly, in the case of species now referred to Uromyces." The use of the parenthesis for the original authority for the species, though somewhat cumbrous and generally discarded by phenogamic botanists, is, on the whole, advocated, especially since the genera of fungi are often not very definitely fixed. "A species of Fries, for instance, may, during five years, be dragged through no one knows how many new genera; and it is with a mildly malicious satisfaction that one sees those modern writers who adopt minute generic subdivision, forced by the prevailing custom to add the '(*Fr.*)' as a slight tribute to the past."

Besides the characters of eight species, previously nondescript, the notes also contain much critical information concerning the synonymy of many of the species, and the geographical distribution of others. An interesting fact is the preponderance, among our Peronosporae, of species germinating by the production of zoöspores, though this would appear to better adapt them to an insular climate than to ours, which is a continental one, subject to extremes of heat and moisture. — (*Proc. Amer. acad.*, May 9, 1883.) W. T. [255

ZOÖLOGY.

Crustacea.

Parasite of the salmon. — Carl F. Gissler in an anonymous article, in the *American naturalist* for August, describes and figures, as a new species of Caligus, a parasite of the salmon of Puget sound. The species is probably Lepeophtheirus salmonis, which infests the salmon upon both sides of the North Atlantic. — S. I. S. [256

Brachyura and Anomura off the coast of New England. — In a preliminary report on the Brachyura and Anomura dredged in deep water off the south coast of New England by the U. S. fish commission in 1880–82, S. I. Smith enumerates thirty-one species taken in sixty-five to six hundred and forty fathoms, and gives full descriptions and figures of the new forms discovered. The report, although only a supplement to a notice of the crustacea dredged in the same region in 1880, describes three new genera and seven new species. Of the thirty-one species enumerated, only four were known from the south coast of New England previous to 1880, and more than half of the whole number were new to science; and yet none of the species belong to the abyssal fauna proper, and nearly all of them were taken most abundantly in less than two hundred fathoms. The dredgings off Martha's Vineyard in 1882 revealed the total, or almost total, disappearance of several of the larger species of crustacea, which were exceedingly abundant, in the same region, in 1880 and 1881. The disappearance of these species was apparently connected directly with the disappearance of the tile-fish (Lopholatilus) from the same region; and on this account complete tables are given of the specimens examined from all the dredgings in the region in question. Five species, which were exceedingly abundant in 1880 and 1881, were not found, or found only very rarely, in 1882; and five others, taken several times in 1880 and 1881, were not taken at all in 1882. These species were specially characteristic of the narrow belt of comparatively warm water, — in sixty to one hundred and sixty fathoms, — which has a more southern fauna than the colder waters either side. Professor Verrill has suggested that there was a great destruction of life in this belt in the winter of 1881–82, caused by a severe storm agitating the bottom-water, and forcing outward the cold water that occupies the great area of shallow sea along the coast, thus causing a sudden lowering of the temperature along the warm belt.

Among the forms described are two new genera of Galatheidæ, in one of which there are no appendages on any of the first five abdominal somites of the adult male. But the most interesting forms are two genera of hermit-crabs, — Parapagurus and Sympagurus, — in which the branchiae present types of structure intermediate between the phyllobranchiae of ordinary paguroids, and the trichobranchiae of the Astacidae, etc. — (*Proc. nat. mus.*, vi., June, 1883.) S. I. S. [257

VERTEBRATES.

Development of muscle fibres and their union with nerves. — Although very numerous researches have been made on the differentiation of striped muscles, and on the termination of their motor nerve-fibres, yet the multifarious observations have often been too incomplete to lead to any but conflicting and unsatisfactory theories. An important contribution toward reducing this unfortunate and excessive confusion to order is made by L. Bremer, who has studied the post-embryonic changes in lizards, frogs, and mice. The nucleus of the muscle-fibre, together with the protoplasm surrounding it, constitutes the so-called muscle-corpuscle; the corpuscle is much more prominent in young than in old muscles, for its protoplasm is gradually differentiated into muscular substance; a small number of corpuscles enters into the formation of each fibre; the substance of the muscle forms a network, which was first partially recognized by Heitzmann (*Wien. sitzungsber.* xvii. abth. 3, 1873); the meshes of this network appear polygonal in transverse, rectangular in longitudinal sections; the network is a modification of the protoplasmatic network of the corpuscles, and is so arranged that there are alternating rows, both transverse and longitudinal, of fine knots and large knots (corresponding to the fine and broad striae); the fine knots are connected by fine threads, and the large knots by coarse threads; hence there is a fine and a coarse net.

The post-embryonic multiplication of fibres takes place by means of the structures described by Margo (*Wien. sitzungsber.* xxxvi. 229) under the name of 'sarcoplasten;' there are lines or chains of muscle-corpuscles, united by the protoplasm net, and derived by proliferation from the corpuscles of the original fibres; the sarcoplast gradually separates from the parent fibre, undergoing muscular differentiation meanwhile, and also becoming connected with the nerve. The growth of the fibre is initiated by a multiplication of the corpuscles; the sarcolemma is not present at first, but appears later, being probably formed by the fused cell membranes of the corpuscles, to which appears to be added a coat of connective tissue, and also around the motor plate between the two sarcolemmic coats, an extension of Henle's sheath of the nerve.

The motor nerve plates are formed as follows: When the sarcoplast begins to change to muscle, the nerve grows towards it until the two meet and unite. In lizards only a single nerve-fibre, in the frog and mouse several together, thus approach the future muscle. At the point of contact, the muscle-corpuscles change, so that an accumulation of protoplasm and a proliferation of nuclei occur there. These accumulations were first described by Kühne under the name of 'muskelspindeln' (*Virchow's arch.*, 1863, 116), and are mentioned by many subsequent writers: Bremer now shows that they are young 'end-plates.' Into these the ramifications of the nerve penetrate, after the medullary sheath has been lost. The details of the process, of course, vary in different animals, as do also the final forms of the motor plates.

Besides the motor terminations, there are others, which the author believes to be probably those of the sensory nerves. The fibres running to them are either small and medullated, or naked and end in ramifications upon the muscle, without any conspicuous collection of nuclei and protoplasm at the place of junction. The smaller nerve endings occur on the same fibres with the motor plates, and probably both exist on every fibre. The smaller endings, Bremer designates as 'enddolden' in contradistinction to the 'endplatten.' (Sach's paper on the sensory nerves of muscles is not cited by Bremer.)

Hensen has advanced the view that the connection between the nerves and the peripheral cells exists from the first in the embryo, and that, as the cells divide, so do the nerves. Bremer's observations show that with muscles this is not the case. Moreover, Kleinenberg's theory of the evolution of muscle and nerve must be at least modified, if not set aside. (That the union of the nerve-filament with the peripheral organ is secondary, is shown also by His. SCIENCE, i. 956.) — (*Arch. mikr. anat.* xxii. 318.) C. S. M. [258

ANTHROPOLOGY.

Folk-lore in the Panjâb. — Mrs. F. A. Steel is collecting the folk-stories among the natives in the Panjâb. No. 18 is a charming shepherd-tale common among the cattle-drover's children in the forests of the Gujrânwâlâ. It is about Little Ankle-Bone. Once upon a time a little shepherd was eaten by a wolf, that hung the ankle-bone of his victim to a tree. Some robbers, dividing their spoil, were startled by the falling of the bone, which became a little lad, and did many wonderful things, taming all the beasts of the field, and fowls of the air. He changes a pond into milk, by the side, of which he sits under an oak-tree, playing his shepherd's pipe, while all the animals come to listen, and to drink out of his marble basins. The series will be continued. — (*Indian antiquary*, xii. 105.) J. W. P. [259

Lorillard City. — After his researches at Chichen-Itza, M. Charnay made an excursion into the country of the Lacandones, — a fierce, indomitable tribe, of whom it is most desirable to have more information.

M. Charnay found the ruins of an ancient city, which he named after his generous patron. In his explorations here, he was assisted by a young Englishman, Mr. Alfred Maudslay, with whom he shares the honor of discovery. The town is about 17° N., on the left bank of the Usumacinta, on the boundaries of Guatemala and the two Mexican provinces of Chiapas and Tabasco. The ruins resemble those of Palenque in the material, arrangement of interiors, decorations, and glyphs. The great stone slabs of Palenque carved with inscriptions and bas-reliefs, are replaced here by lintels covered with superb sculpture (cf. i. 1008.) — (*Proc. roy. geogr. soc.*, v. 44.) J. W. P. [260

Shaking towers. — Col. Lovett, in his journey through northern Persia, visited the shrines of some dervishes, near which is a minar, curious for possessing the same property that makes the shaking towers of Ispahan famous. When shaken by a man standing on the top, it oscillates sufficiently to cause a brick placed on the edge of the cornice to fall. It is about thirty-five feet high, and six feet diameter at the base, tapering gently upwards. This property of vibrating is attributed at Bostam, as it is at Ispahan, to miraculous interposition of the local saint. It is, of course, due to the elasticity of the bricks and cement used, the latter becoming more elastic with age. — (*Proc. roy. geogr. soc.*, v. 80.) J. W. P. [261

Explorations in Guatemala. — Mr. A. P. Maudslay, mentioned in M. Charnay's researches, has published separately some of his own personal explorations, with a map and ground-plans. Starting from Livingstone, Guatemala, he first visited Quirigua, whose ruins consist of raised mounds and terraces, usually faced with stone, and near to these, carved monoliths. The latter are of two kinds: high upright stones, ornamented with human figures and tables of hieroglyphics; and low broad stones, in the shape of some animal. The first named measure three to five feet across, and 12 to 25 feet out of the ground. On both back and front, the principal ornament is a human figure in relief, decked out in the barbaric splendor usual throughout Central America. Mr. Maudslay suggests that the inevitable human face on the thorax may explain the function of the great number of masks from this quarter. The second class of carvings is very interesting. One specimen, weighing about eighteen tons, represents a turtle having a human head, with projecting ears richly ornamented. In place of the tail is the life-sized figure of a woman sitting cross-legged, and holding a manikin sceptre in her hand. The whole surface of the block is profusely ornamented. Nowhere in the neighborhood are there traces of houses. The exploration at Quirigua led to an attempt to fix the site of Chaciyal, mentioned by Cortez.

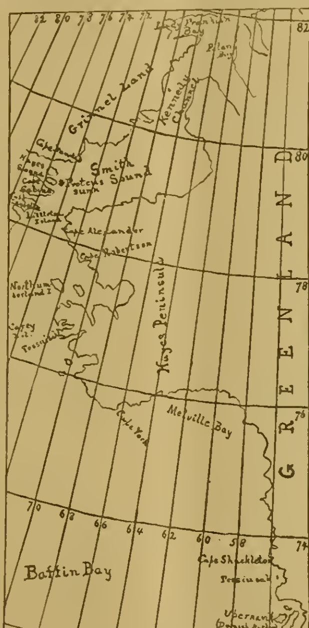
Leaving this spot, Mr. Maudslay visited Copan, where the sculptures impressed him as being above those of Quirigua in execution. From Copan our traveller wandered next to Tikal, north-east of Lake Peten, only once before visited by a foreigner, Bernouilli. All the houses here are built of stone, and coated with plaster. Inside, the walls are seven to eight feet high, and the stone roof forms a narrow gable. The rooms within are very narrow, resembling long passages. The town was laid out in a rectangular form, the slopes terraced with sustaining walls. The houses are often built on raised foundations, stone-faced in the same manner. The most imposing buildings are the five temples raised on pyramidal foundations, in front of which are steep stairways leading up to the doors of the temples. There is no trace of any idol or object of worship in these buildings, but carved slabs and circular altars are found in the plaza. The next point of interest was a ruined town on the Usumacinta. On the top of a steep bank 60 feet high stands the first row of houses, and the town is built on a succession of stone-faced terraces reaching more than 250 feet in height. Instead of the long, narrow interiors as at Tikal, the houses are broken into a number of recesses by buttresses supporting the roof at intervals, and stone is used instead of sapote-wood for lintels. One of the houses at Usumacinta is minutely described by Mr. Maudslay. In nearly all the houses, around the idols, stand earthen pots partly filled with some resinous substance, which the Lacandon Indians probably placed there, showing that the old faith has not died out. At this point Mr. Maudslay met M. Charnay. This very important paper closes with a short sketch of the Lacandones. — (*Proc. roy. geog. soc.*, v. 185.) O. T. M. [262

NOTES AND NEWS.

News of a serious character has been received from the Greely relief expedition. The Proteus and Yantic sailed from St. Johns, Newfoundland, June 29. They arrived safely at Disco on the 6th and 12th of July respectively. The Proteus with Lieut. Garlington and the relief party, with supplies, etc., sailed from Disco for Cory island, arriving on the 16th. On the 21st she started for Smith sound, and reached a point in latitude 78° 52′, longitude 74° 25′ W., a few miles north and west of Cape Sabine, where she was beset and crushed in the pack. The party succeeded in saving boats and provisions sufficient to sustain them during their retreat, and made their way across Smith sound and along the eastern shore to Cape York, and reached Upernavik on the 24th of August, all well. Records had been left at Littleton island which apprised the Yantic, on her arrival, of the disaster. A search was immediately instituted, and on reaching Upernavik, Sept. 2, it was found that the Proteus party, after suffering severe hardships, and traversing six hundred miles of the Arctic sea, had arrived in safety. No news was obtained of the Greely party, no supplies had been landed for them, and their situation must be considered as grave. Some rumors had reached the Danish settlements by parties of Eskimo, which, however, are not to be considered as of any weight; and there is yet no reason for supposing that any ill fortune, further than the loss of anticipated supplies, has befallen Lieut. Greely and his companions. The failure to land supplies was probably due to the conditions of the ice at Littleton island, but nothing can be stated with certainty in advance of more explicit information. The Yantic, with the rescued party, arrived at St. Johns, Sept. 13.

— At a meeting of the Scottish meteorological society, July 26, the following scheme, according to *Nature*, was adopted, looking to the establishment of a zoölogical station in the Firth of Forth: —

It is proposed to enclose the Granton quarry, which has an area at high water of about ten acres, and depths varying to sixty feet, so as to regulate the inflow and outflow of the tide in such a manner, that, while admitting abundance of sea-water at each tide, fish and other animals will be prevented from escaping out of the enclosure. This will be done by means of stakes and wire, with other kinds of netting. The quarry will then be stocked with all kinds of fish and marine invertebrates. When it is desired to separate fish or other animals for special study, this will be done by floating or fixed wire and wood cages.



A barge about sixty-four feet by twenty-seven feet, of great stability, will be moored in the enclosure; upon this will be built a house with laboratories, workrooms, and a library; it will also be furnished with a small windmill to pump up sea-water into a tank on the roof. The water in this tank will be conveyed by pipes to the various tiled tables, glass jars, and aquaria of the establishment. A small cottage will be built on the shore for the accommodation of the keeper and engineer, with one or two spare rooms. A steam pinnace for dredging and making observations in the Firth of Forth and the North sea will be attached to the station.

A naturalist will be appointed whose duty will be to make continuous observations and experiments, assisted by the engineer and keeper. There will be ample accommodation for four other naturalists to work at the station, and carry on investigations; and, so far as the accommodation will permit, British and foreign naturalists will be invited to make use of the station free of charge.

Towards the carrying-out of this scheme, the Duke of Buccleuch has liberally granted a lease of the quarry at a nominal rent, with permission to erect a cottage on the shore. A gentleman who takes a warm interest in the progress of research in Scotland has offered 1,000 *l.* to construct the barge, and fit it up with laboratories and workrooms. Mr. J. Y. Buchanan has promised to fit up one of the rooms on the barge as a chemical laboratory suited to the requirements of the station; Mr. Thomas Stevenson, the society's honorary secretary, has agreed to give his professional services in enclosing the quarry gratuitously; and Mr. John Anderson has undertaken to provide the station with a salmon and trout hatchery. Mr. John Murray will furnish the laboratories with apparatus, and place his large zoölogical library at the service of workers. A number of gentlemen have promised to support the undertaking when once commenced; and it is expected that within a few months the station will be presented with a steam-pinnace and with funds for the erection of a cottage on the shore, — the only desiderata to complete the scheme.

The society granted three hundred pounds for the first year, and two hundred and fifty pounds each for the two succeeding years, toward the expenses of the station. It is expected that by the beginning of November the proper work of the station will be begun. Already several distinguished naturalists have signified their intention to avail themselves of the altogether unique facilities which will be afforded by this zoölogical station for the successful prosecution of biological research.

— In a report on the mineral resources of the United States, during 1882 and the first half of 1883, shortly to be published by the U. S. geological survey, Mr. Albert Williams, jun., has compiled a series of special statistics, of which the following totals will be of interest to our readers.

Omitting the local consumption, there were mined 43,130,863 tons of Pennsylvania anthracite, and 87,963,038 tons of other qualities of coal, including a small amount of anthracite won outside of Pennsylvania; the respective colliery values being $97,044,442 and $109,953,797. Of iron, 1,350,000 tons were mined, worth $44,775,000; while there were consumed in all the iron and steel works, including furnaces, 5,610,000 tons of anthracite and 9,740,000 tons of bituminous coal, 5,130,000 tons of coke, 145,750,000 bushels of charcoal, and 5,800,000 tons of limestone. The product of gold is estimated at $48,750,000, and of silver at $70,200,000. In other words, the mint value of the precious-metal product was $88,048,239 less than the colliery value of the coal produced during the same eighteen months.

Of crude petroleum, 41,415,163 barrels, valued at $35,010,476, were produced, — a diminishing product with an increasing value; while 149,646,232 pounds of copper were mined, valued in New York at $24,538,091, — an increasing product with a diminishing value.

The lead product was 202,890 tons, worth in New York $18,924,550; and of zinc, 51,765 tons, valued at $5,311,620. 75,472 flasks, or 5,873,508 pounds, of mercury were produced, worth in San Francisco $2,100,750. Of nickel, the product in 1882 was 281,616 pounds, worth $209,777, but the reduction-works closed in 1883; while of cobalt, ore and matte, the product for 1882 was valued at $15,000.

Of other metals, there were mined in 1882, 3,500 tons of manganese, with a spot value of $52,500; 2,500 tons of chromium, worth in Baltimore $100,000; and 60 tons of antimony, worth about $12,000. It is stated that a trifling amount of tin ore has been mined, and the production of metallic tin on a small scale begun.

The estimated value of the building-stone quarried in 1882 is $21,000,000; grindstones, $700,000; soapstone, $90,000 (6,000 tons); brick and tile made, $34,000,000; whiteware, $5,000,000; lime, $21,700,000 (31,000,000 bbls.); cements, $3,672,750 (3,250,000 bbls.); pumice quarried, $1,750 (70 tons); phosphates dug, $1,992,462 (332,077 tons); marl, $540,000 (1,080,000 tons); mica, $250,000 (75,000 lbs.); barytes, $160,000 (20,000 tons); asbestus, $36,000 (1,200 tons); and asphaltum, $10,500 (3,000 tons). There were further produced in 1882 and 1883, 9,618,569 barrels (2,693,196,520 lbs.) of salt, valued at $6,480,210; 2,100,750 pounds of borax, worth $562,903; and in 1882, of sodic carbonate, over 1,600,000 pounds; and of copperas, 15,000,000, worth $112,500.

The value of precious stones found in 1882 was, before cutting between $10,000 and $15,000; after cutting, between $50,000 and $60,000. And there were mined 500 tons of corundum, valued at $6,250; 75,000 tons of quartz; and in 1882 and 1883, 687,500 pounds of graphite, worth $55,000.

The total value of the metals produced in the United States, during 1882, is estimated at $219,756,004; and of the non-metallic mineral substances, $234,156,402: making the total mineral product $453,912,406.

No data seem to have been obtained regarding many of the minor mineral products, while in the majority of cases the figures appear to be approximations only. These defects can doubtless be remedied, in the future, by the adoption of better laws and methods for the collection of our mineral statistics.

— Hachette publishes a book of travel by Edmond Cotteau, entitled 'De Paris au Japon à travers la Sibèrie.' It is well illustrated, and, apart from the illustrations, is especially valuable as indicating how unchanged and identical the civilization of old Russia, as seen in Moscow and similar cities, has been transplanted, as it were bodily, to successive and numerous localities stretching from the Ural to the Pacific, and to the borders of the Arctic Sea.

— A dainty and unique little book is published by Charles F. Lummis of Chillicothe, O. It is a miniature quarto, 6.5×7.5 cm. in size, made of twelve leaves cut from the thin paper-like layers of birch bark. Appropriate woodcuts cover the slightly thicker outer pages, while the interior is given to 'Birchbark poems, vol. ii.,' by the publisher. We cannot say much for the eight little 'poems,' of which only the first, on 'silver-birches,' has any special appropriateness; but the setting is excellent and attractive, and reflects well the taste and skill of the author.

— The *Manchester guardian* of July 18 gives the following report of M. Pasteur's speech at Dôle on July 14, when his fellow-townsmen placed a memorial tablet in the wall of the house in which he was born. The tablet says simply, "Here was born Louis Pasteur, Dec. 27, 1822." M. Pasteur's remarks were as follows: "I am deeply touched by the honor which the town of Dôle has conferred upon me; but permit me, while expressing my gratitude, to deprecate this excess of glory. In rendering to me the homage which is usually rendered only to the illustrious dead you encroach too hastily upon the judgment of posterity. Will it ratify your decision? And ought not you, Mr. Mayor, to have prudently warned the municipal council against so hasty a resolution? But, having protested against this outburst of an admiration which I do not merit, permit me to say that I am touched to the bottom of my heart. Your sympathy has united in this commemorative tablet two great things which have been at once the passion and the charm of my life, — love of science, and reverence for the paternal home. — O my father and my mother! O my dear departed, who so modestly lived in this little house! it is to you that I owe all. Your enthusiasms, my brave mother, you transmitted them to me. If I have always associated the greatness of science with the greatness of the country, it was because I have been full of the sentiments with which you inspired me. And you, my dear father, whose life was as rude as your rude trade, you showed me what patience and sustained effort could accomplish. It is to you that I owe the tenacity of my daily work. Not only had you the persevering qualities which made life useful, but you had an admiration for great men and great things. 'Look above, learn there, seek to rise always,' — this was your teaching. I see you again after your day's labor, reading some story of battle from a book of contemporary history which recalled to you the glorious epoch which you had witnessed. In teaching me to read, it was your care to teach me the greatness of France. Be blessed both of you, my dear parents, for what you were; and let me transfer to you the homage which is today bestowed upon this house. — Gentlemen, I thank you for giving me the opportunity of saying aloud what I have thought for sixty years. I thank you for this celebration and for your reception; and I thank the town of Dôle, which does not forget any of its children, and which has borne me in such remembrance." M. Pasteur's father was a tanner.

SCIENCE.

FRIDAY, SEPTEMBER 28, 1883.

THE NATIONAL OBSERVATORY.

We call the naval observatory at Washington 'national,' not because we would ignore its recognized official title, but because we wish to emphasize the facts, so often lost sight of, that it is the property of the nation, that it is the only observatory of the first class which the nation possesses, and that its operations should be equally available for every department of the government. Such an institution is a national one, by whatever name it may be called; and the question of its direction and supervision is one of interest to every government office having need of such astronomical observations as can be made only at a fixed observatory. The general principle that it should be under purely scientific control is one that has generally been conceded in the abstract, but has not always been acted upon. Sears Cook Walker, who, thirty-five years ago, was perhaps the most eminent astronomer of America, propounded this principle in a published letter; but Maury was then near the zenith of his power, and little notice was taken of the opinion of the subordinate. From that time to this, the superintendency has remained in the hands of line-officers of the navy. The officers of our navy are of too high a character, and have too much self-respect, to pretend to a knowledge which they do not possess: we may therefore inquire how it happens that they claim the exclusive direction of an establishment most of whose operations are outside the line of their professional qualifications. Secretary Chandler has never given official utterance to his views; but he is understood to have said that he did not feel authorized to deviate from a precedent which had been sanctioned by forty years of usage. Precedent is, in one form or another, the basis of the principal argument on which the present system is sustained: we shall therefore inquire whether it has any real validity.

In order that such a supposed precedent may afford any sound reason for its continuance, the system must have resulted from the matured judgment of his predecessors, whose acts the new secretary followed. Unless this was the case, unless he was doing what they would have done under the same circumstances, the argument could have had no legitimate weight. Now, if one looks more closely at the case, he will see that there is a great deal of precedent on the other side. With one exception, not a superintendent had ever been appointed before his time who was not a professional astronomer, or had not some standing in the scientific world. Maury, Gilliss, Davis, and Rodgers were all recognized as having, in some form, qualifications arising from eminence in science or from a familiarity with scientific affairs; and it was this consideration which prompted their selection, and not merely the fact that they were naval officers. We might therefore claim that Secretary Chandler himself had deviated from precedent in appointing superintendents on the sole ground of naval rank. Indeed, we believe that Secretary Chandler was the first who ever gave any real hearing to what the astronomers of the country had to say on the subject. On all previous occasions, vacancies in the superintendency had been filled so quickly, that they never had had time to give an organized expression to their views at the critical moment, even supposing they had been disposed to find fault with the selection, which certainly was not always the case. A plaintiff whose suit had been postponed from time to time for forty years might well feel dissatisfied, if, when finally heard, the decision of the judge should be, that the defendant had remained so long in possession, that he must now keep possession, no matter what the merits of the case. It should not be forgotten that the theory that the observatory needs nothing but an administrative officer, whose sole duty it shall be to take charge of the building and grounds, preserve order, and conduct the correspondence, leaving the scientific work to the professors and lieutenants, was never heard of, except when no other argument was available, and is now not likely to be supported even by the line-officers themselves.

The tersest form in which the case is put by these officers is this: "The system has been tried for forty years, and has worked well; let us leave well-enough alone." But has there been any system? Certainly not, unless a total absence of system can be called a system. And in what way has it worked well? This depends on the standard by which we measure it. We may admit that in the eyes of the conservative public every thing which does not lead to utter destruction, or against which nothing is heard, is looked upon as working well. We once heard a popular superintendent highly praised, because, having the professors completely in his power, he did not embarrass them by vexatious interference, but had the forbearance to let them go on with their work without hindrance. Last spring, when the question had given rise to a lively discussion among scientific men generally, one of the most eminent foreign astronomers who has landed on our shores paid us a visit. He was, of course, restrained from any public expression of opinion on the subject, but could respond frankly to all inquiries. When asked for his views, he said in substance that individual astronomers had done important works, and made great discoveries at the naval observatory. But, he added, when we look further, and inquire what the observatory itself has done by organized work, we find a great want. There has been no unity, no continuous plan of work, and few of the results which might have been gained by organized action. He might have stated the case yet more strongly. The published observations of the thirty-five years are of every possible character, from the refined discussions of the accomplished astronomer to the vain efforts of the tyro working in the dark, and the confused records of careless men who did not know what to do, and cared for nothing except to draw their pay, — all put in without discrimination. The astronomer of the future who shall try to make use of the results will be surprised by the kaleidoscopic character of the impression made upon him as he turns from volume to volume. Here a new series of observations suddenly begins. He will follow them through a few months or a few years, and find them as suddenly broken off, right in the middle, perhaps, and just when they might have led to some useful result. New systems of observation and new methods of calculation will be found coming in from time to time without any apparent reason. Every effort he may make to discover a method in the madness will be vain. To find an explanation, he will have to inquire into the *personnel* of the observers. By careful research he will then find, as a curious coincidence, that, when these changes occurred, some observer had died or left the observatory, or there had been a change of observers at the instruments. And this is the so-called 'system,' to the perpetuation of which the country is asked to dedicate the new observatory, to be built at a cost of half a million dollars.

The attitude of the naval officers, under these circumstances, is of much interest, because it depends very largely on them to determine whether this confusion shall continue indefinitely, or whether some permanent plan of work shall be adopted. If the indications of their views and intentions which have reached us since the discussion began are correctly interpreted, they have resolved on a course which cannot but prove equally disastrous to naval and national science. Common report credits them with a determination to 'hold the fort' at all hazards, and to vigorously contest every effort that may be made to place the observatory under scientific control. There are even indications that the dismissal of some or all the civilian astronomers is desired, in order that none but naval officers may be left to do the work.

Such a prospect naturally leads us to consider the relations of the navy to science. Scientific organizations have shown on every occasion their high appreciation of the efforts of naval officers to secure a scientific training for themselves, and to advance knowledge by their own efforts. Every thing they have done has met with generous recognition from their civilian co-laborers, and they are received upon terms of perfect equality in every enterprise in which they have taken part. There is no scientific position which would be denied them on the ground that they were naval officers, and therefore to be regarded as inferiors. To maintain this cordial relationship, nothing more is necessary than that the officers should admit the equality, and make no claims except those which are founded upon merit. When they begin to claim precedence and control on the ground of naval rank, they assume a position in which they will meet with the combined opposition of their scientific co-laborers, and render all co-operation impossible.

The application of these considerations to the present case is very simple. Naval officers will not find, in scientific quarters, the slightest opposition to their doing any work at the observatory which will either advance science, or lead to their own professional improvement. It is, indeed, a mooted question, whether the work can really be well performed by any but a permanent staff of trained assistants, and it must be admitted that the observations made by naval officers in the early years of the establishment were not a success. But the officers may justly claim that what they did then is no test of what they can do now, when a better training has been secured, and a scientific spirit has been infused into the service. There is no such question raised on the scientific side as, Shall you or shall we do the work? Shall you or shall we superintend it? What is, then, the ground taken by the general scientific sentiment of the country? Of course, in answering a question of this kind, differences of individual views will be found, and no answer can be given which all will accept without modification. But we are persuaded that there will be no difficulty in reaching some conclusions which will correctly represent the average common sense of the great mass of those who are interested in the subject. We state them as follows: —

Give the naval officers every possible chance, and let them do every thing which they shall prove themselves able to do. Let the superintendent be the man, who, in the opinion of the astronomers of the country, is best fitted for the place, whether naval officer or civilian.

But let the questions, what shall the observatory do, how shall it be done, and is what is done good, be decided exclusively by the highest scientific authority, acting, not privately, and upon the motion of the superintendent, but officially, with the weight and responsibility of legal appointment. Let this authority represent, not merely the navy department or naval science, but the science of the whole country, and let the superintendent, whoever he may be, be responsible for executing its decisions. The shape it would naturally take would be that of a board of control, composed of the leading astronomers of the country.

We state these points, not as forming a definite plan, or even laying a basis for such a plan, but only as indicating the spirit in which we hold that the case should be considered by the two parties. What we ask is as much for the intellectual benefit of the navy itself as for the good of science, and we earnestly hope that naval officers will meet our views in the spirit in which they are put forth.

THE NATIONAL RAILWAY EXPOSITION.[1] — V.

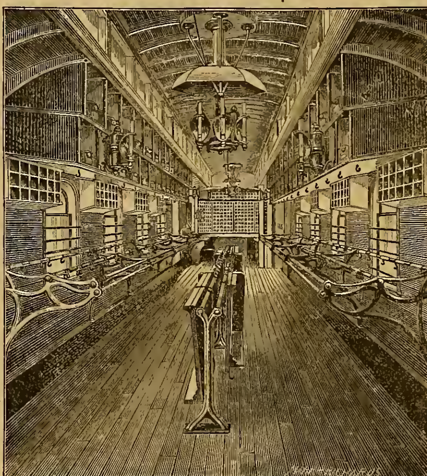
THE postal-car shown by the Harrison postal-bag rack company of Fond du Lac, Wis., appears to be conveniently arranged, and possesses many ingenious but simple devices for facilitating the conveyance and sorting of letters and newspapers. The sorting-tables are not fixed, but are hinged by means of hooks on movable stanchions; and each table, measuring about forty-two inches by eighteen inches, can be detached and stowed away, so that any num-

[1] Concluded from No. 26.

ber can be utilized, and the remaining space left clear. The mail matter can also be sorted directly into bags, which are hung open mouthed, at their four corners, on cast-iron brackets, and these can also be folded out of the way when not required. The letter-boxes are provided with clips, into which labels can be inserted, showing the destination of the letters sorted into each particular box.

The Pullman palace-car company had a very large exhibit of sleeping and dining cars, including an emigrant sleeping-car, which will doubtless prove a great luxury to settlers journeying to the far west. The berths are arranged as in an ordinary sleeping-car, but consist merely of slats of ash, the bedding and mattress (if any) being provided by the emigrants themselves.

A new style of sleeping-car, the second of its kind ever built, was shown by the Paige sleeping-car company. The top berth does not fold up against the roof of the car, but is a species of rectangular hammock, hung at the ends from partitions between the sections. These partitions, in the day-time, are lowered into a space between the backs of the seats. The lower berth is not made on the seat, but on a similar canvas hammock.

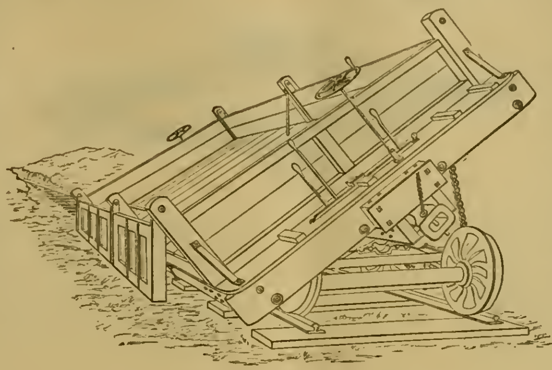


POSTAL-CAR RACKS.

A screw lever dump-car on Van Wormer's patent is shown by the U. S. car company of Boston, Mass. The centre support on the trucks is a species of ball-and-socket joint, combined with segments of two-toothed wheels, — one segment being bolted to the top of the truck-bolster, and the other to the under side of the bottom framing of the car; the effect being, that, when the car is tipped, it rolls on the trucks, the fulcrum on which it rolls being brought directly under the centre of gravity of the car and its load, which, of course, shifts as the car is tipped. When the load is dumped, the position of the centre of gravity tends to restore the car to its normal position: the arrangement, therefore, assists the man in charge both in dumping, and in restoring the car to its running position. The rockers, with the central ball and socket and segmental cogs or teeth on either side, are shown in our illustration. When the car is to be dumped, the side-supports are withdrawn by means of levers on the end-platforms, and the car is tipped to either side by means of a worm actuated by a hand-wheel. As the bottom of the car is solid, it can be made stronger than a hopper-bottom car, and can be used for freight, which requires a flat floor, and cannot be loaded in a hopper-bottom car. It is stated that one man can unload forty thousand pounds of coal, sand, ballast, or iron ore, in two minutes by means of a dump-car, two hours being required to shovel out the same load.

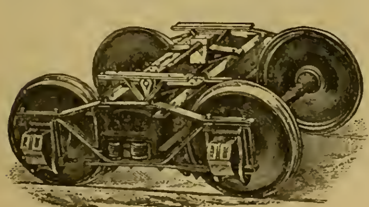
The Suspension car-truck manufacturing company of New York exhibited several trucks made on their principle, suited for freight, passenger, and horse cars, and showed a model truck which traversed an abnormally rough piece of track with a very smooth and easy motion. The car is connected to the truck by means of links, which swing in a vertical plane parallel with the track, instead of at right angles to it, as in the swing-beam truck; while the axle-boxes are connected to the trucks by means of links, which permit independent side-motion to each axle. The normal position of all the links is vertical, and they become inclined as the truck enters a curve, and therefore tend to restore it to a central position when the truck enters a piece of straight track again.

The principle of the truck is entirely novel, and, though really simple, is best understood by a few minutes' examination of a model. Two brackets, resembling the letter A reversed, are attached to the under side of the car. At the apex (now the lowest point) of the A are attached vertical links, the other end of which are attached to the truck at *B*, *B*, in our diagram. As the truck enters a curve, one of these links becomes inclined forward, and the other backward. As the wheel *C* strikes against the outer rail of the curve, it is thrown towards the inside of the curve (assuming the position shown by the dotted lines in the figure), and the suspension-links force that side of the truck forward, while the wheel *D* comes backwards; and therefore the action of the links tends to make the axles radiate to the curve. No centre-pin is used; and therefore, when a car is heavily bumped in switching, it merely swings backward on the links until they become sufficiently inclined to drag the truck after the car. It should be noted that the pin *E*, which connects the links to the truck, is a loose fit in the links, and therefore allows of the necessary radial motion. The top ends of the links, being attached to the truck, are always approximately a fixed distance above the rails; and therefore, when they are inclined, the car itself is lifted, and the weight of the car, hence, tends constantly to keep the links vertical, and maintain the truck in its normal position, with the axles at right angles to the axis of the car, so that it runs steadily on a straight line. The truck appears to be very highly thought of by the master car-builders, whose convention was held in Chicago during the exposition: and it is possible that it may come into extended use, the experience of the Boston and Albany, Connecticut River, and other roads which have used it, being strongly in its favor.



DUMP-CAR.

The Cliff and Righter company of Oswego, N.Y., exhibited a car-spring which gives an equal amount of elasticity, with a less amount of metal than the ordinary elliptic spring. Each half-spring consists of a solid steel bar of oval section, properly tapered towards the ends. Springs as usually made, of four, five, or more plates, resemble a set of somewhat elastic girders, the depth of each of which is the thickness of the plate; and the strength of a spring is the sum of the strength of each individual plate or girder, modified by the fric-



SUSPENSION CAR-TRUCK.

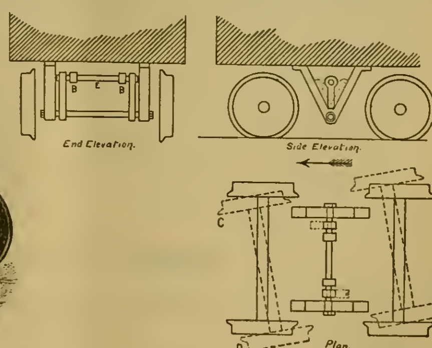


DIAGRAM SHOWING ACTION OF SUSPENSION CAR-TRUCK.

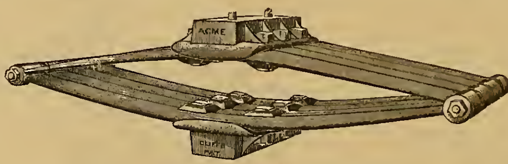
tion between the plates. It is obvious, that, were the plates to firmly adhere together, the strength of the spring would either be very largely increased, or the same strength might be attained by the use of a less number of plates; and the latter course has been carried to its limit by the patentee of the Cliff spring. A spring made of one plate must be of good steel, as, when loaded, the difference in the alteration of the lengths of its upper and lower surfaces is considerable, demanding a highly elastic steel. In the spring we illustrate, four springs are arranged side by side, — a plan which unites the advantages of a plate spring and a solid spring. Should one spring break, the other three will probably carry the load, while four springs side by side weigh no more than a spring of the same total strength, composed of a single bar of the same thickness, but of four times the width. A set of these springs for a passenger-car weighs nine hundred and twenty-eight pounds, while a set of the Pennsylvania railroad standard springs for the same purpose weighs sixteen hundred and thirty-two pounds, a difference of seven hundred and four pounds in favor of the solid spring. These springs have been lately introduced, and are being tried on the Boston and Albany and other railways. The difficulties of tempering and making a spring of one solid bar are considerable; but it is to be hoped they may be surmounted, as the weight of cars is a serious evil, "which has increased, is increasing, and ought to be diminished."



ELLIPTIC CAR-SPRING.

Mr. S. P. Tallman of New York exhibits a safety-drawbar for cars. Two pieces of timber are bolted between the middle sills of a car, and others are bolted to the under side of these timbers and the middle sills, forming a solid mass of timber, which receives both the buffing and drawing strains, the drawbar running through the timber, and being provided with springs at both ends. The spring nearest the draw-head takes the buffing-strain, and the spring at the end of the drawbar serves as a draw-spring. The disposition of the timbers enables them to be secured by more than the usual number of bolts, and the arrangement appears to be strong and simple, and not so liable to failure as the ordinary draught timber.

DRAWBAR.

Numerous refrigerator-cars were exhibited; and doubtless improvements will be much facilitated by the opportunities thus given to secure information, though it is to be regretted that the management of the exposition did not take steps to secure an efficient competitive trial of the cars under practical conditions. Beer, fruit, vegetables, etc., might have been placed in the cars, and locked up for a few days, when a careful examination of the contents would have given some indication of the relative merits of the cars.

The use of continuous brakes on passenger-trains has been found to be so advantageous, that their adoption on freight-trains is merely a question of time. Several forms of continuous brakes, applicable to freight-trains, were exhibited; the Westinghouse brake company showing a cheaper form of their well-known automatic brake, the reservoir being made of cast iron, and bolted to the cylinder. The triple valve, however, and other parts, differ little, except in size, from the brake used on passenger equipment. A cheaper form of brake, which requires no special pump or other fittings on the engine, or even a continuous brake connection through the train, is operated by the action of the ordinary hand-brake on the tender. The consequent compression of the draw-heads in the train is made by the peculiar mechanism of this brake-gear to apply the brake-shoes to the wheels of the cars.

This form of brake is peculiarly applicable to freight-service, as it allows of cars not fitted with the brake being run in the train without interfering with the use of the brake on the cars equipped. This class of brake can hardly be termed 'automatic' in the fullest sense of the term, insomuch as it does not work, should the train part in two. On the other hand, failure on any one car cannot impair the efficiency of the brake on the rest of the train.

The American brake company of St. Louis, Mo., exhibited full-sized working-models of a brake of this class.

Between the floor-sills, and at the inner end of the drawbar, is hung a bell-crank lever, *B*, which carries in one of its jawed ends the push-bar *A*, and, in the other, double-pull rods carrying a spiral spring transmitting the strain to bell-crank levers, *D*,*D*, suspended from the sills by hangers, *C*,*C*. The bell-cranks *D*,*D*, are connected to the brake-beams; and consequently compression on the draw-head acting on the lever *A* causes the brake-shoes to be pressed on the wheels, the amount of pressure being regulated by its transmission through the spiral spring. But, since a brake simply made as above described would not admit of a train being backed, a device is attached which removes the objection, and, further, only allows the brake to be applied when the car is moving at a speed above six miles per hour.

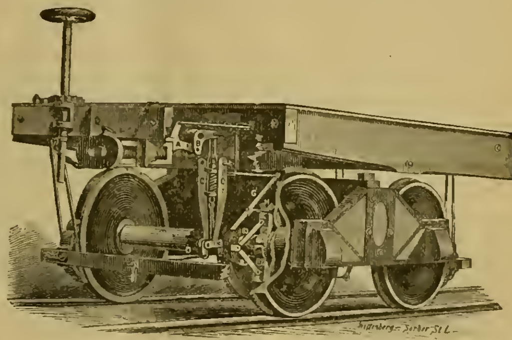
The push-bar *A* can only come in possible contact with the draw-head by the centrifugal force of governor-balls attached to the axle. These balls, *E*,*E*, are attached by means of links to a movable disk, *F*, encircling the axle. One end of a lever, *G*, bears against the disk, and the other end is connected by means of rods, etc., to the push-piece *A*. When the car is running at speed, the governor-balls draw the disk towards them, leaving the lever *G* free to follow it, and permitting the push-bar *A* to drop behind the draw-bar, when the brake is ready for action, going on directly the draw-gear is put in compression. When the speed falls below six miles an hour, the centrifugal force of the governor-weights becomes so feeble, that a spring (not shown in the illustration) restores the disk to its former position, lifting the push-piece *A* clear of the draw-head.

The brakes can be released at any time by the engineer putting on steam, and giving a pull to his train; and the train can be backed from a state of rest without the brakes going on, the push-piece *A* lying on the draw-head, but being unable to fall behind it.

The engineer can apply the brake, when pushing the train, by momentarily applying the brake on the engine or tender, thereby putting the draw-gear in tension, and letting the lever *A* fall behind the draw-head. When steam is again put on, the consequent compression applies the brake.

This brake has been in use for some time on the St. Louis and San Francisco and many other railroads, and appears to give very satisfactory results; the wear being very small, while the first cost is low enough to allow of its extensive application to freight-cars.

The brake exhibited by the Tallman automatic car-brake company of New York also acts by the compression of the draw-heads, which force together two friction-wheels, one of which is keyed on the axle, and the other is geared to a drum winding up the brake-chain. A ratchet-wheel, which can be shifted by hand, prevents the brake from acting when the train is backed.



AUTOMATIC BRAKE.

The Waldumer electric brake company of Chicago exhibited a working-model of a very promising form of continuous brake, which is just emerging from the experimental stage. The weak point of all continuous brakes has been the conveyance of the operating force — compressed air, vacuum, hydraulic power, etc. — along the length of a train, the pipes and couplings being generally expensive, and formed partly of perishable substances, while chains are unsatisfactory from every point of view. Many brakes that work well and promptly on a short train become slow and irregular in their action, when applied to a train of thirty or more vehicles. The instantaneous action of electricity, and the simplicity of the means used for its transmission, make it probable that an electric brake would be especially suited for long freight-trains. The brake is automatic, the fracture of wire or draw-gear ringing bells on engine and caboose, and warning both engineer and conductor that the train has parted, each being then at liberty to apply the brake or not, on his portion of the train, as he may deem best. Owing to the system of circuiting, the brake may be out of order on one car without affecting the rest of the train.

The street-car starter and brake exhibited by Charles T. Brown & Co., Chicago, is an ingenious device for storing the momentum which is destroyed by the usual form of brake, and utilizing it for restarting the car. The motion is not checked by friction, but by the axle, which, through suitable gearing, winds up a spiral spring, the power of which is available to again put the car in motion. The mechanical details appear well worked out, and the car can be run in either direction, and stopped or started on either up or down grades. The heavy pull necessary to start a car is very severe on horses, and this invention would appear to be useful in saving much wear and tear of horse-flesh.

D. H. O'Neale Neale.

A HEARING OF BIRDS' EARS.[1]—I.

The 'musical class' of vertebrates enjoy the sense of audition to a high degree. Otherwise birds would cease to sing. They are the only animals besides man whose emotions are habitually aroused, stimulated, and to some extent controlled, by the appreciation of harmonic vibrations of the atmosphere. Most birds express their sexual passions in song, sometimes of the most ravishing quality to human ears, as that of the nightingale, skylark, or blue-bird; and it cannot be supposed that they do not themselves experience the effect of music in an eminent degree of pleasurable mental perturbations. The capability of musical expression resides chiefly in the male sex; the receptive capacity of musical affections appears to be better developed in the female. There is, however, no anatomical difference in their ears. Quickness of ear is extraordinary in some birds, as those of the genus Mimus (mocking-birds), which correctly render any notes they may chance to hear, with greater readiness and accuracy than is usually within human compass; and it may be reasonably doubted whether any other animals than some of the world's greatest musical composers have a higher experience of acoustic possibilities than many birds possess.

Birds' ears have nevertheless a simple anatomical construction, in comparison with those of mammals. The auditory organ is decidedly of the reptilian type; and the arrangement of the parts is, on the whole, quite like that of reptiles. Thus, the cochlea, which in mammals makes from one and a half to five whorls (two and a half in man), is simply a strap-like prolongation from the vestibule, lacking modiolus, lamina spiralis, etc.; the stapes is the only perfected ossiculum auditûs; the incus is scarcely recognizable as such, and inseparable from the stapes; the malleus is immense, but outside the ear, furnishing the articulation of the lower jaw, of the zygomatic arch, and of the pterygo-palatal bar; the tympanic bone is represented at most by a few specks of ossification. There is ordinarily no external ear; the whole tympanic cavity is exposed on removal of the membrane, which lies very superficial; the eustachian tubes unite before opening into the pharynx; the periotic bone, constituting the otocrane or skull of the ear, is less compact and precise than the 'petrous portion' of the mammalian temporal bone, its three bony elements being more distinct; no mastoid portion is recognizable as such, but pneumatic cells of diploë are numberless, and there is direct passage of air from the ear into the hollow of the lower jaw; one of the semicircular canals invades the occipital bone. Other peculiarities will appear as we proceed with our description, in which comparisons will be chiefly made with the human ear.

Most birds have no external ear, in the sense of a fleshy conch or auricle. In bald-headed birds, the meatus externus appears as a roundish orifice at the lower back corner of the head, just above and behind the articulation of the lower jaw. In nearly all birds, the opening is hidden by an overlying packet of feathers, collectively termed the *auriculars* or ear-coverts, on simply raising and reflecting which the meatus is exposed. The auriculars are peculiarly modified feathers, having loosened barbs, doubtless to lessen interference with the passage of sound. In a few birds the border of the meatus develops a slight tegumentary fold, partially occluding the orifice. In various owls, as of the genera Strix, Aluco, Asio, Nyctala, but not even throughout this group of birds, an immense tegumentary *operculum*, or ear-cover, is developed, which flap shuts down upon the ear-opening like the lid

[1] Complementary to the article entitled 'The nature of the human temporal bone,' *Journal of otology*, January, 1882. Some portions of that article may perhaps be made clearer by the present one, especially those relating to the parts of a temporal bone as elements of mandibular and hyoidean arches. Figs. 1-4 are borrowed from Prof. W. K. Parker's admirable essay on the development of the fowl's skull, in Encycl. Brit., 9th ed., art. Birds; figs. 5-9 are from Prof. I. Ibsen's beautiful memoir, as cited in the text.

of a box. It hinges upon the anterior border of the meatus, and shuts backward. In some cases the operculum is about as long as the whole skull is deep, and half as wide as long — say, two inches long by an inch wide. On raising such an ear-flap and turning it forward, enormous external bony ear-parts, covered with integument, are displayed. Such expanse of the outer ear results from extension of occipital and squamosal bones into a thin shell bounding the meatus externus above, behind, and below. In the best-marked cases of the kind, especially in Nyctala, the parts are exaggerated unsymmetrically on right and left sides, and the whole cranium is distorted. This inflation of the cranium does not affect the inner ear-parts, or the essential organ of hearing. It should be added, in passing, that the so-called 'ears' of various owls, as the 'long-eared' owl, Asio otus, and 'short-eared' owl, Asio accipitrinus, are simply tufts of feathers on top of the head, over the eyes; these topknots having nothing whatever to do with the ears. Their proper name is plumicorns.

Aside from any such irregularities, the outer ear, or meatus auditorius externus, is a considerable, shallow, roundish depression, in the situation shown in fig. 1, where the reference line 5 crosses it, and where the cross-like object (stapes) marked *st* is seen lying in it. Its ordinary boundaries are, the enormous *malleus* or quadrate bone, *q*, in front; the expanded rim of the *squamosal*, *sq*, above; the *tympanic wing of the exoccipital* (a production of the lateral condylar plate of the occipital, *teo* in fig. 2), behind and below. A bone unknown in human anatomy, the *basi-temporal*, which floors the skull from ear to ear, underlying the basi-occipital and basi-sphenoid, also usually contributes to the inferior boundary of the meatus. On removing the quadrate (malleus), the general tympanic depression is seen to be more or less directly continuous with the alisphenoid, and so to conduct into the orbital cavity; the boundary of the meatus being best marked behind and below by the expansive thin-edged shell of the tympanic wing of the exoccipital. To the brim indicated is attached the membrana tympani; the ear-drum being thus from the configuration of the parts quite superficial, instead of being at the bottom of a long cylindrical tube, as in man. There is, in fact, in birds, no 'meatus auditorius externus,' in the sense of a special bony tube; some slight specks of ossification, when any, about the tympanic membrane itself, being all there is of a *tympanic bone* ('external auditory process' of human anatomy).

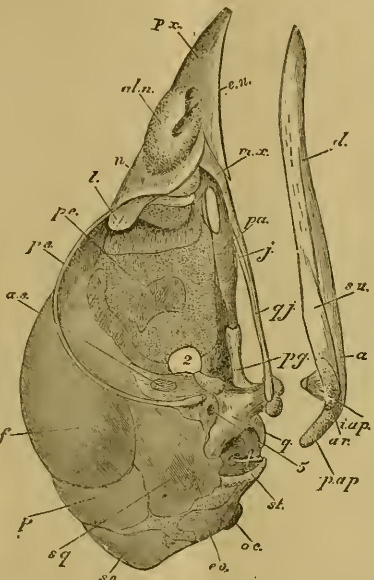


FIG. 1. — Ripe chick's skull in profile, × 3 diameters. (After Parker.) *px*, premaxillary; *aln*, ali-nasal cartilage; *en*, septo-nasal; *n*, nasal bone; *l*, lachrymal; *pe*, perpendicular plate of ethmoid; *ps*, presphenoidal region; *as*, alisphenoid; *f*, frontal; *p*, parietal; *sq*, squamosal; *so*, superoccipital; *eo*, exoccipital; *oc*, occipital condyle; *st*, the cross-like object, the stapes, whose foot fits *fenestra ovalis*; *q*, quadrate; *pg*, pterygoid; *qj*, quadrato-jugal; *j*, jugal; *pa*, palatine; *mx*, maxillary; *2*, *optic foramen*; *5*, *foramen ovale*, for inferior divisions of the fifth nerve. In the mandible: — *d*, dentary; *su*, surangular; *a*, angular; *ar*, articular; *iap*, internal angular process; *pap*, posterior angular process.

Such shallowness, openness, and superficiality of the parts, brings the cavity of the tympanum or middle ear into full view on removal of the tympanic membrane. On looking into this cavity, as may readily be done in clean, dry skulls of any size, many objects of interest may be studied without further dissection. We observe in the first place a large (inconstant) number of *pneumatic foramina* leading in various directions, conveying air from the middle ear-passage into the air-cells of bones of the skull, including the lower jaw. The most special of these is a neat gristly or bony air-tube into the lower mandible. The mouth of the eustachian tube is a large orifice at the lower anterior part of the cavity. This tube, as usual, continues an air-passage to the pharynx, opening at the back of the hard palate by a median orifice in common with its fellow. In sizable skulls, as of a raven, hawk, or eagle, a bristle or even a wooden toothpick readily traverses the conduit which runs between the basisphenoid and the underlying basi-temporal. This whole passageway, from outer ear to tympanic cavity, and thence through eustachian tube to pharynx, represents the persistently patulous part of the first post-oral visceral cleft of the embryo, only occluded by the membrana tympani. Near the eustachian orifice are observed two definite openings. The anterior and superior of these is the fenestra ovalis, fitted, as usual, with the foot of the stapes, as seen in fig. 1, closed by membrane, which further occludes this opening into the *vestibular* cavity. The other is the fenestra rotunda, similarly leading into the *cochlear* cavity. The two are generally close together, separated merely by a bony bridge or bar. The former lies always in the obliterated suture between the proötic and opisthotic elements of the petrosal bone, the latter wholly in the opisthotic; both are thus as in man. Close examination at a point somewhere about the fenestra ovalis will discover a minute foramen, corresponding to the human 'stylo-mastoid foramen' inasmuch as it represents the orifice of exit of the seventh cranial nerve ('portio dura') from the petrosal bone, here in the cavity of the middle ear, there being none such upon the outside of the skull. Thus, in the dry skull of a bird, the hard parts of the tympanic cavity, including the eustachian tube, can readily be inspected from the outside; even the limits of the proötic and opisthotic bones can be determined by the site of the fenestra ovalis, and the ossicula auditus be seen *in situ*. To see these things in the human or any ordinary mammalian ear, requires special preparations, as they lie in a tympanum which is itself at the bottom of a contracted tube. Details of mere size and shape aside, the above general description of the passageways will apply pretty well to any bird, and should suffice for recognition of the parts; though the number and variety of the irregular pneumatic openings (comparable to those of the human mastoid cells) may be puzzling at first sight.

(*To be continued.*)

ON THE KINETIC THEORY OF THE SPECIFIC HEAT OF SOLIDS.

IN a paper entitled 'Kinetic considerations as to the nature of the atomic motions which probably originate radiations,'[1] the writer has given reasons in support of the hypothesis that different chemical atoms are all composed of the same kind of ultimate atoms, which are in every respect equal and similar. Reasons were also given, tending to show that the vibrations of these ultimate atoms originate luminiferous and thermal radiations. And further, supposing radiations to originate in the vibrations of equal and similar ultimate atoms which are set in vibration by the collision of moving molecules, an attempt was made to prove that two unlike masses of gas which are in thermal equilibrium by radiation will also be so when mixed; i.e., when the equilibrium depends upon the collisions of the molecules rather than upon radiation.

The object of the present paper is to consider the probable physical state of solid bodies, especially as to the amount of energy distributed among the different degrees of freedom possible in such bodies, and to show that the same hypothesis of equal ultimate atoms would cause solids which are in thermal equilibrium by radiation to be also in thermal equilibrium when brought into contact, i.e., when the equilibrium depends upon the collisions of the molecules.

Let us notice, in the first place, what is apparently the mechanical significance of Dulong and Petit's law, which may be stated thus: the amount of heat which must be imparted to a chemical atom of a simple solid body to increase its temperature one degree is approximately the same for all the elements. Neumann has further shown, that, for compound solids, those of similar chemical composition require approximately the same amount of heat per chemical atom, but the amount is less than for simple solids. There are, however, a very few unexplained exceptions to these laws, which are due possibly to uncertainty as to atomic weights.

The mechanical explanation of these experimental laws seems to be contained in the statement, that, in simple solids, cohesion and chemism are one and indistinguishable; or, to express it otherwise, we may say that the molecules of simple solids are monatomic, the cohesion being, of course, much greater in some solids than in others.

That this is a correct conception of the relations of the atoms of a simple solid, is made probable by various facts, among which this may be mentioned, — mercury and cadmium, which are known to be monatomic as gases, as solids fulfil Dulong and Petit's law, and are therefore in the same physico-chemical state

[1] SCIENCE, ii. 76.

as other simple solids. Another fact is that already mentioned, viz., the specific heat of compound solids per atom is less than that of simple solids; and to this it may be added, that the specific heat of simple solids is less when the volume is made smaller by hammering, compression, or cooling, which facts will be considered more at length later.

It is shown in the kinetic theory of gases, that, when molecules of unlike gases are mixed, the mean progressive energy of each molecule is the same, whatever its weight.

Now, when a gas is in contact with a solid, will the collisions of the gaseous molecules with those of the solid cause the latter to have the same mean progressive energy of vibration as those of the gas? That will depend largely upon the duration of the collision. If the time occupied by a collision is so brief that only a small portion of a vibration of the solid molecule is described during the collision, then the laws of impulsive forces may be applied, according to which the effect of the finite forces acting during the interval may be neglected.

In case the collision is brief, the distribution of the mean kinetic energy between the molecules of the gas and solid will be very nearly the same as between different gases, and the mean kinetic energy of a simple solid molecule will differ little from that of a gas at the same temperature.

In cases, however, in which the modulus of elasticity of the solids considered is so great as to make the period of vibration of the molecules also brief, their mean kinetic energy would be materially smaller than in the previous case; and, if a solid could be found whose molecules were immovably fixed, no vibratory energy whatever could be imparted to its molecules.

Now, Dulong and Petit's law seems to show that all simple solids, even those having the highest modulus of elasticity, have an elasticity so small, compared with that brought into action between molecules at the instant of free collision, that the distribution of kinetic energy is approximately the same as if the body were gaseous and monatomic. But since the laws of perfect elasticity require that the mean potential energy shall be equal to the kinetic, it follows that the specific heat of a simple solid should be approximately twice that of a monatomic gas at the same temperature and of the same atomic weight.

The actual specific heats of mercury and cadmium gas would be of great interest in this connection, were they known, even though they could only be determined at temperatures far removed from those of their solids.

The foregoing statement has been based upon the assumption that any degree of freedom which suffers partial constraint, as do the degrees of freedom of translation of a gaseous molecule when it becomes solid, will have for that reason less kinetic energy imparted to it during molecular collision. This subject has been treated somewhat at length in previous papers upon the kinetic theory: but in this connection it may be useful to make a quotation from Thomson and Tait: "If a set of material points are struck independently by impulses, each given in amount, more kinetic energy is generated if the points are perfectly free to move, each independently of all the others, than if they are connected in any way."[1]

This mechanical theorem not only has special application to the partial constraints introduced into the freedom of motion of molecules when they change from a gaseous to a solid state, but it applies, also, to the additional constraints introduced into the degrees of freedom of solid atoms when those atoms become more closely bound together by chemism into groups, i.e., into molecules. Evidently, the bonds of union between the atoms of a compound solid molecule are such that these degrees of freedom are considerably more constrained than those which unite the atoms of different molecules; so that, in compound solids, the forces of cohesion and chemism are different, and quite distinguishable the one from the other.

Now, what, according to the mechanical theorem above quoted, is the effect of introducing the additional constraints required in order to group a simple solid, or mixture of simple solids, into molecules, and thus make it a compound solid? The effect will be to diminish the mean kinetic energy of the system as derived from the impacts of the molecules of any gas surrounding it. This is, in fact, what occurs, as appears from the experimental truth previously mentioned, — that the specific heat per atom of compound solids is less than that for simple solids. How much the specific heat per atom is diminished should depend upon the intensity of the chemical attraction, which certainly must be much greater than the cohesion between atoms of simple solids, to cause such marked deviations of specific heat per atom as compound solids exhibit. This result, when combined with that arrived at in connection with the discussion of Berthelot's law, in my paper upon 'An extension of the theorem of the virial,' etc., to the effect that the heat evolved in chemical decomposition is greater

[1] *Nat. phil.*, art. 315.

the greater the attractive force, enables us to enunciate the following law, the truth of which I am at present unable to verify for want of sufficient experimental data: those solids, other things being equal, which evolve the greater amounts of heat of chemical decomposition in changing from simple mixtures to compound solids, are those which have less specific heat per atom. The phrase, 'other things being equal,' in the above statement, refers to the fact that similar compounds which are chemically similar are in strictness comparable. Many other circumstances, moreover, besides want of chemical similarity, may, in special cases, mask the experimental results; yet the truth of the law should be clearly recognizable in any general comparison of specific heats with the heat of formation of compound solids.

Similar principles evidently apply to the cases in which simple solids are permanently decreased in volume by hammering or compression; for then greater cohesive forces are brought into action, and the specific heat is diminished. It remains to be shown, in conclusion, that thermal equilibrium, which has been established by collisions of gaseous and solid molecules, will continue to exist when its continuance depends upon radiations between equal and similar ultimate atoms which are set in vibration by molecular collisions; or, to state it differently, it remains to be shown that the ultimate atoms of a gas and a solid in contact, each have the same mean vibratory energy with respect to each of their degrees of freedom with respect to each other. This appears to be a direct consequence of the laws of constrained motion which have been considered in this and previous papers. It is only necessary that the impacts of a pair of solid molecules with each other should be such as to mutually impart and receive the same mean amounts of energy as would those of a gaseous and a solid molecule at the same temperature, to cause it to be a matter of indifference whether a given solid molecule is struck by another solid molecule or by a gaseous molecule; and, when so struck, each ultimate atom will receive its proper proportion of energy, whether it form part of a solid or of a gaseous molecule.

It is my intention to return to this subject hereafter, and to treat the vibrations of ultimate atoms more at length, in the hope of being able to show, more precisely than has been done so far, how the characteristic differences in the spectra of solids and gases arise.

H. T. EDDY, Ph.D.

CLIMATE IN THE CURE OF CONSUMPTION.—I.

THE prevalence of phthisis pulmonalis is such a well-attested fact, that to adduce statistics to prove it would seem to be labor thrown away. Since the eradication of small-pox in consequence of the introduction of vaccination, phthisis heads the list as the prime cause of the large mortality. The insurance companies recognize the fact, and the statistics of the New-York mutual life-insurance company show, that between the ages of twenty and thirty years the mortality from phthisis is thirty-three per cent of the whole mortality. The U. S. census for 1870 shows that in the state of Maine the mortality from consumption was fifty per cent for the same ages.

Equally well known is the belief in climate as a cure for the disease. There are certain well-recognized climatic conditions known to be favorable to the prophylaxis and cure of the disease. This knowledge is largely empirical, based upon trial and observation; but there is, underlying it, a substratum of conviction, that is justified, on the one hand, by careful clinical observations, and, on the other, by facts ascertained by carefully conducted experiments.

The writer proposes, in the thoughts to be presented, to make these various elements his tests in searching out a desirable climate in the United States for the cure of phthisis. He offers, as his data for forming an opinion, carefully compiled tables, furnished by the Signal-service bureau, U.S.A.; and he wishes to emphasize the fact, at the outset of his remarks, that a climate may become desirable quite as much by comparison as on account of its intrinsic properties; that even though it may not possess in itself all desirable qualities, yet it may contain so many as to be, by comparison with others, the climate par excellence. With this thought in view, the writer has prepared tables embracing all the chief resorts in this country for phthisical invalids, — tables embracing a range of the whole country, from Jacksonville to St. Paul, and from Boston to Los Angeles.

He has given the data for Augusta, Ga., as the best substitute for Aiken, S.C., at which place there is no signal-station; and in doing so he thinks that he is presenting data which will fairly represent the climatic conditions of Aiken.

He wishes to gratefully acknowledge his indebtedness to the chief signal-officer, U.S.A., to the observers at each of the stations included in the tables, and especially to Sergeant F. M. Neal of the Denver station, for their kindness in furnishing him with the data from which the tables are compiled.

TABLE I.

Station. The figures giving the elevation represent the height of the barometer above sea-level.	I. Elevation.	II. Mean 10 yrs. Barometer.	III. Mean 4 yrs. Relative humidity.	IV. Mean 4 yrs. Absolute humidity.	V. Mean 10 yrs. Precipitation	VI. Mean 10 yrs. Temperature.	VII. Mean 5 yrs. Prevailing wind.

Los Angeles, Cal.	350	29.647	65.8	3.77	18.97	59°.8	W.

Elevation.

The effect of a rise in elevation is to diminish the atmospheric pressure. The method of measuring this effect is by means of the mercurial barometer. Disregarding the variations attributable to changes in temperature, humidity, and latitude, it can be broadly stated that the barometer will fall one inch for a rise of 857 feet above sea-level, two inches for a rise of 1,743 feet, three inches for a rise of 2,661 feet, etc.; or, for the purposes of a rough calculation, it may be said that the barometric depression is one inch for every thousand feet of elevation. This depression would indicate a diminution in atmospheric pressure of one-sixth in weight for an elevation of 5,000 feet: or, to state this fact in another way, the atmospheric pressure at sea-level being 15 lbs. to the square inch, at 5,000 feet it would be one-sixth less, or 12½ lbs. To illustrate: if the pressure on the entire surface of the body of a man of middle size be 35,560 lbs. at sea-level, at 5,000 feet it would be 29,635 lbs., a diminution of nearly three tons.

The question for us to consider is, what effect this diminution of pressure has upon the vital functions with reference to the cure of phthisis.

1. *Effect on circulation.* — The heart is a muscular organ, habituated to expend a certain amount of force, which may be roughly estimated as 75,000 kilogrammetres, or 542,475 foot-pounds, *per diem*. To accomplish this work at sea-level, the heart makes 72 beats a minute, or 103,680 beats a day. Allowing, now, an increase of two beats a minute for every thousand feet of elevation, at 5,000 feet there will be an increase of 10 beats a minute, or 14,400 beats a day, — an increase in work equal to about 74,744 foot-pounds in a day.

This in itself would prove that such an elevation is to be avoided in those cases where an enfeebled heart is struggling to overcome the disadvantages produced by organic lesions.

What effect does this increase of heart-work have upon the circulation? The rapidity of circulation is influenced by the force and rapidity of the heart's beat, and by the diminution of the peripheral resistance. At an elevation of 5,000 feet, each of these causes would be at work. To just what extent they work, in producing given results, it is impossible to say; but, allowing that the peripheral resistance and the force of the heart's beats remain the same at 5,000 feet as at sea-level, an increase in frequency of ten beats per minute would indicate, that, on account of this one factor, the blood would make 29,622 additional circulations through the system *per diem*. What effect would this have upon the disease in question?

It is a frequent remark that both waste and repair are more rapid at high altitudes than at sea-level. Experience amongst physicians shows that cases of fibrinous pneumonia are more acute and more rapid in their results at high altitudes than at sea-level. My own experience is, that resolution in such cases is more rapid, and that the chest 'clears up' sooner. May not this be explained on the ground of the increased rapidity of circulation? We know that the clearing-up is brought about by the expectoration of the morbid products of the exudation, and further, and chiefly, by their absorption into the circulation. If this be true of an acute trouble, is it not also applicable to a chronic asthenic one?

Further, the increase of rapidity in the circulation means that the same blood is brought more frequently to the lungs to be oxygenated, — an increase in the number of times, which we have seen to be equal to 29,622 additional times, *per diem.* This would indicate an increase in the activity of the metamorphosis of tissue, and therefore an increased vital force. This is clinically perceptible in the exhilaration that invalids experience on coming to higher altitudes, and by the increase in appetite dependent upon the demand for material to meet the additional metamorphosis.

There is the other side, however, which must be alluded to. An increase in the rapidity of the circulation means an increased flow or tendency of blood to the diseased parts, involving, as it does, a greater activity of these parts. This is temporarily noticeable in every case of phthisis pulmonalis coming to higher altitudes, and is evidenced by an increased expectoration. This, as we have said, may be beneficial by assisting to remove the morbid products; but in enfeebled cases, where the ravages of the disease are great, it may be highly injurious in assisting the already great breaking-down of the tissues. Again: there is an increased demand for oxygen dependent on all of these causes, and, in cases where the amount of lung-tissue involved is so great as to cause a considerable embarrassment of the respiration, this additional strain is not desirable.

2. *Effect on respiration.* — We must now study another effect produced upon the system by an increase in elevation, and that is, the effect produced upon the respiration. Here, too, we shall have to speak of gross results, and leave minutiae unexplained.

Experience shows that the respirations are deepened and fuller, and that they are, at first, at least, increased in number.

This can be explained somewhat in the following way. The nervous action, the effect upon the respiratory centre, etc., is so complicated, that, despite its importance, we shall leave it without attempting its solution; and we shall only attempt an explanation of the quasi physical or mechanical results.

The lungs are elastic bags suspended in a closed cavity. During inspirations the respiratory muscles draw the ribs upwards, enlarge the cavity, and produce a partial vacuum, in consequence of which the air rushes in to fill up this vacuum, and the lungs are inflated.

It is evident that in inspiration the respiratory muscles, in raising the chest-walls, displace a certain amount of air, and overcome a certain resistance due to atmospheric pressure, and that these muscles, accustomed to exert a given amount of force to overcome this resistance (which may be roughly measured by the difference between the positive pressure on the outside and the negative pressure on the inside of the chest-walls), would continue to exert this force, even though the resistance were diminished. As a result of this, we should expect either a greater expansion of the chest from the same expenditure of force, or an increase in the number of inspirations.

The beneficial results of a greater depth of inspiration will be more clearly seen if we contrast it with the bad results of diminished respiration. Ruehle, in Ziemssen's Cyclopaedia, says, —

"The diminished respiration in the upper parts of the lungs, and the exaggerated respiration in the lower parts resulting from this cause, serve to explain the very general fact that pulmonary consumption almost always begins at the apices of the lungs. But there is probably another cause in the peculiar position of these parts. They project from three to four centimetres above the clavicles; and this projecting portion, being situated outside the chest, is subjected to the pressure of the external air. The supraclavicular region sinks in during deep inspiration, and consequently the inspiratory expansion of the apices is less than that of other parts of the lungs."

It is evident, if Ruehle be right, that a diminution of atmospheric pressure means a greater expansion of the apices, due to a diminution of atmospheric pressure bearing on those parts, and also a greater expansion of the entire chest.

There is, however, a theory often advanced, that the greater depth of respiration is due to the fact, that, in consequence of the diminution of the amount of oxygen dependent upon the decreased atmospheric pressure, an individual will have to breathe more frequently and deeper to gain the amount of oxygen necessary for aerating the blood. The theory, it seems to us, is misunderstood, and the question needs investigation.

We have shown that there is an increased demand for oxygen dependent upon an increased tendency of the blood to the lungs.

It is known, also, that the transpiration of gases through tubes, which the bronchi really are, is hindered by a diminution of pressure, and that in consequence of this, in a given time, under the same conditions of expansion, etc., less air will enter the lungs at 5,000 feet elevation than at sea-level. This is another cause why the respirations should be either deeper or more frequent.

It is further known that the osmose of gases through a thin septum, as in the lungs, is less rapid the less the pressure, or, in other words, that the rapidity of the osmose of gases is dependent upon the pressure to which they are subjected. This being so, as the density of the oxygen and carbonic acid in the blood is nearly constant, if the density of these gases in the air be diminished, there will be an effect produced upon the rapidity of their osmose. In the case of oxygen, it is claimed that an individual will get less of it at 5,000 feet elevation than the system requires, and that, unless the conditions of respiration be changed, there will be a 'starvation of oxygen,' i.e., an asphyxia. In consequence of all this, it has been claimed that a greater depth and frequency of respiration is demanded to meet this want.

In regard to the osmose of oxygen, we know, that, even though there be a hindrance due to the diminished density of the gas in the air, there is still, on the other hand, an increased rapidity of the circulation, which would favor osmose; and it may be assumed that the effects of these two conditions counterbalance one another.

In regard to a starvation of oxygen being produced by a diminution in the amount of the gas at a higher elevation, the *rationale* is somewhat as follows: there exists in the atmosphere, under all pressures, 23 parts by weight of oxygen. At sea-level, there are 130.4 grains of the gas in every cubic foot, while, at 5,000 feet, this amount will be diminished one-sixth, so that there will only be 108.6 grains to the cubic foot. The question then is, whether a density of 108.6 grains to the cubic foot of air will produce a starvation of the gas in the human economy.

It has been estimated that the tension of the oxygen of the venous blood of the dog is 2.9%, or 22 mm., of mercury. It has been further estimated that the tension of the oxygen of the pulmonary air-cells is at least 10% of the atmospheric pressure, which, at 5,000 feet, would amount to 63.3 mm. of mercury; so that it is evident, that, even under this diminution of pressure, the difference between the density of the oxygen in the inspired air and in that of the venous blood brought to the lungs is sufficiently great to admit of a free osmose.

Further than this, we know that the amount of tidal air passing in and out of the chest of an average man is 500 cc., or 31 cubic inches. Allowing 17 respirations to the minute, this will make 510 litres, or 18 cubic feet, of oxygen inspired *per horam*. At 5,000 feet this air would contain 1,955 grains of oxygen. Now, the absolute absorption of oxygen at sea-level is only five per cent of that contained in the air, and the amount that is absolutely needed each hour, at sea-level, is only 117 grains. As the absolute demand for oxygen is only 117 grains each hour, and as the actual amount contained in the inspired air at an altitude of 5,000 feet is, for the same time, 1,955 grains, it is evident that here, again, the supply is greatly in excess of the demand, and that the term 'starvation of oxygen,' as explanatory of the increased depth and rapidity of the inspirations at high altitudes, is a misnomer.

But in addition to the absorption of oxygen there is the elimination of carbonic acid to be accounted for. It is evident, that, as the tension of the gas in the venous blood coming to the lungs is nearly constant, any diminution of its tension in the air will favor its osmose from the blood to the air, and that the effect produced upon the osmose of this gas by rise of elevation is the reverse of the effect upon the osmose of oxygen.

In concluding this part of our subject, we wish to emphasize the fact that we think that the benefit to be derived from simple elevation, in cases of phthisis pulmonalis, is to be attributed largely to the greater depth of the inspirations, and consequently to the greater distension and activity of all parts of the lungs (the diseased apices as well as the healthy bases), and to the increased elimination of morbid products brought about by the increased rapidity of the circulation.

3. *Ozone.* — In addition to the foregoing reasons for favoring a high altitude in the cure of phthisis, we wish to consider, further, the influence of elevation upon the ozone of the atmosphere.

The assertion is generally made, that, as "we ascend heights, the amount of the ozone rapidly increases;" and yet there does not seem to have been any direct experimentation on this point. If there be more free ozone, it may be due, not to any increased production over that of lower levels, but rather to a diminished consumption. Further than this, the starch and iodide test is so dependent upon other elements than the simple presence of ozone, that it is not thoroughly reliable. It is also open to the error of reacting to substances other than ozone. Still, admitting the statement that there is more nascent ozone at high elevations, the explanation of its action in the cure of phthisis is still to be sought. Some rather visionary theorists, as it seems to the writer, claim that it finds a direct admission to the diseased spots in the lungs, and, by its poorer oxidizing, it burns up *in loco* the morbid products.

We should rather attribute its influence to the fact, that, where ozone exists free, there is no decomposing matter to be oxidized. It seems to us to be indicative of the existence of pure air, rather than a direct agent in destroying the morbid products in the lungs.

4. *Immunity from phthisis.* — Another argument in favor of elevation in the cure of phthisis is, that at certain heights there exists an immunity from the disease. The disease is not endemic at such elevations.

This is in the nature of negative evidence; but it is certainly valuable as an element of prophylaxis, and we think that it can be applied as an argument in favor of cure. Ruehle (*op. cit.*) says, "A height of *at least* 1,800 or 2,000 feet seems to be requisite for this purpose. Phthisis is rare on the Hartz, Styrian (in Purzgau), and Swiss mountains." Jaccoud (Flint's Practice of medicine, p. 296) "states that the observations for fifteen consecutive years warrants him in asserting, that, in Alpine situations elevated 4,000 feet, tuberculosis is unknown; and especially is this true of villages at an elevation of 5,500 feet." Dr. Irwin reports for Fort Defiance (6,500 feet), north-western New Mexico, "During a service of some seven years in New Mexico and Arizona, I never saw or heard of a case of tuberculous disease amongst the native inhabitants of those territories." And Dr. Denison, in his work entitled 'Rocky Mountain health resorts,' writes, "After having quite thoroughly canvassed the subject among physicians of Colorado, I place the altitude of approximate immunity of this state at 6,000 feet."

Taking a mean of all these quotations, we may safely assert, that, broadly speaking, an altitude of from 5,000 to 6,000 feet affords an approximate immunity from this disease.

5. *An aseptic atmosphere.* — Lastly, we will speak of the influence of elevation in the cure of phthisis in producing an aseptic atmosphere. In these days of germ-theories and of Koch's experiments, we cannot but give emphasis to this element of antisepsis as an element of prophylaxis and cure of phthisis. Professor Tyndall's experiments show the abundance of germs floating in the air at sea-level, and an entire absence of such germs at the altitude of the 'Belle Alp' hotel (7,000 feet). Whether a lower elevation will furnish this aseptic atmosphere has not been proven experimentally; but it would seem to be reasonable to argue that an elevation corresponding to that of immunity from phthisis would furnish such an atmosphere.

Résumé. — There are other elements, such as humidity of the air, temperature, precipitation, etc., more or less dependent upon elevation, which we shall have occasion to speak of more at length. But, to make a *résumé* of our study to this point, we can say that a rise in elevation increases the heart-beat and the rapidity of the circulation, thereby hastening the absorption of the morbid products in phthisis, and increasing the metamorphosis of tissue, and hence the vital force; that it likewise produces greater depth of respirations, and a more healthy action of the diseased portions of the lungs; that it gives a purer air, and affords an approximate immunity from the disease; and, finally, that it affords an aseptic atmosphere, in which the Bacillus tuberculosis does not exist. The extent of elevation desirable for the production of this effect can be stated to be at least 5,000 feet.

Having arrived at these conclusions, it remains for us to apply them to our subject. By consulting table I., columns i. and ii., it will be seen, that, of all the resorts for the cure of phthisis in this country, the eastern slopes of the Rocky Mountains alone furnished the desirable elevation. The distance between Denver and Santa Fé is in the neighborhood of 375 miles in extent. Throughout this whole extent, pleasant locations for invalids are to be found at elevations varying from 5,000 to 6,000 feet.

(To be continued.)

HISTOLOGY OF INSECTS.

Inspired by Weissmann's well-known researches on the post-embryonic development of insects, Viallanes has studied the structure and changes of various tissues, principally in Musca vomitoria, but also in other insects during their metamorphoses. His results occupy nearly an entire volume,[1] and make an important addition to knowledge, the more welcome because the author deals chiefly with those tissues which have heretofore been least worked

[1] Vol. xiv. sér. vi. of Ann. sc. nat., zool.

upon. The long memoir embodies a large number of valuable data, the outcome of work which we believe to be thorough and careful. The collation of the literature is good, but not complete, some omissions being important. We are unable to give here more than the chief general conclusions.

The skin of the larvae studied consists of a single layer of large flattened cells, covered externally by the hard chitinous cuticula (containing lime in Stratiomys), which is smooth in Musca and Eristalis, but divided in Stratiomys into fields corresponding to the cells. Below the cells, and lying directly against them, is a thin anhistic membrane, which is comparable to the basal membrane in crustacea and adult insects.

The peripheral nervous system is of great interest. Between the integuments and the muscles of the larvae are found peripheral ganglia, which do not belong either to the ventral chain or to the stomatogastric system. No analogous observation has hitherto been made upon insects. The peripheral ganglia of the larva of Tipula are very remarkable from their regular disposition and their symmetry: there is a pair in each segment. Those of Musca are irregularly scattered between the skin and the muscles. Analogous ganglia are found in Eristalis, but are localized in the plexus, whence spring the nerves of the special sense-organs in the anterior region of the body. In the description of the peripheral nerves the author adds little to what was previously known.

The sensory nerves end in two ways, — either by a connection with sensory hairs of the epidermis, or with free terminations. In the former case the axis-cylinder dilates, at the base of the sensory hair, into a bi-polar ganglion cell. The sensory hair is a conical hollow process of the cuticula. It is secreted by a special, large, slightly modified epidermal cell, the protoplasm of which fills the cavity of the hair, and lines its base. The distal prolongation of the bi-polar cells unites with the protoplasm of the hair-cell, and does not run directly to the hair. This apparatus appears to subserve touch, smell, etc. The free terminations are found beneath the epidermis, as thread-like prolongations of a very rich dermal plexus, formed by very numerous multi-polar anastomosing nervous cells. (Besides the description of similar structures in other animals cited by Viallanes, *cf.* Canini and Gaule, Science, ii. **279**.)

Involuntary striated muscles. The larval heart is histologically comparable to a vertebrate capillary, being formed of flat cells soldered border to border. In the protoplasm of these cells, muscular fibres are formed, so that the cells are at once comparable to the endothelium and muscularis of the capillary. Within each single cell the fibrilla begins and ends with a thin disk or stria; therefore the space between the two disks is the unit of the fibril. In young larvae the heart is a simple tube without lateral openings. The striated muscles of the digestive tube are probably histologically identical with those of the heart, i.e., modified single cells; but Viallanes was unable to make out the cell-limits. In the walls of the stomach of Tipula is an intramuscular ganglionated nerve-plexus, which probably innervates the muscles; but the final terminations were not seen. This is regarded as confirmatory of Ranvier's law (*Leç. d'anat. génér.*, 1880, 463).

In regard to the voluntary muscles the following conclusions are drawn: the fibrillae of insects are homologous with those of vertebrates, although the latter are indivisible, while in insects certain fibrillae (of the wing-muscles) may be decomposed into fibriculae. In insects, as in vertebrates, the fibrillae are united into 'colonettes,' or little clusters, being closely cemented together by a homogeneous and continuous substance, into which neither protoplasm nor nuclei ever penetrate. In vertebrates a large number of colonettes are united within a common envelope, the sarcolemma, to form the fibre or primitive bundle. In insect larvae this disposition is maintained, but in the wing-muscles the sarcolemma is absent; the primitive bundle then consists of a few colonettes (Musca), or even of one colonette only (*cf.* Ciaccio, Science, i. **247**, whose paper is not cited). In the leg-muscles there is but a single colonette in each fibre, and the sarcolemma is scarcely developed. As regards the motor plates the following points are noted : 1°. In the larva of Stratiomys chamaeleon, each of the fibres, constructed on the vertebrate type, has several Doyère's cones, to the summit of each of which runs an axis-cylinder accompanied by a nucleated sheath. Before innervating the muscle, the nerves form a plexus; in the cone the axis-cylinder forms a terminal arborization by successive dichotomous branchings inside the sarcolemma; the fundamental substance contains neither granular matter nor nuclei. 2°. In Tipula there is a similar arrangement, but only one cone to each fibre; the terminal arborization is much more extended, and bears nuclei; and the basal substance of the cone is granular, and nucleated as in the terminal plates of Amniota. 3°. In the caudal muscles of Eristalis and the leg-muscles of Dytiscus, each fibre of which contains only a single colonette, the motor nerves form no arborization, but break up into their constituent fibrils as soon as they reach the sarcolemma.

The second part of the memoir deals with the very remarkable changes in the larval tissues at pupation. The corpuscles of the blood of the larva are embryonic cells analogous to the leucocytes of vertebrates, and are found in the same form in the pupae. The muscular fibres of the larva disappear at the commencement of pupal life, and in two ways: — First, by 'évolution régressive :' the nuclei of the muscle become spherical, and each surrounded by a coat of protoplasm, thus becoming a muscle-corpuscle, which proliferates, and gives rise to a great number of rose-colored granules, which multiply until the muscular substance entirely disappears, as if it supplied nutriment to the granules; these last finally separate, and spread themselves through the body cavity. Second, by degeneration: the nuclei keep becoming rarer until they all disappear, and meanwhile the contractile substance disappears as if dissolved away on the outside. In consequence of these processes, the body cavity is charged with a quantity of matter resembling the vitelline elements of birds. The cells of the so-called fat-body produce, during the first days of pupal life, numerous granules, which enlarge, and are ultimately set free by the rupture of the cell-membrane. These granules arise independently of the nucleus, but closely resemble small cells. The cells of the tracheae and salivary glands do not disappear at the time of metamorphosis, as has been thought, but, on the contrary, they proliferate by endogenous cell-formation, the parent cell being first enlarged; the parent nucleus is finally discharged; the embryonic cells thus generated separate, and fall into the general body cavity. The *körnchenkugel* produced by pupal histolysis, and described by Weissmann, are of two kinds, and do not arise from the disintegrated matter, as supposed; but the smaller are derived from the muscle-corpuscles, the larger from cells of the fat-body. The epidermis of the larval head and thorax dries up and falls off. It is not immediately replaced by the definite cell-layer, but first by a thin cuticle, which Viallanes considers to be probably the thickened basement membrane of the larva.

Part third treats of the histogenesis of the tissues of the imago. The skin of the head and thorax is developed from Weissmann's imaginal disks. In the description of these, Viallanes follows Ganin in general, but he thinks that the mesoderm of the disks is formed at the expense of some of the embryonic cells in the body cavity. Other points are also brought forward, among which we note especially that the wing of the pupa contains at first numerous tracheae, which disappear before the end of the stage. In the abdomen, also, there are imaginal disks, four in each segment, and formed by local thickenings of the epidermis; all other parts of the epidermis or hypoderm degenerate, and are resorbed. The disks form two layers, the outer making the new epidermis, and the inner the mesoderm; the disks grow at their borders until they everywhere meet, and form a continuous tissue. The method of regeneration is the same as in the thorax, except that the disks are developed later: the difference assumed by Weissmann and Ganin is not real. The author compares the imaginal disks with the plates in Pilidium.

The internal muscular mass of the thorax is derived from a single anlage, composed of little cells embedded in a small amount of homogeneous basal substance. This anlage then separates into six cords, corresponding to the definite muscles; these grow by peripheral accretion; the muscular substance is then differentiated around the cells, which are disposed with great regularity in the midst of the colonettes, becoming, in fact, the muscle-corpuscles (the necessity of omitting a fuller account is much regretted. — *Rep.*). The muscles of the legs are derived from the mesoderm of the imaginal disks; the general process of their histogenesis, despite many interesting differences, is the same as that of the wing-muscles. The author makes an excellent comparison between the unicellular muscles (heart, stomach) and the pleuricellular (wings, legs), or, as we might name them, the mesenchymal and myothelial muscles.

Nearly a fifth of the entire memoir is devoted to the development of the eye. The brief *résumé* (p. 302–305) is the most succinct and perfect account of the structure of the compound eye with which we are acquainted. In the first section the structure of the developed eye of the pupa, before it becomes pigmented, is described. The following is the author's table of the parts of the visual apparatus: —

Œil composé . . .	Cornée à facettes. Couche des cellules cristalliniennes. Couche des rétinules ou rétine. Limitante postérieure de l'œil composé.
Couche des fibres post-rétiniennes.	
Lame ganglionnaire	Limitante antérieure de la lame ganglionnaire. Couche des cellules ganglionnaires. Couche des fibres en palissade. Limitante moyenne de la lame ganglionnaire. Couche des fibres nucléées. Limitante postérieure de la lame ganglionnaire.
Couche des fibres préganglionnaires.	
Ganglion optique .	Névrilemme. Couche des cellules en chapelets. Croissant du noyau central. Éventail du noyau central. Écorce grise du ganglion optique.

Concerning the development of the eye, we give the following conclusions. In the larva, before metamorphosis, the eye is represented by three parts, — the imaginal disk of the eye proper, the neural stem, and the optic ganglion. The disk of the eye comprises the same three layers as the other imaginal disks. Before the metamorphosis of the larva, the superficial cells of the exodermic layer become enlarged and elongated, and acquire a strong affinity for coloring-matters; they are the optogenic cells. This change begins in the centre, and spreads towards the periphery of the disk. The mesoderm of the disk of the eye, unlike the other two layers, is different from the corresponding portion of other disks, since it is composed of fine nerve-fibrillae mingled with nuclei; by teasing, it can be shown that each fibril is connected with the inner end of an exoderm cell. The nervous stem unites the disk of the eye with the optic ganglion, and is composed of the nerve-fibrils mingled with nuclei. The optic ganglion is constituted by the outer portion of the brain; its nucleus consists of white, its cortex of gray, matter; in the lateral portion of the cortex, is the complex anlage of the *lame ganglionnaire*, in which all the principal constituent parts of the definite *lame ganglionnaire* can be recognized. At the moment of metamorphosis the following phenomena occur: the provisory layer of the disk of the eye disappears, the exoderm enlarges, its borders unite with the neighboring disks, its cuticle becomes the faceted cornea, and its optogenic cells each form, by the known process, an elementary eye. The anlage of the *lame ganglionnaire* emigrates from the optic ganglion, then enlarges, and spreads out so as to intervene between the ganglion and the eye. The details of the differentiation of the *lame* are carefully described.

I cannot conclude this notice without referring to the admirable manner in which this valuable memoir is written, and the great clearness with which the facts and conclusions are presented.

CHARLES S. MINOT.

EXPERIMENTS TO DETERMINE THE GERMICIDE VALUE OF CERTAIN THERAPEUTIC AGENTS.

In the *American journal of medical sciences* for April, Dr. Sternberg gives an account of his study of this important question. The objects of the author were, —

To ascertain the exact value, as germicides, of some of the agents most frequently employed in medical and surgical practice, with a view to the destruction of pathogenic micro-organisms, hypothetical or demonstrated.

To compare this value, established by laboratory experiments, with the results of clinical experience, for the purpose of ascertaining what support, if any, the germ-theory of disease receives from modern therapeutics.

Assuming that the active agent in infective material is a living micro-organism, or 'germ,' disinfection will be accomplished by those chemical agents only, which have the power of destroying the vitality of this organism. We require to know: —

a. What is the absolute germicide power of various disinfecting agents, in order to select the best with a view to economy and efficiency;

b. Are all disease-germs destroyed by these agents in the same proportion? and, if not,

c. What agents are the most available for special kinds of infective material?

In therapeutics we should know, in addition to this: —

d. What is the minimum quantity of each of these agents which will restrict the multiplication of each specific disease-germ in a suitable culture-medium? — this with reference to medication, with a view to accomplishing a like result within the body of an infected individual.

Evidently, any thing like a complete answer to these questions is quite impossible in the present state of knowledge, and we must content ourselves with such partial or approximate answers as can be obtained by laboratory experiments upon the comparatively small number of pathogenic organisms which abound in organic liquids undergoing putrefaction.

The experiments were conducted by using small sealed flasks containing bouillon free from micro-organisms. The smallest quantity of a fluid containing such organisms introduced into one of the flasks would cause it to 'break down' within twenty-four hours, it being exposed during this time to a temperature of 100° F.

To test the germicide power of a chemical reagent, living bacteria are subjected to its action in a known proportion for a given time, and are subsequently used to inoculate sterilized bouillon in one of the flasks. Failure to multiply in this fluid, when exposed for twenty-four hours or more to a temperature of 100° F., is evidence that reproductive power — vitality — has been destroyed by the reagent used. On the other hand, failure to disinfect, i.e., to destroy the vitality of the bacterial organisms used as a test, is shown by the 'breaking-down' of the culture-fluid.

Standard solutions of the reagents to be tested are prepared with distillled water. The germs are exposed, in small glass tubes, to the action of these agents for two hours. The tubes are sterilized in the flame of an alcohol-lamp immediately before each experiment; they are open, and covered by a bell-glass during the time of exposure.

At the end of the time of exposure, a small quantity of the fluid from one of the tubes is introduced into a flask containing sterilized bouillon, and this is exposed to a temperature of 100° F. for twenty-four hours.

The micro-organisms which have been used in the experiments herein reported, to test the germicide power of the reagents named, were obtained from the following sources: —

a. A micrococcus from gonorrhoeal pus.

b. A micrococcus from pus obtained from an acute abscess (whitlow) at the moment that it was opened by a deep incision. This micrococcus is morphologically identical with the preceding.

c. A pathogenic micrococcus, having distinct morphological characters obtained from the blood of a septicaemic rabbit.

d. Bacterium termo, and other bacterial organisms (micrococci and bacilli) from 'broken-down' beef-tea which had been freely exposed to the air.

In the following table, which is arranged according to the germicide value of the agents named, all experiments are given in which the micrococcus from pus was used as a test.

Mercuric bichloride (0.005 per cent), efficient in the proportion of one part in	20,000
Potassium permanganate (0.12 per cent), efficient in the proportion of one part in	833
Iodine (0 2 per cent), efficient in the proportion of one part in	500
Creosote (0.5 per cent), efficient in the proportion of one part in	200
Sulphuric acid (0.5 per cent), efficient in the proportion of one part in	200
Carbolic acid (1 per cent), efficient in the proportion of one part in	100
Hydrochloric acid (1 per cent), efficient in the proportion of one part in	100
Zinc chloride (4 per cent), efficient in the proportion of one part in	50
Tinc. ferri chloridi (4 per cent), efficient in the proportion of one part in	25
Salicylic acid dissolved by sodium borate (4 per cent), efficient in the proportion of one part in	25
Caustic potash (10 per cent), efficient in the proportion of one part in	10
Citric acid (12 per cent), efficient in the proportion of one part in	8
Chloral hydrate (20 per cent), efficient in the proportion of one part in	5

The following-named reagents, as far as the experiments go, are not shown to have any germicide value; viz., —

	Per cent.
Fowler's solution failed in the proportion of . . .	40
Sodium hyposulphite failed in the proportion of . . .	32
Sodium sulphite, exsiccata, failed in the proportion of .	10
Ferric sulphate (saturated solution) failed in the proportion of	16
Potassium iodide failed in the proportion of . . .	8
Liq. zinci chloridi failed in the proportion of . . .	8
Boracic acid (saturated solution) failed in the proportion of	4
Zinc sulphate failed in the proportion of	20
Sodium borate (saturated solution) failed in the proportion of	4
Sodium salicylate failed in the proportion of . . .	4

Having ascertained the germicide value of certain reagents for a single micro-organism, the question arises as to whether we are justified in assuming that other organisms of the same class, and especially pathogenic bacteria, will be destroyed by the same reagents in like proportion, or, in other words, whether we can generalize from the data obtained. It is evident, that, if each of the reagents named gives identical results with several distinct species of bacteria, we shall be justified in assuming that the value obtained will be constant for other organisms, known or unknown, of the same class; whereas, if marked differences are found as to the vital resistance of different bacterial organisms to these reagents, no generalization will be possible, and the value for each distinct organism of the class can only be fixed by experiment. To solve this question, experiments have been made as follows: —

a. Upon the micrococcus of pus.

b. Upon the micrococcus of septicaemia in the rabbit.

c. Upon bacterium termo, in its active motile stage, as found in a fresh culture.

d. Upon the bacteria in broken-down beef-tea which had been freely exposed to the air, and in which all active development had ceased.

The results show, that, in general, those reagents which destroyed the vitality of the micrococcus from pus are destructive to organisms of the same class, and that their relative value as germicides is not changed when a different micro-organism is used as the test of this value. Moreover, the reagents which were found to be practically valueless as germicides in the first series of experiments — e.g., ferric sulphate, sodium sulphite, and hyposulphite, boracic acid, etc. — proved to be equally without value when the test was extended to other micro-organisms of the same class. But the reagents found to possess decided germicide power have, in some cases, a different value for different organisms: in other words, the vital resistance of different bacterial organisms to the reagents in question is not in all cases the same.

Thus, sulphuric acid failed to destroy B. termo and the micrococcus from pus in the proportion of 0.25 %; but one-fourth of this amount (0.06 %) destroyed the vitality of the septic micrococcus.

Caustic potash destroyed the septic micrococcus in the proportion of 2 %, but failed to kill the micrococcus of pus in four times this amount (8 %). The value, as a germicide, of the solution of ferric sulphate and sulphuric acid in water, which has been extensively recommended by sanitarians as a disinfectant, evidently depends upon the sulphuric acid which the solution contains. To insure the destruction of all bacterial organisms and of the reproductive spores of those species which multiply by spores as well as by transverse fission, such a solution should be used in sufficient quantity to subject the material to be disinfected to the action of the acid in the proportion of at least five per cent for a period of two hours.

The quantity of carbolic acid used to accomplish the same result should not be less than five per cent, for it is necessary to keep on the safe side; and we do not know, at present, whether all of the pathogenic bacteria, hypothetical or demonstrated, form spores or otherwise. In the case of the anthrax bacillus and of Koch's bacillus of tuberculosis, this has been proved to be true; and we have ample experimental evidence to show that these reproductive bodies possess very great resistance to heat and to those chemical reagents which destroy bacterial organisms in their ordinary condition of rapid growth and multiplication by fission.

Evidently, therapeutic value — assuming the correctness of the germ-theory — cannot be gauged by germicide power alone, for it is possible that a reagent which possesses this power in but slight degree, or not at all, may nevertheless be capable of restricting the development of pathogenic organisms, and thus limiting their power for mischief.

The following table shows the percentage required to destroy vitality, and also that required to prevent the development of the micrococcus of pus: —

Reagent.	Percentage required to destroy vitality.	Percentage capable of preventing development.
Mercuric bichloride . . .	0.005	0.003
Iodine	0.2	0.025
Sulphuric acid	0.25	0.12
Carbolic acid	0.8	0.2
Salicylic acid and sodium biborate	2	0.5
Alcohol	40	10
Ferric sulphate	Failed in saturated solution.	0.5
Boracic acid		0.5
Sodium biborate		0.5

An inspection of the table shows that the potent germicides in our list restrict multiplication in quantities considerably less than are required to destroy vitality. In the case of iodine the difference is eightfold; in that of carbolic acid, fourfold; in that of sulphuric acid, twofold, etc.

We also see that the agents at the bottom of the list, — ferric sulphate, boracic acid, and sodium biborate, — in the proportion of five-tenths per cent, prevent the multiplication of bacterial organisms, and are consequently antiseptic agents of value, although in saturated solution they fail to kill these organisms.

In the case of ferric sulphate, and also of zinc sulphate and zinc chloride, this power to prevent the development of micro-organisms seems to be due to precipitation of the organic material in the nutritive medium rather than to any direct action upon the living organisms, which, as we have seen, are not killed by a far greater quantity of the reagent.

The conclusions at which Dr. Sternberg arrives, are, that the vital resistance of bacterial organisms to chemical reagents differs, within certain limits, for different species. And certain species show special susceptibility to the germicide action of particular reagents; e.g., the septic micrococcus to alcohol, and B. termo to boracic acid.

There is, therefore, reason for supposing that different pathogenic organisms may differ in like manner, as to susceptibility to the action of various reagents administered medicinally with a view to their destruction. Nevertheless, the comparative germicide value of the reagents tested is the same for the several test-organisms, and, allowing certain limits for specific peculiarities, it is safe to generalize from the experimental data obtained in the practical use of these reagents as disinfectants. But it must be remembered that the resisting power of reproductive spores is far greater than that of bacterial organisms in active growth (multiplication by fission), and the data obtained for the latter cannot be extended to include the former.

The antiseptic value of the reagents tested depends upon their power to prevent the multiplication of putrefactive bacteria; and this is not necessarily connected with germicide potency, for some reagents which fail to kill these micro-organisms are, nevertheless, valuable antiseptics, e.g., ferric sulphate and boracic acid.

Clinical experience has demonstrated the value of all the potent germicide reagents tested in one or more of the diseases which there is the most reason to believe are due to the presence of pathogenic micro-organisms in the *primae viae*, in the blood, or in the tissues; e.g., intermittent-fever, typhoid-fever, dysentery, erysipelas, syphilis, etc. The 'germ-theory' as to the causation of these diseases receives, therefore, very strong support from modern therapeutics; but the experiments do not justify the belief that any one of the reagents tested can be administered as a specific in germ-diseases generally. This also accords with the results of clinical experience, and makes it possible to believe that the specific, self-limited diseases are also 'germ' diseases.

LETTERS TO THE EDITOR.

The practical value of soil-analysis.

In *Bulletin* lvi. of the New York agricultural experiment-station, Dr. Sturtevant gives the reasons for which the station declines to make soil-analyses 'for the purposes of the individual farmer;' summarizing them in the statement that such ayalyses "can offer no solution of the problem of what fertilizer, and how much, to apply."

Were this statement made in a somewhat less general and absolute manner, I should have no fault to find with it; for in the case of the long-cultivated fields of the state of New York, which have been subject to indefinitely varied culture-conditiohs and the use of fertilizers, the cases in which chemical analysis alone would point with any degree of certainty to the true cause of failure to produce profitable crops would be exceptional; and the station would be likely to be overrun with requests for an indefinite amount of comparatively useless routine work.

But when Dr. Sturtevant broadly adds his denial "that analyses of soils can give us definite information concerning their productiveness," he seems to go beyond the limits justified by the record, and beyond what the context following would appear to show he intended to say. If the clause above quoted were to read, instead, "while denying that analyses of *cultivated* soils can give us definite information regarding their *present* productiveness," I should agree with him so far as the great majority of cases is concerned, — so much so, that it is only exceptionally that I undertake the analysis of a cultivated soil, but usually go back to its virgin ancestor for information as to its general character; and from this, and the usually simple history of its cultivation, pretty definite inferences as to the prominent wants even of a cultivated soil can in very many cases be deduced, as is proved by the practical results. Dr. Sturtevant's own statement as to the frequency and consequent practical importance of such inquiries would seem to justify the taking of some pains to approach its solution, before proclaiming an absolute *non possumus*.

As for virgin soils, which over wide areas have been subject to uniform or uniformly variable conditions, it is *a priori* reasonably presumable, and I think experience confirms the inference, that, other things being equal, the amount of available plant-food, and therefore the durability of a given soil under the usual culture, without replacement, is sensibly proportional to the plant-food percentages shown by the usual method of analysis. Whether or not other things are really equal can only be ascertained by intelligent examination in the field as well as in the laboratory; and soil-specimens taken by non-experts rarely fulfil this condition.

While, therefore, believing that Dr. Sturtevant's action in this matter is well advised under the circumstances, I nevertheless believe that my contrary practice in regions but sparsely or recently settled is at least equally well justified, and that the importance of affording the settler at least an approximate insight into the present and ultimate durability of his soil, and its general character and adaptations, is so great as to justify a considerable public expenditure, upon a well-considered plan carefully carried out by competent persons both in the field and in the laboratory, even with our present limited knowledge of the chemistry of soils — which, I cannot but remark, is not likely to be increased very rapidly if the composition of soils serving for culture-experiments continues to be ignored, as has so largely been the case heretofore. The prime importance of the presence of a certain minimum percentage of lime, for example, is manifestly so great, that no experimenter can afford to be ignorant of the presence or absence of a proper supply of that substance in his soil; and the cases in which analysis shows the extreme scarcity or extreme abundance of lime, phosphates, or potash, in virgin soils and subsoils, are far more frequent than the contemners of soil-analysis suppose. In the former case the practical value of the indication is too obvious to be overlooked, and is amply attested by the results following the application, e.g., of phosphate fertilizers in such cases. We might not be able to detect the addition thus made to the phosphates of the soil by the most careful analysis; but the fact that the soil is naturally poor in phosphates will remain a fruitful truth forever after.

I trust that the record which will be shown in the census report of cotton production, now in press, will form a convincing illustration of the legitimate uses of soil-analysis. E. W. Hilgard.

University of California, Sept. 1, 1883.

Do humming-birds fly backwards?

The Duke of Argyll, in his Reign of law (p. 145), lays it down in italics, that '*no bird can ever fly backwards*.' He mentions the humming-bird as appearing to do so, but maintains, that, in reality, the bird falls, rather than flies, when, for instance, he comes out of a tubular flower. But this morning, while watching the motions of a humming-bird (Trochilus colubris), it occurred to me to test this *dictum* of the duke; and, unless my eyes were altogether at fault, the bird did actually fly backwards. He was probing one after another the blossoms of a Petunia-bed, and more than once, when the flower happened to be low down, he plainly rose, rather than fell, as he backed out of and away from it. I stood within a yard or two of him, and do not believe that I was deceived.

It may not be amiss to add that the Duke of Argyll's objections seem to be purely theoretical, since the 'Reign of law' was published in 1866, and it was not till 1879 that the author came to America and saw his first living humming-bird.

Bradford Torrey.

Boston, Sept. 14, 1883.

Wright's ice-dam at Cincinnati.

I notice on p. 320 of Science, vol. ii. no. 31, an inaccurate report of what I said at the Minneapolis meeting, which does injustice both to Mr. Wright and to myself, and which I would beg to have corrected.

The reporter makes me speak slightingly of Mr. Wright's discovery of the ice-dam at Cincinnati, as not sufficing to explain our Pennsylvania terraces. On the contrary, I expressed my admiration for the discovery as furnishing precisely the explanation we need for the *local-drift* terraces of the Monongahela, and the *rolled-northern-drift* terraces of the lower Alleghany, Beaver, and upper Ohio rivers.

The reporter probably mixed this up with what I said afterwards respecting the *rolled-drift* terraces of eastern Pennsylvania, which only reach a height of 800′ A. T., in Northumberland county, and require some explanation, perhaps, quite unconnected with that which Mr. Wright certainly furnishes in a most satisfactory manner for the 800′ to 1,100′ A. T. terraces of the Ohio River basin. J. P. Lesley.

Second geological survey of Pennsylvania,
Philadelphia, Sept. 15, 1883.

Erratic pebbles in the Licking valley.

While engaged in tracing the outcrop of 'Clinton ore' in eastern Kentucky, in the fall of 1882, I became interested in the pebbles, which in certain localities, and up to a certain height, were very abundant in the surface-soil.

Most abundant were rounded quartz pebbles, probably from the millstone grit. Somewhat less abundant were fragments of chert, showing little or no wear derived from the sub-carboniferous limestone. Still less abundant, though by no means rare, were some from the carboniferous, often containing characteristic fossils. They were confined, so far as I could determine, to the valley of the Licking and its larger tributaries. Vertically, they range from the river-bottoms to the top of the table, formed by the upper Silurian rocks, which borders on the Devonian escarpment; so that these tables are quite uniformly covered with the material.

The distribution of the material is such as could only have been made while the valley was temporarily occupied by a lake. I was therefore led, though with some hesitation, to suppose that the glacier must have crossed the Ohio at Cincinnati, damming the river. I was not at the time aware of the labors of Mr. Wright in tracing the glacier across the Ohio.

Having now the certainty that there was a dam at the required point, I think I may have no hesitation in saying, that, during a portion of the glacial period, the valley of the Licking was occupied by a lake which overflowed laterally, and whose bottom became littered with materials brought from the mountains of eastern Kentucky by floating ice. They are most abundant where the ice may be supposed to have had freest access.

Terraces which might have been expected are wanting in the region in which my observations were made. Possibly they may be found in other parts of the valley, especially above; their absence in the region in question being due to the fact that only small portions of the region would have reached above the lake-level, which, by their disintegration, could furnish the material for terraces.

The overflow was probably to southward, but I could not search for it. Could it be traced, the amount of erosion might give some data for an estimate of time. G. H. Squier.

Trempealeau, Wis., Sept. 14, 1883.

Depth of ice during the glacial age.

In the issue of Science for Sept. 7, reporting my paper at Minneapolis, I am made to say, that, during the glacial period, the ice was indeed "600 feet over New England, and very likely of equal depth over the area to the west." I said 6,000 feet over New England. The evidences of glaciation are distinct upon the Green Mountains to a height of nearly 5,000 feet. The lower summits of the White Mountains, like Carrigain (which is 4,300 feet above the sea), are covered with transported bowlders; and there can be little question that some found by Professor Charles Hitchcock, within a few hundred feet of the summit of Mount Washington, were transported thither by glacial agency. Such is the evidence for New England.

For the region north of Pennsylvania and the Ohio River, direct evidence of such a great depth of ice is naturally wanting; but, according to Ramsay, glacial scratches are numerous upon the summit of Catskill Mountains in New York, at an elevation of 2,850 feet above the sea. In southern Ohio there are numerous places where the ice, within a mile or two of its farthest extension, surmounted elevations which are about 500 feet higher than the plains to the north of them. I see no reason why it should not have been as deep over the bed of Lake Erie as over the region to the north of the White Mountains, though there are there no glaciometers like Mount Washington to measure the height of the frozen mass.

G. Frederick Wright.

Oberlin, O., Sept. 13, 1883.

The 'stony girdle' of the earth.

In your issue of Sept. 7, just received, you are kind enough to insert a synopsis of the two abstracts of papers which I sent to the Minneapolis meeting. Allow me the space necessary to make a correction and some brief explanations. We are required to furnish these 'abstracts' to suit a printed form of small note size, which is apt to lead to small chirography: hence I suppose the mistake in reading and printing the title.

It should read, 'stony girdle,' and was in inverted commas to show that the name did not originate with me. My special object was to call attention to its being, in a great measure, the same belt which forms the prime-vertical when the pole of the land-centre at Mount Rosa is brought to the zenith. The unfavorable comments to which you allude have force as a general rule; namely, that closet geology is not comparable to observations in the field. Yet *all generalizations* may be called closet geology, as being the result of a large number of facts collected in the field, and compared subsequently. As it would, however, be presumptuous in any one to offer generalizations who had not had somewhat extended opportunities for observation, I may be permitted to mention, as some justification, those I have enjoyed. In North America my observations, partly in special work, partly during travel, have ranged from Rainy Lake, north of Lake Superior, to Saltillo, in Mexico, and from the Atlantic states to the head waters of the Gila, in Arizona. In the eastern continent, I travelled from the north of Scotland to Cairo in Egypt, ascending Etna, and spending the vacations of three summers, during college-life, in Switzerland among its mountains, ranging subsequently from western France to the Crimea. In 1824 I saw the 'Perte du Rhône,' where that river disappeared for miles, and then re-appeared,—a phenomenon no longer to be seen, as the superincumbent rocks, some years later, caved in, and converted the subterranean into a subaerial bed for that fine stream.

In 1829 I visited the scene of the catastrophe at New Madrid; and while granting a local subsidence for the immediate cause, as claimed in the able paper by Dr. Macfarlane, of which you give an abstract, I am compelled to believe that the remote cause was due to a seismic movement, felt, as Mallet states, at least two hundred miles from New Madrid, and, indeed, affecting large and more distant areas about that time, as mentioned in Key to geology, p. 77.

These opportunities, in connection with the specimens and notes of reference brought home, permit a review of general geology, which I thought might enable me to present to the student of geography and geology some broad principles and truths into which the details subsequently obtained by him might be appropriately fitted: hence the paper read at the Boston meeting, showing that the eastern trend of each continent was distant one-fifth of the circumference of the globe from its adjoining continental trend; also that each continent presented a central focus, from which a circle with radius of 36° would embrace the land proper, — sometimes excluding a peninsula, such as Hindostan, sometimes including adjacent islands, as those of Madeira, Canary, and Cape Verd, as belonging to the main continent, Africa. The Montreal papers were designed to show the important seismic fissurings radiating from the pole of the land-centre; also the relation between solar and terrestrial dynamics, where seismic phenomena are transmitted along great circles coinciding with the sun's apparent path, or along belts of the earth's crust which are secondaries to the ecliptic.

The occurrences of the last few weeks seem to corroborate the generalization offered, inasmuch as Ischia is on the 30° fissure from Rosa, at no great distance; while Java and the Straits of Sunda, as well as Guayaquil, more recently disturbed, are on or close to the prime-vertical.

If these generalizations belong rather in the category of instruction for the student than of contributions to science, perhaps my twenty-five years of natural-science teaching may present some excuse. Certainly, my great aim and desire are to arrive at important scientific truths, especially general laws in the dynamics of our globe. RICHARD OWEN.

Mr. Morse's papers at Minneapolis.

A number of errors have been made in the report of my papers which were read at the Minneapolis meeting.

In the paper on an apparatus for warming and ventilating apartments, the statement that the temperature of a hall was raised 40° above the outside temperature is incorrect. I said that the air, as it entered the room *from the heater*, had been raised 40° above the outside air.

In the paper on the methods of arrow-release, I spoke of the English method, which was probably that of the Saxon, and said that American archers followed the English. The Japanese never use thumb-rings, to my knowledge. The Koreans, Chinese, Manchu Tartars, and Persians use the thumb-ring.

A more serious mistake occurs in the report of my paper on the indoor games of the Japanese. I said very distinctly, that, in the game of chess, pieces captured could be used by the capturer against his opponent. In comparing the Japanese games with ours, I made no allusion to seven-up or whist. With every one I regard whist as next to chess in character as a highly intellectual game.

You will confer a great favor by publishing these corrections. EDW. S. MORSE.

Salem, Mass., Sept. 16, 1883.

Evidences of glacial man.

In SCIENCE, no. 32, p. 384, the statement is made, respecting Miss Babbitt's Minnesota finds, that "thus far, at best, the glacial workman is known only by his chips." What better evidence, I would inquire, is needed, if those chips are of artificial origin?

Is not this sufficient? Are not shavings and sawdust as good evidence of men working in wood, today, as are the planes and saws they use? From the very nature of the case, it is unreasonable to find as abundant and easily recognized evidence of man in drift-deposits as upon the surface-soils; yet this is what some of those present at the Minneapolis meeting of the American association for the advancement of science seemed to require.

In the case of the 'paleolithic' implements of the Delaware River valley, other evidence than the chipped stones has been found. The human tooth, lately described in detail in the Proceedings of the Boston society of natural history, is, of itself, evidence of man's presence at the time the gravels, in which it occurred, were laid down. Other human remains have also been found.

A word, too, with reference to the implements. These are nearly all as unmistakably artificial as the most finished arrow-head. Objects of identical character are found among the relics of the recent Indians, and are not questioned. Why, then, should a similar class of objects, found in gravel-deposits that antedate the superincumbent surface-soils, be questioned?

There is no doubt overshadowing the existence of man in the Delaware valley as long ago as the close of the glacial period: his presence, then, is not merely 'a theory advanced by Dr. Abbott,' as you suggest, but a fact susceptible of actual demonstration.

Professor Mason, in his address (in the same issue), asks, "What is the real import of such discoveries as those of Dr. Abbott and Professor Whitney in establishing the great antiquity and early rudeness of the American savage?" Speaking for myself, I would suggest that his question contains its answer. My discoveries have established the glacial age of man on the Atlantic seaboard of America, and at that time his culture was that stage known as 'paleolithic.'

Chas. C. Abbott, M.D.

Trenton, N.J., Sept. 18, 1883.

THE ALPHABET.

The alphabet, an account of the origin and development of letters. By Isaac Taylor, M.A., LL.D. 2 vols. London, *Kegan Paul, Trench, & Co.*, 1883. 16+358; 398 p. 8°.

Mr. Taylor has produced an admirable work on the interesting subject of alphabetic writing. It abounds in wealth of collected material, down to the very latest discoveries (some of them of the utmost importance). By lavish and well-chosen illustration it puts this material before the apprehension of the reader or student with the most desirable clearness; and its digest and criticism of former opinions is made with impartiality and independence of judgment, while the author adds abundantly of new views, and arguments to support them. No other existing work of a like character can bear any comparison with it; and it deserves to have, as it doubtless will attain, a wide circulation and popularity.

In the main, these volumes are filled with the history of our own alphabet and its relatives, or of the ancient Phoenician with its descendants and probable ancestor, since other systems of alphabetic writing are comparatively insignificant in number and in importance. The Chinese characters are not alphabetic, although one or two derivatives from them (as the Japanese *kata-kana*) have that character. The cuneiform mode of writing ended its career in an alphabetic system, the Persian; but all the peoples using cuneiform passed over, more than two thousand years ago, to the side of the Phoenician. There have been other hieroglyphic schemes, in the old world and the new, that made advances, no one can say just how far, toward alphabetism; but they are long since perished without descendants. All these, together with such theoretic basis as he chooses to lay for the science, Mr. Taylor despatches in the first chapter (seventy pages) of his first volume; the rest is devoted to our alphabet: the various kindred Semitic forms of it being treated in the former volume, and the Indo-European forms, with the few outside stragglers, in the latter, under the divisions of Greek, derivatives of Greek (Italian, Coptic, Slavonic, Albanian, Runic, Ogham), Iranian, and Indian. The method is not to be condemned, although we might have desired a more ample theoretical introduction. The fundamental principle of alphabetic history is distinct, and briefly statable: all writing begins necessarily with the depiction of scenes and objects, or is purely pictorial; it everywhere tends to pass over into a depiction of the names of objects; and, when it has fully reached that condition, it has become alphabetic. There can be no such thing as an alphabet not starting from a pictorial stage, any more than a spoken language without an initial imitative root-stage. But while in language we can only get back by inference to such a state of things, because the beginnings of language are so remote from us, in writing we find the pictorial stage abundantly represented.

Whether that stage is discoverable in the actual history of our own alphabet, is a question not yet absolutely settled. Every step by which our familiar letters go back to the primitive Semitic alphabet, usually called by us Phoenician, is traced out with the utmost distinctness. The Phoenician is purely, though defectively, alphabetic. It must, then, have come from a pictorial original. Three such systems of writing are found in its neighborhood, — Egyptian, cuneiform (the perhaps sufficient, though rather scanty, evidences of whose hieroglyphic origin are given by our author), and the recently discovered and still obscure Hittite. Did it come demonstrably from one of these, or has it an ancestor now lost to us? As is well known, De Rougé's work, published less than ten years ago, attempted to show its derivation from Egyptian, from hieratic characters, of known hieroglyphic originals; and his view is widely, though by no means universally, accepted. Mr. Taylor is a firm believer in it, and sets it forth with much clearness and force. We find ourselves unable fully to share his conviction. De Rougé endeavored to prove more than was reasonable, and found it so easy to prove all he undertook, that his very success casts a shade of unreality over the whole comparison. We may allow that his identifications are both possible, and, as a whole, plausible quite beyond any others yet made. Yet whereas the derivation of the Greek or of the Arabic alphabet, for example, is past all doubt, and he would rightly be passed by as a time-waster who should attempt to re-open the question, no reproach can attach to the scholar who, unconvinced by De Rougé, should try to find another and better solution of the problem, as some are actually doing. Mr. Taylor overstates the desirableness of acquiescing in the best solution hitherto discovered; the right to doubt an inference not yet made certain is a precious and indefeasible one. It would be highly gratifying to regard the derivation of Phoenician from Egyptian as not less certain than that of English from Phoenician, since then we should have followed up the history to its very beginning; for the character of the Egyptian as a wholly original mode of writing, carrying on its face the evidence of its steps of development from the initial stage, is beyond dispute. Considering that Mr. Taylor holds the hieroglyphics to be the antecedent phase of Phoenician letters, we wish that he had made his exposition of the system somewhat fuller, and especially that he had told in more detail how he regards the alphabetic value of certain of the hieroglyphs as having been arrived at: the point is by no means so clear as were to be wished.

It would take far too much space to go through the book and notice all the points of special interest in it; but attention may be called to a few. Mr. Taylor has a new and well-supported theory as to the Mediterranean alphabet from which the Germanic runes were taken: he holds it to have been the Greek of the Euxine colonies and Thrace, transmitted in peaceful intercourse along the commercial route of the Dnieper, some centuries before the Christian era. His discussion of the Ogham cryptograms is less satisfactory. The Glagolitic (an early Slavonic) alphabet receives from him a suggested explanation which has met with general favor. The earliest Semitic monuments — the sarcophagus of Sidon, the Moabite stele, the recently discovered Siloam inscription — are fully treated, the last being given in facsimile. Some of the most original parts of the author's work lie in the discussion of the South Semitic alphabets and their derivatives. It is to them that he traces the immense group of the alphabets of India by a theory which wears a more plausible and acceptable aspect than any other yet suggested; it must, of course, stand the test of time, and of examination by other experts, before it can be admitted as final. Even in so old and well-worked departments as the varieties of Semitic and Greek writing and their mutual relations, Mr. Taylor brings to light much that is new and interesting, laying under contribution the most recent finds, and combining them with independence of judgment and sound sense. There is nowhere any effort at brilliancy or show of profundity: sober, earnest work is the keynote of the treatise, which in this respect compares favorably with certain other recent publications, French and German, on the same subject.

In conclusion, we may notice adversely a point or two. The now accepted explanation of Pehlevi, as needing to be read out of its Semitic signs into Iranian words, should not be credited to 'the sagacity of Professor Haug' (ii. 239). That explanation was distinctly offered by the veteran Westergaard, in the preface to his Zendavesta, in 1854, when Haug was fresh from the university; and in the latter's earliest article 'on the Pehlevi language and the Bundepesh,' published in the same year, there is to be found no hint of the doctrine.

It is hardly correct to ascribe the success of right methods in paleography in any measure to Darwinism (ii. 363). That every successive phase of a historical institution is the outgrowth of a preceding phase, and differs little from it, is a truth long coming to clear recognition and fruitful application in every department of historic research, prior to and in complete independence of any doctrine of evolution in the natural world. Only error and confusion have come of the attempts made to connect Darwinism and philologic science. On the other hand, Mr. Taylor appears to make a too mechanical application of the doctrine of historical development in denying altogether the possibility of an element of free invention in alphabetic growth. Man is capable of devising something a little different from, or like and additional to, what he has already won and knows how to use. One who has a language can invent another, regarded by him as an improvement on the former: the thing has happened repeatedly, and is no violation of the law of gradual and unconscious growth of human speech. So, notwithstanding the law of alphabetic development, a man who practises various modes of writing can devise a new one, for cryptographic or tachygraphic purposes, or other. And a community that is receiving and adapting an alphabetic system from another community may, in like manner, well enough add a sign or two of its own device: hence the question whether our X is an out-and-out invention of the Greeks, or a differentiated K, is one of paleographic probabilities, not to be settled in favor of the latter alternative by denying the possibility of the former; and so in other like cases.

The number of interesting questions to which this work furnishes a trustworthy reply is surprising; and, while sparing of notes, it yet gives references sufficient to set upon the right track any one desirous of investigating more fully the matters with which it deals.

THE FOSSIL FLORA OF GREENLAND.

Die fossile flora der polarländer. Von Dr. OSWALD HEER. Vol. vii. Zürich, *Wurster*, 1883. 275 p., 62 pl. 4°.

THIS volume contains, 1°, the flora of the upper cretaceous schists of Patoot; 2°, the tertiary flora of Greenland; 3°, a short memoir on insects' remains found in connection with the plants (cf. SCIENCE, i. 1095); 4°, general remarks on the affinities of the plants in relation to their geological age and the climatic circumstances indicated by their characters; 5°, a memoir by Steenstrup on the geology of the localities where remains of plants and coal-deposits have been found; 6°, the marine fauna, with descriptions of the species of invertebrate animals found especially in connection with the plants of Patoot.

This last locality represents the upper member of the cretaceous of Greenland; the lowest being that of Kome, the middle that of Atane. The flora of Patoot has a predominance of conifers and ferns, no Cycadeae, and few monocotyledons, about one-half of the plants being dicotyledons. The table of distribution, which represents the whole cretaceous flora of Greenland, enumerates 335 species, — 88 for Kome, 177 for Atane, and 118 for Patoot. From the characters of the plants, the schists of Kome are referable to the Neocomian. Atane, whose flora is related to that of the Dakota group of Kansas, represents the Cenomanian, while Patoot is apparently Senonian. Most of its species are related to those of Atane, only a few being identified with eocene species from Sezanne and with some miocene types. The plants of the tertiaries of Greenland have been procured from twenty different localities. Their description is also followed by a table of distribution. Of the 282 species enumerated, 33 are known from the tertiary of North America, 10 of them from the Laramie group. The greater number are identified with species found in the lower miocene of Europe, the Aquitanian group, whose flora is widely represented in most of the states, from Hungary to England and France, and from Italy to North Germany. This tertiary flora of Greenland has been predominant, and has preserved its characters for many thousands of years; for the lower strata, where its remains have been found, are separated from the upper, which have the same kinds of plants, by thousands of feet of basaltic masses the deposits of which have been continuous for long periods of time.

In the general remarks considering the climatic conditions which have governed the vegetation as indicated by the characters of the flora, Heer says, that in 1868, from data derived from the determination of 105 species of plants, he had estimated the mean temperature at 9° C.; but now the tertiary flora of Greenland, known by a larger number of plants of various types, — among them a palm, species of Laurus, Magnolia, Diospyros, Sapindus, Zizyphus, etc., whose analogues are now found in Virginia, the Carolinas, etc., — indicates by its constituents a mean temperature of 10° to 11°.

The few mollusks and star-fishes, mostly found at Patoot, have been determined by the French paleontologist, de Loriol. He considers them to be related to some of those described by Meek from the Fox Hill group. Steenstrup's memoir on the geology of the localities where the plants have been found is precise and detailed. It is illustrated by a number of good sections.

The work is accompanied by a map of the western coast of Greenland between 69° 15′ and 72° 30′ north latitude.

THE CHESAPEAKE OYSTER-BEDS.

Report on the oyster-beds of the James River, Virginia (etc.). Coast-survey report for 1881. Appendix, no. 11. By FRANCIS WINSLOW, U.S.N. Washington, *Government*, 1882. 87 p., 22 pl., 3 maps. 4°.

AMONG the various investigations of the U.S. coast survey since its organization, the bearing of which is not confined to their geodetic, topographic, or hydrographic relations, the present publication is conspicuous.

By direction of the late superintendent Patterson in 1878, an investigation of the oyster-reefs or natural beds of the Chesapeake and vicinity was entered upon by Lieut. Winslow with the coast-survey schooner Palinurus. The intention was to determine the limits of the beds, their hydrographic features, the nature of the natural and artificial changes which they undergo, and the present distribution of living oysters upon them. It was proposed to thoroughly investigate a limited area, subsequent extension of the work to all the Chesapeake beds to be left for future decision. Under the term 'Chesapeake' we include here not only the beds in the waters of the bay specifically so called, but those in the extensions of salt water from the bay into the various inlets, arms, rivers, etc., adjacent to and continuous with it.

Originally the oyster beds or 'rocks,' as they are not inappropriately termed by the fishermen, were patches of suitable ground upon which these bivalves had lived for ages, and, dying, left their shells to be overgrown by successive generations. Matted together by this living cement, the successive layers of dead shells and associated *débris* gradually rose toward the surface, covered with distorted, misshapen bivalves in masses like those of the Floridian 'coon oysters.' These beds were separated pretty sharply from the adjacent muddy bottoms, a differentiation which the vertical increase tended to intensify. Horizontal increase doubtless took place, but very slowly. From an economical stand-point the oysters upon these beds were inferior on account of their inconvenient shape and excessive crowding. Among the various conflicting statements drawn out by investigations into the oyster-industry, one fact seems to be generally admitted by fishermen and by experts; namely, that a moderate amount of dredging over the original 'oyster-rocks' was beneficial. This dredging extended the area of the beds, 1°, by dragging the dead shells and 'cultch' over upon adjacent muddy bottoms, and placing it where new spat could settle and grow; and, 2°, by distributing the living oysters more sparsely over the ground, so that they had a chance to grow into regular and even shape and relatively larger size. It is recognized by dealers, — even when the dredging has been carried on, as at present is the case in the Chesapeake, to a disastrous extent, — that the few remaining oysters which are obtained are of larger size and finer flavor than common.

Since the trade in oysters began, the beds have undergone great changes in area and productiveness, until, at present, in two years, on certain beds, the product has diminished in the ratio of six to one, the market-price has nearly doubled, while the demand is constantly increasing. If it were not for supplies received from other sources, the oyster-eaters of cities about the Chesapeake would have to pay nearly European prices for their favorite shell-fish.

It is true that there are numerous laws on the statute-books of Maryland and Virginia; that police steam-launches and men have been enlisted and a sort of war enacted, in time of peace, by state authorities, — all ostensibly in protection of the oyster-beds. Actually the laws are a dead letter; dredging is boldly carried on in close time before the eyes of the 'oyster police,' without the offenders being molested; and the only occasion for active measures arises when a Virginia dredger trespasses in Maryland waters, or *vice versa*. Gore is then apparently in demand, but, in spite of vehement protestations, turns out almost as scarce as oysters.

It was upon this state of things that Lieut. Winslow entered, when he undertook this work without previous experience, or any knowledge of the biological questions involved, except such as might be gleaned from the valuable little work of Moebius on the North Sea fisheries of Europe. Many of the observations which he was directed to take, are, in the present state of our knowledge, productive of no definite result, though eventually they may prove very useful. Thus, observations of the specific gravity and temperature of the water at the bottom and surface, when the total depth was only a few feet, may be said to be almost absolutely fruitless. It is well known that our common oyster flourishes in water which varies at different seasons from the freezing-point to 80° F., and that similar differences of specific gravity must occur between the extremes of its geographical range. Consequently the differences, in summer, of fractions of degrees of temperature in the water over oyster-beds, are of no consequence whatever. What these changes of temperature may signify, when taken in connection with the act of spawning or the development of the embryo, is quite another question, purely biological, and which can be properly treated only by a biological expert of high rank and long experience.

The result of these superfluous observations and detailed description of each individual bed, even condensed as they are, as far as possible, by the author, is to overload the text with details of no interest, and thus to obscure to the reader the value of the investigation, the really interesting facts, and the merits of the investigator, which are neither few nor small. They will amply repay any one who has patience to wade through the mass of details, and pick out those of present value, of which there are many. Space forbids any attempt to summarize them. A large area of the beds was delineated, and the approximate number of marketable oysters upon them determined. Profiles of the beds were obtained in numerous instances, and the character of the subsoil, or bottom under the beds, determined as were the conditions of sedimentation. Nearly all the beds examined are described in detail. Valuable biological data were obtained through the efforts of Dr. W. K. Brooks and Mr. H. J. Rice, most of which have been already made public in other ways. Much information on the general topic was obtained by questioning the fishermen, whose replies, though biassed by self-interest, may be set off against one another, and a residuum of useful facts obtained.

FIG. 1.—LOWER SIDE OF TILE EXPOSED JULY 9–AUG. 2. (TWO-THIRDS NATURAL SIZE.)

To our judgment, apart from the survey and delimitation of many oyster-beds, the most important results of this investigation are, 1°, the determination of the approximate quantity of oysters to the square yard over a great portion of the beds; and, 2°, the data in regard to the rapidity of growth of the young mollusks as indicated by the tile-collectors, and the proportion of mortality among them from causes not yet fully explained. The determination of the small mollusk Astyris, as an enemy of the infant oyster, though not conclusive, is of interest, and, if finally confirmed, important.

The determination of the number of oysters, though as a matter of course approximate only, is important as giving a point of comparison by which future decrease may be measured by repeating the investigation in similar fashion.

There is no doubt that in a comparatively limited time the majority of the Chesapeake beds will be practically destroyed, so far as producing oysters for a market is concerned. Some forty thousand people will have to seek employment in a different field. Probably, under the circumstances, this is the best thing that could happen; for it is doubtful if any less drastic medicine would have the slightest effect on the population residing in the vicinity of the oyster-beds, who, in the face of all the facts, have persisted in setting themselves like flint against any modification or check on their career of destruction. The present observations on the growth and surviving percentage of young oysters on the tile-collectors would have been much fuller and more valuable, had not the oystermen cut the buoys adrift, stolen the thermometers and lines, and destroyed such collectors as they could reach unseen, with the stupid notion that some reservation of beds, or limitation of fishing, was to result from the investigation. Twenty-four bundles of tiles were set and buoyed between July 1 and 14, and by Aug. 1 all but one were

FIG. 2.—LOWER SIDE OF TILE EXPOSED JULY 9–AUG. 23. (TWO-THIRDS NATURAL SIZE.)

removed or destroyed. Fig. 1 represents a portion of one of these tiles, which was placed in position July 9. On July 19, when first examined, there were a few oysters upon it, but so small that a microscope was necessary to reçognize them. On Aug. 2 it was again examined, and the tile of which a portion is figured was removed from the bundle. There were then from 26 to 348 young oysters on a tile; the total number upon the whole bundle was 1,506.

The third examination was made Aug. 23, when it was found the oysters had increased very much in size and numbers. On the tiles remaining, there were 1,334 oysters. A tile of which a portion is represented in fig. 2 was then removed. On Oct. 10 the bundle was again examined. The oysters had decreased fifty-five per cent in numbers; but two-thirds of them were now over three-quarters of an inch, and two specimens over two inches long, though the shells were still extremely delicate. Part of one of these tiles is represented by fig. 3.

FIG. 3.—UPPER SIDE OF TILE EXPOSED JULY 9–OCT. 10. (TWO-THIRDS NATURAL SIZE.)

It was thus determined, that in 1879 the attachment of the young oysters began about the middle of July, and continued about a month, as after Aug. 20 there were no signs of fresh attachments; that fully fifty per cent died from natural causes within six weeks, no traces of predacious mollusks being noticed on the dead shells, though the evidence on this point is imperfect; that, the attachments being far more profuse on the concave under side of the tiles, the spat just previously must be on or near the bottom, and must rise to attach themselves; lastly, that the rate of growth is much more rapid than had previously been supposed, and may reach two inches in length in three months. Numerous other points of interest may be gleaned from the report, for which we have not space. Enough has been said, however, to show the value of Lieut. Winslow's work, the intelligence and assiduity with which it was carried on, and the wide field which awaits further investigation.

THE PEBBLES OF SCHLESWIG-HOLSTEIN.

Die sedimentär-geschiebe des provinz Schleswig-Holstein. Von Dr. C. GOTTSCHE. Als manuscript gedruckt. Yokohama, *Lévy & Salabelle*, 1883. 6+66 p., 2 maps. 8°.

THIS treatise by Dr. Gottsche, who is at present in Yedo, was an accepted thesis for admission to the position of private teacher at the Kiel university in 1880, printed privately in German at Yokohama in 1883, and seems to be a very painstaking and pretty thorough description of the pebbles, whether of rocks, minerals, or fossils (seventy-six kinds in all), found in four quaternary sedimentary beds at Kiel, with especial reference to the identification of their source, and is accompanied by two maps, — one showing with straight lines thirty directions in which such pebbles of the lowest bed appear to have been transported, and the other giving with similar lines the dissemination of three particular kinds of rock in the same Baltic region. Many of the lines are only a couple of hundred miles long, but some are six hundred or more. The author himself points out that the pebbles have not by any means necessarily been carried along those straight lines; and the place of origin may not necessarily have been exactly at the points where identical rocks are only found at present. Nevertheless the lines show that the transfer has in general been from the north-east, north, or north-west, and never from the westward or southward of Kiel. Of course, there need have been no more than two directions of movement, south-westerly and south-easterly; for the pebbles carried a part of their course in one direction may have been carried the rest of the way in the other, and so produced any resultant direction between the two; or materials carried by floating ice may have come in a far more crooked course (and the places of origin are all on the shores of the Baltic, or on streams flowing into it). The lower sedimentary bed, with only a couple of exceptions, contains, so far as now known, every kind of pebble found in the upper ones, so that no inferences can yet be drawn as to changes with time in the direction of transport. The main result would seem then to be, that the Kiel sediments have all come from more northern parts of the Baltic basin, and might have been carried chiefly by floating ice, without a climate so very different from the present one.

The author is highly to be commended for his liberality in printing his pamphlet of sixty-six large octavo pages at his own expense, and that, too, in a country where good European printing is particularly troublesome. The two maps might, perhaps, have been advantageously combined in one, if one of the two sets of lines had been of a different character (say, dotted or broken) or of another color; for the very object of cartographic representation is to show at one view as much as can possibly be distinguished clearly of any given subject, — to assemble for convenient comparison on one sheet as many as may be of the scattered facts of nature bearing upon any given point.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Spectra of comets observed in 1881. — P. Tacchini discusses the varying appearances presented by the spectra of the comets *b* and *c* 1881, and accompanies his remarks with an extensive series of nearly forty lithographed drawings illustrating the changes which occurred. These changes, for the most part, consist merely in variations of the brightness and diffusion of the observed bands, and not in any alterations of position. He gives also a single figure of the spectrum of Encke's comet, observed the same year, and a set of twenty drawings of the comets (*b* and *c*) themselves. The paper, with its accompanying plates, constitutes an important collection of observed data; and some slight discrepancies between these representations and those of other observers raise interesting questions. — (*Mem. soc. spettr. ital.*) C. A. Y. [263

Uranus. — Within the last few months, considerable attention has been paid to this planet, and a number of series of observations upon it have been published. Safarik (*Astr. nachr.*, 2505), Meyer (*Astr. nachr.*, 2524), and Schiaparelli (*Astr. nachr.*, 2526), all present the results of their measures made for the purpose of determining its diameter and ellipticity. The observations of Schiaparelli are the most numerous and complete. He finds for the equatorial diameter of the planet 3″.911, and, for the polar, 3″.555 (both reduced to the mean distance 19.1826). This gives the ellipticity of the planet $\frac{1}{11}$, nearly the same as that of Saturn. He also reports the existence, upon the planet's disk, of spots and changes of color, too faint, however, to admit of delineation by means of a telescope of only eight inches aperture. In fact, to have seen them at all with such an instrument is a most remarkable evidence of the wonderful clearness of the Italian sky. The writer of this notice also made a series of observations upon the same object, in May and June, with the twenty-three inch equatorial of the Princeton observatory. Markings upon the planet's disk were unmistakably visible as belts resembling those of Jupiter and Saturn. The equatorial diameter determined by the writer's measures is 4″.280, and the polar, 3″.974, giving an ellipticity of $\frac{1}{14}$. Mädler, in 1843, obtained 4″.304 and 3″.869 for the two diameters, and an ellipticity of $\frac{1}{10}$. There can no longer be any doubt that the planet has a rapid rotation nearly in the plane of the satellite-orbits. — C. A. Y. [264

MATHEMATICS.

Perimeter of the ellipse. — Mr. Thomas Muir, referring to a recent article by M. Mansion, infers that the following formula, which he has known for some time, for calculating approximately the perimeter of an ellipse, has not yet been published. Denoting as usual by a and b the semi-axes of the ellipse, the expression for the perimeter is

$$2\pi \sqrt[\frac{3}{2}]{\frac{a^{\frac{3}{2}} + b^{\frac{3}{2}}}{2}};$$

or, *the perimeter of an ellipse is approximately equal to the perimeter of a circle whose radius is the semi-cubic mean between the semi-axes of the ellipse.* — (*Mess. math.*, xii. no. 10.) T. C. [265

Calculus of variations. — The general problem of the calculus of variations is to find the variation of an n-tuple integral of a function of n independent variables, and of depending also upon a number of arbitrary functions of these variables, together with the differential coefficients of the functions. M. Picart in his paper, which he entitles *Theorie nouvelle du calcul des variations*, confines his attention to a triple integral containing only one arbitrary function, and solves several of the more fundamental problems connected with the determination under various conditions of the variation of the integral. In particular, he shows how the problem of relative maxima or minima can be conducted to that of absolute maxima or minima. — (*Nouv. ann. math.*, Feb.) T. C. [266

PHYSICS.

(*Photography.*)

Photographing Reichenbach's flames. — The question of the actual existence of these flames, surrounding the poles of powerful magnets, has again been brought up for discussion in scientific circles. Numerous persons have claimed to be able to see them, and some even to be able to distinguish between the poles and the color of the flames. Reichenbach himself attempted to photograph them by the daguerrotype process, but was apparently dissatisfied with the results he obtained. Mr. William Brooks has taken the matter up, and thinks he has obtained actual impressions of the flames, by means of photography, on sensitive dry plates prepared especially for the purpose. In total darkness a perforated blackened card was placed one-eighth of an inch above the poles of a permanent horseshoe-magnet, and a sensitive plate placed an eighth of an inch above the card. With five minutes exposure he obtained a result; and this was repeated many times, the most remarkable thing being, that sometimes he obtained a positive and sometimes a negative image, under precisely the same conditions. Another curious effect obtained was, that some printed matter, which was under the wash of Indian ink used to blacken the card, was perfectly readable when the plate was developed. This latter result, however, was obtained on only one occasion. He also succeeded in obtaining prints through a glass plate on which were painted figures in black varnish. This was contrary to the experience of Reichenbach, who considered that the rays were not transmitted through glass. — W. H. P. [267

Hydrokinone. — Of this new developer, first introduced by Capt. Abney, Mr. Charles Ehrmann says, "The best results I have obtained with ten grains of hydrokinone to eight ounces of water, and caustic ammonia (1 to 7) added gradually as the development progressed. The negatives are of a non-actinic color, similar in tone to one slightly intensified with uranium and prussiate of potash; therefore the development need not be carried on very far, thus preserving all finer modulations. An injudicious amount of alkali will produce green fog." — (*Phot. times*, July.)

Of this same developer, Mr. Edwin Banks claims that it is much more powerful than pyro, and that it will bring out a fully developed picture with at least half the exposure that is necessary when pyro is employed. At first sight this seems strange, when it is observed how much more powerfully the latter absorbs oxygen; but the explanation probably lies in the fact that hydrokinone is more gradual in its action, and has a greater selective power, than pyro. With a collodio-bromide film, for instance, which is not so much protected from chemical action as one of gelatine, pyrogallic acts with such energy when mixed with an alkali, that the whole film is reduced immediately, and no image, or only a faint one enveloped in fog, appears: hence a powerful restrainer must be used to keep this action within bounds. A soluble bromide, which is the salt commonly used, has this effect, but, unfortunately, at the same time partially undoes the work which the light has done, rendering it necessary to give a longer exposure. But with hydrokinone no restrainer is necessary, unless a great error in exposure has been made. It does its work rapidly and cleanly, in this respect resembling ferrous oxalate. It does not discolor during development so much as pyro, and consequently does not stain the film so much, whilst full printing vigor is very easily obtained without having to resort to intensification. The color and general appearance of the negative are more like those of a wet plate, since the shadows remain quite clear, and free from fog. It seems almost impossible to fog a plate with it. One grain of hydrokinone to the ounce is strong enough for most purposes. With some samples of hard gelatine it is advisable to use two; but with most kinds and with collodion, one grain is sufficient. Two or three drops of a saturated solution of washing-soda to the ounce of the hydrokinone solution rapidly develops the image, and the addition of a few drops more to complete development is all that is needed. A soluble bromide acts very powerfully as a retarder and restrainer. With a mere trace added, development is very much slower. — (*Brit. journ. phot.*, July 6.) W. H. P. [268

ENGINEERING.

Sources of error in spirit-levelling. — Precise levelling in this country has been done by the U. S. lake survey, which has determined the elevation of all the great lakes with a probable error of less than one foot; by the coast and geodetic survey, which is carrying a line of levels across the continent from Chesapeake Bay to San Francisco; and by the Mississippi River commission, which has a line from the Gulf as far north as central Iowa, to be connected with Lake Michigan, and thence with the sea-level at New York. Mr. J. B. Johnson has been connected with some nine hundred miles of this work, and discusses the sources of error. He first classifies errors into compensating and cumulative. Then he treats them as, 1°, errors of observation, in the instrument or in the rod; 2°, errors from instrumental adjustment; 3°, errors from unstable supports; 4°, atmospheric errors, from wind, from tremulousness of the air caused by difference of temperature, and from variable refraction. He concludes, that, with good instruments and proper care, thirty miles of line should be duplicated a month with one Y-level and a target-rod, and all discrepancies brought within five-hundredths of a foot into the square root of the distance in miles; or with the U. S. precise levels and speaking-rods, reading three horizontal wires, one instrument should bring the discrepancies within two-hundredths of a foot into the square root of the distance in miles.

The Mississippi River levels have been well within this limit. — (*Journn. assoc. eng. soc.*, March.) C. E. G. [269

GEOLOGY.

Lithology.

Gold in limestone. — According to Prof. C. A. Schaeffer, gold occurs in a ferruginous cretaceous limestone from Williamson county, Tex. This rock lies near the surface, and fifty-two samples procured *in situ* by him averaged $15.20. Twenty contained no gold, while thirty-two assayed from $1.00 up to $231.50 per ton. He regards the gold as having originally existed in the limestone in pyrite, which has since been removed and the gold locally concentrated. — (*Trans. Amer. inst. min. eng., Boston meeting.*) M. E. W. [270

The Ottendorf basalt. — Rudolf Scharizer discusses the occurrence, microscopic and chemical composition, of this Silesian (Austria) basalt, its alteration, and contact phenomena with the grauwake-sandstone. The paper is quite full of chemical analyses. Olivine, somewhat serpentinized, is the predominating mineral, enclosed in a ground-mass of augite, magnetite, biotite, anorthite, nepheline, etc. The chemical analysis indicates that the rock is closely allied to the peridotites, if it does not belong to them. — (*Jahrb. geol. reich.*, xxxii. 471.)

The same journal contains an extended paper by Messrs. Teller and John, on the geological and lithological characters of the dioritic rocks of Klausen in the South Tyrol, a series of very diverse rocks including gabbros or norites. — (*Ibid.*, 589.) M. E. W. [271

METEOROLOGY.

The rain-storm in Ontario on July 10. — The Canadian meteorological service has made a special investigation of this storm, which caused such unusual destruction in the vicinity of London, Ontario. Observations from over one hundred observers were received and studied. The isobaric curves show only such undulations as generally accompany showers and thunder-storms in the summer season; and there was nothing in the maps to warrant the expectation of any storm, beyond the 'local showers' which were officially predicted, and which occurred in other parts of Ontario. The fluctuations in barometric pressure were hardly appreciable, and there was but little wind. Indeed, the only peculiarity of the storm was the unaccountable and unexpected precipitation, which exceeded four inches where the maximum occurred. This amount was recorded in an elliptical area of country, extending in a direction about north-west and south-east, and covering a territory of about twenty by fifty miles. The devastation at London was due to the fact that the two branches of the Thames River, which there unite, approach from nearly contrary directions, the river flowing away nearly at right angles to the branches. The question is therefore raised, whether it would not be advisable to divert one of the branches, that it may meet the other at an acute angle, and thus lessen the probability of a repetition of the catastrophe. The need of an increased number of rainfall observers is pointed out, that means may be afforded for extensive study into the little-known subject of the course and causes of local rains. — (*Can. weath. rev.*, July.) W. U. [272

GEOGRAPHY.

(*Alpina.*)

Ascent of Indrapura, Sumatra. — An account is recently published of the persevering and first successful attempt of Veth and Van Hasselt, several years ago (1877), to ascend this highest of the Sumatran volcanoes. They had to choose a way through the dense forest of the lower slopes, and over the sharp, loose rocks nearer the summit; and sudden heavy rains caused them much delay, so that eight days were spent in reaching the highest point, although the rim of the crater was gained a day earlier. Elephant-tracks were not found above 1,500 met., rhinoceros-tracks not above 2,600; but wild goats had been on the very summit. Above 2,500 met., large trees were absent; and above 3,000 only a few plants had found place to grow on the naked volcanic rocks. The barometer read 482.4 mm., and the thermometer, 8° C., corresponding to a height of about 3,700 metres. The surrounding country had the appearance of a uniform forest wilderness, occasionally broken by volcanic peaks and ranges, and showing a cultivated region by its lighter color in the distance near the coast. A deep crater lay within the sharp, ragged walls; several streams ran down to a pool at the bottom, a thousand metres below the rim, whence sulphurous vapors and clouds of steam rose into the great caldron. The volcano was in eruption in 1842, when described by Junghuhn. The descent was accomplished without serious difficulties. — (*Deutsche geogr. blätter*, vi. 1883, 130.) W. M. D. [273

(*South America.*)

Bolivian rivers. — On the occasion of Dr. E. R. Heath's account of his exploration of the Beni and other rivers flowing from the Andes north-eastward to the Amazon system, Mr. C. R. Markham, secretary of the Royal geographical society, gave a general description of the region, part of which he had visited in 1853. The mountains in which the rivers rise are part of the eastern range of the Andes, rising into great peaks like Illimani and Illampu, to a height exceeding 21,000 feet, with fossiliferous silurian rocks up to their summits. To the west is the great interior plateau of the Titicaca basin; to the east, the rivers descend, bearing gold gravels to the great plains, covered with unbroken forest. This eastern region has been very little explored; and the india-rubber and cinchona bark gathered about the upper streams are carried westward over the mountains to the Pacific ports, rather than down the rivers to the Amazon and the Atlantic. Markham sketches the history of exploration here from the time of the Inca expedition in the fifteenth century to the expeditions of Maldonado down the Amarumayu in 1866, and Heath down the Beni in 1880; these being the only travellers who have followed the rivers down to their junction. Dr. Heath mapped the whole course of the Beni with great care, taking astronomical observations, and measuring the width, depth, and velocity of the water. On reaching the Madeira, as the river is called below the junction of the Beni and Mamoré, he ascended the latter to Exaltacion, and then followed Yacuma, and crossed the country beyond its source to Reyes again on the Beni, where his return was celebrated by a public reception and a special mass. The people here were greatly excited over his report on the number of rubber-trees in the country he had passed through; and from 185 men engaged in collecting 104,000 pounds of rubber in 1880, the number increased to 644 in four months, and must now reach one or two thousand. From Reyes he ascended the Beni to La Paz. His report is very brief, and contains little beyond an itinerary; rapids and rocks are occasionally mentioned, and a few lakes were passed, but there is no material given toward a physical description of the country.—(*Proc. roy. geogr. soc.*, v. 1883, 313, map. [Dr. Heath's paper is also given in the *Bull. Amer. geogr. soc.*, 1882, no. 3.]) W. M. D. [274

BOTANY.

American smuts. — Farlow, in some notes on Ustilagineae, gives the first account of American Entylomata, his list including eight species, one only of which appears under another genus in earlier lists. Four of these are, for the present, described as new, though two may prove to be identical with species growing on the same host genera, in other countries. One is doubtfully considered to be a form of a European species; the balance occur also in the old world. Two American species of Cornu's new genus Doassansia — D. Farlowii Cornu and D. epilobii Farlow — are recorded; the former in the ovaries of Potamogeton, the latter in leaves of Epilobium. — (*Bot. gazette*, Aug.) W. T. [275

Fertilization of Leptospermum. — In a fourth paper on the indigenous plants of Sydney, E. Haviland considers the structure of the reproductive organs of this genus and its mode of fertilization. Cross-fertilization is regarded as probably the rule, brought about, 1°, by the difference in the times of maturing of the anthers and stigma; and, 2°, by changes in their relative positions. — (*Linn. soc. N. S. Wales; meeting* June 27.) [276

ZOÖLOGY.

Mollusks.

Astarte triquetra Conrad. — This minute and peculiar shell, recently rediscovered by Mr. Hemphill in Florida, but described by Conrad more than thirty years ago, proves to be a new form, Callicistronia, perhaps related to Tivela, with a small sinus in the pallial line, two large cardinal teeth in one valve, and one in the other. It is viviparous. More than fifty young ones were found in a single specimen, recalling the habit of Psephis. — W. H. D. [277

Anatomy of Urocyclus. — Dr. Paul Fischer has examined the soft parts of Urocyclus longicauda F. from Madagascar. The digestive tract resembles that of Parmacella and Limax. There is a large mucus-vesicle analogous to the vestibular prostate in Parmacella, Tennentia, and Ariophanta. Otherwise the reproductive organs resemble those of Helicarion, and a slug described in detail by Keferstein under the name of Parmarion in 1866, and which proves to be a true Urocyclus. This genus is African, while Parmarion is of Asiatic and East-Indian distribution. Urocyclus has an oxygnathous arcuate jaw, a rhachidian, thirty-nine lateral and thirteen uncinal teeth in one hundred and twenty-five rows. Dendrolimax of Heynemann appears to differ from Urocyclus merely in the absence of the mucus-vesicle, and will fall into synonymy. — (*Journ. de conchyl.*, xxii. 4.) W. H. D. [278

VERTEBRATES.

Reptiles.

Nerve-endings in the caudal skin of tadpoles. — The epidermis of the skin of tadpoles has two layers of cells. In the deeper cells, on the tail, appear peculiar bodies, first seen by Eberth (*Arch. mikros. anat.*, ii. 90) and Leydig (*Fortschr. naturf. ges. Halle*, 1879, taf. ix. fig. 32). The latter compared the bodies in question with the nettles of lasso-cells, giving to the cells containing the bodies the strange name of 'byssuszellen.' Pfitzner (*Morph. jahrb.* vii. 727) showed that these bodies are united with nerve-filaments, every one of the cells being so supplied. The nerves of the skin had been studied by Eberth (*l.c.*) and Hensen (*Virchow's arch.*, xxxi. 51 ; *Arch. mikros. anat.*, iv., 11). Canini and Gaule have studied the subject afresh, rectifying and supplementing the previous writers. The bodies in the basal epidermal cells appear as thick rods curved into bizarre and varying shapes. Each is connected with a nerve-filament (sometimes, but not always, as maintained by Pfitzner, two filaments run to one cell). The filaments descend through the gelatinous corium (cutis), to unite just below with a thick nucleated network of threads, which, from their reactions, are regarded as nervous tissue, and distinct from the cojacent plexus of connective-tissue corpuscles. This network, again, is connected with a deeper-lying, coarser plexus, corresponding to Ranvier's *plexus fondamentale*. These peculiar end-organs are not found, except in the tail: they are probably sensory, but Gaule hesitates to deny Leydig's interpretation. — (*Arch. anat. physiol., physiol. abth.*, 1883, 149.) C. S. M. [279

Birds.

Xenicidae, a new family. — On dissection of a specimen of Xenicus longipes and one of Acanthositta chloris, Mr. Forbes found the syrinx to be strictly mesomyodian. On account of this, the long tenth primary and the non-bilaminate tarsus, the birds are removed from the vicinity of Sitta as a family, Xenicidae, of non-oscinine Passeres in the vicinity of the Pittidae. — (*Proc. zoöl. soc. Lond.*, 1882, 569.) J. A. J. [280

Anatomy of the todies. — After a careful examination of the structure of this group, Mr. Forbes concludes that the todies are an isolated form of anomalogonatous birds, with no clear affinity to any living group. He therefore proposes to raise them to the group Todiformes, equivalent to the Passeri, or Piciformes.—(*Proc. zoöl. soc. Lond.*, 1882, 443.) J. A. J. [281

Illinois birds. — Nehrling continues his annotated list of Illinois birds in the full and learned manner so distinctive of German work. The present instalment contains thirty-nine species, from the bobolink to the great horned owl inclusive.—(*Journ. f. ornith.*, xxxi. 84.) J. A. J. [282

Mammals.

The os intermedium of the foot. — Dr. Karl Bardeleben gives a *résumé* of his observations upon the bones of the foot. A well-developed intermedium is present in many species of marsupials, but not in all. Its presence in a given species does not always imply its existence in closely allied species. For example: it occurs in Chironectes variegatus, but not in C. palmatus. The bone varies in size from one centimetre to a fraction of a millimetre. It does not exist in marsupials of which the hand has undergone regressive alterations, e.g., Halmaturus Bennetti, H. giganteus, etc. The separation of an intermedium is indicated in the monotremes, many edentates, as well as in the genera Elephas, Hippopotamus, and Tapirus, by a fissure, more or less deep, in the astragalus. Dr. Bardeleben suggests the name 'os trigonum' for the bone in question. — (*Zool. anz.*, no. 139.) F. W. T. [283

Odontoblasts and dentine. — R. R. Andrews has studied the development of teeth in pig embryos, and publishes the remarkable conclusion that the odontoblasts entirely disappear, forming the matrix of the dentine, and have nothing to do with the dentinal fibrils, which he claims arise from deeper layers, probably from nerve-fibres. (We are not prepared to agree with these views.) — (*N. E. journal of dentistry*, ii. 193.) C. S. M. [284

(*Man.*)

Measurements of the depth of sleep. — Two of Vierordt's pupils, Mönninghoff and Piesbergen, have made the depth of sleep the subject of an investigation. They worked upon the principle that the depth of sleep is proportional to the strength of the sensory stimulus necessary to awaken the sleeper, that is, to call forth some decisive sign of awakened consciousness. As a sensory stimulus they made use of the auditory sensation produced by dropping a lead ball from a given height. The strength of the stimulus was reckoned, in accordance with some recent investigations of Vierordt, as increasing, not directly as the height, but as the 0.59 power of the height. For a perfectly healthy man, the curve which they give shows that for the first hour the slumber is very light; after 1 hour and 15 minutes, the depth of sleep increases rapidly, and reaches its maximum point at 1 hour and 45 minutes; the curve then falls quickly to about 2 hours 15 minutes, and afterwards more gradually. At about 4 hours 30 minutes, there is a second small rise which reaches its maximum at 5 hours 30 minutes, after which the curve again gradually approaches the base line until the time of awakening. Experiments made upon persons not perfectly healthy, or after having made some exertion, gave curves of a different form. — (*Zeitsch. f. biol.*, xix. 114.) W. H. H. [285

ANTHROPOLOGY.

Notes on Mitla. — In July, 1881, Mr. Louis H. Aymé visited the ruins of Mitla, which lie in Oaxaca directly south of Vera Cruz. Mitla is not so grand, so magnificent, as Uxmal; but it has a beauty of its own, as it nestles quietly at the foot of the mighty mountains, the ruins of grim 'Fortin' standing sharp against the evening sky; and, as the sun sinks, one might fancy he heard the weird chant of the priests, the lament of the mourners for the dead who rest in Lyobaa, the Centre of Rest. Appended to M. Aymé's itinerary is a translation by Mr. S. Salisbury, jun., of the description of Mitla, by Francisco de Burgoa, written in 1674. Then follows a report of the various buildings constituting the north and south groups, which for detailed statement and brevity is a model archeological document. Mr. Aymé is able to correct some of the errors of his predecessors. It is gratifying to quote the following: "The buildings are carefully looked after by the government, and have an intelligent guardian in the person of Don Felix Juero." Comparing the present account with Burgoa's, Mr. Aymé concludes that in 1644 the ruins were practically as they are to-day. — (*Proc. Amer. antiq. soc.*, ii. 82.) J. W. P. [286

The Olmecas and the Tultecas. — Mr. Philipp J. J. Valentini gives some very cogent reasons for thinking that the sanguine hopes of the decipherers of American hieroglyphics will never meet the realization of those who unravelled the sacred languages of Egypt and Mesopotamia. Except for the wonderful similarity which early Mexican civilization bears to that of the ancient nations of the eastern hemisphere, only a fraction of the workers could have been induced to undertake the labor. The right way to treat these matters is to moderate our expectations. With such motive, the author then endeavors to fix the main epochs, and to inquire who were the Olmecas and the Tultecas. The former search results in fixing the dates of all we know concerning Mexican history between the years 232 and 1521 of the Christian era. Mexican history begins with the record of a race of giants, the Quinamé, or Quinametin, who are claimed to have been a people of Maya origin, found by the Nahuatls on the Atoyac River, when they were migrating southward. When the name of the Olmecas appears in the early Mexican records of the Nahoas, we must not hesitate to recognize in them that people east of Anahuac who spread along the Atlantic slopes and south through Yucatan, Tabasco, and the whole of Guatemala, and whom we designate to-day by the collective name of Maya. No nation, empire, or language of Tultecas ever existed. The Tultec exodus is shown to refer to the migrations of the Colhuas who shared with the Mexicans the rule of the uplands. Their journey to Culiacan was not from the Pueblos, but from the borders of the Gulf of Mexico. — (*Proc. Amer. antiq. soc.*, ii. 193–230.) J. W. P. [287

North-eastern Borneo and the Sulu Islands. — Although north-eastern Borneo is close to the Sulu group, there is a great difference in the people. The Sulus are Malays, with a considerable infusion of Arab and Chinese blood. The Bajaws, or sea-gypsies, lead a nomadic life in their boats, each boat containing an entire household. The Sulus are divided into coast Sulus and the Orang Gumber, living among the hills, and they are much above the Bajaws in character. The latter are stronger in physique, but timid and treacherous. On the coast-line of Borneo is an extraordinary mixture. At Melapi, sixty miles up the Kina Batangan, are Sundyaks, Malays, Javanese, Sulus, Bajaws, Bugis, Chinese, Arabs, Klings, and many others; while of the Buludupies, the indigenous inhabitants, there are hardly any of pure blood left. These indigenes are an interesting people, their ancestry showing distinct signs of a Caucasian type. The rest of north-eastern Borneo is inhabited by tribes of the race styled Eriaans, Dusuns, or Sundyaks, who are of Dyak blood, with perhaps an infusion of Chinese. The Chinese language, dress, etc., are entirely lost, however. Slavery of a clan or feudal type is universal, and the Mohammedan religion prevails. The Sundyaks are divided into many tribes, some of which are gaining in power. *Cf.* i. 552. — (*Proc. roy. geogr. soc.*, v. 90.) J. W. P. [288

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

PUBLIC AND PRIVATE INSTITUTIONS.

Dudley observatory, Albany, N.Y.

Comet b, 1883 (Brooks). — By means of observations secured at the Dudley observatory on Sept. 5, 9, and 18, I derived on the 19th the following parabolic elements, marked I. The remarkable similarity of these elements to those given by Schulhof and Bossert for the Pons comet of 1812 pointed unmistakably to their identity. The elliptic elements of the Pons comet (here marked II.) are transcribed from the memoir of Schulhof and Bossert (p. 150), except that they are reduced to the mean ecliptic and equinox of 1883.0, and a value of T, derived from observations of the present apparition, is substituted.

I.		II.	
T = 1884, Jan., 25.788 (G.M.T.).		T = 1884, Jan., 25.696 (G.M.T.).	
Node	254° 13′.6	Node	254° 8′.8
Node to perihelion .	199 14 .4	Node to perihelion .	199 12 .9
Inclination	74 47 .1	Inclination	74 63 .3
Log. q.	9.87944	Log. q.	9.88930
		Eccentricity . . .	0.95527

The value of T in II. was determined by approximation from the observation of Sept. 5. The remaining observations do not indicate any important change in its value. The following ephemeris results from elements II. The geocentric positions are referred to the mean equinox of 1883.0.

In the light scale, .19 corresponds to that of discovery in 1812, and 1.00 to the time when the comet was reported as visible to the naked eye in the apparition of 1812. The places of the above ephemeris represent the observations already made within about 30″ in each co-ordinate, and with a very uniform minus value of 'c-o' throughout. This seems to be the fault of the elliptic elements. Any considerable change in the time of perihelion passage diminishes the discrepancy in one co-ordinate at the expense of the other.

It is remarkable that the present comet should have been picked up when its light ratio was six times as small as it was at discovery, in 1812. It was then regarded as a faint object. Were it not for the overwhelming testimony from other sources, one might doubt, on the ground of brightness, the identity between the present comet and that of 1812. The following rough ephemeris may be of interest: —

	a	δ	Light.		a	δ	Light.
1883.	h. m.	°		1884.	h. m.	°	
Dec. 3 .	18 45	− 45.7	.6	Feb. 1 .	0 34	− 28.3	2.3
" 13 .	19 37	− 41.7	1.0	" 11 .	1 02	− 37.2	1.5

The identity of the Pons comet of 1812 with comet *b*, 1883, was announced in an 'associated press' despatch from the Dudley observatory on the evening of Sept. 19. LEWIS BOSS.

Sept. 21, 1883.

Massachusetts institute of technology, Boston, Mass.

Extension of the course in biology. — Advantage is at once to be taken of the extension in the building accommodations, and the improvement in the financial resources of the institute, to greatly enlarge the space heretofore given to biological work, and to increase the instructing staff of this department of the school.

The removal of the physical laboratory to the new building on Clarendon Street affords the long-desired opportunity for the expansion of the biological laboratory, heretofore confined to a single small room in the low brick annex. The large north room (90 x 28 ft.) on the first floor of the main institute building (the Rogers Building), with its admirable light and its many facilities, will be devoted to the purposes of the natural-history course, and will be fitted up with appropriate apparatus and instruments. Within a short time, it is also anticipated that a room in the basement (being one of those now occupied by the chemical or by the metallurgical department) will be available for use in dissections and in the coarser work of a biological laboratory.

Dr. W. T. Sedgwick, a graduate of the Sheffield scientific school, and recently connected with the biological department of the Johns Hopkins university, having been appointed assistant professor of biology, will assume charge of the biological laboratory at the opening of the next school year, and will give the instruction in physiology, botany, and general biology, now provided for in the regular courses of the institute, especially in the so-called natural-history course, as well as take charge of the work of special students in these branches.

The instruction given in geology by Professor Niles, and in zoölogy and paleontology by Professor Hyatt, will be continued. Mr. W. O. Crosby has been appointed assistant professor of mineralogy and lithology, and will hereafter give, throughout the school year, the instruction which has heretofore been confined to a single term. The advantages of the extension of the chemical and physical laboratories, abundantly provided for in the new building of the institute, will be enjoyed by the students of the natural-history course, in common with those of the other regular courses.

In view of the foregoing enlargement of facilities and opportunities for study and research in the branches especially embraced in this course, it is recommended to students looking forward either to becoming naturalists, or to the subsequent study and practice of medicine.

NOTES AND NEWS.

The comet recently detected by W. R. Brooks at Phelps, N.Y., has become an object of unusual interest since its identification with the comet of 1812, the return of which has been anticipated about this time. Mr. Brooks first noticed the comet as a suspicious object on the night of Sept. 1, and directed the attention of astronomers to it, after a second observation. During the first half of September it was repeatedly observed at various places; but its great distance and consequently slow movement made it difficult to obtain trustworthy approximations to its orbit, and thus delayed the recognition of its character. Its identity with the comet of 1812 was first announced, so far as we are informed at present, by the Rev. George M. Searle of New York, in a letter published on Sept. 18. A communication from him to Harvard college observatory, with which he was formerly connected, was received there on the morning of Sept. 20, and contained a statement of the process by which he reached the interesting conclusion previously announced. This consisted in determining, from the positions of the Brooks comet, the corresponding points of intersection with Encke's orbit of 1812; the result for the time of perihelion passage being 1884, Jan., 25.17, and the longitude of the perihelion being closely accordant with that given by Encke.

Professor Boss of the Dudley observatory, as will be seen on an earlier page, arrived independently at the same conclusion by computing parabolic elements from observations of Sept. 5, 9, and 18, which exhibited a close similarity with those of the orbit of 1812. The circular which he has issued upon the subject states that he communicated his result to the associated press on the evening of Sept. 19.

The communication of Father Searle to Harvard college observatory, already mentioned, induced Mr. Chandler to examine the question, with the aid of the most recent observations. The result was to furnish further confirmation of the asserted identity; and the positions obtained at the observatory as late as Sept. 22 make it still more evident. The difference between the observed place and that resulting from the orbit of 1812, as corrected by the recent publication of Schulhof and Bossert, but with the time of perihelion passage assumed as 1884, Jan., 25.780, is as follows: —

Diff. R.A. — $0^s.1$. (O—C.)
" Decl. + 66″.

This agreement is entirely within the uncertainty of the orbit of 1812, from the old observations.

The comet has also exhibited phenomena of great interest in regard to the development of its structure by its approach to the sun. When first observed this year, it was a very faint and small nebulous object, but the appearance of a stellar nucleus was noted at Harvard college observatory by Mr. Wendell on Sept. 3. The nucleus was afterwards less distinct. This may have been due to unfavorable conditions of observation, or it may possibly indicate a preliminary series of changes like those which the comet has just exhibited. On Sept. 21, as seen at Harvard college observatory, the comet was still very faint. A slight condensation at one place could be seen with the large equatorial, but this could hardly be called stellar. The next night, Sept. 22, the appearance of the comet had so completely changed that it was difficult to believe it the same object previously seen. It now resembled a star nearly as bright as one of the eighth magnitude. Very little nebulosity could be detected about it, but some was seen early in the evening, while the comet was sufficiently high in the sky. During the evening it appeared to be gaining perceptibly in brightness. The next night, Sept. 23, it was seen at times between clouds, and was found to have again changed its appearance. It was now even brighter than before (although still slightly inferior to a star of the eighth magnitude), but it had lost its stellar appearance, and had become blurred, regaining the ordinary character of a cometic nucleus. Traces of the development of a tail were also perceptible. The rapidity of this series of changes is very unusual, if not unexampled.

The comet will doubtless become visible to the naked eye, and will prove an interesting object, although it cannot at present be confidently expected to rival the fine comets of recent years in apparent dimensions and brilliancy.

— Nordenskiold has returned from his exploration of the interior of Greenland, without fully effecting his purpose. From the contradictory reports that have been published by the daily press, we gather that he entered the interior from Auleitsivik Bay, near Disco Island, and himself penetrated to the distance of nearly ninety miles, when the snow became too soft for sledges. His Laplanders pushed much farther on snow-shoes, or about half way across the continent, if they took a direct easterly course, of which we are not assured. On the east coast his vessel subsequently pushed as far northward as Cape Dan, but was prevented from making its way farther northward by the ice.

— The first of the authoritative publications of the International fisheries exhibition contains an excellent account, by G. Brown Goode, of the fishery industries of the United States, both historical and statistical, including all the marine products that are derived from the animal and vegetable life of the seas, as well as a careful though condensed account of the labors of the federal fish commission.

— Professor Simon Newcomb, U. S. Navy, superintendent of the *American ephemeris* and *Nautical almanac*, Washington, and Dr. Benjamin Apthorp Gould, director of the National observatory at Cordoba, Argentine Republic, have been elected corresponding members of the Berlin *Akademie der wissenschaften*.

— According to *Nature*, the balloon of the Paris observatory has been in working order for some weeks. Its capacity being only sixty cubic metres, it was found difficult to use it, except in calm weather. The motions of the registering apparatus are an obstacle to correct readings. The experiments, conducted by Admiral Mouchez, are stated to be only preliminary to further aerostatical experiments. The subject is quite new, scientific ballooning being only in its infancy; and it is only by gradual investigation that the extent of the services it can render to science can be ascertained.

— Professor P. Denza discusses in the *Comptes rendus* the question of the connection between eclipses and terrestrial magnetism. From the time of the total solar eclipse of Dec. 22, 1870, regular observations of magnetic declination have been made at the observatory of Moncalieri during the progress of all eclipses of the sun, as well as some eclipses of the moon. The needle has been observed at intervals of only a few minutes on such occasions; and the entire series of observations extends through twenty eclipses, the last being the Egyptian solar eclipse of May 17, 1882. His discussion indicates no connection between the amount of magnetic disturbance and the magnitude of solar eclipses; and in general it may be regarded as established from his investigation, that the passage of the moon between the earth and the sun in eclipses of the latter, and the passage of the moon through the shadow of the earth in eclipses of the former, have no influence whatever upon terrestrial magnetism.

— The *Illustriste zeitung* reports that the fossil remains of several iguanodons have been found at Bernipart, in Belgium. The skeleton of one of these fossil monsters has been carefully put together, and removed to the Natural history museum at Brussels, where a special case has been made for it, and placed in the courtyard, no convenient space being found inside. The same journal reports the discovery of the remains of animals of the bronze age, made during the extension of the fortifications of Spandau. Among other things were the bones of a species of dog, the leg-bone of a gigantic horse, and the bones of a small species of pig, somewhat like the present Indian one. The remains have been examined by Professor Nehring, who also discovered the remains of a small-limbed goat and of a sheep.

— Mr. Winslow Upton, of the U. S. signal office at Washington, has been elected professor of astronomy at Brown university, Providence, R.I. It is understood that his acceptance of the position is conditional upon the erection of an astronomical observatory which the college authorities have under consideration.

— Professor Piazzi Smyth has published his views upon the subject of a prime meridian for the whole world. They furnish an excellent illustration of the fact that a man's peculiar opinions on any one subject may warp his judgment upon matters wholly removed from it. He advocates the adoption of the meridian of the Great pyramid, because it "passes over solid, habitable, and for ages inhabited, land through nearly the whole of its course from north to south. Its line is capable, therefore, of being laid out along almost all that distance by trigonometrical measurement, and marked by masonried station-signals." Among other equally cogent arguments are the statements that the pyramid "dates from before all human written history, all known architecture, all living architecture;" that "its meridian divides the lands and numbers of the people of the earth much more nearly than any other;" and that it passes not very far from Jerusalem, near which the prime meridian of the world ought to be located by Christian people.

The last idea is developed more fully by M. du Caillaud, who has addressed a letter to the president of the Paris geographical society, urging the adoption of the meridian of Bethlehem, thus harmonizing the longitude reckoning with the customary method of numbering the years from the birth of Christ.

— At Wabash college, Crawfordsville, Ind., a new laboratory is in process of erection, which is to be devoted entirely to biological work. One room, 50×100 feet, with balcony and side-aisles, will contain the general collection of many thousand specimens; a second room will contain the herbarium of twenty thousand species; and a third will be devoted to other collections. Special students are directed to the fact that the collection of crinoids from the Keokuk beds in the vicinity is complete, and that botanical material is on hand in great abundance for consultation. There will be three laboratories provided with every needed appliance, — one for general botanical work, the second for zoölogical work, the third for special work with compound microscopes. The last laboratory, in particular, is to be devoted exclusively to original research.

— Frederick A. Fernald, in criticising, in the September *Century*, Mr. A. Melville Bell's paper in SCIENCE for June 1, objects to the forms of the visible-speech letters which Mr. Bell would employ as symbols for the six consonant sounds in our language which have no proper letters to represent them, and suggests the discarding from their present use in our alphabet of the duplicated symbols *q*, *x*, and c, and using them instead for the sounds represented by *ng*, *zh*, and *ch*. "Perhaps it will be decided to replace *w* and *y* by vowels, as in Franklin's scheme; if so, these, with one Anglo-Saxon letter, alredy lookt upon with favor, would make up the six lacking consonants." To this suggestion it may be objected, that the use of familiar letters in an unfamiliar sense would be a source of constant confusion. For example, we should have to read cat and coke as *chat* and *choke*, pleaxure as *pleasure*, roux as *rouge*, sig as *sing*, etc. The alterations of spelling, too, would be seriously numerous; as in siks for *six*, egzist for *exist*, kueen for *queen*, knite for *quite*, etc. The use of the Anglo-Saxon þ and ð for the two sounds of *th* would certainly be an improvement on present practice; but the writing of *w* (in *way*) and *y* (in *yea*) as vowels would be altogether wrong, as these sounds are demonstrably not vowels, but consonants. *Wh*, also, is a true consonant, — the non-vocal correspondent of *w*, — and has not, as alleged, the sound of *hoo*. If *wh* had this sound, the sentence, "I saw the man whet the knife," would not be — as it is — unmistakably distinct from "I saw the man who ate the knife." *Ch* (in *chair*) is not, as alleged, a simple consonant, but a compound consisting of a shut position of the tongue (*t*), followed by a hiss (*sh*); and either the silent position or the hiss may be prolonged *ad libitum*.

"Even *such* a man, so woe-begone," etc.

Give due lingering emphasis to the word 'such,' in the above quotation, and the compound character of the *ch* — misunderstood by many writers — will be apparent. The letter c should consistently stand for *sh*, not *ch*, in Mr. Fernald's proposition; but, if a better method of completing our alphabet cannot be adopted, by all means rather let the A B C remain as it is.

— *Le Temps* has published the following directions by Pasteur to those exposed to the contagion of cholera.

The precautions to be taken, indicated to the members of the French cholera commission, all relate to the case when it is necessary to guard against the excessive causes of contagion.

1°. Do not use the potable water of the locality, when the commission enters on its investigations, without having first boiled the water, and, after it has cooled, shaken it for some minutes (two or three minutes are sufficient) in a bottle half full and corked.

One may use the waters of the locality, provided one draws them at a spring, in vessels which have been purified by exposing them to a temperature of 150° C., or, better, to a higher heat. One can advantageously employ natural mineral waters.

2°. Use wine which has been heated in bottles some 50° to 60°, and drink from glasses likewise purified.

3°. Only make use of food thoroughly boiled, or of fruits well washed with water which has been boiled, and which has been kept in the same vessels in which it was boiled, or which has been transferred from these vessels to others disinfected by heat.

4°. The bread used should be cut in thin slices, and kept at a temperature of 150° C. for twenty minutes or more.

5°. All vessels used for food should be exposed to a temperature of 150° C. or more.

6°. Bed linen and towels should be plunged in boiling water, and dried.

7°. Water for washing should be boiled, and have added to it, after cooling, one five-hundredth part of thymic acid (one litre of dilute alcohol for two grams of acid) and one-fiftieth part of phenic acid (one litre of water for twenty grams of acid).

8°. Wash the hands and body often during the day with the boiled water to which the thymic or phenic acid has been added.

9°. It is only in case one has to handle the bodies of those who have died from cholera, or the clothes and linen soiled with their discharges, that it is necessary to cover the mouth and nostrils with a mask, formed of two pieces of fine wire gauze, with wadding between, one centimetre thick. The mask should be exposed to a temperature of 150° each time before it is used.

— The Wisconsin agricultural experiment-station was organized by the board of regents of the University of Wisconsin, in June, 1883. The work of the station is in charge of W. A. Henry, agriculture; William Trelease, botany and horticulture; H. P. Armsby, agricultural chemistry. The bulletins of the station will be sent to all interested. The first number contains an account of experiments at the station in feeding skim-milk to calves and pigs.

— Mr. C. F. Mabery has resigned his position at Harvard college, and accepted the chair of chemistry at the recently organized Case school of applied science at Cleveland, O.

— The British association for the advancement of science will meet next year in Montreal, on Aug. 27.

— Next year's meeting of the Swiss naturalists will be held at Lucerne.

— The jury which will examine the electric lighting machinery offered for competition at the Cincinnati industrial exposition has begun its work. It is hoped that the comparative tests will be the most satisfactory yet obtained. Awards of five hundred and three hundred dollars will be made for the best and second best systems of electric lighting, both incandescent and arc.

— We learn from *Symons' meteorological magazine* for August, that the government has granted Professor Lemström a sum of 37,000 marks for the continuation of his auroral experiments in Finnish Lapland. These investigations will include the electrical current which produces the aurora, terrestrial currents, and magnetic perturbations.

— Professor Henry F. Osborn of Princeton has published in the July number of the *Quarterly journal of microscopical science*, in a more extended form and with the accompaniment of a lithographic plate, the results of his researches on the foetal envelopes of marsupials. The interest and importance of these investigations are already known, at least to the embryologists among our readers, for Professor Osborn's conclusions were first published in SCIENCE.

— The thirty-eighth volume of the *Mémoires du dépôt de la guerre*, recently printed by the Russian general staff under the editorship of Rylke, and of which only one hundred and fifty copies are issued, contains, among other things, an account of the astronomical and trigonometrical work in eastern Siberia, by Bolsheff, Polianoffski, and Kramereff; a memoir of Kulberg on the Russian geodetic operations in Armenia; a report by Lebedeff on triangulation, topographic and astronomical work in Bulgaria; a list of astronomical stations in the Khirgiz steppes by Bondorf; and Stebnitzki's report on the results of his experiments with a reversible pendulum. Of this important work, absolutely necessary for those seriously interested in the study of the geography of Russia and adjacent countries, there is probably not a copy in America.

— Mr. Miles Rock, assistant astronomer at the U.S. naval observatory, has accepted the appointment of chief astronomer and engineer commissioner on the international boundary commission of Guatemala, to locate the boundary between that country and Mexico. He will sail from New York Oct. 1, and expects to be absent about a year.

— Professor H. M. Paul, late of the Imperial university of Tokio, has returned to this country, and accepted a position in Washington under the Transit of Venus commission.

— The *Comptes rendus* of Aug. 13 gives some extracts from a letter of M. A. Richard to M. de Lesseps, on the cultivation of date-palms. M. Richard states that these palms grow best on a soil saturated with salt, as has been proved at Alicant and elsewhere. The land around Elche, in Valencia, is irrigated from the Vinalopo, which is extremely salt, rising, as it does, in Mount Pinoso, the rocks of which contain much salt and sulphate of lime. This water, having been used for centuries for watering the palm-plantations, has at last formed a crust, which has to be broken with a pick-axe to admit the water below. The town of Alicant has planted its beautiful boulevard along the shore with date-palms, and, as fresh water is very precious there, the trees are regularly watered with sea-water. All the plantations recently made along the shore from Huertas to Rio Monegro have their roots literally in the sea-water, being planted at but a few feet from the sea.

SCIENCE.

FRIDAY, OCTOBER 5, 1883.

NATIONAL TRAITS IN SCIENCE.

THERE are at present three principal currents of scientific work, — German, English, and French. The scientific writings of each nationality are characteristic, and, taken as a whole, offer in each case distinctive qualities. German influence is now predominant over the scientific world, as French influence was uppermost during the earlier part of this century; but the sway of Germany over western thought is far more potent and wide-spread than was ever that of France. As students once gathered in Paris, so they now flock to Germany; and thence back to their own lands they carry the notions of German science, and labor to extend, imitate, and rival them. Thus German ideas have been spread abroad, and established in foreign countries. This has set a common standard for scientific work, which is accepted in most European countries. German influence is evident by its effects in Switzerland, Russia, Italy, Poland, Belgium, England, and America, and in degrees indicated by the order given: in France, Spain, and Portugal, it is hardly noticeable. Holland and the Scandinavian countries have for many years achieved so much and so excellent work, that their scientific development may be said to have accompanied rather than to have followed that of Germany.

German science has unquestionably distinctive qualities. Its pursuit is a special and honored calling, attractive to the highest talent: its productions have the stamp of professional work. The German scientific man is first and principally an investigator: he is obliged to be so, otherwise he loses in the race. He wins his position in the hierarchy of learning by the original researches he carries out. To succeed under these circumstances, a man must discover something which is a real addition to knowledge; and to do this, he must be thoroughly familiar with all that has been previously accomplished in his field. Moreover, to advance beyond his peers, the investigator must utilize every possible extraneous advantage; more especially must he have a mastery over the methods to be employed, and be familiar with all novelties and refinements therein. It cannot be gainsaid that these requirements are more fully answered in Germany than anywhere else. It is certain, that, excepting of course a small minority, German scientific publications always contain something really new, and unknown before: each article is a scientific progress, which, however slight, still brings an actual increment to our store of information. Another result of this professional thoroughness is equally striking and characteristic. Being fully posted as to the status of his department, the German often displays a singularly just and keen appreciation of what problems are for the moment best worth studying, as being open for solution, and leading to something farther, or else filling a gap left. He is thus enabled to render his work efficient. It is sad to think how much scientific work is wasted because the labor is not wisely directed.

In German scientific writings the excellence of the matter usually contrasts vividly with the defective style and presentation.. Indeed, the Germans, despite the superiority of their modern literature, are awkward writers, and too often slovenly in literary composition. Conciseness and clearness are good qualities, which may assuredly be attained by the expenditure of thought and pains; but these the German investigator seems unwilling, in many cases, to bestow upon his pen-work, but follows the easier plan of great diffuseness. Besides this, another defect is not uncommon, — the ill-considered arrangement of the matter. This occurs in all degrees, from a well-nigh incredible confusion, to be sometimes found even in elaborate and important essays, to a slightly illogical order. In this regard, a curious and not infrequent variety of this fault deserves mention. According to the headings of the chapters or sections, the division of topics is perfect; but under each head the matters are tumbled together as if a clerk was contented to stuff his papers in anyhow, if only he crammed them into the right pigeon-hole.

Speaking broadly, the German mind lacks conspicuously the habits of clearness and order. There have been celebrated exceptions, but they were individual. The nation regards itself as having a decidedly philosophical bent, meaning a facility at taking broad and profound views of the known. We venture to contradict this opinion, doing it advisedly. Their profundity is mysticism, their breadth vagueness, yet a good philosopher must think clearly. It is a remarkable but little heeded fact, that Germany has not contributed her share to the generalizations of science: she has produced no Linné, Darwin, Lyell, Lavoisier, or Descartes, each of whom bequeathed to posterity a new realm of knowledge, although she has given to the world grand results by the accumulated achievements of her investigators. The German's imperfect sense of humor is another obstacle which besets him on every path. He is cut off from the perception of some absurdity, like that of Kant's neumenon, for instance. One cannot explain this to him: it were easier to explain a shadow to the sun, who always sees the lighted side. To state the whole epigrammatically, German science is the professional investigation of detail, slowly attaining generalizations.

English science is the opposite of this, — amateurish rather than professional. Some might call it insular, yet we should hardly join them in so doing. In fact, the professional investigator has hardly been a recognized character in the English social organization: until recently he was barely acknowledged, even by the universities, which sought instructors who knew and could teach, who might investigate and discover in a subsidiary, and, as it were, unofficial way. A large number of English scientific men were disconnected from the universities and colleges after their own student years, and were half or wholly amateurs; and their writings show the effects of this separation, not always, to be sure, but in many cases with painful evidence, by a lack of thoroughness, an imperfect acquaintance with other investigations, and a failure to grasp the essential part of the problem: in brief, such writings appear behindhand and superficial. Yet amid these poorer productions are to be found a right goodly number of the best scientific articles we possess in any language. Of late years the proportion of the good has steadily increased, and investigation is now more correctly appreciated than ever before. Indeed, there is no more encouraging event in the recent progress of science than the sudden elevation of the standard of original research in England. The English are trained writers: their scientific articles excel the German in literary merit, being seldom slovenly either in arrangement or style, and rarely wearisome from sheer diffuseness. Very noteworthy is the fertility in generalizations of the English: this is with them the outcome of individual endowments, a single master attaining a broad conclusion, — a process of individual effort quite unlike the German democratic method of generalizing by the accumulations of many. Is it too much to say that the English and Scotch are the Greeks of modern philosophy?

French science is decidedly provincial: it is apart, having only an imperfect, uncertain acquaintance with the great world outside, and its international interests of original research. The French have lagged far behind the great movements of recent years. Consider only how backward they have been in the comprehension and acceptance of the Darwinian theory; and remember, too, that it were wiser to take out the mainspring from a watch than to eliminate evolution from biology. French scientific articles are well written, the matter is admirably classified, it is all very clear. The keen, artistic sense of the nation displays itself here; but it also deludes them into presenting a rounded survey of a greater field than is demanded by the actual discoveries they report. To satisfy this yearning for artistic completeness, elaborate and tedious disquisitions, and hackneyed principles, and facts long known, are interpolated; and even worse may be, when the imagination helps to create the completeness. Most scientific men harbor a little distrust of French work. This sentiment is further fostered by the almost systematic neglect of German research on the part of the French. Such a frank exhibition of rancor makes one suspect the impartiality of the French in science generally: indeed, we believe that science has never been so depressed in France as at present. Italy is above her; but Italy, with all her innate ability, is striving to learn from Germany, and has already risen high, and will rise higher. We trust and believe that the present phase of French science which abounds in inefficient work will soon end, and the people terminate their present voluntary isolation. The French stay at home: they used to travel abroad much. Let us hope that they will soon resume their ancient habit, and, above all, that they will re-establish mental intercourse with foreigners. There are *savants* in France who are esteemed throughout the scientific world: may their number rapidly increase!

America's contributions to pure science are by no means very extensive, or often very important: compared with the great volume of German production, they seem almost insignificant. We have never duly fostered research, for we have bestowed upon it neither the proper esteem nor office. There are, we suppose, at least six thousand 'professors' in the United States: are one hundred and fifty of them active investigators? The time seems remote when every American professor will be expected to be also an investigator; but among us is a little band of men who have before them the model of Germany, and who are working earnestly for the intellectual elevation of their country. Their first object is necessarily to render research more important in public estimation, and so to smooth the way for a corps of professional investigators. Every thoughtful person must wish success to the attempt.

CLIMATE IN THE CURE OF CONSUMPTION.[1] — II.

Humidity.

There is a unanimity of opinion amongst authorities in regard to the relation of moisture to the production of phthisis. The seventh annual report of the registrar-general of Scotland showed that the death-rate from phthisis diminished in proportion to the dryness of the location. Dr. H. I. Bowditch of Boston has shown that phthisis is prevalent in damp soils in the United States. "It is also common in Holland, and other countries liable to damp fogs and an atmosphere saturated with moisture" (Reynold's System of medicine, iii. 548). Ruehle, in Ziemssen, says, "It appears that moist air favors consumption." Dr. Austin Flint says, "It may be stated that the prevalence of the disease is less in climates either uniformly warm and dry or uniformly cold and dry." And Dr. C. T. Williams writes, "As to the desirability of moist climates for consumptive patients, the evidence is decidedly against their use in the treatment of ordinary chronic phthisis."

If we attempt to explain why it is that phthisis is more prevalent in moist climates than in dry, we might assign as a cause the prevalence of germs, or the impurity of the air, containing the effluvia of decay, or perhaps the greater susceptibility of the system to cold in moist climates; or it may be that the air, being so near saturation, cannot take up the requisite amount of the aqueous vapor exhaled from the lungs. *Causa latet vis est nota* may adequately express the state of our knowledge in regard to this point. A moist climate is acknowledged to be a breeder of phthisis; and, *au contraire*, a dry climate is known to afford a certain exemption from the disease. This is shown by the fact that the disease is rare in Iceland, in the island of Morstrand, on the steppes of Kirghis, and in the interior of Egypt; in all of which places the element of elevation is wanting. It may, then, be conceded, that dryness of the air is an important element in the prophylaxis and cure of phthisis.

The method of determining the humidity of the air is that introduced by Regnault, known as the wet- and dry-bulb test. It can easily be seen that the results obtained will depend on the exposure of the thermometers, and on the accuracy of the readings. Moreover, the amount of moisture that the air is capable of

[1] Concluded from No. 34.

holding varies with the atmospheric pressure and temperature.

While it seems to us that a table showing the relative humidity, i.e., the percentage of saturation of the air, would be sufficiently accurate as a basis of comparison, yet, as it might be objected that such a table would be subject to error, we have appended another table, giving the absolute moisture, or the number of grains of vapor to the cubic foot of air. This second table we have computed from Glaisher's tables.

Consulting these tables (table I., columns iii. and iv.), it is seen that Denver and Santa Fé afford a very low relative and absolute amount of atmospheric moisture, — a relative amount, which, as between Denver and Jacksonville, is as 1 to 3, and, as between Denver and Los Angeles, is as 1 to 2.

This proves, that, on the eastern slopes of the Rocky Mountains, we have, in addition to the favorable element of elevation, a second, that of dry air, as an element of climatic influence in the cure of phthisis.

Precipitation.

Closely related to the foregoing, is a consideration of the mean annual precipitation, or the mean annual amount (in inches) of rain and melted snow. Its bearing on our subject is apparent in several ways.

1. Of the precipitation, a certain part is lost by evaporation, and tends to increase the humidity of the air. This amount will depend upon the amount of moisture in the air, or its degree of saturation, and also upon the amount of the precipitation left upon the surface of the ground to be evaporated. It is evident that the greater the porosity of the soil, the greater will be its absorptive power, and the less the evaporation from it. Such a porous soil is found on the eastern slopes of the Rocky Mountains. Loose, sandy, and gravelly, it eagerly drinks up all the rainfall; and such a thing as mud is rarely seen.

2. It is well known that pulmonary troubles are most prevalent during 'thaws,' in those places where the snow lies upon the ground in winter. Now, in the district of the Rocky Mountains under consideration, there is, in the first place, only a slight amount of snowfall, so that sleighing is exceptional, and, in addition, the warm sun soon melts the snow, and the thirsty, porous soil drinks it up; so that the annual 'spring thaw' of our Eastern States is a *res incognita* in this country. The writer remembers very distinctly several snowfalls of fourteen to twenty-two inches on a level, of which there was not a vestige left in ten days; and during that time the air was not chill and raw, and there was but little slush.

3. Further than this, the amount of the precipitation has a bearing upon our subject, as indicating approximately the ability of the invalid to lead an out-of-door life. We shall defer our discussion of this point to a later part of this paper.

Turning, now, to the tables, we see (table I., column v.) that in Denver the mean annual precipitation for a period of ten years is only 14.77 inches in rain and melted snow, — an amount which is only one-fourth of that at Jacksonville, and which, with Santa Fé, gives the smallest showing in our range.

We can therefore add this element of climate to the other two of elevation and dry air as a point in favor of the Rocky Mountains in the cure of phthisis.

Temperature.

The writer in Reynold's System (*op. cit.*) says of this matter of the relation of the temperature of climate to the cure of phthisis, "It was formerly supposed that warm climates were beneficial for consumptive patients. . . . But it will be invariably observed that unaccustomed warmth is injurious. . . . What is really required, is a cool, temperate climate, free from great alterations of temperature." Dr. Austin Flint (*op. cit.*) calls attention to the fact, that "the disease is oftener developed during the spring months and the hot months of summer," when either there is a great deal of moisture in the air, or the debilitating effects of heat are present as factors. On the other hand, Ruehle says that the temperature has "nothing to do with the prevalence of consumption."

It is known that the effect of heat is to raise the body temperature, to lessen the number of respirations, to quicken the pulse, to lessen the digestive powers and the appetite, to diminish the excretion of urea because of the diminishing of the ingesta, and to depress the nervous system, especially if the heat be accompanied with excessive moisture. It seems, then, that it can be stated as a fair inference from the foregoing, that a dry, temperate climate is to be sought by the phthisical invalid. The Rocky Mountains furnish a dry climate. The table (table I., column vi.) shows that the mean temperature is nearly a mean between the extremes in our range. The question will, however, be presented in a better form farther on.

Winds.

The points of importance in regard to the winds are their velocity and direction. It is well known that they are regulated somewhat by changes in atmospheric pressure and temperature.

Velocity. — It is known that a cold wind abstracts body-heat, and in proportion to its velocity. By consulting our tables (table II., part ii.) it will be seen that the mean daily velocity of the winds at Denver is less than it is in the Eastern States; and that as a consequence, while the mean temperature is nearly the same, the chilling effect will be much less. On the other hand, as it has a considerably greater velocity, and as there are fewer calms than at either Augusta or Los Angeles, it has a proportionately greater purifying power in bringing fresh ozone, and in blowing away the products of decomposition.

Direction. — Of more importance than the velocity, is the direction of the winds. The favorable and unfavorable directions vary for different places, according to their geographical location. The east and north winds are known to be the trying ones along the Atlantic coast; and our table shows that the north-east wind is the prevailing one at both Augusta and Jacksonville. The west wind, blowing from the Pacific Ocean, and bringing fogs, is the trying one on the California shore; and the table shows that this is the prevailing one at Los Angeles. The south wind is the salubrious one for the eastern slope of the Rocky Mountains, in Colorado; and our table shows that this is the wind that blows there most frequently.

We can therefore add this element to the others, — of elevation, dryness of air, small amount of precipitation, and mean temperature, — as favorable to the Rocky Mountains as a place for phthisical patients to resort.

Clear, fair, and cloudy days.

We now come to the consideration of our last general point, that is, to an investigation of the number of clear, fair, and cloudy days; or, in other words, to a consideration of the amount of sunshine.

As to the direct effect upon health produced by light and sunshine, we are still in ignorance. Whether the blood is made to course more rapidly, and the nerves transmit impulses more readily, under the influence of the solar ray, is not known. It is well known that the actinic rays have a powerful chemical effect upon vegetation; but whether or not they have a like influence upon the human economy is unknown.

Without attempting to refine, there are certain broad and positive effects in the cure of phthisis attributable to sunshine. The experience of the profession is fittingly expressed by the words of Dr. Austin Flint: "I would rank exercise and out-of-door life far above any known remedies for the cure of the disease."

In the table which we present (table III.), and which is a mean of daily observations for a period of five years, a cloudy day is one in which the heavens are from seven-tenths to entirely obscured by clouds; a fair day is one in which the heavens are from four to seven-tenths clouded; all else are classed as clear days. From this it will be seen, that for our purposes clear and fair days may be classed as one, and may be put into juxtaposition with the cloudy days. Consulting these tables, it will be seen, that in Denver the mean number of cloudy days in a year is only one-half of what it is in either Augusta or Jacksonville, that it is less than a half of what it is in St. Paul, and that it is slightly less than what it is in Los Angeles.

TABLE III.

Salt Lake, Utah	141	131	93
Los Angeles, Cal.	164	148	51

To put this fact in another way, it is seen, that in Denver there is only about one-eighth of the entire year when an invalid would be kept in the house on account of the weather; in Jacksonville and Augusta he would be confined to the house, for the same reason, one-quarter of the year; in St. Paul he would be kept in-doors between a third and a quarter of the time; while in Boston he would have to be housed a good third of the time.

Admitting, then, the force of Dr. Flint's statement, our tables show that there is no place in this whole country, where it is possible for the invalid to enjoy so much fresh air and sunshine, as in the Rocky Mountains. For three hundred and twenty days out of every three hundred and sixty-five it is possible to roam at large, and to breathe in health.

We feel, that, so far, our tables have shown that the Rocky Mountains furnish climatic conditions of elevation, humidity, precipitation, temperature, winds, and sunshine, which recommend them as a resort for phthisical invalids superior to any thing to be found in this country.

Observations by seasons.

Having arrived at these general conclusions, the writer wishes to call attention very briefly to their accuracy and importance as applied to the different seasons of the year. He wishes to lay stress upon the evidence which goes to show that Colorado and New Mexico furnish favorable resorts for phthisical invalids during the winter and spring, — the very seasons that are most trying in the east, the seasons that they are obliged to avoid, and to seek new abodes at the resorts. The elements of elevation and barometric pressure will remain nearly constant the year round. But how is it in regard to the *humidity* of the air in Colorado during the winter and spring? The writer has selected at random, and without reference to whether the showings would be favorable or unfavorable for a given place, the year 1880 as his basis for comparison. By referring to table IV., part i., it will be seen, that both the relative and absolute humidity for Denver during the winter and spring is absolutely, and by comparison, very small; that, as compared with Augusta and Jacksonville, it makes a wonderful showing in these respects; and that the ratio of the absolute humidity as between Denver and Los Angeles is as 1 to 3 for these seasons.

When we turn to our tables (table IV., part ii.), we learn that the amount of *precipitation* at Denver for these seasons was almost *nil;* that the mean monthly precipitation at Denver for the given time was only a small fraction of an inch in rain and melted snow. Carry out, now, the comparison between Denver and Augusta, Jacksonville and Los Angeles, and see the tremendous difference in this particular between these places, — a showing immensely in favor of Denver. It will be seen that our general conclusions are very much strengthened by this particular application, and that we have brought strong additional evidence in favor of Colorado as a resort for persons affected with phthisis pulmonalis.

When we turn to our tables to learn in regard to the *winds* at these places for the given seasons, we see that the conclusions previously reached in regard to Denver, in this particular, still hold true (table V.).

Temperature. — We come now to our last observation, and to a brief discussion of what some may consider the weak point in regard

to Colorado as a resort for invalids. It has been seen that most authorities favor a cold climate; but they add the proviso that it should be free from change. By consulting table VI., part ii., it will be seen that the mean monthly range of temperature is larger for Denver than for almost any other point in our scale. It will be seen, further, that the minima (table VI., part i.) of temperature are very nearly the lowest in the scale, — not so low, to be sure, as the minima at St. Paul, but decidedly lower than at Augusta, Jacksonville, and Los Angeles. This state of affairs demands an explanation.

We have seen that the air of Colorado is both dry and rare, — two conditions that favor rapid radiation. We have seen, further, that the soil is of a porous, sandy nature, — a kind

that will easily absorb heat, and as easily give it off. Furthermore, there is but little verdure or shade, — another condition, too, which will favor both absorption and radiation of heat. In consequence of these conditions, the soil and air are, on the one hand, rapidly heated in the morning, and they are equally rapidly cooled at night. The nights are always cool in Colorado, — a condition that renders the summer months enjoyable and invigorating. But the question, after all, is, whether this diurnal change of temperature is injurious to Colorado as a resort for invalids. We claim that it is not, and for this reason: it makes but little difference to the invalid how cold the nights are, for at that time he should be indoors, where he can regulate the temperature; but it is of importance that it should be warm at mid-day, so that he can take his exercise regularly and comfortably. We have seen, that so far as conditions of sunshine, humidity, and rain and snow fall are concerned, the invalid can lead an out-of-door life a greater percentage of the time in Colorado than anywhere else in this country; and we claim that he will never find these factors counterbalanced by the element of temperature. An experience of several years warrants the writer in asserting that an invalid can, with perfect comfort and safety, spend several hours in the saddle nearly every day of the three hundred and sixty-five. One has but to read 'H. H.'s' writings to learn how attractive out-of-door life is in Colorado, even in mid-winter; and we can positively assert that we have known of picnics being held day after day, in the open air, in the very heart of the winter, and that there are days and weeks in mid-winter when one can sit with doors and windows open.

As proof of what we say, we append the mid-day temperature at Denver for each month of the year for three years.

In conclusion, the writer would state, that while his personal experience in regard to a desirable climate for the cure of phthisis has been such as to convince him of the great superiority of the climate of the Rocky Moun-

TABLE VII.—DENVER, MEAN MONTHLY TEMPERATURE, 1 P.M.

tains over any other in this country, yet in this article he has tried to put aside any personal bias, and he desires to carry conviction only in so far as he has been able to adduce facts, and to interpret them rationally and logically. He would state, further, that, if the reader should take exception to any interpretation given to the facts, the tables still stand as the best and most reliable data of these facts attainable, and they are not to be controverted.

SAML. AUG. FISK, M.D.

Denver, Col.

REARING OYSTERS FROM ARTIFICIALLY FERTILIZED EGGS AT STOCKTON, MD.

IN order to test the feasibility of such an undertaking on a considerable scale, a pond three and a half feet deep was excavated on the premises of Messrs. George V. Shepard and H. H. Pierce, not far from Stockton, near the shore of Chincoteague Bay, and connected with the latter by a trench ten-feet long, two feet wide, and three and a half feet deep. Before the water was let into the trench connecting the pond with the bay, a wooden diaphragm — made in the form of a box three feet deep, and two and a half feet wide, and two inches thick, and lined on the inside with gunny-cloth; the sides of the box being perforated with numerous auger-holes, and filled with clean sharp sand, so as to form a filter — was placed in the trench vertically and transversely, and so secured that no water, except such as had first filtered through the diaphragm, could gain access to the pond. In this way the natural fry from the bay was effectually excluded from our artificial enclosure from the very start, so that the results of our experiment might not be vitiated. In the construction of this simple apparatus we depended entirely upon the rise and fall of the tide to partially renew the water in the pond in the intervals between the tides. The tidal rise and fall of the water in the enclosure was from four to six inches, or from six to eight inches less than the rise and fall of the tide in the open bay. Into the enclosure, covering about fifty square yards, artificially fertilized spawn was poured at odd dates, from July 7 to the first week of August.

The spawn was taken from the adults much in the same way as from fishes; the right valve of the adult animals being removed, and the ducts of the reproductive organs stroked with a pipette to force out the eggs and milt from the females and males. The products mixed together in water were then allowed to stand in pails for a few hours, until the eggs had developed as far as the swimming stage. The spawn so prepared was then distributed over different parts of the pond, and left to take care of itself.

The collectors used were simply oyster-shells strung upon galvanized wire; strings of shells being suspended to stakes driven into the bottom of the pond at intervals corresponding to the dates when fresh lots of spawn were introduced, each stake being marked with the date when it was put in place. The suspended oyster-shells were introduced so as to afford the young fry clean surfaces to which it could attach itself. On the 22d of August Mr. Pierce found that some of the shells hanging to the stakes had spat attached, ranging from one-fourth to three-fourths of an inch in diameter, and which had undoubtedly been derived from some of the brood placed in the pond by us. Some specimens of these young oysters are now in my possession, attached to the perforated oyster-shells used as collectors.

To our great surprise, we found that the water in the pond maintained about the same specific gravity as that in the bay, or 1.0175 to 1.018, and that the temperature of the water was also the same as in the open bay. The microscopic vegetable food upon which the oyster feeds was found to multiply rapidly in the enclosure, inasmuch as it was confined by the gate or diaphragm, so that it could not escape. The water in the pond was also found to remain sweet, and free from putrefactive odors. It will accordingly be seen, that all the conditions of success had been established, as was fully proved by the result.

While it is too soon to affirm that artificial breeding may be profitably available on an extensive scale in practical oyster-culture, our experiment has demonstrated a number of very important facts. These are: 1. Oyster-spat may be reared from artificially fertilized eggs; 2. The spat will grow just as fast in such enclosures as in the open water; 3. Food is rapidly generated in such enclosures; 4. The density of the water in the ponds is not materially affected by rains, or leaching from the banks; 5. Ponds are readily excavated in salt-marsh lands, and can in all probability be used for fattening and growing Ostrea virginica for market just as successfully as Ostrea edulis and angulata are grown by a similar method on the coasts of France. Pond-culture, where there are salt-marshes adjoining arms of the sea the waters of which have a density below 1.020, can doubtless be carried on profitably in connection with the intelligent use of simple, cheap collecting-apparatus placed in both open and confined waters to catch a 'set' of spat, which can then be transferred to ponds or open beds. The methods of spawn-taking and pond-culture introduced by the writer are inexpensive and very simple, and can be understood and conducted by any person of ordinary intelligence, and are fully described in papers already published, or in course of publication, by the U. S. fish-commission, under the auspices of which he has been enabled to carry out his investigations. The experimental difficulties have been overcome. It remains for practical men to avail themselves of whatever of value has been determined by these experiments. There are thousands of acres of salt-marsh land along the eastern coast of the United States, which, with proper preparation, might be made to yield a living to a large number of persons, and which is now not productive of any thing except mosquitoes and malaria.

Pond-culture has one other decided advantage over culture in the open water; namely, that it is possible to effectually exclude from the artificial enclosures certain enemies of the oyster, such as whelks and star-fishes.

J. A. Ryder.

THE EXPLOSION OF THE RIVERDALE.

The boiler of the steamer Riverdale exploded on the 28th of August, a few minutes after the boat had left her wharf at New York, and started for her destination on the Hudson River above the city. Several lives were lost, and the boat itself was sunk in sixty feet of water. The boiler was raised, and placed upon the wharf near the Delamater iron-works; and the boat, a worthless wreck, was towed to the New-Jersey side of the river.

The steamer had two 'flue-boilers' 25 feet (7.6 m.) long, 6 feet 4 inches (1.93 m.) in diameter, containing four 'direct' flues 14 inches (0.36 m.) in diameter, two of 9 inches (0.23 m.) diameter, and five 'return' flues of 11½ inches (0.28 m.) diameter. The shell was of no. 3 iron, and the area of heating-surface was 676 square feet (63 sq. m.). The iron was of good quality, and was in good condition throughout, except along the bottom, where it gave way. The form, proportions, and workmanship of the boiler were good. The builders, Messrs. Fletcher & Harrison of New York, were among the most reputable constructors of engines and boilers in that city, and were noted for doing good work.

On examination, it was found that the bottom was corroded along its whole length, and had been patched in a number of places where the iron had become dangerously thin, and that in some places the sheets were reduced to one-fourth their original thickness. The shell had been repeatedly patched, and five 'soft patches' were found on the girth-seams. The rupture seems to have started in the thin parts of the bottom, and to have followed the weakened girth-seams quite around, and divided the mass into two parts of nearly equal size, tearing the middle sheet out of the shell entirely.

A coroner's jury made an inspection, examined such witnesses as could be found and such experts as could be induced to testify, and rendered a verdict to the effect that the boiler ruptured in consequence of the weakness of the sheets on the bottom of the shell, which were unable to sustain the working pressure allowed by the U. S. inspector; which weakness had been produced by corrosion on the interior, due to the action of the feed-water. It was further asserted, that the boiler was tested in June up to a pressure of 62 pounds (5 atmos. abs.), and burst ten weeks later under a pressure of but 32 pounds (3 atmos.), in consequence of the neglect of the inspector to observe its condition at the time of testing it. The engine-driver and the inspector were censured by a vote which was not unanimous. The jury expressed the opinion that the present law is not sufficiently explicit and mandatory, and that the use of the test by hydrostatic pressure is insufficient to detect and reveal such defects as here existed.

The inspector acknowledged that he did not try the strength of the boiler with the hammer, as is now usual in all thorough examinations by competent engineers, but merely looked it over; and that at previous inspections he had not entered the boiler, but had only looked in at the manhole. The evidence of the most superficial and inefficient 'inspection' was conclusive; and the fact that proper inspection would have revealed the dangerous condition of the boiler was equally well proven. The so-called 'inspection' was a farce; and the inspector, in a spirit of indifference or indolence, took the chances of an explosion.

The exploded boiler weighed 27,000 pounds (12,247 kilos), and contained 25,000 pounds (11,340 kilos) of water. The explosion was not remarkably violent, but was what old engineers are accustomed to call a 'burst' rather than an explosion. The consequences were, however, sufficiently serious. The energy producing the effects seen in the case of a true explosion may be imagined, when the amount of heat-energy stored up in such a boiler is calculated. The quantity of heat transformed into mechanical energy by a mass of water and of steam of such magnitude, set free, and expanding down to the pressure and temperature of the atmosphere, from the pressure and temperature at which it existed in the boiler of the Riverdale, would amount to above 1,500,000,000 foot-pounds (over 200,000,000 kilogrammetres). This would be sufficient to throw the boiler and its contents, were the heat all utilized, as in a perfect steam-engine, five miles high. This may give some faint idea of the enormous forces at work, and the tremendous energy stored in a steam-boiler, even where the pressure of the steam is very low, as it was in this case.

It will be concluded, from what has been above stated, that a steam-boiler of the most ordinary and least dangerous type has stored within it an inconceivable amount of available energy in the form of heat, which may be at any moment transformed, in part, into mechanical energy with terribly destructive results, both to life and property; that this powerful agent for good or for evil can only be safely utilized when the utmost care, intelligence, and skill, are employed in its application, and in the preservation of the vessel in which it is enclosed; that the present code of law relating to the care, management, and inspection of steam-boilers, is entirely inadequate to insure safety; that the inspection of steam-boilers, as at present practised by the employees of the government, is not only liable to be inefficient, but is likely to prove worse than none, as it gives to the owner, and perhaps often to the man in charge, of the boiler, a feeling of security which is entirely without basis in fact, and which may therefore cause the neglect of that watchfulness which might otherwise prevent accident; that simple pressure produced by the test-pump, as now provided for by the law, is not a sufficiently effective method of detecting weakness in the boiler, or to be relied upon to the exclusion of other better and well-known methods of test.

The fact that the hydrostatic test is not conclusive as to the safety of a boiler has long been well known and admitted among intelligent engineers. The steam ferryboat Westfield met with precisely such an accident a dozen years ago; and it was shown at the coroner's inquest, at which the writer assisted that official in the examination of his expert witnesses, that the boiler had been inspected, and had been tested, but a few weeks before, by the U.S. inspector, who applied a pressure considerably in excess of that at which the explosion took place. The cause of the accident, by which a large number of people lost their lives, was precisely that which caused the explosion of the Riverdale's boiler, and the method of rupture was the same. In either case, proper methods of inspection would have saved the lives of the sufferers.

It is undoubtedly true, that many of the inspectors are conscientious, experienced, skilful, and painstaking men, and do their duty in spite of the defects of the existing law; but it is also true that now and then a careless or incompetent inspector will neglect the simplest details of his work, and that we must expect occasional repetition of this sad experience, until the law is intelligently framed, and so administered that the passing of a defective boiler by the inspector shall become as nearly as possible an impossibility.

Robert H. Thurston.

Hoboken, Sept. 23, 1883.

THE AMERICAN SOCIETY OF MICROSCOPISTS.

The sixth annual meeting was held this year in Chicago, Aug. 7–11. The usual number of members was present, and the meeting was full of interest from the beginning to the end. The forenoon session of Tuesday was given to organization, and the report of the president on the official action of the executive officers for the year. At the afternoon session, papers were read as follows. Microscopical examination of seminal stains on cloth, by F. M. Hamlin. After pointing out the defects of Koblanck's method, that usually given in the manuals, he explained his own, which he had found eminently successful. It is in brief as follows. "1. If the stain to be examined is upon any thin cotton, linen, silk, or woollen fabric, cut out a piece about one-eighth inch square, lay it upon a slide previously moistened with a drop of water, and let it soak for half an hour or so; . . . then with a pair of needles unravel or fray out the threads at the corners, put on the glass cover, press it down firmly, and submit to the microscope. 2. If the fabric is of such a thickness or nature that it cannot be examined as above, fold it through the centre of the stain, and with a sharp knife shave off the projecting edge thus made, catching upon a slide moistened with water the particles removed. After soaking a few minutes, say five to ten, the powdery mass will sink down through the water, and rest upon the slide. The cover-glass may now be put on, and the preparation examined."

College microscopical societies, by Sarah F. Whiting. The author discussed, first, the question 'What use can a microscopical society subserve?' second, 'How can it be made a success?' Such a society, in its range of topics, can take in almost all the physical and social sciences; and an enthusiasm created in it will help many of the departments of college-work. The society welcomes the incoming classes, and affords an opportunity for a change to those accustomed to years of dry drill in the mathematics and languages of the preparatory schools. It opens their eyes to the perfections of nature, awakens in them a curiosity, and stimulates interest in all the scientific studies of the college course. There are interesting subjects of microscopical investigation, carried on in society, which do not come under any department of college instruction. The live college microscopical society will not only awaken interest in students and teachers, but will attract the attention of the authorities who control the funds, and the community generally. The conditions of success in such a society are just what they are in every other scientific society the object of which is not alone investigation, but instruction of its members and others. There must be desirable members, those who are willing to work: all must have something to do. "The freshmen, by their exclaiming, fan the flame of enthusiasm, and, before they can do any thing alone with the microscope, can serve the society on the lamp committee." There should be a class in microscopical technology, apparatus, a library, and especially the current scientific journals.

Cataloguing, labelling, and storing microscopical preparations, by Simon H. Gage. This paper pointed out the advantages of properly cataloguing, etc., one's microscopical preparations, and then gave in detail the course found to be successful by the author. "The catalogue should indicate all that is known of a specimen at the time of its preparation, and all the processes by which it is treated. It is only by the possession of such a complete knowledge of the entire history of a preparation that one is able to judge with certainty of the comparative excellence of methods." The card method is advocated. "The cards are postal-card size, and each preparation has its own card. . . . These may be arranged alphabetically; and, as new preparations are made, new cards may be added in their proper order, while those of destroyed or discarded preparations may be removed without in any way marring the catalogue. Finally, the cards may be kept in a neat box which occupies but little more space than a manuscript book." The cabinet should allow the slides to be flat, exclude dust and light. Each slide should have a separate compartment, numbered to agree with the slide. The floor of the compartment should be beveled at the end, so as to facilitate removal; and the drawers of the cabinet should be independent, but so close together that slides will not fall out when tipped; and each should be numbered with Roman letters.

The president, Albert McCalla, delivered his annual address, Tuesday evening, in Weber music-hall. His theme was 'Verification of microscopical observation.' Referring to the scientific spirit and a common bond of the society's organization, he said, "In this intensely practical age of ours, we are in danger of forgetting that the true aim of science is simply the pursuit of truth, and that the mighty benefits, the invaluable and almost countless gifts, of wealth and ease and safety, which result from scientific discovery, and which so greatly bless the world to-day, will result most surely when science has an eye single to the search for simple truth, — truth that to the practical world seems often abstract and unimportant. . . . We are not all botanists, not all zoölogists, nor all students of lithology; yet we have a well-defined common ground. We are all deeply interested in the physics of the microscope and in the methods of its use; and, in order to be skilled in that department of investigation we have severally chosen, we must be more or less fully practical in microscopical work in many fields." To prove that "only as theories are submitted to repeated and varied forms of verification is error eliminated and final truth obtained," numerous facts were cited from the history of scientific progress; after which, the means of verification of microscopical observation were discussed. These are repetition of observation, use of the camera lucida, photomicrography, media and reagents, improved lenses and apparatus, and a better knowledge of optics.

Wednesday forenoon was devoted to papers on bacteria. T. J. Burrill read a paper on preparing and mounting bacteria. He stated that the elements of successful staining are as follows: "1. The organisms should be decidedly and conspicuously stained; 2. The general mass of embedding-material should be left unstained, or so different in color that the organism can be distinctly seen; 3. There should be no granular or other precipitations from the staining-material; 4. The color should be suitable for the purposes required, and permanent if the object is to be mounted; 5. The process should be as simple as possible, and free from manipulative difficulties. . . . Except for a few special results, aniline dyes are by far the most serviceable in staining bacteria. However, no one staining-material, nor any single method of procedure, can be made to answer well the requirements for all kinds of bacteria."

Dr. H. J. Detmers presented some conclusions reached by himself while studying the diseases of cattle in Texas. Bacteria he regarded as unquestionably the cause of certain fevers. Under certain conditions, all bacteria become pathogenetic; but these conditions are not yet fully understood.

Dr. George E. Fell read a paper on the clinical advantages of ozone, and its effects on the micro-organisms of infusions. After giving the favorable results of the use of ozone by Dr. F. W. Bartlett in scarlet-fever, diphtheria, whooping-cough, typhoid-fever, etc., he gave in tabular form the results of a series of experiments by himself, — experiments in which bacteria, and other forms indigenous in infusions, were subjected to the influence of air charged with ozone.

Following the discussion on the three preceding papers, Dr. G. E. Blackham presented the report of committee on oculars. The report recommends naming oculars, like objectives, by their equivalent focal lengths in English inches. For the tubes of oculars the standard medium size, 1.25 inch is recommended, with the alternatives of 1 inch and 1.35 inch for those who wish smaller or larger tubes; also for the upper tube of the ocular .75 inch, and, for sub-stage tube, 1.50 inch. The purpose of the society is to secure uniformity in these sizes, so that apparatus of different makers shall be interchangeable, as objectives have been since the adoption of the 'society screw.'

The first paper in the afternoon was a critical study of the action of a diamond in ruling lines on glass, by Prof. William A. Rogers. The author stated his theory relating to the method which Nobert may possibly have employed in the production of his plates briefly thus: "The lines composing Nobert's finest bands are produced by a single crystal of the ruling-diamond, whose ruling qualities improve with use. . . . When a diamond is ground to a knife-edge, this edge is still made up of separate crystals, though we may not be able to see them; and a perfect line is obtained only when the ruling is done by a single crystal. When a good knife-edge has been obtained, the preparation for ruling consists in finding a good crystal. Occasionally excellent ruling-crystals are obtained by splitting a diamond in the direction of one or more of the twenty-four cleavage planes which are found in a perfectly formed crystal. A ruling-point formed in this way is, however, very easily broken, and soon wears out. Experience has shown that the best results are obtained by choosing a crystal having one glazed surface, and splitting off the opposite face. By grinding this split face, a knife-edge is formed against the natural face of the diamond, which will remain in good condition for a long time. When a ruling-crystal has been found which will produce moderately heavy lines of the finest quality, it is at first generally too sharp for ruling lines finer than 20,000 or 30,000 to the inch, even with the lightest possible pressure of the surface of the glass. But gradually the edges of this cutting-crystal wear away by use, until at last this particular crystal takes the form of a true knife-edge which is parallel with the line of motion of the ruling-slide: in other words, when a diamond has been so adjusted as to yield lines of the best character, its ruling-qualities improve with use. If Nobert had any so-called 'secret,' I believe this to have been its substance.

"The problem of fine ruling consists of two parts, — first, in tracing lines of varying degrees of fineness; and, second, in making the interlinear spaces equal. The latter part of the problem is purely mechanical, and presents no difficulties which cannot be overcome by mechanical skill. It will be the aim of the present paper to describe the more marked characteristics of lines of good quality ruled upon glass. . . . A perfect line is densely black, with at least one edge sharply defined. Both edges are perfectly smooth. Add to these characteristics a rich black gloss, and you have a picture of the coarser lines of a perfect Nobert plate. In the study of the action of a diamond in producing a breaking fracture in glass, the microscope seems to be of little service; but we can call it to our aid in the study of its action in ruling smooth lines. One would naturally suppose that a line of the best quality would be produced by the stoppage of the light under which it is viewed by the opaque groove which is cut by the ruling-diamond. Without doubt, this is the way in which lines are generally formed; but it is not the only way in which they can be produced. An examination under the microscope will reveal the fact, that in some instances, at least, a portion of the glass is actually removed from the groove cut by the diamond; and that the minute particles of glass thus removed are sometimes laid up in windrows beside the real line, as a plough turns up a furrow of soil. . . . The particles of glass removed take four characteristic forms: (*a*) They appear as chips scattered over the surface of the glass; (*b*) They appear as particles so minute, that when laid upon a windrow, and forming an apparent line, they cannot be separated under the microscope; (*c*) They take the form of filaments when the glass is sufficiently tough for them to be maintained unbroken; (*d*) They take a circular form. . . . It must not, however, be supposed that lines of the best quality always present the appearance described above." These characteristic results were illustrated by plates, with the fragments and fibres in place. The author also referred to Mr. Fasoldt's claim, that he has succeeded in ruling lines one million to the inch. He thinks the limit just a trifle too high; but, if reduced one-half, he is by no means sure but that it may be reached.

Following this was a paper by A. H. Chester, describing a new method of dry mounting, in which the cover-glass is easily removable. The object is fastened to the slide in the usual way, and a tin cell built up about it sufficiently high for the cover to clear the object; then a ring of larger bore is cemented on, making a flange to receive cover. The latter ring, having been punched out of tin foil by a gun-wad punch, and put in place with the smaller hole uppermost, makes a groove above the cover, into which a spring-brass ring is put, holding the cover in place. The advantages of this method are many, — the objects may be easily viewed uncovered; dust or moisture accumulating in the cell may be removed; the mounting is quickly done, etc.

In the evening session, Mr. W. H. Walmsley read a paper giving the latest and best results and methods, by himself and others, in the art of photomicrography. The photographs in illustration were exhibited by L. D. McIntosh by means of his solar microscope with ether oxygen light.

Following this was a short paper by D. S. Kellicott, giving an account of certain stalked infusoria found in the crayfish. Two species, believed to be peculiar to the gill-chambers, were described. One of these is new to science, and was named Cothurnia variabilis. The well-marked varieties seem to be due to situation; i.e., those on the hairs of the lining-membrane are relatively longer, with a spine at the upper edge of the aperture of the lorica, but without a spine on the ventricose front of the same, while a stouter variety, situated on the membrane itself, has a spine in front, but none on the edge of the aperture. A third variety occurs on the gills: it also has a spine on the ventricose part of the shell, but the aperture is horizontal instead of vertical. They are so abundant as to encumber the gills of the host, rendering them brown to the eye. An Epistylis from the same host was named E. Niagarae: it is close to E. balanorum, a marine form. The same writer, at another session, described Cothurnia lata n. s., found on Diaptomus, and also gave a general account of two internal parasites of the crayfish.

The first paper Thursday morning was on the effects of division of the vagi on the muscles of the heart, by A. M. Bleile. The object of the paper was the demonstration of nutritive or trophic nerves for the heart, and was a continuation of work reported in the Proceedings of the society last year.

Following this, T. S. Up de Graff described certain fresh-water worms. One, a rotifer, is new: it was named Brachionus Gleasonii. Independent of the spines, its length is 0.145 inch, the front of the carapace without spines. The posterior edge bears five curved spines: there is one, also, on the dorsal part of the shell, — a peculiar feature.

The remainder of the session was occupied by short papers, by Francis Wolle, on fresh-water algae, and one by John Kruttschnitt on ferns and their development.

In the afternoon the session was opened by a report upon a standard centimetre, prepared by the U. S. bureau of weights and measures, by W. A. Rogers. The lines of the centimetre are ruled on a plate of platinum-iridium soldered to brass with silver. The report describes the plate, and compares its divisions with a standard. The original basis of this unit is a metre upon copper, prepared for Professor Rogers by Professor Tresca of the Conservatoire des arts et métiers at Paris. The report concludes thus: —

1. That the centimetre *A*, measured by the middle defining line, is exactly a hundredth part of the metre des archives reduced to sixty degrees Fahrenheit. It can therefore be safely adopted as the unit in all measures with low-power objectives.

2. That the second millimetre of the scale is exactly a thousandth part of the metre des archives when at the same temperature.

The centimetre is now the property of the society; it having been tendered to it by the national committee on micrometry, and accepted and adopted as a standard or basis for future studies and discussions in micrometry. The scale is in the hands of Dr. George E. Fell. A committee was appointed for securing copies on glass. The rules for its control and use will soon be published.

After this report, Dr. George E. Blackham read a communication on the relation of aperture to amplification in the selection of a series of microscopic objectives. The author showed that amplification is not the only element which enters into the problem of rendering visible minute details, but the aperture of the objective forms another element. Working, then, on the general lines laid down, he had selected as a set of powers, sufficient for all the work of any microscopist, the following: —

One 4-inch	objective	of	0.10 n.a.	= 12°	an angle, nearly.
" 1 "	"	"	0.26 n.a.	= 30°	" " "
" $\frac{1}{6}$ "	"	"	.94 n.a.	= 140°	" " "
" $\frac{1}{8}$ "	"	"	1.42 n.a.		

"The first two to be dry-working objectives, without cover-correction; the third to be dry-working, with cover-correction; and the fourth to be a homogeneous immersion objective, with cover-correction; and all to be of the highest possible grade of workmanship. The stand should have a tube of such length that standard distance of ten inches from the front surface of objective to diaphragm of eye-piece can be obtained on it, and to be furnished with six eye-pieces; viz., 2-inch, 1-inch, and $\frac{3}{4}$-inch Huyghenian, and $\frac{1}{2}$-inch, $\frac{1}{3}$-inch, and $\frac{1}{4}$-inch solid."

In the evening the annual *soirée* took place, in connection with the State microscopical society of Illinois, at the Calumet club-house. There were two hundred and fifty microscopes on the tables. A great variety of objects were shown to a party of five hundred guests of the club.

There were a number of reports and papers to be disposed of on Friday, the society adjourning at five P.M.

The first paper was by Dr. W. T. Belfield, on the detection of adulteration in lard. Photographs representing crystals of pure and adulterated lard were exhibited. Those of the former are long, thin plates, with beveled ends, while the crystals of tallow are plume-shaped, resembling somewhat an ostrich feather.

Dr. V. S. Clevinger presented a paper on the pathology of the brain.

Dr. Thomas Taylor's paper, on internal parasites in the domestic fowl, was read. The parasites referred to were a mite from the lungs, another mite in the cellular tissue, and an encysted nematoid from the crop.

A paper on the termination of the nerves in the kidneys was presented by M. L. Holbrook. The author's method may be stated thus: "The fresh kidneys, as well as those preserved in chromic-acid solutions, were frozen in the freezing-microtome of Dr. Taylor, and the sections allowed to remain in the gold solution for varying periods of time, from forty minutes to several days. When removed, they were carefully washed in distilled water, and placed in a strong formic acid of a specific gravity of a hundred and twenty degrees for from five to eight minutes, or in a twenty-five-per-cent solution of the same for hours and even days. Sometimes I obtained very good specimens by placing the sections first in a dilute twenty-five-per-cent solution of formic acid for twenty-four hours, and afterward staining them with chloride of gold until they reached the color desired. . . . The nerves supplying the kidneys are mainly of the non-medullated variety. They accompany the larger arteries of this organ, either in bundles, or in flat, expanded layers; and the latter features I found more common than the former. Sometimes an artery would be found encircled by a network of non-medullated nerves in a bewildering number. Hundreds of such nucleated bundles of fibres could be traced around, above, and below an artery, freely branching, bifurcating, and supplying all the neighboring formations with a large number of delicate fibrillae. . . . The bundles of nerve-fibres give off delicate ramules to the afferent vessels by which they enter the tuft; and here they produce a delicate plexus spun around its capillaries. It was impossible to decide where the ultimate fibrillae branch in the capillaries of the tuft. . . . Sometimes I obtained specimens in which it seemed as if the ultimate fibrillae branched beneath the covering, flat epithelia in the delicate connective tissue between the convolutions of the capillaries. . . . In perfect specimens there is no difficulty in satisfying one's self of the fact that every tubule is encircled by a plexus of non-medullated nerve-fibres, coursing either in the immediate vicinity of the tubule, in the interstitial connective tissue, or within the dense layer subjacent to the epithelia, known as the *membrana propria*, or even with the layer along the feet of the epithelia themselves."

Short papers were read by Dr. Salmon Hudson, on the yeast-plant; by J. M. Mansfield, on division of labor among microscopists; by Dr. L. M. Eastman, on egg-like bodies in the liver of the rabbit; by Dr. George E. Fell, on a peculiarity in the structure of the human spermatozoon. Dr. Lester Curtis made some observations on vessels of the spinal cord of the cat; and Dr. F. M. Hamlin, on mounting foraminifera. New apparatus was described as follows: new microscope-stand with concentric movements, by J. D. Cox; new modification of the Spitzka microtome, by V. S. Clevinger; and a new binocular arrangement, by Edward Bausch.

The next annual meeting will be held at Rochester, N.Y., in August, 1884.

The officers for the present year are: president, Hon. Jacob D. Cox; vice-presidents, William A. Rogers, T. J. Burrill; secretary, D. S. Kellicott; treasurer, George E. Fell; executive committee, Albert H. Chester, William Humphreys, and H. A. Johnson.

Heights in feet, Depths in fathoms

THE JAVA UPHEAVAL.[1]

The details which have reached us during the past week, of the terrible seismical manifestation at Java, prove it to be one of the most disastrous on record. Probably, moreover, it is the greatest phenomenon in physical geography which has occurred during at least the historical period, in the same space of time. The accompanying sketch-map will afford some idea of the extent and nature of the change which has taken place, and the character of the sea-bed and the land in the region affected.

The volcanic island of Krakatoa lies about the

[1] Taken from *Nature*, Sept. 6.

middle of the north part of the passage between Java and Sumatra, a passage which has formed an important commercial route. The strait is about seventy miles long and sixty broad at the south-west end, narrowing to thirteen miles at the north-east end. The island, seven miles long by five broad, lay about thirty miles from the coast of Java; and northwards the strait contracts like a funnel, the two coasts in that direction approaching very near to each other. A few weeks ago, as we intimated at the time, the volcano on the island began to manifest renewed activity. The whole region is volcanic; Java itself having at least sixteen active volcanoes, while many others can only be regarded as quiescent, not extinct. Various parts of the island have been frequently devastated by volcanic outbursts, one of the most disastrous of these having proceeded from a volcano which was regarded as having been long extinct. The present outburst in Krakatoa seems to have reached a crisis on the night of Aug. 26. The detonations were heard as far as Soeràkarta; and ashes fell at Cheribon, about 250 miles eastwards on the north coast of Java. The whole sky over western Java was darkened with ashes; and, when investigation became possible, it was found that the most wide-spread disaster had occurred. The greater part of the district of North Bantam has been destroyed, partly by the ashes which fell, and partly by an enormous wave generated by the wide-spread volcanic disturbance in the bed of the strait. The town of Anjer, and other towns on the coast, have been overwhelmed and swept away; and the loss of life is estimated at 100,000. The island of Krakatoa itself, estimated to contain 8,000,000,000 cubic yards of material, seems to have been shattered, and sunk beneath the waters; while sixteen volcanic craters have appeared above the sea between the site of that island and Sibisi Island, where the sea is comparatively shallow. The Soengepan volcano has split into five; and it is stated that an extensive plain of 'volcanic stone' has been formed in the sea, near Lampong, Sumatra, probably at a part of the coast dotted with small islands. A vessel near the site of the eruption had its deck covered with ashes eighteen inches deep, and passed masses of pumice-stone seven feet in depth. The wave reached the coast of Java on the morning of the 27th, and, thirty metres high, swept the coast between Merak and Tjiringin, totally destroying Anjer, Merak, and Tjiringin. Five miles of the coast of Sumatra seem to have been swept by the wave, and many lives lost. At Tanjong Priok, fifty-eight miles distant from Krakatoa, a sea seven feet and a half higher than the ordinary highest level suddenly rushed in, and overwhelmed the place. Immediately afterwards it as suddenly sank ten feet and a half below the high-water mark, the effect being most destructive. We shall probably hear more of this wave, as doubtless it was a branch of it which made its way across the Pacific, and that with such rapidity that on the 27th it reached San Francisco harbor, and continued to come in at intervals of twenty minutes, rising to a height of one foot for several days. The great wave generated on May 10, 1877, by the earthquake at Iquique, on the coast of Peru, spread over the Pacific as far north as the Sandwich Islands, and south to New Zealand and Australia; while that at Arica, on Aug. 13 and 14, 1869, extended right across the Pacific to Yokohama (*Nature*, vol. i. p. 54). It is misleading to speak of such waves as tidal: they are evidently due to powerful, extensive, and sudden disturbances of the ocean-bed, and are frequently felt in the Pacific when no earthquake has been experienced anywhere, though doubtless due to commotions somewhere in the depths of ocean. So far, these are all the facts that are known in connection with this last stupendous outburst of volcanic energy. It has altered the entire physical geography of the region, and the condition of the ocean-bed. The existing charts of the strait, with their careful soundings, are useless for purposes of navigation; and, when quiescence is restored, a new series of soundings will be necessary. Doubtless the results of the outbreak will receive minute attention at the hands of the Dutch government; and, when all the data are collected, they will form valuable material for the study of the physical geographer.

LETTERS TO THE EDITOR.

Humblebees vs. field-mice.

In SCIENCE of Sept. 7 the vice-president of section F (biology), in his address of Aug. 15, referring to the aid given by humblebees in fertilizing Trifolium pratense, is reported as saying, "Bumblebees prefer to raise their colonies in old nests of meadow-mice. I mentioned in my last report, that it had been suggested that we should not keep many cats, nor allow hawks, foxes, or dogs to catch these mice; for they make nests which are quite necessary for the bumblebees, which help fertilize our red clover, and thereby largely increase the yield of seed."

I would beg leave to differ from the author of the suggestion referred to, on the ground, that, if carried out, the effect produced would be apt to be quite the contrary of that intended. As field-mice prey upon the nests and combs of the humblebees, acting as a great check to their increase in numbers, the greater the precautions taken to prevent the killing of the mice, the greater would be the tendency towards the extermination of the humblebee, and therefore the less would be the yield of seed, resulting from the lack of aid rendered by these insects in fertilizing the red clover.

In support of my objection, I would refer to Darwin's Origin of species, sixth edition, third chapter, where, under the head of "Complex relations of all animals and plants to each other in the struggle for existence," he says, "The number of humblebees in any district depends in a great measure on the number of field-mice, which destroy their combs and nests; and Col. Newman, who has long attended to the habits of humblebees, believes that 'more than two-thirds of them are thus destroyed all over England.'" E. NUGENT.

Pottstown, Penn., Sept. 15, 1883.

The influence of winds upon tree-growth.

I observe that in the vicinity of Cambridge and Boston, wherever the common New-England elms stand in a moderately isolated site, and one exposed to the wind, they lean, in a large majority of cases, trunk and all, to the south-east. This is true, also, to a less extent, of maples; but the oak, ash, poplar, and pine stand sturdily erect. I believe the leaning of the elastic-fibred elms is due to the prevailing winds, which are from the west and north-west, these winds being also the strongest and coldest. At the office of the U. S. signal-service in Boston, observations are taken three times a day. In 1882, out of 1,095 observations taken, 298 showed the wind to be in the west, and 225 showed it to be in the north-west: in other words, about half (or forty-seven per cent) of the observations showed the wind to be somewhere between west and north-west. For the other five years the record is as follows: —

1877.	1878.	1879.	1880.	1881.
247 W.	229 W.	273 W.	301 W.	278 W.
169 N.W.	231 N.W.	257 N.W.	153 N.W.	175 N.W.

So much for the prevailing direction of the wind. There seems to be no other cause than this, to which we can assign the phenomenon of growth in question. All the many exceptions to the rule are to be explained, doubtless, by local causes, — shelter, neighborhood of other trees, and other more occult conditions of fibre. The works on forestry and botany seem not to notice the fact of asymmetry in tree-growth. It is only a repetition, on a larger scale, of the graceful deviation from monotonous symmetry which characterizes all leaf and branch structure.

W. S. KENNEDY.

Importance of lime-juice in the pemmican for arctic expeditions.

The recent failure to relieve the party under Lieut. A. W. Greely at Lady Franklin Bay leads us to recur to the repeated difficulties which have marked the history of former arctic expeditions. We have re-examined the accounts of the English expedition of the Alert and the Discovery, under Nares and Stephenson, which left England, May 29, 1875. It was the first English arctic expedition which had orders to endeavor to reach the North Pole. It had the advantage of the advice of experienced arctic navigators, its commander Nares having been a member of several such expeditions.

Thus it surprises the reader, that more thorough precautions were not made against the scurvy. The *London quarterly review* for January, 1877, has the fullest account of the ravages committed by that disease with the sledge-parties sent out by Nares. Of the sledge-party under Commander Parr it says,—

"Of seventeen of the finest men of the navy, who composed the original party, but five were (on return) able to walk alongside. One was dead, and the remainder in the last extremity of illness."

It gives a minute account of the prostration by scurvy of the two other sledge-parties, — one under Commander Beaumont, and one under Commander Aldrich. Concerning the latter, the *Review* says, —

"To quote from the journal of Commander Aldrich, who led the western division, would be to repeat the same dreadful details. The party broke down, and were supported by the same pluck, and brought back alive — that is all one can say — by the help of God and the same determined courage. Surely, nothing finer was ever recorded than this advance of three sledges, — one to the north, another to the east, a third to the west, — laden down with sick and dying men, in obedience to an order to do their best, each in their separate direction. It is the old story, — too common in English annals, — the organization broke down, and individual heroism stepped in to save the honor of the day. But at what a cost!"

All this was because the parties had no lime-juice. And Capt. Nares, "with a chivalry and candor which do him honor, whether he has failed in judgment or not, declared that such was the fact, and that the omission was made by his orders and on his responsibility." He said, —

"Acting on my lights and experience at the time, I followed the example of such men as M'Clintock, Richards, Mechan, and McClure, of the Investigator, and started off our sledges with as nearly as possible the same rations as had proved fairly successful on all previous occasions; that is, without lime-juice for issue as a ration, a small quantity for use as a medicine being carried by the sledges, which were not expected to be able to obtain game. . . . Up to the middle of May the lime-juice remains as solid as a rock. No sledge-party employed in the arctic regions in the cold month of April has ever been able to issue a regular ration of lime-juice. In addition to the extra weight to be dragged, that its carriage would entail, there is the even more serious consideration of the time necessary in order to melt sufficient snow."

He added, —

"Of course, hereafter, lime-juice in some shape or other must be carried in all sledging journeys; and we earnestly *trust that some means will be found to make it in a lozenge*, for, as a fluid, there is, and will always be, extreme difficulty in using it in cold weather, unless arctic travelling is considerably curtailed."

The *Quarterly review*, in quoting these manly remarks of Capt. Nares at Guildhall, says, —

"Even if it should be found that Sir George failed in judgment in this matter, he has in our opinion shown the finer form of fitness for command, in his readiness to assume the responsibility of his acts."

His frankness and manliness in assuming the whole blame to himself have evidently, in great measure, disarmed criticism.

But this brings us to the main object in this letter; and that is, to recur to the remedies which this story has suggested. If lozenges of lime-juice in a shape for arctic exploration have not been manufactured, they certainly can at least now be found at the druggists in a shape to be used as troches for colds.

But the efficient remedy is to have pemmican made which is permeated with lime-juice, as recommended in the 'Report of the surgeon-general of the navy for 1880' (see p. 356). Gen. P. S. Wales said, —

"The indispensable necessity of lime-juice in the sledging-parties, and the difficulties of carrying it, and preparing it for use, induced me to suggest the propriety of combining the juice and pemmican in the proportion of one ounce to the pound of the latter. The pemmican is greatly improved in taste and flavor, and will, I believe, be more assimilable. This is an important modification, as there are persons who cannot eat the ordinary article."

The article was prepared as proposed, and tried in Washington, and pronounced to be very palatable.

Gen. George H. Thomas, in preparing for one of his battles, issued a general order, enjoining upon his whole army strict attention to minutiae, saying that "the loss of a battle might be due to one missing linchpin."

In recurring to this recommendation from the office of the surgeon-general of the navy, we have thought that it may be considered opportune, when the minds of many are now turned upon the arctic expeditions. We think that recommendation was followed, so far as the preparations of the Jeannette and the Rodgers were concerned; but, alas! they never got so far as to turn their attention to fitting out explorations with sledge-parties.

BENJAMIN ALVORD.

Rensselaeria from the Hamilton group of Pennsylvania.

Will you kindly afford me a small space to correct an error in your report of the discussion which followed the reading of my paper at Minneapolis? On p. 327 of your issue for Sept. 7 occur the following sentences: —

"The differences between them [the fossils exhibited and the Oriskany species of Rensselaeria] were slight, though well marked. Professor Hall described some of these differences, and Mr. Claypole acknowledged that a certain V-shaped groove was wanting in his specimens. Professor Hall thought that possibly the fossils should be referred to Amphigenia, which had many similarities to Rensselaeria."

The V-shaped groove in question is one of the generic marks of Amphigenia; and its absence, therefore, was urged by me as excluding the fossils from that genus, and inferentially as a strong argument in favor of placing them in Rensselaeria.

As the above-mentioned error places me (and I think Professor Hall also) in false positions, and involves a grave mistake in paleontology, I am induced to ask your insertion of this correction, which I have submitted to Professor Hall for his approval.

I ought to add that the suggestion of Amphigenia by Professor Hall was only the result of a momentary impression on the first sight of the fossil, and one which he immediately withdrew, on observing the absence of the V-shaped groove above alluded to.

E. W. Claypole.

Aurora.

The auroral display here to-night was unusually brilliant. I observed it first at 7.04 p.m. At this time a low but rather brilliant arch of light spanned the north-eastern horizon, the crest of the arch having an altitude of about 20°. During the next three minutes, the lights rapidly took on the 'streamer' form, gradually shooting upward to a little beyond the zenith, and at this time stretching from east, 10° south, around to west, 15° north, on the horizon. During about two minutes, the waving-curtain aspect was very pronounced in the north-east, after which only striated patches flamed out here and there, moving alternately west and east. These patches all converged toward the zenith, but left with one the impression of being pendulous and very near. The atmosphere appeared very clear, the moon full and bright, the twilight still strong; and there was light enough yet to enable one to read a newspaper, but with difficulty. The streamers, however, lay in sharp contrast against the blue sky, even where the twilight was strongest.

At 7.15 the lights began to die rapidly away, and at 7.50 none were to be seen; but at 8, and again at 8.13, there were distinct but small curtains to be seen in the north-west. At 8.20 there began a magnificent display. Three large curtains formed one above the other, the lowest about 20° above the horizon in the north-west. They drifted gently toward the zenith, swaying and folding just enough, it seemed, to suit the almost imperceptible breeze which was stirring. The lights could be easily seen within 7° of the moon; and yet it cast its shadow on the carpet in a room 13 by 14, where two kerosene-lamps were burning, one of them a no. 1, and the other a no. 2, burner. At 9.10 scarcely a trace of the aurora could be seen. A little later, a very faint diffuse light covered the northern sky to an altitude of about 25°. This soon became striped, and afterwards appeared to move bodily toward the zenith. At 10.20 the lower sky had become a deep blue; and just above it, at an altitude of 30°, a broad arch of bright but uniform light formed across the sky; and above this, extending past the zenith, were similar but much fainter bands. Five minutes later, the bright band unfolded a curtain which dropped in exquisite folds toward the horizon. This lasted less than two minutes, the whole belt of light becoming striated, but leaving a clear space next to the horizon; then followed about five minutes during which the illuminated portion of the sky seemed to be throbbing, and sending out waves of subdued light, which spread southward over the blue vault, dying away before the zenith was reached. This movement soon became more violent; and between 10.40 and 10.45 the lights had more the appearance of flames bursting rapidly from the sky, and spreading to the zenith, where they often turned abruptly toward each other, and met. This appearance continued growing gradually less marked until 12.15 a.m., when there was scarcely a trace of auroral display. At 12.40 a faint arch of diffuse light could be seen in the north, like that already described.

River Falls, Wis., Sept. 16, 1883.

THOMPSON'S PHILIPP REIS.

Philipp Reis: inventor of the telephone. A biographical sketch, with documentary testimony, translations of the original papers of the inventor, and contemporary publications. By Sylvanus P. Thompson, B.A., D.Sc., professor of experimental physics in University college, Bristol. London, *E. & F. N. Spon*, 1883. 9+182 p., 3 pl. 16°.

The rapid development of the literature of the telephone, and the wide-spread interest in matters relating to it, have rendered the most important details of its history familiar to the general reading public, as well as to the scientific world. The account of the life and labors of Philipp Reis, by Prof. S. P. Thompson, while repeating many of these well-known details, contains some interesting notices of the life and personal characteristics of the inventor, and of the various steps by which he brought his instruments to their final stage. Following the brief biographical sketch, are descriptions of the various forms of apparatus devised by Reis, with numerous illustrations; a statement of what the author terms the inventor's claim; copies of Reis's own publications respecting his invention, and of certain contemporary accounts of it and its operation; with the testimony of persons who witnessed his experiments. An appendix discusses the variable resistance of imperfect contacts, a comparison of Reis's receiver with later instruments, the doctrine of undulatory currents, with some additional notes and references relating to Reis's invention.

Had the efforts of the author been directed to the presentation of these things as matters of history merely, the book might be regarded as a valuable and interesting summary of facts relating to an important invention, and would demand but a brief notice here; but a cursory examination of it is sufficient to show that the author has failed to maintain that judicial attitude of mind which is indispensable to the just and impartial record of historic verities. His book is throughout a labored special pleading, with the attempt to prove that Reis's invention not only anticipated, but actually embodied, the essential features of the present telephonic apparatus. Space will not permit the consideration of all the points which might be criticised, nor is it necessary. A few of the most important are sufficient to illustrate the spirit which pervades the work, and to show how the facts of history are perverted in the endeavor to maintain a false and illogical position.

It has been generally accepted as true, that Reis designed his transmitter to act as a contact-breaker, which should open and close the circuit once for each vibration produced by the sound to be transmitted. The support for this view is found not only in the repeated statements of Reis himself, but also in the construction of the apparatus. Reis says, in his own description of his transmitter (p. 56), "each sound-wave effects an opening and a closing of the current;" and again, in his letter to Mr. Ladd (p. 84), "If a person sing at the station A, in the tube (x) the vibrations of air will pass into the box and move the membrane above; thereby the platina foot (c) of the movable angle will be lifted up and will thus open the stream at every condensation of air in the box. The stream will be re-established at every rarefaction. For this manner the steel axis at station B will be magnetic once for every full vibration."

With these and other most distinct statements of Reis, as to the intention and action of his apparatus, before him, Professor Thompson, nevertheless, asserts that it was never designed to break the circuit. Thus, on p. 14 he says, "Theoretically, the last was no more perfect than the first, and they all embody the same fundamental idea: they only differ in the mechanical means of carrying out to a greater or less degree of perfection the one common principle of imitating the mechanism of the human ear, and applying that mechanism to affect or control a current of electricity by varying the degree of contact at a loose joint in the circuit." And again (p. 132), "Now this operation of varying the degree of pressure in order to vary the resistance of the interruptor or contact-regulator, was distinctly contemplated by Reis." Further, the author maintains that the combination of an adjusting-screw with a spring shows that Reis intended the platinum contact-piece to have a following motion, so as to make a contact with varying pressure. He says on p. 133, "By employing these following-springs, he introduced, in fact the element of *elasticity* into his interruptor; and clearly he introduced it for the very purpose of avoiding abrupt breaking of the contact." If we examine the illustrations of the different forms of the transmitting apparatus, we shall see that this device was employed for a very different purpose. In the earliest form, represented in fig. 1, the screw presses the spring *away* from the membrane, and, when the latter recedes in its vibration, the spring carrying the platinum point is prevented by the screw from following it, — an arrangement that tends to prevent, and was designed to prevent, a following contact, and insures a breaking of the circuit when the distance of the point is properly adjusted. The same is the case with the form of transmitter illustrated in fig. 2. In the form represented in fig. 3, the screw is present, and works against a spring; but the screw passes through a stout and firm piece of metal, and presses the spring which carries the contact-piece forward, that is, toward the membrane, thus giving it a rigid support. The spring serves merely to push back the contact-piece when the screw is reversed, a very simple and common mechanical device for giving motion in opposition to the thrust of a screw. In the lever form, seen in figs. 4 and 5, the

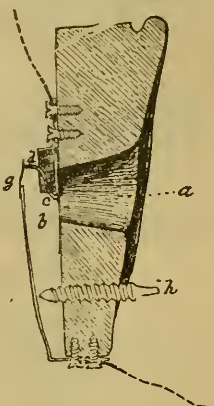

FIG. 1.

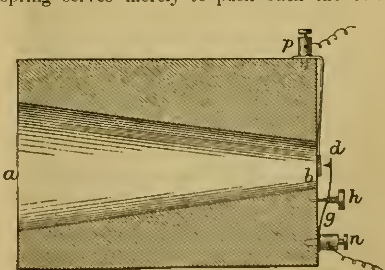

FIG. 2.

screw is arranged in a similar manner, so as to regulate the distance of the contact-piece from the end of the lever most remote from the membrane. In all these instruments the screw acting upon the spring is expressly contrived to facilitate such an adjustment as will insure

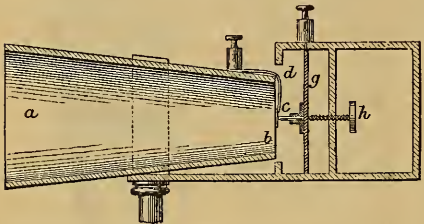

Fig. 3.

the breaking of contact under the impact of the sound-waves. Its function is related to the tension and elasticity of the membrane, to make a pressure so light in any case, that the vibrations should be able, without fail, to separate the contact-pieces.

To say, as Professor Thompson repeatedly does, that Reis employed his mechanism with the express intention of producing a variable current by the change of contact-resistance, and that he consciously and purposely utilized this principle, — at that time hardly recognized anywhere, and of which the practical application was not discovered till several years later, — is a gross misrepresentation, and an utter perversion of the facts. Reis did not know, and could not know, that the strength of a current could be controlled by the varying pressure of the conducting-surfaces between which it passes. Nowhere in his writings, — whether in his description of the instruments, or in the prospectus issued with them, or in his letter to Mr. Ladd, — nor in the article of Professor Böttger and the report of Von Legat, is there the remotest suggestion that the transmitter acted, or was intended to act, otherwise than by breaking the circuit. Nor is any thing of the kind to be found in any of the publications of the day, relating to this matter. With the knowledge which we now possess, of the varying resistance of pressure-contacts, it is indeed easy, by a slight modification, to cause the contact-pieces to vary the current by change of pressure, and thus reproduce the vibration-form with approximate accuracy. But to do this, it is necessary to prevent them from separating so as to break contact and interrupt the current. Such a modification, however slight it may be, totally changes the function of the contact-pieces, and amounts to a radical transformation of the apparatus. It is the very thing Reis studiously sought to prevent.

That Reis speaks of the form of acoustical vibrations, and their graphical representation by a curve, is no proof that he supposed his transmitter to act otherwise than by breaking the circuit. Yet Professor Thompson says (p. 165), "It is certain that Reis did not in any of his writings explicitly name an undulatory current: but it is equally certain that, whether he mentioned it or not, he both used one and intended to use one." Reis nowhere claims that his apparatus realized the normal vibration-form, even in the case of a simple tone; and there is no evidence in all his writings to show that he had ever considered the motions at the receiver to be the same as those of the original sound, except so far as there was a correspondence in period or rate of these motions with those at the transmitter. The idea of causing the motions in the receiver to have the same vibration-form as those in the transmitter originated with Bell, as did the method of securing this correspondence, which is indispensable to the reproduction of spoken words, by the use of an undulatory current. Says Sir William Thomson (*Tel. journ. and electr. rev.*, v. 293), "Mr. Graham Bell conceived the idea — the wholly novel and original idea — of giving continuity to the shocks, and of producing currents which would be in simple proportion to the motion of the air pro-

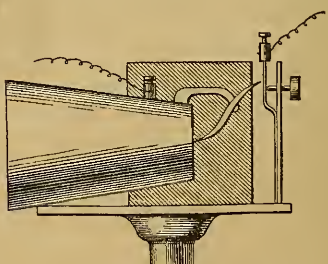

Fig. 4.

duced by the voice, and of reproducing that effect at the remote end of a telegraphic wire." The author of this book will scarcely have the hardihood to assert that his illustrious countryman, one of the greatest masters in electrical science, uttered these words in ignorance of a thing so well known as Reis's telephone.

As a further support to his position, the author lays great stress upon the statement that Reis's apparatus could and did transmit spoken words so as to be understood. As to the fact of speech having been transmitted occasionally, it is doubtless true that some words were recognized, but imperfectly, and with difficulty; and it is true, also, that when imperfectly meeting the conditions set upon it by the inventor, the apparatus, when applied to transmit spoken words, will, with skilful handling, sometimes 'deviate into sense' so far, that an occasional word or short phrase can be made out with effort, by attentive listening with the ear close to it. Professor Böttger, who took an enthusiastic interest in the matter, says that the operators could communicate words with each other, but adds, 'only such, however, as they had already heard frequently.' Of the other experimenters and witnesses whose testimony is given in the book, some were able to understand portions of what was said; others failed. Every one familiar with telephonic experiments knows how easy it is to recognize these familiar phrases by the mere intonation, and how different this is from understanding words not previously known. Is it any thing surprising, that the words of a familiar song should appear to be recognized when the air is heard? Granted that the spoken words were sometimes reproduced so as to be understood, it must also be admitted that the apparatus accomplished this so imperfectly as to be of no practical value. To make it practically efficient required a modification that was in itself a radical change and a distinct invention. That this was also Reis's opinion, will be seen from the extracts given in a subsequent paragraph.

There is good evidence, in the later writings and advertisements of Reis, that he had come to the conclusion that the faithful reproduction of the complex motions which occur in articulate speech was impossible, and that he had silently abandoned the idea of reproducing speech. A further proof of this is found in the addition of the telegraphic signal-apparatus to the later forms of the instrument, to enable the experimenters to communicate with each other. Professor Thompson's argument that the Morse signal-apparatus, if intended for verbal communication, should have been reversed, meets the facts but half way; for the complete telephonic installation required a transmitter and a receiver at each end of the wire, so that the Morse signals could be sent in either direction with the same facility as the telephonic. Moreover, as if to prevent any possible question as to its use, Reis himself expressly says that the Morse apparatus is for the purpose of enabling the operators to com-

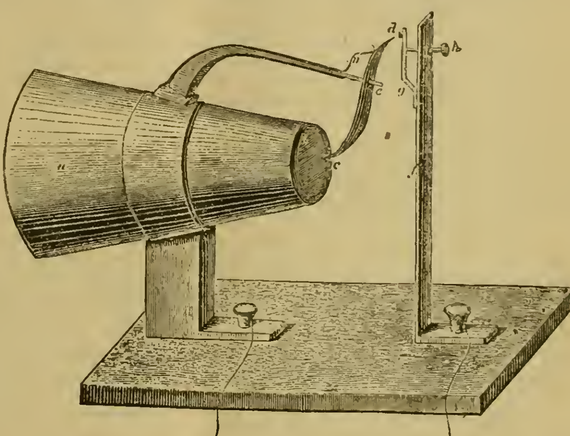

Fig. 5.

municate with each other; and, in the prospectus issued with the instruments, he describes a special alphabet, which he had devised to enable words to be spelled out. If these could be transmitted telephonically, why take this unnecessary trouble? This very provision is a most emphatic testimony that Reis, at this time, had become convinced that the apparatus as a transmitter of speech was a failure, and that, his original idea having proved impracticable, he had contented himself with sending musical tones.

In respect to this point, the letter of Reis, written by himself in English to Mr. Ladd, and given at p. 81, is most significant. He says, "Tunes and sounds of any kind are only brought to our conception by the condensations and rarefactions of air or any other medium in which we may find ourselves." And again, on p. 82, "these were the principles wich (*sic*) guided me in my invention. They were sufficient to induce me to try the reproduction of tunes at any distance." And again, on the same page, "The apparatus consists of two separated parts; one for the singing-station A, and the other for the hearing-station B." Also in the same letter, p. 84, "If a person sing at the station A, in the tube (x) the vibrations will pass into the box and move the membrane above." Respecting the word 'tunes,' used by Reis, the author remarks, in a foot-note to p. 81, "This word, as the context and ending of the paragraph shows, should have been written *tones*. The letter, written in English by Reis himself, is wonderfully free from inaccuracies of composition; the slip here noted being a most pardonable one since the plural of the German *ton* is *tönen*, the very pronunciation of which would account for the confusion in the mind of one unaccustomed to write in English." The resemblance of *tönen* to *tunes* is not so remarkably close that it would be likely to mislead one whose knowledge of English is such as Reis shows himself in this letter to possess. The author does not attempt the explanation of the words 'singing' and 'sing' in the same letter. It is surprising that he should have allowed these words to pass unnoticed, for it was vital to his argument to prove that Reis mistook them for 'speaking' and 'speak.' The resemblance is about as close as in the other case, but in neither is the explanation likely to be admitted by the unprejudiced reader.

In taking himself back to the time of Reis's telephone, the author has failed to identify himself with the conditions of that time, and to leave behind him the subsequent acquisitions of science. He makes statements and claims which could only find their justification in a world very differently furnished with facts from this one. As an illustration of the mental disposition resulting from this, the following sentence from the author's preface may serve: "The testimony now adduced as to the aim of Philipp Reis's invention, and the measure of success which he himself attained, is such, in the author's opinion, and in the opinion, he trusts, of all right-thinking persons, to place beyond cavil the rightfulness of the claim which Reis himself put forward of being the inventor of the Telephone." But did any one ever dispute this claim during his life? and has the author forgotten that no possible basis for a rival claim existed until more than two years after Reis's death? — unless we except the suggestions of Bourseul, in 1854, which, while they certainly did anticipate the general idea of Reis's invention, were never carried to the stage of experiment, and were never set up in opposition to him, unless it has been done recently. The author can hardly have been ignorant of these suggestions; but, if not, he has carefully refrained from mentioning them. Reis never claimed that no new principle could ever be discovered which would enable the ends he sought to be attained in a different way, and more perfectly. His first article upon the subject ends with these words: "There may probably remain much more yet to be done for the utilization of the telephone in practice. For physics, however, it has already sufficient interest in that it has opened out a new field of labor." And Von Legat closes his report with this remark: "There remains no doubt, that, before expecting a practical utilization with serviceable results, that which has been spoken of will require still considerable improvement, and, in particular, mechanical science must complete the apparatus to be used."

The chief aim of the book is clearly this, — to endeavor, in direct opposition to the facts, to establish the untenable proposition that the Reis transmitter was designedly contrived by him to vary the contact-resistance by pressure, giving it a microphonic action, failure to accomplish which is fatal to its success in conveying spoken words. Professor Thompson has not always been of this opinion, and in another place he has given a correct account of the relation of Reis's invention to that of Bell. In his 'Elementary lessons in electricity and magnetism,' published in 1881, we find, on pp. 405 and 406, these words, — "The first attempt to transmit sounds electrically was made in 1852 [misprint for 1862] by Reis, who succeeded in conveying musical tones by an imperfect telephone. The transmitting part of Reis's telephone consisted of a battery and a contact-breaker, the latter being formed of a stretched membrane, capable of taking up sonorous vibrations, and having attached to it a thin strip of platinum, which, as it vibrated, beat to and fro against the tip of a platinum wire, so making and breaking contact. . . . Reis also transmitted speech with this instrument, but very imperfectly, for the tones of speech cannot be transmitted by abrupt interruptions of the current. . . . In 1876 Graham Bell invented the articulating telephone. In this instrument the speaker talks to an elastic disk of thin sheet-iron, which vibrates, and transmits its every movement electrically to a similar disk in a similar telephone at a distant station, causing it to vibrate in an identical manner, and therefore to emit identical sounds." Here we have Reis spoken of as inventing '*an* imperfect telephone,' while Bell invented '*the* articulating telephone.' Reis's instrument was a 'contact-breaker,' and conveyed 'musical tones.' Reis's instrument transmitted speech 'very imperfectly,' and there is not the slightest suggestion of microphonic action in the transmitter. Yet two years later we have statements diametrically opposed to these.

The least that can be said of such varying and contradictory evidence is, that it totally destroys the credibility of the witness, and nullifies his claim to be accepted as a scientific authority, unless good reason is shown for the different opinion. The documents quoted in the book give no substantial reason for this change of ground, as they add very little of any importance to what was already generally known. The motive for the later opinions may be more intelligibly traced in the following items, which will be found in the *Telegraphic journal and electrical review*, vol. xii. p. 72, Jan., 1883, and p. 317, April 14, 1883, in the list of English patents: — "2578. Telephonic instruments. Sylvanus P. Thompson. Dated May 31. 6d. This invention relates to telephonic instruments, and chiefly to improvements in receivers of a well-known form or type, invented by Phillip Reis." "3803. Improvements in telephonic apparatus. Sylvanus P. Thompson. Dated August 9. 6d. Relates to telephonic transmitters based upon the principle discovered by Philipp Reis in 1861, namely that of employing current-regulators actuated, either directly or indirectly, by the sound-waves produced by the voice. By the term 'current-regulator,' the inventor means a device similar to that employed by Reis, wherein a loose contact between two parts of a circuit (in which are included a battery and a telephonic receiver) offers greater or less resistance to the flow of the electric current, the degree of intimacy of contact between the conducting-pieces being altered by the vibrations of the voice."

For a contrast of colors, we may put side by side with these sentences the following, from the preface to the book now under consideration: "To set forth the history of this long-neglected inventor and of his instrument, and to establish upon its own merits, without special pleading, and without partiality, the nature of that much-misunderstood and much-abused invention, has been the aim of the writer. . . . He has nothing to gain by making Reis's invention appear either better or worse than it really was."

Further comment upon the value of such testimony as is contained in this book is superfluous. What Reis accomplished, and what he failed to do, are now familiar matters of history. His well-earned fame can only suffer from such misstatement of facts, and the unjust exaggeration of his actual achievements.

OBLIGATIONS OF MATHEMATICS TO PHILOSOPHY, AND TO QUESTIONS OF COMMON LIFE.[1] — I.

Since our last meeting, we have been deprived of three of our most distinguished members. The loss by the death of Professor Henry John Stephen Smith is a very grievous one to those who knew and admired and loved him, to his university, and to mathematical science, which he cultivated with such ardor and success. I need hardly recall that the branch of mathematics to which he had specially devoted himself was that most interesting and difficult one, the theory of numbers. The immense range of this subject, connected with and ramifying into so many others, is nowhere so well seen as in the series of reports on the progress thereof, brought up, unfortunately, only to the year 1865, contributed by him to the reports of the association; but it will still better appear, when to these are united (as will be done in the collected works in course of publication by the Clarendon Press) his other mathematical writings, many of them containing his own further developments of theories referred to in the reports. There have been recently or are being published many such collected editions, — Abel, Cauchy, Clifford, Gauss, Green, Jacobi, Lagrange, Maxwell, Riemann, Steiner. Among these, the works of Henry Smith will occupy a worthy position.

More recently, Gen. Sir Edward Sabine, K.C.B., for twenty-one years general secretary of the association, and a trustee, president of the meeting at Belfast in the year 1852, and for many years treasurer, and afterwards president of the Royal society, has been taken from us at an age exceeding the ordinary age of man. Born October, 1788, he entered the Royal artillery in 1803, and commanded batteries at the siege of Fort Erie in 1814; made magnetic and other observations in Ross and Parry's north-polar exploration in 1818–19, and in a series of other voyages. He contributed to the association reports on magnetic forces in 1836, 1837, and 1838, and about forty papers to the *Philosophical transactions;* originated the system of magnetic observatories, and otherwise signally promoted the science of terrestrial magnetism.

There is yet a very great loss, — another late presi-

[1] Inaugural address by Arthur Cayley, M.A., D.C.L., LL.D., F.R.S., Sadlerian professor of pure mathematics in the University of Cambridge, president of the British association for the advancement of science, for the Southport meeting. From advance proofs kindly furnished by the editors of *Nature.*

dent and trustee of the association; one who has done for it so much, and has so often attended the meetings; whose presence among us at this meeting we might have hoped for, — the president of the Royal society, William Spottiswoode. It is unnecessary to say any thing of his various merits. The place of his burial, the crowd of sorrowing friends who were present in the Abbey, bear witness to the esteem in which he was held.

I take the opportunity of mentioning the completion of a work promoted by the association, — the determination, by Mr. James Glaisher, of the least factors of the missing three out of the first nine million numbers. The volume containing the sixth million is now published.

I wish to speak to you to-night upon mathematics. I am quite aware of the difficulty arising from the abstract nature of my subject; and if, as I fear, many or some of you, recalling the presidential addresses at former meetings, — for instance, the *résumé* and survey which we had at York of the progress, during the half-century of the lifetime of the association, of a whole circle of sciences (biology, paleontology, geology, astronomy, chemistry) so much more familiar to you, and in which there was so much to tell of the fairy-tales of science; or, at Southampton, the discourse of my friend, who has in such kind terms introduced me to you, on the wondrous practical applications of science to electric lighting, telegraphy, the St. Gothard Tunnel and the Suez Canal, gun-cotton, and a host of other purposes, and with the grand concluding speculation on the conservation of solar energy: — if, I say, recalling these or any earlier addresses, you should wish that you were now about to have, from a different president, a discourse on a different subject, I can very well sympathize with you in the feeling.

But, be this as it may, I think it is more respectful to you that I should speak to you upon, and do my best to interest you in, the subject which has occupied me, and in which I am myself most interested. And, in another point of view, I think it is right that the address of a president should be on his own subject, and that different subjects should be thus brought in turn before the meetings. So much the worse, it may be, for a particular meeting; but the meeting is the individual, which, on evolution principles, must be sacrificed for the development of the race.

Mathematics connect themselves, on the one side, with common life and the physical sciences; on the other side, with philosophy in regard to our notions of space and time, and in the questions which have arisen as to the universality and necessity of the truths of mathematics, and the foundation of our knowledge of them. I would remark here, that the connection (if it exists) of arithmetic and algebra with the notion of time is far less obvious than that of geometry with the notion of space.

As to the former side: I am not making before you a defence of mathematics; but, if I were, I should desire to do it in such manner as in the 'Republic' Socrates was required to defend justice, — quite irrespectively of the worldly advantages which may accompany a life of virtue and justice, — and to show, that, independently of all these, justice was a thing desirable in itself and for its own sake, *not* by speaking to you of the utility of mathematics in any of the questions of common life or of physical science. Still less would I speak of this utility before, I trust, a friendly audience, interested or willing to appreciate an interest in mathematics in itself and for its own sake. I would, on the contrary, rather consider the obligations of mathematics to these different subjects as the sources of mathematical theories, now as remote from them, and in as different a region of thought, — for instance, geometry from the measurement of land, or the theory of numbers from arithmetic, — as a river at its mouth is from its mountain source.

On the other side: the general opinion has been, and is, that it is indeed by experience that we arrive at the truths of mathematics, but that experience is not their proper foundation. The mind itself contributes something. This is involved in the Platonic theory of reminiscence. Looking at two things — trees or stones or any thing else — which seem to us more or less equal, we arrive at the idea of equality; but we must have had this idea of equality before the time when, first seeingt he two things, we were led to regard them as coming up more or less perfectly to this idea of equality; and the like as regards our idea of the beautiful, and in other cases.

The same view is expressed in the answer of Leibnitz, the '*nisi intellectus ipse*,' to the scholastic dictum, '*Nihil in intellectu quod non prius in sensu*' ('There is nothing in the intellect which was not first in sensation' — 'except [said Leibnitz] the intellect itself'). And so again, in the 'Critick of pure reason,' Kant's view is, that while there is no doubt but that all our cognition begins with experience, we are nevertheless in possession of cognitions *a priori*, independent, not of this or that experience, but absolutely so of all experience, and in particular that the axioms of mathematics furnish an example of such cognitions *a priori*. Kant holds, further, that space is no empirical conception which has been derived from external experiences, but that, in order that sensations may be referred to something external, the representation of space must already lie at the foundation, and that the external experience is itself first only possible by this representation of space. And, in like manner, time is no empirical conception which can be deduced from an experience, but it is a necessary representation lying at the foundation of all intuitions.

And so in regard to mathematics, Sir W. R. Hamilton, in an introductory lecture on astronomy (1836), observes, "These purely mathematical sciences of algebra and geometry are sciences of the pure reason, deriving no weight and no assistance from experiment, and isolated, or at least isolable, from all outward and accidental phenomena. The idea of order, with its subordinate ideas of number and figure, we must not, indeed, call innate ideas, if that phrase be defined to imply that all men must possess them with equal clearness and fulness: they are, however, ideas which seem to be so far born with us that the possession of them in any conceivable degree is only the development of our original powers, the unfolding of our proper humanity."

The general question of the ideas of space and time, the axioms and definitions of geometry, the axioms relating to number, and the nature of mathematical reasoning, are fully and ably discussed in Whewell's "Philosophy of the inductive sciences" (1840), which may be regarded as containing an exposition of the whole theory.

But it is maintained by John Stuart Mill that the truths of mathematics, in particular those of geometry, rest on experience; and, as regards geometry, the same view is on very different grounds maintained by the mathematician Riemann.

It is not so easy as at first sight it appears, to make out how far the views taken by Mill in his 'System of logic ratiocinative and inductive' (ninth edition, 1879) are absolutely contradictory to those which have been spoken of. They profess to be so. There are most definite assertions (supported by argument): for instance, p. 263, "It remains to inquire what is the ground of our belief in axioms, what is the evidence on which they rest. I answer, they are experimental truths, generalizations from experience. The proposition 'Two straight lines cannot enclose a space,' or, in other words, two straight lines which have once met cannot meet again, is an induction from the evidence of our senses." But I cannot help considering a previous argument (p. 259) as very materially modifying this absolute contradiction. After inquiring, "Why are mathematics by almost all philosophers . . . considered to be independent of the evidence of experience and observation, and characterized as systems of necessary truth?" Mill proceeds (I quote the whole passage) as follows: "The answer I conceive to be, that this character of necessity ascribed to the truths of mathematics, and even (with some reservations to be hereafter made) the peculiar certainty ascribed to them, is a delusion, in order to sustain which it is necessary to suppose that those truths relate to and express the properties of purely imaginary objects. It is acknowledged that the conclusions of geometry are derived, partly at least, from the so-called definitions, and that these definitions are assumed to be correct representations, as far as they go, of the objects with which geometry is conversant. Now, we have pointed out, that, from a definition as such, no proposition, unless it be one concerning the meaning of a word, can ever follow, and that what apparently follows from a definition follows in reality from an implied assumption that there exists a real thing conformable thereto. This assumption, in the case of the definitions of geometry, is not strictly true. There exist no real things exactly conformable to the definitions. There exist no real points without magnitude, no lines without breadth, nor perfectly straight, no circles with all their radii exactly equal, nor squares with all their angles perfectly right. It will be said that the assumption does not extend to the actual, but only to the possible, existence of such things. I answer, that, according to every test we have of possibility, they are not even possible. Their existence, so far as we can form any judgment, would seem to be inconsistent with the physical constitution of our planet at least, if not of the universal [*sic*]. To get rid of this difficulty, and at the same time to save the credit of the supposed system of necessary truths, it is customary to say that the points, lines, circles, and squares which are the subjects of geometry exist in our conceptions merely, and are parts of our minds; which minds, by working on their own materials, construct an *a priori* science, the evidence of which is purely mental, and has nothing to do with outward experience. By howsoever high authority this doctrine has been sanctioned, it appears to me psychologically incorrect. The points, lines, and squares which any one has in his mind are (as I apprehend) simply copies of the points, lines, and squares, which he has known in his experience. Our idea of a point I apprehend to be simply our idea of the *minimum visibile*, the small portion of surface which we can see. We can reason about a line as if it had no breadth, because we have a power which we can exercise over the operations of our minds, — the power, when a perception is present to our senses, or a conception to our intellects, of *attending* to a part only of that perception or conception, instead of the whole. But we cannot *conceive* a line without breadth; we can form no mental picture of such a line: all the lines which we have in our mind are lines possessing breadth. If any one doubt this, we may refer him to his own experience. I much question if any one who fancies that he can conceive of a mathematical line thinks so from the evidence of his own consciousness. I suspect it is rather because he supposes, that, unless such a perception be possible, mathematics could not exist as a science, — a supposition which there will be no difficulty in showing to be groundless."

I think it may be at once conceded that the truths of geometry are truths precisely because they relate to and express the properties of what Mill calls 'purely imaginary objects.' That these objects do not exist in Mill's sense, that they do not exist in nature, may also be granted. That they are 'not even possible,' if this means not possible in an existing nature, may also be granted. That we cannot 'conceive' them depends on the meaning which we attach to the word 'conceive.' I would myself say that the purely imaginary objects are the only realities, the ὄντως ὄντα, in regard to which the corresponding physical objects are as the shadows in the cave; and it is only by means of them that we are able to deny the existence of a corresponding physical object. If there is no conception of straightness, then it is meaningless to deny the existence of a perfectly straight line.

But, at any rate, the objects of geometrical truth are the so-called imaginary objects of Mill; and the truths of geometry are only true, and *a fortiori* are only necessarily true, in regard to these so-called imaginary objects. And these objects, points, lines, circles, etc., in the mathematical sense of the terms, have a likeness to, and are represented more or less imperfectly, — and, from a geometer's point of view, no matter how imperfectly, — by corresponding physical points, lines, circles, etc. I shall have to return to geometry, and will then speak of Riemann; but I will first refer to another passage of the 'Logic.'

Speaking of the truths of arithmetic, Mill says (p. 297) that even here there is one hypothetical element: "In all propositions concerning numbers, a condition is implied without which none of them would be true; and that condition is an assumption which may be false. The condition is, that 1=1; that all the numbers are numbers of the same or of equal units." Here, at least, the assumption may be absolutely true: one shilling=one shilling in purchasing-power, although they may not be absolutely of the same weight and fineness. But it is hardly necessary: one coin+one coin=two coins, even if the one be a shilling and the other a half-crown. In fact, whatever difficulty be raisable as to geometry, it seems to me that no similar difficulty applies to arithmetic. Mathematician or not, we have each of us, in its most abstract form, the idea of a number. We can each of us appreciate the truth of a proposition in regard to numbers; and we cannot but see that a truth in regard to numbers is something different in kind from an experimental truth generalized from experience. Compare, for instance, the proposition that the sun, having already risen so many times, will rise to-morrow, and the next day, and the day after that, and so on, and the proposition that even and odd numbers succeed each other alternately *ad infinitum:* the latter, at least, seems to have the characters of universality and necessity. Or, again, suppose a proposition observed to hold good for a long series of numbers, — one thousand numbers, two thousand numbers, as the case may be: this is not only no proof, but it is absolutely no evidence, that the proposition is a true proposition, holding good for all numbers whatever. There are, in the theory of numbers, very remarkable instances of propositions observed to hold good for very long series of numbers, and which are nevertheless untrue.

I pass in review certain mathematical theories.

In arithmetic and algebra, or, say, in analysis, the numbers or magnitudes which we represent by symbols are, in the first instance, ordinary (that is, positive) numbers or magnitudes. We have also in analysis, and in analytical geometry, *negative* magnitudes. There has been, in regard to these, plenty of philosophical discussion, and I might refer to Kant's paper, 'Ueber die negativen grössen in die weltweisheit' (1763); but the notion of a negative magnitude has become quite a familiar one, and has extended itself into common phraseology. I may remark that it is used in a very refined manner in book-keeping by double entry.

But it is far otherwise with the notion which is really the fundamental one (and I cannot too strongly emphasize the assertion), underlying and pervading the whole of modern analysis and geometry, — that of imaginary magnitude in analysis, and of imaginary space (or space as a *locus in quo* of imaginary points and figures) in geometry. I use in each case the word 'imaginary' as including real. This has not been, so far as I am aware, a subject of philosophical discussion or inquiry. As regards the older metaphysical writers, this would be quite accounted for by saying that they knew nothing, and were not bound to know any thing, about it. But at present, and considering the prominent position which the notion occupies, — say, even, that the conclusion were that the notion belongs to mere technical mathematics, or has reference to nonentities in regard to which no science is possible, — still it seems to me, that, as a subject of philosophical discussion, the notion ought not to be thus ignored. It should at least be shown that there is a right to ignore it.

Although in logical order I should perhaps now speak of the notion just referred to, it will be convenient to speak first of some other quasi-geometrical notions, — those of more-than-three-dimensional space, and of non-Euclidian two- and three-dimensional space, and also of the generalized notion of distance. It is in connection with these, that Riemann considered that our notion of space is founded on experience, or, rather, that it is only by experience that we know that our space is Euclidian space.

It is well known that Euclid's twelfth axiom, even in Playfair's form of it, has been considered as needing demonstration, and that Lobatschewsky constructed a perfectly consistent theory, wherein this axiom was assumed not to hold good, or, say, a system of non-Euclidian plane geometry. There is a like system of non-Euclidian solid geometry. My own view is, that Euclid's twelfth axiom, in Playfair's form of it, does not need demonstration, but is part of our notion of space, of the physical space of our experience, — the space, that is, with which we become acquainted by experience, but which is the representation lying at the foundation of all external experience. Riemann's view, before referred to, may, I think, be said to be, that, having *in intellectu* a more general notion of space (in fact, a notion of non-Euclidian space), we learn by experience that space (the physical space of our experience) is — if not exactly, at least to the highest degree of approximation — Euclidian space.

But suppose the physical space of our experience to be thus only approximately Euclidian space: what is the consequence which follows? *Not* that the propositions of geometry are only approximately true, but that they remain absolutely true in regard to that Euclidian space which has been so long regarded as being the physical space of our experience.

It is interesting to consider two different ways in which, without any modification at all of our notion of space, we can arrive at a system of non-Euclidian (plane or two-dimensional) geometry; and the doing so will, I think, throw some light on the whole question.

First, imagine the earth a perfectly smooth sphere; understand by a plane the surface of the earth, and, by a line, the apparently straight line (in fact, an arc of great circle) drawn on the surface. What experience would in the first instance teach would be Euclidian geometry: there would be intersecting lines, which, produced a few miles or so, would seem to go on diverging, and apparently parallel lines, which would exhibit no tendency to approach each other; and the inhabitants might very well conceive that they had by experience established the axiom that two straight lines cannot enclose a space, and the axiom as to parallel lines. A more extended experience and more accurate measurements would teach them that the axioms were each of them false; and that any two lines, if produced far enough each way, would meet in two points: they would, in fact, arrive at a spherical geometry, accurately representing the properties of the two-dimensional space of their experience. But their original Euclidian geometry would not the less be a true system; only it would apply to an ideal space, not the space of their experience.

Secondly, consider an ordinary, indefinitely extended plane; and let us modify only the notion of distance. We measure distance, say, by a yard measure or a foot rule, any thing which is short enough to make the fractions of it of no consequence (in mathematical language, by an infinitesimal element of length). Imagine, then, the length of this rule constantly changing (as it might do by an alteration of temperature), but under the condition that its actual length shall depend only on its situation on the plane, and on its direction; viz., if for a given situation and direction it has a certain length, then whenever it comes back to the same situation and direction it must have the same length. The distance along a given straight or curved line between any two points could then be measured in the ordinary manner with this rule, and would have a perfectly determinate value; it could be measured over and over again, and would always be the same: but of course it would be the distance, not in the ordinary acceptation of the term, but in quite a different acceptation. Or in a somewhat different way: if the rate of progress from a given point in a given direction be conceived as depending only on the configuration of the ground, and the distance along a given path between any two points thereof be measured by the time required for traversing it, then in this way, also, the distance would have a perfectly determinate value; but it would be a distance, not in the ordinary acceptation of the term, but in quite a different acceptation; and, corresponding to the new notion of distance, we should have a new non-Euclidian system of plane geometry. All theorems involving the notion of distance would be altered.

We may proceed farther. Suppose that as the rule moves away from a fixed central point of the plane it becomes shorter and shorter: if this shortening take place with sufficient rapidity, it may very well be that a distance which in the ordinary sense of the word is finite will in the new sense be infinite. No number of repetitions of the length of the ever-shortening rule will be sufficient to cover it. There will be surrounding the central point a certain finite area, such that (in the new acceptation of the term 'distance') each point of the boundary thereof will be at an infinite distance from the central point. The points outside this area you cannot by any means arrive at with your rule: they will form a *terra incognita*, or, rather, an unknowable land (in mathematical language, an imaginary or impossible space); and the plane space of the theory will be that within the finite area, that is, it will be finite instead of infinite.

We thus, with a proper law of shortening, arrive at a system of non-Euclidian geometry which is essentially that of Lobatschewsky; but, in so obtaining it, we put out of sight its relation to spherical geometry. The three geometries (spherical, Euclidian, and Lobatschewsky's) should be regarded as members of a system: viz., they are the geometries of a plane (two-dimensional) space of constant positive curvature, zero curvature, and constant negative curvature, respectively; or, again, they are the plane geometries corresponding to three different notions of distance. In this point of view, they are Klein's elliptic, parabolic, and hyperbolic geometries respectively.

Next as regards solid geometry: we can, by a modification of the notion of distance (such as has just been explained in regard to Lobatschewsky's system), pass from our present system to a non-Euclidian system. For the other mode of passing to a non-Euclidian system, it would be necessary to regard our space as a flat three-dimensional space existing in a space of four dimensions (i.e., as the analogue of a plane existing in ordinary space), and to substitute for such flat three-dimensional space a curved three-dimensional space, say, of constant positive or negative curvature. In regarding the physical space of our experience as possibly non-Euclidian, Riemann's idea seems to be that of modifying the notion of distance, not that of treating it as a locus in four-dimensional space.

I have just come to speak of four-dimensional space. What meaning do we attach to it? or can we attach to it any meaning? It may be at once admitted that we cannot conceive of a fourth dimension of space; that space as we conceive of it, and the physical space of our experience, are alike three-dimensional. But we can, I think, conceive of space as being two- or even one-dimensional; we can imagine rational beings living in a one-dimensional space (a line) or in a two-dimensional space (a surface), and conceiving of space accordingly, and to whom, therefore, a two-dimensional space or (as the case may be) a three-dimensional space would be as inconceivable as a four-dimensional space is to us. And very curious speculative questions arise. Suppose the one-dimensional space a right line, and that it afterwards becomes a curved line: would there be any indication of the change? or, if originally a curved line, would there be any thing to suggest to them that it was not a right line? Probably not; for a one-dimensional geometry hardly exists. But let the space be two-dimensional, and imagine it originally a plane, and afterwards bent (converted, that is, into some form of developable surface), or converted into a curved surface; or imagine it originally a developable or curved surface. In the former case there should be an indication of the change, for the geometry originally applicable to the space of their experience (our own Euclidian geometry) would cease to be applicable; but the change could not be apprehended by them as a bending or deformation of the plane, for this would imply the notion of a three-dimensional space in which this bending or deformation could take place. In the latter case their geometry would be that appropriate to the developable or curved surface which is their space; viz., this would be their Euclidian geometry. Would they ever have arrived at our own more simple system? But take the case where the two-dimensional space is a plane, and imagine the beings of such a space familiar with our own Euclidian plane geometry: if, a third dimension being still inconceivable by them, they were by their geometry or otherwise led to the notion of it, there would be nothing to prevent them from forming a science such as our own science of three-dimensional geometry.

Evidently, all the foregoing questions present themselves in regard to ourselves, and to three-dimensional space as we conceive of it, and as the physical space of our experience. And I need hardly say that the first step is the difficulty, and that, granting a fourth dimension, we may assume as many more dimensions as we please. But, whatever answer be given to them, we have, as a branch of mathematics, potentially if not actually, an analytical geometry of n-dimensional space. I shall have to speak again upon this.

Coming now to the fundamental notion already referred to, — that of imaginary magnitude in analysis, and imaginary space in geometry; I connect this with two great discoveries in mathematics, made in the first half of the seventeenth century, — Harriot's representation of an equation in the form $f(x) = 0$, and the consequent notion of the roots of an equation as derived from the linear factors of $f(x)$ (Harriot, 1560–1621: his 'Algebra,' published after his death, has the date 1631); and Descartes' method of co-ordinates, as given in the 'Géometrie' forming a short supplement to his 'Traité de la méthode,' etc. (Leyden, 1637).

I show how by these we are led analytically to the notion of imaginary points in geometry. For instance: we arrive at the theorem that a straight line and circle in the same plane intersect *always* in two points, real or imaginary. The conclusion as to the two points of intersection cannot be contradicted by experience. Take a sheet of paper and draw on it the straight line and circle, and try. But you might say, or at least be strongly tempted to say, that it is meaningless. The question, of course, arises, What is the meaning of an imaginary point? and, further, In what manner can the notion be arrived at geometrically?

There is a well-known construction in perspective for drawing lines through the intersection of two lines which are so nearly parallel as not to meet within the limits of the sheet of paper. You have two given lines which do not meet, and you draw a third line, which, when the lines are all of them produced, is found to pass through the intersection of the given lines. If, instead of lines, we have two circular arcs not meeting each other, then we can, by means of these arcs, construct a line; and if, on completing the circles, it is found that the circles intersect each other in two real points, then it will be found that the line passes through these two points: if the circles appear not to intersect, then the line will appear not to intersect either of the circles. But the geometrical construction being in each case the same, we say that in the second case, also, the line passes through the two intersections of the circles.

Of course, it may be said in reply, that the conclusion is a very natural one, provided we assume the existence of imaginary points; and that, this assumption not being made, then, if the circles do not intersect, it is meaningless to assert that the line passes through their points of intersection. The difficulty is not got over by the analytical method before referred to, for this introduces difficulties of its own. Is there, in a plane, a point the co-ordinates of which have given imaginary values? As a matter of fact, we do consider, in plane geometry, imaginary points introduced into the theory analytically or geometrically, as above.

The like considerations apply to solid geometry; and we thus arrive at the notion of imaginary space as a *locus in quo* of imaginary points and figures.

I have used the word 'imaginary' rather than 'complex,' and I repeat that the word has been used as including real. But, this once understood, the word becomes in many cases superfluous, and the use of it would even be misleading. Thus: 'a problem has so many solutions.' This means so many imaginary (including real) solutions. But if it were said that the problem had 'so many imaginary solutions,' the word 'imaginary' would here be understood to be used in opposition to real. I give this explanation the better to point out how wide the application of the notion of the imaginary is; viz. (unless expressly or by implication excluded), it is a notion implied and presupposed in all the conclusions of modern analysis and geometry. It is, as I have said, the fundamental notion underlying and pervading the whole of these branches of mathematical science.

I consider the question of the geometrical representation of an imaginary variable. We represent the imaginary variable $x + iy$ by means of a point in a plane, the co-ordinates of which are (x, y). This idea, due to Gauss, dates from about the year 1831. We thus picture to ourselves the succession of values of the imaginary variable $x + iy$ by means of the motion of the representative point: for instance, the succession of values corresponding to the motion of the point along a closed curve to its original position. The value $X + iY$ of the function can, of course, be represented by means of a point (taken for greater convenience in a different plane), the co-ordinates of which are X, Y.

We may consider, in general, two points, moving each in its own plane; so that the position of one of them determines the position of the other, and consequently the motion of the one determines the motion of the other. For instance: the two points may be the tracing-point and the pencil of a pentagraph. You may with the first point draw any figure you please: there will be a corresponding figure drawn by the second point, — for a good pentagraph, a copy on a scale different, it may be; for a badly adjusted pentagraph, a distorted copy; but the one figure will always be a sort of copy of the first, so that to each point of the one figure there will correspond a point in the other figure.

In the case above referred to, where one point represents the value $x+iy$ of the imaginary variable, and the other the value $X+iY$ of some function, $\phi(x+iy)$, of that variable, there is a remarkable relation between the two figures: this is the relation of orthomorphic projection, the same which presents itself between a portion of the earth's surface and the representation thereof by a map on the stereographic projection or on Mercator's projection; viz., any indefinitely small area of the one figure is represented in the other figure by an indefinitely small area of the same shape. There will possibly be for different parts of the figure great variations of scale, but the shape will be unaltered. If for the one area the boundary is a circle, then for the other area the boundary will be a circle: if for one it is an equilateral triangle, then for the other it will be an equilateral triangle.

I have been speaking of an imaginary variable $(x+iy)$, and of a function, $\phi(x+iy)=X+iY$, of that variable; but the theory may equally well be stated in regard to a plane curve: in fact, the $x+iy$ and the $X+iY$ are two imaginary variables connected by an equation. Say their values are u and v, connected by an equation, $F(u, v) = 0$: then, regarding u, v, as the co-ordinates of a point *in plano*, this will be a point on the curve represented by the equation. The curve, in the widest sense of the expression, is the whole series of points, real or imaginary, the co-ordinates of which satisfy the equation; and these are exhibited by the foregoing corresponding figures in two planes. But, in the ordinary sense, the curve is the series of real points, with co-ordinates u, v, which satisfy the equation.

In geometry it is the curve, whether defined by means of its equation or in any other manner, which is the subject for contemplation and study. But we also use the curve as a representation of its equation; that is, of the relation existing between two magnitudes, x, y, which are taken as the co-ordinates of a point on the curve. Such employment of a curve for all sorts of purposes — the fluctuations of the barometer, the Cambridge boat-races, or the funds — is familiar to most of you. It is in like manner convenient in analysis, for exhibiting the relations between any three magnitudes, x, y, z, to regard them as the co-ordinates of a point in space; and, on the like ground, we should at least wish to regard any four or more magnitudes as the co-ordinates of a point in space of a corresponding number of dimensions. Starting with the hypothesis of such a space, and of points therein, each determined by means of its co-ordinates, it is found possible to establish a system of n-dimensional geometry analogous in every respect to our two- and three-dimensional geometries, and to a very considerable extent serving to exhibit the relations of the variables.

It is to be borne in mind that the space, whatever its dimensionality may be, must always be regarded as an imaginary or complex space, such as the two- or three-dimensional space of ordinary geometry. The advantages of the representation would otherwise altogether fail to be obtained.

I omit some farther developments in regard to geometry, and all that I have written as to the connection of mathematics with the notion of time.

(To be continued.)

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

STATE INSTITUTIONS.

Illinois state laboratory of natural history, Normal, Ill.

Experiments with diseased caterpillars. — Prof. S. A. Forbes is making a special study of 'schlaffsucht,' or some very similar disease, among our native caterpillars. He has so far proven that the disease is characterized by an enormous development of bacteria in the alimentary canal, the same forms appearing in the blood before death; that it is contagious by way of the food ingested; that the characteristic bacteria may be easily and rapidly cultivated in sterilized beef-broth; and that caterpillars whose food has been moistened with this infected broth, speedily show the bacteria in the alimentary canal, and, later, in the blood, and soon all die of the disease. Other caterpillars of the same lot, receiving the same treatment, except that the food is moistened with distilled water instead of the infected broth, remain unaffected. These bacteria are likewise cultivable in vegetable infusions, but multiply there less freely.

Every step of the investigation is fortified by stained and mounted preparations, which are being submitted to cryptogamists. It has already been determined that the bacterium infesting a brood of Datana ministra in his breeding-cages is identical with the Micrococcus bombycis of the silk-worm; the form, measurements, modes of aggregation, and behavior to reagents, of the two, being the same. Datana Angusii, feeding upon walnut, was also occasionally infested by this M. bombycis, but much more commonly by a spherical species, probably undescribed.

In the cabbage-worm (Pieris rapae) occurs still another species of Micrococcus, very minute ($5\,\mu$ in diameter), globular, and usually either single or in pairs. This is far the most virulent of the insect affections, which is being studied by Forbes, — the most like a plague. In its earlier stages it can usually be recognized by the light tint of the larvae, an ashy green, so different from the ordinary color that one may pick out the diseased worms at a glance. These soon become torpid, and commonly die in a few hours. After death, decomposition is peculiarly sudden and rapid. A pale individual, picked out in the evening while still active, at eight o'clock the following morning was dead, blackened, and almost deliquescent, the whole body being reduced to a semi-fluid condition. This Micrococcus multiplies rapidly in beef-broth, rendering the fluid turbid.

The cultures of these Micrococci are made by the most rigorous use of the modern methods of 'pure culture.'

Only M. bombycis has thus far been successfully used by Forbes for the infection of healthy larvae; but experiments with the other species are now in progress. Measures are also being taken to learn the length of life of these bacteria when kept in hermetically-sealed tubes, with the expectation that this will furnish a means of preserving and transporting them for practical use, if this should prove to be worth while.

Forbes is also experimenting with the various ferment-germs appearing spontaneously in organic infusions, and has noted the occasional appearance of large numbers of Saccharomyces in the intestines of unhealthy larvae, and of those whose food has been treated with fermenting vegetable infusions.

NOTES AND NEWS.

We deeply regret to announce the death of Dr. Hermann Müller, on Aug. 25. Next to Darwin, Müller has done the most to advance our knowledge of the mutual relations between plants and animals in one of its many phases. Some notice of his life and work will be given in a future number.

—The boundary-line between Guatemala and Mexico, which, as we announced last week, Mr. Miles Rock has been commissioned to locate, is about two hundred miles in length; and one or two years will be required to finish the work. Astronomical stations will be established along the line, and topographical and profile maps will be made to extend as far as time and means will permit. If possible, the longitude of Guatemala City will be determined telegraphically by connecting with some point on the coast occupied by the U. S. hydrographic party under Lieut.-Commander Davis.

Mr. Rock has also been commissioned by the Smithsonian institution to collect notes on anthropology in the country over which his survey extends, and to photograph whatever archeological ruins he may meet with during the progress of the survey. He sailed from New York on Oct. 1, in the steamer Acapulco.

—The annual report of the librarian of the public library of Cincinnati for the year ending June, 1883, has just been issued. The total number of volumes and pamphlets in the library is 149,750. "The average number of books loaned daily for home use has been 680. The average number delivered for use in the reading-room has been 379 per day." In tables showing the number of books issued for home use and for consultation are given percentages for various classes. Fiction heads the list with 81.4% in books for home use, and 28.3% in the reading-room. Science and arts are represented by only 2.9% for home use, but rise to 24.8% for books consulted at the library. The number of volumes of fiction circulated during the year was 167,678, and of science and arts only 5,928. In the consulting-room, however, 39,539 volumes of fiction were issued, and 33,916 volumes in science and arts. Though these figures show a marked preponderance in the circulation of fiction over science and arts, as indeed they do over every other class, the preponderance is perhaps more apparent than real. As the librarian says in his report, these percentages are often misleading. "They lead the public to believe that a much larger than a true proportion of the work of a library is in the distribution of books calculated to entertain rather than to instruct. Probably not more than one-sixth of the time devoted to a volume of history or of science is devoted to a novel by the average reader; and yet in these figures volumes of history and science count equally with volumes of fiction and juvenile literature."

In a table 'showing the number and the classes of books used during each month of the year,' we find some interesting figures. More books were used during the months of January and March than during any other two months of the year. In philology there was nearly a regular increase from month to month from July to January, and a decrease to June. In history, from 1,387 volumes in December, there was an increase to 1,818 in January, decrease to 1,385 in February, and increase again to 1,586 and 1,581 in March and April respectively. In geography and travels, March takes the lead with 1,006. In science and arts the increase is regular from July (2,558) to January (4,656), when the decrease commences; and in June we have 2,838. In the totals we find that nearly 40% of the books were used during the months of December, January, February, and March; while only about 28% were used during June, July, August, and September.

—The latest news from the French deep-sea explorations on the Talisman is comprised in a letter from M. Alph. Milne-Edwards, at Teneriffe. Every thing had worked in a satisfactory manner. Many soundings had been made off the coast of Morocco, and interesting profiles of the bottom thereby developed. Bottom and water specimens were simultaneously obtained, and the work was even carried on at night by the aid of electric lights. Considerable zoölogical collections had been made, and the professor was especially devoting himself to the study of their distribution in depth. The character of the fauna already enabled a tolerable estimation of the depth to be made from an examination of the animals contained in any particular haul of the dredge. By the use of extremely large nets, better luck had been secured in the capture of deep-sea fishes than had previously attended their efforts, and a large number of specimens had been obtained. On leaving the Canaries, the expedition would proceed to the Cape Verde Islands, and thence along the so little known African coast.

—Mr. H. J. Johnston-Levis publishes the accompanying map of Ischia (scale 1 : 80,000) in *Nature*, with some further account of the recent earthquake. In company with Prof. P. Franco of Naples, he travelled over the whole island without detecting any sign of volcanic action. If isoseismal lines are drawn over the injured districts, we find, he says, "that they assume the form of elongated ellipsoids, whose major axes run nearly east and west." In the

first isoseismal area, *a*, *a*, destruction was total; in the second, *b*, *b*, many houses are fallen, and the rest will require rebuilding; in the third, c, c, they were severely fissured; the fourth, in which houses were only very slightly fissured, not only includes the whole island, but must extend into the sea some distance. "From a careful examination of observed azimuths and angles of emergence, all point to a plate-shaped focus, whose strike extends in a line from Fontana, just west of Menella, to near the beach at Lacco. The plane of this fissure is probably roughly perpendicular to the surface, but may slightly dip towards the east, as the isoseismals are slightly nearer on the eastern side of the seismic vertical, which, as a necessity, is not represented by a point, but a line on the surface. The rupturing of this plate-like fissure was apparently greatest at a point nearly midway between its extremities." The ancient eruptive centres and craters are marked on the map in dotted circles.

—Ensign S. J. Brown, U. S. navy, has been elected professor of mathematics in the navy, and assigned to duty at the Naval observatory in Washington.

—Thouar writes from La Paz, under date of May 31 last, that in his search for Crevaux he had arrived by the way of Tacna, across the Cordilleras, on the 28th. The Bolivian government, by Sig. A. Quijarro, minister of foreign affairs, had shown great interest in the plans, and desire to assist to the extent of its power. An expeditionary corps had been equipped, and directed to march on Teyo, the Toba capital, which it is designed to occupy while part of the force descends the right bank of the Pilcomayo to Ascension. This expedition should have left Caiza in the month of June last, while, on the 3d, Thouar intended to start for Caripari, *viâ* Oruro, Potosi, Sucre, and Tarija.

—Endeavors have been made during the past session of the English parliament to obtain such amendments of the Factory acts as would protect not only the overworked and overheated workers in the bakehouses, but those desperate men who face certain death by poisoning in the manufacture of white lead. No act of parliament, however, will be of any real use until some improved process makes safety as cheap as danger. Lately, with this object in view, Prof. C. Gardner has perfected an invention through which, by electrical energy and the cheap production of carbonic acid, applied through a special apparatus, in combination with the necessary acid vapor at the proper temperature, the formation of white lead of the purest color and best quality is rapidly and cheaply carried out in closed chambers; the lead resting upon shelves, which are lifted out when converted, and emptied, without any dust being raised, into a combination of machinery closed in, from which it comes forth as white paint ground ready for the market, or, if required, as dry powder. In either case the dangerous operations of the 'white bed,' and washing and stoving, are completely done away with, and no opportunity is given for the dust to enter the air, or touch the persons of the workers.

—Mr. G. Brown Goode, U. S. commissioner to the fisheries exhibition, sailed from London for the United States on the 19th ult.

—The summer station of the U. S. fish-commission at Wood's Holl, Mass., will remain open until about the 20th of this month, at which time the commissioner will return to Washington.

—Dr. R. W. Shufeldt, U.S.A., who was engaged in making collections in Louisiana, has been released from duty on account of ill health.

—Mr. Robert Ridgway has left his duties at the national museum for the present on account of ill health, and is recruiting in New York.

—Dr. Charles Rau has in preparation a monographic work upon prehistoric fishing-implements. It will be published as one of the Smithsonian Contributions to knowledge.

—Professor Lester F. Ward has returned from the west. He reports having thoroughly explored about seventeen hundred miles of the Missouri River.

—The very prevalent idea that aniline dyes have poisonous properties has inspired the German chemist, Dr. Grandhomme, to investigate the subject as illustrated in the coal-tar color-works of Messrs. Lucius and Brüning at Höchst-on-the-Main. Nowhere else could these researches have been conducted in so satisfactory a manner, as the Höchst color-works employ six hundred and seventy-two men in the actual manufacture of the colors, exclusive of their large staff of mechanics and laboratory assistants. One regulation provides that no workman shall enter any other department than his own; so that the works offer an excellent field for accurate observation. The following results were obtained by Dr. Grandhomme from personal observation, and the tables of accident and illness kept in the works. Nitrobenzol is known to be poisonous, yet symptoms of nitrobenzol-poisoning only appeared in the cases of illness reported in that department during four years. Aniline is unquestionably poisonous; yet, out of one hundred and seventy-one cases of illness in that department, only eighteen were due to aniline: none were fatal, and the average duration of the illness was one and one-half days. Magentas made by the arsenic process, and duly purified, are recognized as poisons; but the symptoms recorded are those produced by arsenic, which, in some inferior magentas, exists in the proportion of even eight per cent. No illness caused by pure magenta was recorded at Höchst, and aniline no more exists in the finished magenta than manure exists in wheat. In the department where blue colors were made, only one case of aniline-poisoning was recorded; none in the violet and green departments. A special disease appeared in the eosine department, causing extreme perspirations from the pores of the hands, but not among the men employed in packing the finished colors. No special disease was noted in the naphthol and alizarine departments. The use of alcohol was found to reduce the power of the constitution to bear the action of aniline: so no alcoholic drinks were allowed in the Höchst works, and no men addicted to drinking admitted.

—In Namaqua-land, South Africa, no rain has fallen since Aug. 15, 1881, and plants, animals, and men are dying of drought and starvation. Wheat and seeds have been sent by the Cape Colony, and a relief committee has been formed.

—Tillo has determined the total length of navigable rivers in European Russia, which is only 72,000 kilometres for that vast territory, a deficiency due to the dryness of the climate.

SCIENCE.

FRIDAY, OCTOBER 12, 1883.

HERMANN MÜLLER.[1]

THE sad news has just reached this country of the death of Professor Müller, at Prad, on the 25th of August.

Since the death of Mr. Darwin, Dr. Müller has occupied the position of most prominence among students of the mutual relations between flowers and insects, — a study which, in the last decade, has contributed as much as any branch of biology to the substantiation of the main points of adaptive evolution. Müller was born at Mühlberg, Sept. 23, 1829, and was a younger brother of the well-known Brazilian naturalist, Fritz Müller, much of whose work has passed through his hands before its publication.

Between 1848 and 1852 he studied at the universities of Halle and Berlin, devoting himself to natural history. In the latter year he passed the Oberlehrer examinations, and served his novitiate in the Berlin realschule. In 1854 he received his first appointment as teacher in the school at Schwerin, and the following year took the natural sciences in the realschule at Lippstadt, where he remained as teacher and director until his death.

Previously to the attainment of his degree, Dr. Müller had shown considerable zeal in natural history explorations, which were continued, in 1855, in the vicinity of Krain, where he did some especially interesting work on the blind insects found in the caves at this place, the results of his studies appearing in the *Stettiner entomologische zeitschrift* for 1856–57. After settling at Lippstadt, he gave particular attention to botany and entomology, working up, in particular, the local phenogamic flora, and later the mosses of Westphalia, sets of which were distributed by him between 1864 and 1866.

About this time the classical work of Darwin on the fertilization of orchids by insects directed his attention to the pollination of flowers, — a subject, which, neglected since the time of Sprengel, was then attracting several biologists. His familiarity with Westphalian plants and insects fitted him especially for work of this nature; and his first contributions[2] showed that he was also possessed of the requisite powers of observation and interpretation.

From this time on, his leisure was given to field-work in this specialty, many of his summers being spent in the Alps. While Delpino, Hildebrand, and others were not slow to follow in the steps of Mr. Darwin, showing, both from the structure of flowers and the results of many careful experiments, how they must *a priori* be fertilized, Müller observed, in addition, how their pollination is actually effected; and our knowledge of the degree to which the reciprocal adaptations of flowers and their visitors extends may be set down as in large part the result of his labors.

In the past ten years, numerous papers from

[1] The portrait on this page is engraved from a photograph by Ophoven of Lippstadt, kindly furnished by Prof. William Trelease of the University of Wisconsin.

[2] Beobachtungen an Westfälischen orchideen (*Verhandl. naturh. ver. Preuss. Rheinl. u. Westfalens*, 1868) and Anwendung der Darwin'sche lehre auf bienen (*ibid.*, 1872).

his pen have appeared in the *Botanische zeitung*, *Bienen zeitung*, *Kosmos*, *Nature*, etc., while, as editor of the department of Justs' *Jahresbericht*, relating to pollination and dissemination, he has contributed reviews of all of the more important publications bearing on his specialty. Beside these, he published two books, — Befruchtung der blumen durch insekten, und die gegenseitigen anpassungen beider (which appeared in 1873, served as the basis of a very instructive series of articles in *Nature*, and was largely drawn upon by Lubbock in the preparation of his little work on British wild-flowers, and which, supplemented by the more recent observations of its author, has lately been translated into English); and Alpenblumen, ihre befruchtung durch insekten und ihre anpassungen an dieselben (a volume of equal size, published in 1881, and, like its predecessor, filled with instructive facts).

From the first, Dr. Müller was a pronounced evolutionist, perhaps erring in too exclusive contemplation of a limited part of the evidence of derivation; and, like many others of the German school, inclined to push evolutionary logic to its ultimate if undemonstrable conclusion of materialism.

As a teacher he was most excellent, having the faculty, not only of imparting ideas to his pupils, but of inspiring their enthusiasm. In his specialty he was a careful observer, noting and accounting for many minute structural peculiarities in both flowers and insects, which, so long as their utility remained undiscovered, were explicable only by the theory of types in nature. So far as observation is concerned, his work is above criticism. As a rule, too, his inferences are correctly drawn, though the limitation of his studies to a small part of the world has at times rendered his enthusiasm over the biological significance of some supposed new adaptation, subject to the criticism of specialists previously familiar with the structure, if not with its meaning.

As a friend, Dr. Müller was always cordial, ever ready with encouragement and assistance for younger workers in the line of his specialty. He had, however, little patience with inaccuracy in observation, and, both publicly and in private, criticised errors with vigor; but, though his criticisms were sometimes severe, they were seldom unkind, and never unjust. By his death, biological science loses not only one of its most enthusiastic and able devotees, but also one, who, by the independent and thorough nature of his work, may be styled not inappropriately an epoch-maker.

THE USE OF THE SPECTROSCOPE IN METEOROLOGY.

In April last it was thought desirable to add to the regular meteorological observation made at the Shattuck observatory, Dartmouth college, the hygrometric indications of the spectroscope. The observations were made in accordance with the directions of J. Rand Capron in his 'Plea for the rain-band.' The instruments used were two direct vision spectroscopes: one a 3½-inch 'vest-pocket' instrument of Hofmann's; the other 10 inches in length, and capable of separating the *D* lines with direct sunlight. The observations made in this way were found to be interesting, but unsatisfactory. The difficulty which an observer must always find in estimating confidently the degree of intensity of the absorption lines and bands with the widely varying lights of fair and cloudy weather, makes the arrangement of some method of measurement very desirable. After a few trials in other directions, the device described below was decided upon, and has proved satisfactory. It was thought that the absorption *lines* of aqueous vapor, seen with a spectroscope of rather high power, are better adapted to delicate measurement than the broad *band* seen with a low power. The small spectroscope used shows the dark band on the red side of the *D* line with great clearness; but the absorption lines are only visible when particularly strong. With the larger instrument, however, the spectrum is so elongated that the general darkening near *D* is hardly noticeable; while the two moisture lines to be found there are very prominent. The apparatus illustrated is designed to measure the variation in intensity of the darker line of this pair (the *a* of the *D* group of Janssen's map).

The only methods of measurement of the intensity of absorption lines, known to the writer, are those of Janssen and Gouy. The former, in 1871, in his work in mapping the atmosphere lines, used for comparison black lines of various widths, ruled on white paper, and viewed through vessels filled with darkened water.[1] Gouy made some measurements of solar lines by photometric methods; isolating a narrow strip of the spectrum adjacent to the line, and comparing its light with that of a strip of equal width containing the line. From these data he calculated the intensity of the line, not in photometric, but in linear units.[2] The method adopted by the writer is entirely different from either of these; and, as far as known, is new.

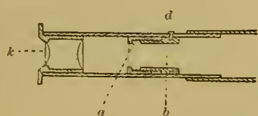

FIG. 1.

What was desired was the production of an artificial absorption spectrum, the intensity of whose lines could be varied at will, until one of the lines thus produced should be sensibly the same as the line to be measured. Fig. 1 is a section of the attachment to the spectroscope made for this purpose. The dark lines required are diffraction fringes produced at the focus of the positive eye-piece, which are therefore seen projected on the spectrum. They are produced by placing a silk fibre a little beyond the focus of the eye-piece. In the figure, the piece *a* slides in the tube, bearing with it a single silk fibre placed vertically and just in the middle of the field of view of the eye-piece. The fibre is maintained vertical by means of a projecting pin sliding in a longitudinal slot in the tube, as shown at *s* in fig. 2. The sliding motion is given to it by means of the piece *b*, which turns freely, but cannot slide, being retained by the screw *d* fitting in a groove made entirely around the piece. Two openings are made in the tube, on opposite sides, so that *b* can be turned directly with the fingers. One of these windows is shown at *n* in fig. 2. By turning in one direction, the silk fibre may be put nearly in the focus: by turning back, it can be made invisible. When near the focus, the fibre appears as a pair of dark parallel lines and quite close together. As it is drawn away from the focus, the lines appear to separate somewhat, growing constantly fainter until they disappear. The fainter diffraction fringes produced are invisible in the rather weak light of the spectrum. Whole revolutions of the screw *b* are read off on the graduation at the side of the slot, and fractions (tenths) are read from the piece itself, which is graduated as a micrometer screw. The lines thus produced resemble closely the *D* group, particularly when both are strong, when a very sharp eye is required to distinguish the spurious lines from the genuine. As the movement of the eye from side to side would modify the appearance of the interference lines, making one darker than the other, the spectrum must be viewed through a narrow vertical opening, making such motion impossible. For this purpose a piece of black paper (not shown in the figure), provided with a vertical slit of perhaps 0.7 mm. width, must be placed on the eye-lens at *k*. Even with this, a little care is necessary in the position of the eye, that the pair of lines shall always be equal. The slight darkening of the spectrum between the two lines, which occurs, is in this case not objectionable, as it imitates pretty closely the general absorption in the space between *D* and the *a* line of the *D* group. The instrument, as figured, is provided with a tangent screw at *e*, by which the whole tube containing the eye-piece can be moved horizontally, thus shifting the field of view so that any line of the spectrum can be brought to the side of the comparison lines. The instrument is mounted on a wooden base, grooved at the top to receive it. At the back side is a large knob by which the instrument is held when taking an observation. When directed to any

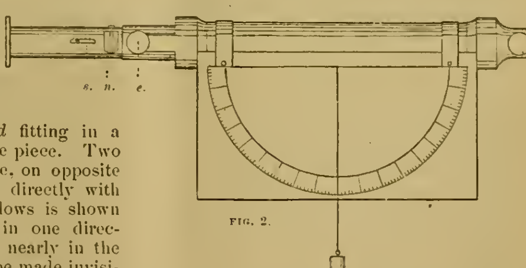

FIG. 2.

part of the sky, the altitude can be determined by means of the graduated circle and hanging weight shown in the figure.

Another device, much simpler, and of use,

[1] *Ann. phys. chim.*, xxiii. 274.
[2] *Comptes rendus*, lxxxix. 1033 and xci. 383.

it is believed, for general observation when less accuracy is required, is shown in fig. 3. A collar represented in section at *a* is inserted into the tube of the spectroscope, and fastened permanently so that its front side shall be just in the focus of the eye-piece. From the lower front edge to the upper back edge, a silk fibre passes, drawing back as it rises. The fibre will evidently appear in the field of view, as represented at *b*, as lines of diminishing intensity. A set of horizontal, equidistant spider-lines are attached to the front edge, hence just in focus. The line whose intensity is to be measured is made to appear parallel and near to one of the interference lines; and its intensity is expressed by the number of the spider-line at which the intensities correspond, counting downwards. And here it may be mentioned that such a scale of intensities (or, indeed, the scale afforded by the micrometer screw readings in the preceding apparatus) is not a scale of equal parts, a change of a unit in case of a line of high intensity being more than in case of a low intensity. This is, however, believed not to be a serious disadvantage in practice.

a Fig. 3. *b*

The advantages of any practicable method of measurement over a mere estimation are evident enough. When estimated by the eye, it is believed to be impracticable to distinguish more than five grades of strength, while by this method quite fine shades of intensity can be measured; and what is, perhaps, of equal importance, measurements made against dark and light sky are apparently identical, a change in the brilliancy of the background affecting the appearance equally of the absorption and interference lines. Evidently an unaided estimation would very likely be at fault in such a case.

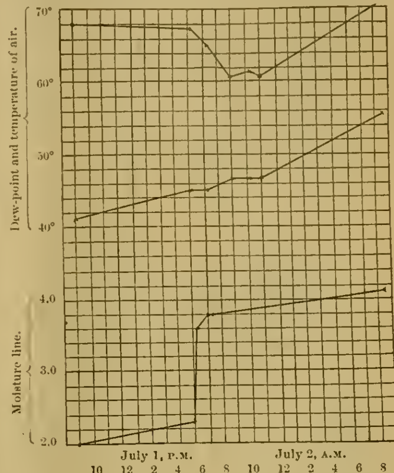
As to the accuracy actually attained in practice, it is found, in looking over the record of about a month past, that the whole range of the readings made at one observation, in ordinarily favorable weather, averages 0.3 of a revolution of the micrometer screw; and, as from four to twelve or more readings are always taken, according to the amount of variation noted, the probable error of the mean may be considered as about 0.03, as computation has shown in a number of cases. Now, as the whole range of the instrument used is from 1.0 to 5.7, it is evident that many grades of intensity are capable of appreciation. It is to be remembered, that these readings are purposely made in various quarters of the sky, so that discrepancies in readings are partly due to want of uniformity in the hygrometric state of the atmosphere. It should be stated, also, that such accuracy is not attainable below 2.0, as the value of a unit is then considerably less than above that value.

The regular record made at the observatory is as follows: The ordinary meteorological record is made three times daily. With the spectroscope, at least three sets of readings are taken, comprising measurements of the intensity of the moisture line at the horizon, at altitudes of 10°, 20°, 30°, and 90°. In all cases, the readings are taken in all quarters of the sky where there is sufficient light. A set of readings is also taken by setting the micrometer at 2.0, giving a faint line just visible in dark weather, and then measuring the altitude at which the moisture line is of the same strength. Such readings of altitude rarely vary more than 2° to 4° in settled weather. The strength of line and of the 'rain-band' is also estimated by the eye at each observation. At the same time the readings of the wet and dry bulb hygrometer are taken, as well as of a Regnault's condensing hygrometer. The wet and dry bulb hygrometer can be ventilated by means of a bellows, as suggested by Mr. H. A. Hazen, in a recent number of Science. Notes are made of the direction and velocity of the wind, of the clouds, and condition of the air.

One of the most interesting of the powers of the spectroscope thus used is its ability to detect relatively moist tracts in the atmosphere. While in settled weather entire uniformity at all points of the horizon is generally noted, in unsettled weather considerable differences are often observed. An excellent example of this power of the instrument occurred on May 26. During the morning when the observations were made, the air was very clear and dry, the moisture line therefore weak. At 6 A.M., measurements made entirely around the horizon showed that the line became invisible very uniformly at an altitude of 10°, except for about 45° of the north-eastern horizon, where the altitude of disappearance was 20°, while the intensity of the line at the horizon here was about double that elsewhere. There was no wind blowing, and no clouds of any kind were visible except a few wisps of cirrus cloud high in the east. These facts were all noted in the record at the time. At seven o'clock, when the next readings were taken, to my surprise this moist tract was found to be nearly filled up with a bank of stratus cloud, with no other clouds visible. At the same time a similar moist region, of 15° altitude and perhaps 35° length, was discovered in the south-east; and this in turn was found fifteen minutes later to be partly filled with cloud. After an hour or so they had all disappeared. The appearance was as though a body of air heavily charged with moisture, having become heated, was seen rising bodily at six o'clock, while at seven the consequent cooling had condensed in part its moisture.

One of the most striking facts noted is the suddenness with which a hygrometric change occurs, as indicated by the spectroscope. During the fine weather of June 30 and July 1, the spectroscope had indicated unusually dry air with almost absolute uniformity. During July 1, as the diagram shows, there had been a very slight increase in the moisture present, as indicated by an observation at six P.M. Fifteen minutes later, happening to glance through the spectroscope, I was greatly surprised to see how much blacker the line looked. A new set of readings was taken, giving a much higher amount of moisture, as indicated by the sudden rise in the curve. The sky was almost entirely free from clouds, with a light breeze from the south-west. Measurements were made in both cases all along the western half of the horizon, the eastern being too dark at that hour. At seven o'clock a moderately dense bank of stratus clouds had risen in the west to an altitude of 15° or 20°. The record at seven and seven-thirty showed little further hygrometric change. The sky was soon entirely overcast with clouds. This hygrometric change was not a mere momentary one, connected with cloud-formation; but the later record showed it to be the beginning of a period of moist air and showery weather. The hygrometer, it will be noted in the diagram, gave little sign of change for some hours. Other sudden changes of equally striking character have been observed. That, as has been suggested by Capron and others, the physical state of the suspended water, the size of the aqueous particles, may have an influence in its light-absorbing power, and so explain in part such changes, is very possible; but the evidence that such is the case appears to be far from conclusive.

It is believed that a series of spectroscopic observations, continued for a considerable period of time at different stations, would give much light on a number of important questions in meteorology, particularly in the study of the formation of showers and storms. The instrument is apparently admirably adapted to do this work, by its ability to trace accurately the motions of masses of vapor in the upper atmosphere. The discussion of the more important questions which arise in carry-



ing on this investigation is deferred until a larger mass of figures and facts have been accumulated. C. S. COOK.

NOTES ON SASSAFRAS-LEAVES.

THERE are three distinct forms of sassafras-leaves. The simplest is ovate, varying to oval and obovate. A second form is three-lobed, the incisions running from near the middle of the upper half of the leaf's edge to the centre of the blade. The third form is midway between the entire and three-lobed sorts, and has but one side-lobe; the opposite half of the leaf being entire. It is as if one-half of a three-lobed leaf were joined by the midrib to the opposite half of an entire one of the same size. This form may be very appropriately called the 'mitten.'

In the study of these three forms, branches of sassafras have been gathered from a large number of places through the surrounding country. Some have been obtained from the woods, and others from the open field. Branches were cut from the largest trees and from the smallest, from vigorous trees and those of slow growth. Ten hundred and fifty leaves were examined: and of these, five hundred and thirteen were entire: four hundred

4
1
2
3

and fifty-eight, three-lobed; and seventy-nine, 'mitten form.'

The first leaves of spring were invariably entire, and a lobed leaf was rarely found until the fourth leaf was passed in counting from the base of the branch toward the tip. No regular order was discovered. In one case the arrangement was as follows: three entire, four three-lobed, one 'mitten,' one three-lobed, one 'mitten,' one three-lobed, one 'mitten,' one three-lobed; on another branch, four entire, one 'mitten,' five three-lobed, one 'mitten,' three three-lobed, three 'mittens.' The leaves on short spurs of old trees were nearly all small and entire; when the branches were somewhat longer, and the leaves larger, there were one or more three-lobed or 'mitten' leaves in the middle of the stem. A number of branches taken from slow-growing trees gave the following aggregate: entire leaves, seventy: 'mittens,' six; three-lobed leaves, three. A vigorous young sprout gave twenty-seven three-lobed leaves, one 'mitten' near the middle of the stem, and no entire leaves. Another had two entire blades at the base, and twelve three-lobed leaves above. A number of these rapidly-growing young trees together gave twenty-seven entire leaves, fourteen 'mittens,' and eighty-one three-lobed leaves.

The entire and smaller leaves are in the majority on slowly-growing trees; while, on the young sprouts, larger three-lobed leaves predominate. The 'mitten' form is mostly found with the entire leaves. This form of leaf is probably about equally divided between the 'right-handed' and 'left-handed;' though, of the number found (seventy-nine), those with the 'thumb' to the left, when held with under side upward, exceeded the other sort by half. About every thirteenth leaf is a 'mitten,' — a form not found mentioned in the botanical description of the sassafras.

There seems to be no order in the arrangement of the three forms upon the branch. Leaves from the buds were examined, and all of the three forms were found. Each kind is distinct, from a very early state; and there is no indication that one ever passes into the other. No intermediate forms have been found. The venation of the three forms is very much the same. There is a midrib running lengthwise through the leaf, and a strong lateral vein on each side, which runs from near the base to beyond the middle of the leaf. Smaller veins form the framework of the middle and upper parts of the leaf. The portion of parenchyma absent in a lobed leaf is midway between the strong lateral veins. This is very clearly shown in a 'mitten,' where one side is lobed, and the other entire. It would seem as if the lobing is a failure to fill up the framework, and apparently due to a too vigorous growth of the veins, and a lack of a sufficient amount of the soft, filling tissue. In the formation of leaves the sassafras is certainly 'at loose ends,' but in this it is not alone.

Fig. 1 shows an entire sassafras-leaf; fig. 2, a three-lobed leaf; and fig. 3, a 'mitten.' Fig. 4 shows the young leaves of the three forms. All the illustrations are drawn from nature.

Byron D. Halsted.

New York, July 2, 1883.

THE UNITS OF MASS AND FORCE.

In the original definition of the gram it was regarded as a weight, and therefore a force, being the weight at the level of the sea, and at the latitude of 45°, of one cubic centimetre of water at its maximum density. It was thus virtually defined as a force. But as we shall soon see, although defined as a unit of force, it has become in practice a unit of mass. In the C. G. S. system of units this change is accepted, and the definition is modified accordingly; that is, one cubic centimetre of water is taken as the unit of mass, and this mass is called the gram without reference to its weight.

In volume i., *Cours de physique*, M. Jamin criticises this change. The high standing and character of this great work, as well as the eminence of its author, entitle his views to respectful consideration, especially as the question involves the fundamental elementary conceptions of physics in a way to render it of interest to the general student.

We set out with the proposition that what we commonly consider units of weight, such as the *kilogram* and *pound*, practically become units of mass in all the ordinary affairs of life. The reason is, that in practice bodies are weighed by balancing them against pieces of metal, and not by means of a spring balance. A pound weight is indeed heavier the farther north we go; but then, whatever we weigh with it is heavier in the same ratio. Accordingly, if by means of a weight we weigh a pound of tea at the equator, at the poles it will still weigh the same as a pound weight, although in reality heavier than at the equator. This is obviously a great practical and commercial convenience; because the quantity or mass of the tea is the important question to those who deal in it, while its gravitating force is of secondary importance. Were a perfect spring balance used which measured absolute weight, the dealer who should purchase tea at one latitude, and sell it at another, would be subject to a gain or loss, depending upon the difference in the force of gravity.

It is not, however, on merely commercial grounds that the change rests. For scientific purposes a unit is used as a term of comparison between different quantities of the same kind, and must be so defined and chosen as to fulfil this function with the greatest convenience. Now, a unit of force which shall furnish a direct and convenient standard of comparison between forces or weights at different places is entirely impracticable. At any one place the weight of a given mass of metal may be taken as a convenient unit; but this unit will change when we go to any other place, owing to the difference in the force of gravity. Indeed, every student of physics knows that the measure of the force of gravity at any one place is one of the most delicate and difficult problems in physics. In the definition which refers to the latitude of 45° it is assumed that the force of gravity is the same at all points on this parallel. We now know that this is not the case, and that if we adopt such a unit we shall have to define the exact spot on the earth's surface which is taken as the standard. Reference to such a standard would be impracticable. Hence a unit of force must be subsidiary to the unit of mass. The most convenient way of fixing it is to take the unit of mass as known, and to determine the force of gravity at the place of observation. The combination of the two gives a standard by which weight may be expressed in force. To be more explicit: if we have a piece of metal the mass of which we know to be one gram, and if we determine the force of gravity at the place to be n, then the gravitating force of that piece of metal will be known to be n units of force. In practice this must be the method used in physics, if an accurate measure of forces is really required.

Let us now consider M. Jamin's objections. He says that the mass of a body is not susceptible of direct determination; for to measure it we must commence by determining its weight in a balance, and afterwards dividing by the number which expresses the acceleration of gravity at the latitude of 45° and at the level of the sea. It is difficult to attribute this remark to any thing but inadvertence, since the division by g at 45° is necessary only on the French system. If we measure it by means of a balance having grams as weights, the resulting weight is at once the mass on the C. G. S. system, no matter where the weighing is made, and therefore needs no division whatever.

He then adds, "Suppose, on the contrary, that we have to measure a force: we determine it directly by means of weights at the place of observation. Afterwards we apply to these weights the corrections relative to the latitude and the altitude, to have an expression of the force as the function of a normal gram. We must remark that we cannot avoid these corrections to taking mass as the fundamental unit; because it is always weights that we measure, and the course followed in the experiments is necessitated by the nature of things." This is quite true, but it does not prove that one system affords any more convenient unit of force than the other.

Simon Newcomb.

STANDARD RAILWAY TIME.

The problem of simplifying the system of time standards used by the railways of this country seems to be near solution. The representatives of various railway-lines, who are to-day in session at Chicago, will receive the report of the secretary, Mr. W. F. Allen, and, it is expected, will take final action. For some years past, committees of various scientific bodies, as the American metrological society, the American association for the advancement of science, and the American society of civil engineers, have called attention to the urgent need of reform in the standards of time in use, and suggested plans for action. The railways, which are naturally most interested in the movement, have recently taken hold of the matter in earnest. The plan which has met with the most favor is that in which five standards of time, differing by consecutive hours, are proposed for the whole territory occupied by the United States and Canada. These are based upon the meridians from Greenwich, but receive other names for purposes of convenience. It is proposed by the railways that in Canada the standard shall be known as *intercolonial time*, and shall coincide with the local time on the meridian four hours, or 60°, west of Greenwich. In the United States the standards will be known as *eastern*, *central*, *mountain*, and *Pacific time*, and coincide with the local times on the meridians five, six, seven, and eight hours, or 75°, 90°, 105°, 120°, respectively, west of Greenwich. The advantage of this system is, that the standards will differ from the true local times of the various parts of the country by amounts not greater than thirty minutes, if the divisions are made rigidly according to longitude, and no one will be inconvenienced thereby. The great difficulty, however, of the plan, lies in the selection of the places where the changes of one hour are to be made; and as some of these, especially that between eastern and central time, must pass through country well settled, no matter how much freedom is allowed in selecting the points of change, it has seemed to many that the inconvenience would be great. Railway interests require that the changes be made at the termini of sections of the road, which are often large cities. At these points there will be two times, — one for eastern, one for western roads, differing by an hour. In dealing with this practical difficulty, the railways have shown a desire to conform as nearly as possible to the theoretical system, but have adopted the principles that "changes from one standard to another should be made at well-known points of departure," and that "these changes should be made at the termini of roads, where changes now occur, except on the transcontinental lines and in a few other unavoidable cases, where they can be made at the ends of divisions."

At the railway-time conventions held in St. Louis and New-York City in April last, the following resolutions were adopted: —

1°. That all roads now using Boston, New York, Philadelphia, Baltimore, Toronto, Hamilton, or Washington time as standard, or standards based upon meridians east of those points, or adjacent thereto, shall be governed by the seventy-fifth meridian or 'eastern time' (four minutes slower than New-York time).

2°. That all roads now using Columbus, Savannah, Atlanta, Cincinnati, Louisville, Indianapolis, Chicago, Jefferson City, St. Paul, or Kansas City time, or standards based upon meridians adjacent thereto, shall be run by the ninetieth meridian time, to be called 'central time' (one hour slower than 'eastern time,' and nine minutes slower than Chicago time).

3°. That west of the above-named section the roads shall be run by the one hundred and fifth and the one hundred and twentieth meridian times respectively (two and three hours slower than 'eastern time').

4°. That all changes from one hour standard to another shall be made at the termini of roads or at the ends of divisions.

Another resolution provided that the secretary should prepare a pamphlet containing an explanation of the subject, with accompanying maps, and endeavor to secure the acquiescence of all parties to the proposed plan, that the next convention might take final action.

The report of the secretary contains a fine railway-map, with the standards proposed for each road designated by different colors. It is the intention to use the eastern standard from Maine and the eastern coast to Detroit, Mich., and Bristol, Tenn.; but all the Ohio and Georgia railways will use the central standard, as well as those in Pennsylvania west of Pittsburg. The western railways whose termini are in Buffalo, Salamanca, and Charlotte, are allowed to use the central standard as far east as those points. The important places where the change of one hour from eastern to central time occurs, are Detroit, Buffalo, Pittsburg, Charlotte, and Augusta. The change from central to mountain time is made at Bismarck, North Platte, Wallace, Coolidge, and others; from mountain to Pacific time, at Ogden, Yuma, and others.

The secretary, Mr. Allen, has received assurances from the great majority of roads, that the system is approved. At the beginning of this month, railways operating 70,000 miles of road had responded favorably; and replies were coming in daily, none in the United States having refused assent. The roads centring in Boston gave assent, provided satisfactory arrangements could be made with the Cambridge observatory, upon which they depend for their time-signals. Of this there can be no doubt, as it may be assumed that every observatory in the country will contribute its part in the movement which inaugurates such a needed reform. The eastern standard differs from Boston time by sixteen minutes.

It seems almost certain, then, that the convention now in session will authorize the proposed change, and appoint a time when the plan shall be put into practical operation. On that date the observatories will make the change in their signals which the railways use, and the system will at once be under trial. The next question will be, whether the cities will adopt the railway system for their use. Of this there can be little doubt; and, in cases where two standards differing by an hour come together, it will be necessary to adopt one of the two for the city standard. The state of Connecticut, which several years ago hastily adopted New-York time for the standard, will have the small change of four minutes to authorize. All these adjustments may be left to the future. They will be made or not, as the popular interests demand. Of the wisdom of the action of the railway managers there can be no doubt. Without discussing the relative merits of the plan adopted, and others which have been suggested, it is certain that the present confused arrangement should be abolished. The new plan is simple and practicable; and its adoption is an important reform, which is deserving of hearty support and encouragement.

LETTERS TO THE EDITOR.

Phalansterium digitatum Stein.

There is no published evidence that the infusorial colony here referred to has been seen by any observer except its German discoverer. It is stated not to occur in English waters; and this uncommon animalcule had not been taken in America, until the writer recently found it in considerable profusion, attached to the leaflets of Myriophyllum from a millpond near this city. The colonies and the enclosed zoöids differ from their German relatives in no essential character, the only perceptible divergence being in the somewhat smaller size of the American Infusorium.

The tubular colonies, which take an irregular digit-like form, and branch somewhat dichotomously, are in great part built up of granular digestive rejectamenta remarkable for their coarseness. The distal extremity of each tubule is slightly inflated, each zoöid sitting singly in the hollow thus formed, except after having undergone the reproductive process, when two or more may be present, the flagellum alone extending beyond the aperture.

The conical collar, embracing the flagellum for some distance above its point of origin, is often thickened by an outward flow of the body-sarcode; but whether a regular circulation takes place in the collar substance could not be determined.

Although the zoöids are apparently entirely free from all connection with the walls of the zoocytium, they have the power of suddenly darting back into the tubules for a distance equal to two or three times their length. They seem to exercise this accomplishment at pleasure, but especially when any unwelcome object comes in contact with the flagellum. I have seen a large animalcule glide across the front of a colony, and each zoöid in regular succession, as its flagellum was touched, shoot back into the tube, remaining there some minutes before cautiously reapproaching the aperture.

I have several times witnessed the reproductive process, and have verified the statement that it takes place by transverse fission. An interesting fact in this connection is, that the only other species of the genus reproduces itself by dividing longitudinally, a method directly the opposite of that which obtains with the present form.

The two posteriorly located contractile vesicles pulsate at intervals of about thirty seconds.

Dr. Alfred C. Stokes.

Trenton, N.J.

Solar constant.

I enclose a translation of a portion of a letter to me from Dr. Josef Pernter of the Austrian meteorological service. Dr. Pernter writes: —

"Speaking of radiation, I remember to have read several times in Science, under the 'letters to the editor,' various things concerning the solar constant, — lately, a letter from John LeConte, but which, like former communications, appears to make the subject a little unclear.

"The solar constant is a quantity of heat, and the number which is the expression for the solar constant must mean calores. If, for example, Violle says the solar constant is 2.54, then it must be 2.54 calores. But since the solar radiation is a summation, during time, extending over space, the duration and the surface certainly come into the question. The minute has been taken as the unit of time, and the square centimetre as the unit of space.

"That the solar constant is 2.54 calores, means, therefore, that the sun's rays bring to the outside of our atmosphere, in each minute, 2.54 heat-units upon each square centimetre. What becomes of these heat-units, or calores, does not belong at all to the conception of the solar constant.

"The new solar constant of Langley, 2.84, signifies, consequently, that the amount of heat furnished per minute per square centimetre by solar radiation is 2.84 calores. But this number, 2.84 calores, must be comprehended. Lately the term 'calore' has been used in two significations, — the large calore, or the amount of heat that raises one kilogram of water 1°; and the small calore, or the amount of heat which raises a gram of water 1°. The latter, or small calore, is applied to the solar constant. Expressed in large calores, the solar constant of Langley would not be 2.84, but .00284 calores; that is, 1,000 times smaller.

"After these explanations, one can immediately say how many great or small calores fall upon the square metre per minute from the solar radiation; viz., 10,000 times as many as on the square centimetre."

Dissemination of Phlox.

I have had for some time past, on my table, some capsules of Phlox Drummondii, which is so commonly cultivated in gardens. The capsules were picked while still green, and had dried gradually. Several times I have been puzzled at finding small seeds and parts of the capsule of a plant on the table, and could not think where they came from; but, a day or so since, I heard a sharp pop, and, looking up, saw that one of the capsules had burst, and sent the seed several feet away. Since then it has often occurred. This is an evident means for the dissemination of the seed. The most of the capsules I have examined have perfected only one seed, instead of three; and the sudden opening of the capsules have sent the seeds flying far and wide.

The Iroquois institutions and language.

The very courteous and complimentary manner in which my work on the Iroquois book of rites has been noticed in a recent number of this journal has made me reluctant to take exception to any portion of the review. On further consideration, however, I must beg to be allowed, in the interests of both science and history, to refer to one or two of the remarks of my friendly critic. He expresses the opinion that 'the sceptical reader' may be inclined to regard the portion of the work which relates to 'the league and its founders' rather as 'classic historical romance' than as history; and this on the sole ground (as I understand his suggestion) that the Iroquois cannot be supposed to have been capable, five hundred years agō, of the intellectual efforts implied in this narrative. This suggestion, it will be seen, opens up the entire question of the comparative mental capacity of civilized and uncivilized, or rather unlettered, races.

The question is one altogether too large to be fully discussed in this place. But as regards the particular subject now referred to, I may remark that the existence of the league itself, with all its judicious and statesmanlike regulations, is a fact of which there can be no possible question. Any one can see this remarkable constitution in full and vigorous operation among the three thousand Iroquois on their Canadian reservation. There is ample evidence to show that this league existed in its present form when the people who maintained it first became known to European explorers. It is clear, therefore, that whatever intellectual power was needed for its formation was possessed by the Iroquois before they acquired any tincture of foreign civilization.

But why should their capacity for forming such a government be questioned? The Iroquois tribes, when first known to Europeans, and doubtless for centuries before that time, were in a social stage at least as far advanced as that of our German ancestors in the days of Tacitus. We know that these barbarians, if we choose so to style them, had evolved a regular system of government, combining very ingeniously the methods of democracy and aristocracy, and comprising the germs of the English constitution. On this point the often-cited passage of Montesquieu will bear to be requoted and emphasized. "In perusing," writes the great legist, "the admirable treatise of Tacitus 'On the customs of the Germans,' we find it is from that nation the English have borrowed the idea of their political government. *This beautiful system was invented first in the woods.*" Will any one reply that the German barbarians, being of the Aryan stock, must be supposed capable of intellectual achievements which barbarians of the Indian race could not be expected to compass? I think the able and liberal-minded reviewer will agree with me, that reasoning of this 'high priori' sort, which assumes the very point in question, would be any thing but logical or satisfactory.

The reviewer is kind enough to say that many of the chapters in my volume "indicate immense research, and are of great value both ethnologically and philologically." I can assure him that equal diligence was exercised in preparing the chapters on the league and its founders, and I know of no reason why they should be deemed less accurate or less valuable. In these, moreover, as well as for the other portions of the work, I have been careful to indicate the sources of my information. Nothing will be easier than for any one who has doubts as to its correctness to repeat my inquiries, and to satisfy himself on that point. But I am happy to say that the communications which reach me from many quarters seem to show that no such doubts are likely to be entertained; at least, by any well-informed persons. Writers of the highest authority on American and Indian history receive the statements of the book as entirely authentic, and speak of it in terms too flattering for me to repeat.

Let me conclude by expressing the pleasure with which I have learned from this review that the valuable work of the excellent and indefatigable missionary-linguist, the late Father Marcoux, on the Iroquois language, is about to be published by the Bureau of ethnology. The idioms of the Huron-Iroquois group stand, perhaps, at the head of the best-known Indian languages as subjects of philosophical study. It is doubtful if even the Quichua or the Aztec equals them in comprehensive force, or in subtlety of distinctions. More than two centuries ago the learned missionary Brebeuf was struck with the resemblance of the Huron to the Greek; and in our own day Professor Max Müller, after a careful study of the Mohawk tongue, has expressed the opinion that the people who wrought out such a language 'were powerful reasoners and accurate classifiers.' The works of M. Marcoux, in conjunction with those of his distinguished pupil and successor, M. Cuoq, will afford ample means for the study of one, and perhaps the finest, of this remarkable group of languages.

In connection with this subject, it is proper to refer to the doubt expressed by the reviewer as to the correctness of the linguistic works of the French missionaries. It is suggested that they have made mistakes in grammar, and in particular that they have not been able to distinguish between the feminine and the indeterminate inflections. Now, it must be remembered that the intelligent and well-educated missionaries, whose competency is thus questioned, have for many years spoken and written the Iroquois language almost as familiarly as their native speech, and have published many books in that language for the use of their converts. Their predecessors, whose experience they have inherited, had been engaged in the same work for more than two hundred years. To suppose them so grossly ignorant of the grammar of the language as is now suggested is much the same as supposing a professor of Latin in an English or American college to be unable to distinguish between the genitive and the accusative cases in that language. If the work of Marcoux is so erroneous, it is clearly unfit to be published in a national series like that of the Ethnological bureau. In justice both to the missionaries and the bureau, I am glad to be able to show, by the best possible evidence, that the suspected errors do not exist. The Iroquois must be supposed to know their own language. The text of their Book of rites, fortunately, presents a test which is conclusive. In preparing the translation of this text, with the aid of the best native interpreters, I had occasion, as the appended glossary shows, to make constant use of the publications of M. Cuoq on the Iroquois tongue, and found them invariably correct. In particular, I may mention, the indeterminate form frequently occurs, employed precisely as indicated by him. The bureau may therefore safely add the work of M. Marcoux to the other valuable publications which have done so much credit to the scholarship of their authors and to the liberality of the government.

H. Hale.

THOMSON AND TAIT'S NATURAL PHILOSOPHY. — I.

A treatise on natural philosophy. By Sir William Thomson LL.D., D.C.L., F.R.S., and P. G. Tait, M.A. Vol. i., part ii, new edition. Cambridge, *University press*, 1883. 25+527 p. 8°.

The first edition of vol. i. (23+727 p.) of this work was published by the delegates of the Clarendon press at Oxford, 1867. The authors then intended, as appears from their preface, to complete the work in four volumes. The remaining three volumes have, however, never appeared, much to the regret of all students of mathematical physics; and the authors state that the "intention of proceeding with the other volumes is now definitely abandoned."

In 1879 a new and enlarged edition was published of a portion of vol. i., entitled part i. (17+508 p.), including that part of the first edition contained in the first 336 pages; and now we have the remainder of vol. i., entitled part ii., which has been enlarged by important additions from 390 to 527 pages.

At p. 22 will be found a schedule of the alterations and additions in part i., and, at p. 24, those of part ii. "The most important part of the labor of editing part ii. has been borne by Mr. G. H. Darwin," whose remarkable papers in the Philosophical transactions upon the mathematical physics of the earth, past and present, have placed him in the front rank of the cultivators of that science. His contributions to part ii. are duly accredited to him in the above-mentioned schedule.

The original object of this treatise is stated to be twofold; viz., "to give a tolerably complete account of what is now known of natural philosophy, in language adapted to the non-mathematical reader, and to furnish to those who have the privilege which high mathematical acquirements confer, a connected outline of the analytical processes by which the greater part of that knowledge has been extended into regions as yet unexplored by experiment."

From the nature of the case, the success of the authors in the attainment of their first object was small, compared with the second; for in order to give an intelligible account, to one unaccustomed to mathematical reasoning, of the general tenor and results of such reasoning, requires not only capacities such as few mathematicians have had in our day, except Clifford, but requires, also, an amount of space incompatible with the second and principal object which the authors had in view. In order, however, better to reach the non-mathematical reader, the authors published a work entitled 'Elements of natural philosophy, part i.,' which was only an abridgment of this 'treatise,' made by simply omitting all the advanced mathematical developments.

The second and principal object, however, of the authors, was one in which they, perhaps, were better fitted to succeed than any who could be selected. Their object was a large one, and its attainment was undertaken in a large way. It involved the presentation of the general subject of kinematics, or the geometry of motion considered apart from the forces causing it, including the exposition and use of generalized co-ordinates; and the consideration of harmonic motion, which "naturally leads to Fourier's theorem, one of the most important of all analytical results as regards usefulness in physical science," and including, also, the higher parts of the analytical discussion of curves and surfaces in space, of three dimensions. Next it required an extended development of dynamical laws and principles founded on Newton's Principia, comprising the dynamics of a particle and of a rigid body, and the whole of what is now termed kinetics worked over and "developed from the grand basis of the conservation of energy." The scope of the work demanded, also, the establishment of the principal formulae of spherical harmonics, a branch of analysis whose character we shall explain more at length hereafter.

All these and other subjects, which are usually regarded as but distantly related to the subject in hand, form a necessary part of a work whose object is as wide as that proposed by the authors. But it is hardly too much to say, that every important theory treated has received at their hands, not only elucidation, but additions of importance.

In order to make this paper as useful as may be, it has seemed best, in what follows, to content ourselves with the attempt to give an account to mathematical readers of the more important developments contained in the work, and not to engage in the task of trying to make an elucidation of its contents suitable for the general reader.

When we come to consider in particular the contents of part ii., it is found to be upon the general subject of *statics;* though many subjects, such as elasticity, the tides, etc., not usually treated in works on that subject, are here included. It consists of three chapters, the first of which is but five pages in length, and is merely introductory. It states and illustrates the utter impossibility of submitting the *exact* conditions of any physical question to mathematical investigation by reason of our ignorance of the nature of matter and molecular forces, but shows that approximate solutions obtained by neglecting forces which do not affect the conclusions sought to be established, and by regarding bodies as rigid which are nearly so, lead to practically the same results, as to the equilibrium and motion of bodies, as we should be led to by the solution of the infinitely more transcendent problem which has regard to *all* the forces acting.

In case, however, we consider the bending or other deformations of bodies regarded as elastic, we make a second approximation to the exact treatment of physical questions; and, by introducing modifications of elasticity due to changes of temperature, we should make a third approximation, which might be carried one step farther by taking account of conduction of heat, and farther still by considering the modifications of ordinary conduction due to thermo-electric currents, etc. In view of all this, the authors say, "The object of the present division of this volume (i.e., part ii.) is to deal with the first and second of these approximations. In it we shall suppose all solids either *rigid* (i.e., unchangeable in form and volume) or *elastic;* but, in the latter case, we shall assume the law connecting a compression or a distortion with the force which causes it, to have a particular form deduced from experiment. . . . We shall also suppose fluids, whether liquids or gases, to be either *compressible* or *incompressible*, according to certain known laws; and we shall omit considerations of fluid friction, although we admit the consideration of friction between solids."

The next chapter (v.) comprises pp. 6 to 100, and its especial object is set forth in the introductory section (454), as follows: "We naturally divide statics into two parts, — the equilibrium of a particle, and that of a rigid or elastic body or system of particles, whether solid or fluid. In a very few sections we shall dispose of the first of these parts, and the rest of this chapter will be devoted to a digression on the important subject of attraction." In other words, this chapter is devoted, with the exception of a couple of pages, to an extended treatment of attraction according to the law of the inverse square of the distance as applied to gravitation, electricity, and magnetism.

After a brief investigation of the usual formulae for the attraction of the spherical shell, circular disk, thin cylinder, circular arc, etc., the main subject of the chapter is reached, which is the modern mathematical theory of potential; which theory is the principal means now employed in the discussion of questions relating to the distribution of attracting matter, and the forces caused by it. This theory, due as it is to the analytical discoveries of Laplace, Green, Gauss, and others, might, nevertheless, have long remained comparatively barren of fruitful results in physics, had it not been for the genius of Faraday, who, though unskilled in the use of analysis, had a most powerful grasp of geometric and physical relations. In the words of another,[1] "Faraday, in his mind's eye, saw lines of force traversing all space, where mathematicians saw centres of force attracting at a distance; Faraday saw a medium where they saw nothing but a distance; Faraday sought the seat of the phenomena in real actions going on in the medium, they were satisfied that they found it in a power of action at a distance." He conceived of lines of gravitational force as holding the planets in their orbits. These lines radiated through all space from the attracting body as a nucleus, regardless of the existence or non-existence of bodies upon which the attraction could be exerted. Furthermore, Faraday thought of each attracting body as surrounded at different distances by successive level surfaces, — like that of the ocean, for example, or the upper limit of the atmosphere; which surfaces cut the lines of force everywhere at right angles. This was not only true of gravitating matter, but each electrified body also had its system of lines of electrical force, and its corresponding system of level surfaces; and each magnet had its magnetic system as well. The geometry of these lines and surfaces is the basis of Faraday's reasoning in his 'Experimental researches,' and is the geometric truth hidden in the analytic discoveries clustering around Laplace's, Poisson's, and Green's theorems.

That we may call these relations more clearly before the mind, consider for a moment the so-called 'equation of continuity' of an incompressible fluid; which equation is divined from the geometric truth, that the quantity of such a fluid, which flows into any assumed closed surface, taken entirely within it, is equal to that flowing out, or that the total *flow* is *nil*. This is precisely expressed by the equation

$$\int F\,d\,S = 0, \qquad (1)$$

in which $d\ S$ is the area of the element of the assumed closed surface, F is the normal flow per square unit at that element, and the limits of integration are so taken that it extends over the entire surface. There is also another form of the equation of continuity, expressing the kinematic truth, that, in an incompressible fluid, the variations of the component velocities in the directions x, y, z, balance; i.e., their algebraic sum is *nil*, which may be written thus: —

$$\frac{du}{dx} + \frac{dv}{dy} + \frac{dw}{dz} = 0, \qquad (2)$$

in which u, v, w, are the component velocities in the directions x, y, z, respectively.

Now, it is not difficult to picture to the mind the motions occurring within the mass of an incompressible fluid; such as water, for example. In whatever way it may be moving, we can think of stream-lines along which the different parts of it flow. A number of these lines, side by side, can be taken to form a stream, and can be thought of as bounded by a kind of tubular surface; which surface might be regarded as the boundary of the stream, which isolates it from surrounding streams. If the stream has the same velocity at every point along the tube, then its cross-section must be uniform; but, where the velocity is less, the cross-section is proportionately increased, and *vice versa*. This follows from the fact that the same quantity must pass each cross-section per unit of time. A tube in which a unit of volume passes a given cross-section per unit of time is called a *unit-tube*. Now, the forces of attraction in free space, caused by any distribution of matter, electricity, or magnetism,

[1] Preface of Maxwell's Electricity and magnetism.

follow precisely the same laws as the velocities and flow of incompressible fluids; for, consider for the moment the lines of force starting from the surface of some attracting body (a magnet, for example). They gradually diverge as the distance increases, and curve away into space. Each one of these lines may be taken as the representative of a definite amount of attraction, which is the same at all points along it; and if a tubular surface be supposed to exist, including everywhere certain of these lines which lie beside each other, and no others, the total amount of force acting across every cross-section of the tube is the same: hence equations (1) and (2) apply as well to forces of attraction as to velocities of an incompressible fluid, provided F, u, v, w, be taken to be the component forces along the normal and along x, y, z, respectively, and provided that none of the attracting matter be contained within the closed surface considered in equation (1), or at the point considered in equation (2). In order to the farther development of these equations, let us compute the work which would be obtained in carrying a unit of attracted material from one given position to another. The work is found from the usual expression

$$V = - \int (u\,dx + v\,dy + w\,dz), \qquad (3)$$

in which u, v, w, being component forces, the limits of the integration are the co-ordinates of the two given points; but what path is taken between these points is of no consequence, because the amount of work depends alone upon their difference of level:

$$\therefore u = - \frac{dV}{dx}, v = - \frac{dV}{dy}, w = - \frac{dV}{dz}, \qquad (4)$$

in which the right-hand numbers are partial differential coefficients. V is evidently a function of the cö-ordinates such that its value depends upon position, and not upon the kind of co-ordinates employed. The point which fixes the lower limit of the integral in (3) is usually taken at infinity; and the value of V taken between it and the point fixing the upper limit is called the *potential* of the latter point.

By help of (3), we may put equation (1) in the form

$$\int \frac{dV}{du}\,dS = 0, \qquad (5)$$

in which du is the element of the normal to the closed surface considered.

And by substituting in (2) the values given in (4), we have,

$$\frac{d^2 V}{dx^2} + \frac{d^2 V}{dy^2} + \frac{d^2 V}{dz^2} = 0, \qquad (6)$$

which is Laplace's equation, and is often written in the abbreviated form, $\nabla^2 V = 0$. Poisson showed, that, when the point at which the potential is to be computed is within the mass of the attracting matter, the right-hand member of (6) should no longer be *nil*, but $4\pi\rho$ instead, in which ρ is the density of the matter at that point. Similarly, the right-hand member of (5) becomes $4\pi m$ when an amount of matter m is included within the closed surface considered.

Equation (6) states that V must be such a function of the co-ordinates, that, if we take its three partial second differential coefficients and add them, their sum is *nil*. What possible algebraic forms are there which fulfil this condition? They are, of course, to be found by attempting to solve the differential equation (6). But it is to be seen beforehand, from the manner in which that equation was established, that it must have an infinite number of solutions; for V must be such a function as to be capable of expressing the work to be obtained from a unit of attracted matter when brought from infinity into the presence of attracting matter, whatever its distribution in space. The function V must therefore, in general, be different for every different distribution of attracting matter.

The integration of equation (6), and the discussion of its various solutions, constitute the branch of mathematics called spherical harmonic analysis; and to it the authors have devoted pp. 171 to 219, in part i. The formulae there obtained are employed, whenever required in the present chapter, to express the potential, or the attraction of matter distributed according to laws not conveniently to be treated by less elementary methods.

As the study of spherical harmonics has been comparatively neglected in this country, a short digression, explaining some of their properties, may be useful.

From the nature of attraction, it being toward fixed centres, it appears that polar co-ordinates would be more suitable to express its relations than rectangular co-ordinates; and, in fact, equation (6) is usually transformed to polar co-ordinates in space before integration, which co-ordinates may be taken to be the radius vector, the latitude, and the longitude of the point at which the potential is computed.

It may be shown that there are two general forms of solution of this polar differential equation, — one in ascending powers of the radius vector; and the other in ascending powers of its reciprocal, with coefficients depending upon sines or cosines of the angular co-ordinates.

As these series may be broken off at any point by the vanishing of the arbitrary numerical coefficients introduced during integration, these solutions may be in terms of the radius vector of any degree, positive or negative.

It is then found that a most important and simple class of solutions, called zonal harmonics, is those which are independent of the longitude, and consequently contain but two variables, — the radius vector and the latitude.

If in any harmonic we assume some special value of the radius vector for consideration, we evidently confine our attention to a spherical surface; and the expression is then spoken of as a surface harmonic, in distinction from that in which the radius vector is a variable, in which case it is called a solid harmonic.

On the surface of a sphere of given radius, it is possible to suppose the values of a surface-harmonic to be laid off graphically along the radii to each point, toward or away from the centre, according to their sign. This will give a picture to the mind of the distribution of the surface-harmonic.

Now, in a zonal harmonic of the first positive degree (which varies as the sine of the latitude) the surface-distribution is all positive on one side of the equator, and all negative on the other. A simple zonal harmonic of the second degree has a distribution like that included between a nearly spherical ellipsoid of revolution about the polar axis and a sphere when the two intersect along two parallels of latitude. The ellipsoid may be prolate or oblate. The number of zones depends, in any case, upon the degree of the zonal harmonic, and is such that the number of parallels of latitude at which the distribution changes sign is the same as the degree; and they are symmetrically situated about the equator, so that in the odd degrees the equator is itself such a parallel.

There are other solutions, called sectorial harmonics, in which the surface-distribution changes sign at equidistant meridians, and other solutions still, which are a combination of these two, called tesseral harmonics, in which the sign of the distribution changes, checker-board fashion, at parallels and meridians. The sectorial harmonics are, however, in reality, nothing more than the combination of a number of zonal harmonics of the same degree, whose poles are situated at equal distances along the equator; and the tesseral harmonics are combinations of the sectorial with the zonal harmonics. Indeed, the most general harmonic is one by means of which any surface-distribution whatever may be expressed by properly determining the constant coefficients, and is merely a combination of zonal harmonics superposed one upon another, with poles situated in some irregular manner upon the surface of the sphere. This brings us to the fundamental theorem stated in section 537, upon which the special importance and usefulness of these functions rest, — "A spherical harmonic distribution of density (i.e., matter) on a spherical surface produces a similar and similarly placed spherical harmonic distribution of potential over every concentric spherical surface through space, external and internal; and so, also, consequently, of radial component force. . . . The potential is, of course, a solid harmonic through space, both external and internal; and is of positive degree in the internal, and of negative degree in the external space," as is evidently necessary, if the series expressing the potential in these two cases are to converge. When we come to treat in the same equation the potentials of a given point due to two different bodies, or systems of bodies, a remarkable relation is found to exist between them, called, from its discoverer, Green's theorem, which, though somewhat complicated when expressed in rectangular co-ordinates, has been put by Maxwell in a simple form, which may be written

$$\int V_1 dm_2 = \int V_2 dm_1, \qquad (7)$$

in which the subscripts refer to the first and second systems respectively, and the integrations are to be extended so as to include the total masses m_1 and m_2 respectively of the two systems. Laplace's and Poisson's equations are, of course, particular cases of Green's theorem. Thomson has effected an important extension of Green's theorem, given on pp. 167 to 171, part i. Constant references are made to these theorems, not only as to their direct application, as we have presented it, but in their application to the inverse question of determining what the distribution of matter must be to produce a given distribution of potential.

The most extended and important application of the theories of attraction and potential treated in this chapter is that of ellipsoids and ellipsoidal shells, — a subject which is closely connected with that of the figure of the earth, and one which has engaged the prolonged attention of many of the most powerful mathematical intellects of the past. A full account of the course of discovery in this field is found in Todhunter's History of the theories of attraction and figure of the earth, 2 vols.

Ten pages of new matter (pp. 40–50) have been inserted in this edition, embracing modern investigations of importance on this subject.

(*To be continued.*)

OBLIGATIONS OF MATHEMATICS TO PHILOSOPHY, AND TO QUESTIONS OF COMMON LIFE.[1] — II.

I SAID that I would speak to you, not of the utility of the mathematics in any of the questions of common life or of physical science, but rather of the obligations of mathematics to these different subjects. The consideration which thus presents itself is, in a great measure, that of the history of the development of the different branches of mathematical science in connection with the older physical sciences, — astronomy and mechanics. The mathematical theory is, in the first instance, suggested by some question of common life or of physical science, is pursued and studied quite independently thereof, and perhaps, after a long interval, comes in contact with it, or with quite a different question. Geometry and algebra must, I think, be considered as each of them originating in connection with objects or questions of common life, — geometry, notwithstanding its name, hardly in the measurement of land, but rather from the contemplation of such forms as the straight line, the circle, the ball, the top (or sugar-loaf). The Greek geometers appropriated for the geometrical forms corresponding to the last two of these the words σφαῖρα and κῶνος, our sphere and cone; and they extended the word 'cone' to mean the complete figure obtained by producing the straight lines of the surface both ways indefinitely. And so algebra would seem to have arisen from the sort of easy puzzles in regard to numbers which may be made, either in the picturesque forms of the Bija-Ganita, with its maiden with the beautiful locks, and its swarms of bees amid the fragant blossoms, and the one queen-bee left humming around the lotus-flower; or in the more prosaic form in which a student has presented to him in a modern text-book a problem leading to a simple equation.

The Greek geometry may be regarded as beginning with Plato (B.C. 430–347). The notions of geometrical analysis, loci, and the conic sections, are attributed to him; and there are in his 'Dialogues' many very interesting allusions to mathematical questions, — in particular the passage in the 'Theaetetus' where he affirms the incommensurability of the sides of certain squares. But the earliest extant writings are those of Euclid (B.C. 285). There is hardly any thing in mathematics more beautiful than his wondrous fifth book; and he has also, in the seventh, eighth, ninth, and tenth books, fully and ably developed the first principles of the theory of numbers, including the theory of incommensurables. We have next Apollonius (about B.C. 247) and Archimedes (B.C. 287–212), both geometers of the highest merit, and the latter of them the founder of the science of statics (including therein hydrostatics). His dictum about the lever, his 'Εὕρηκα,' and the story of the defence of Syracuse, are well known. Following these we have a worthy series of names, including the astronomers Hipparchus (B.C. 150) and Ptolemy (A.D. 125), and ending, say, with Pappus (A.D. 400), but continued by their Arabian commentators, and the Italian and other European geometers of the sixteenth century and later, who pursued the Greek geometry.

The Greek arithmetic was, from the want of a proper notation, singularly cumbrous and difficult; and it was, for astronomical purposes, superseded by the sexagesimal arithmetic, attributed to Ptolemy, but probably known before his time. The use of the present so-called Arabic figures became general among Arabian writers on arithmetic and astronomy about the middle of the tenth century, but it was not introduced into Europe until about two centuries later. Algebra, among the Greeks, is represented almost exclusively by the treatise of Diophantus (A.D. 150), — in fact, a work on the theory of numbers, containing questions relating to square and cube numbers, and other properties of numbers, with their solutions. This has no historical connection with the later algebra introduced into Italy from the east by Leonardi Bonacci of Pisa (A.D. 1202–1208), and successfully cultivated in the fifteenth and sixteenth centuries by Lucas Paciolus, or de Burgo, Tartaglia, Cardan, and Ferrari. Later on, we have Vieta (1540–1603), Harriot, already referred to, Wallis, and others.

Astronomy is, of course, intimately connected with geometry. The most simple facts of observation of the heavenly bodies can only be *stated* in geometrical language; for instance, that the stars describe circles about the Pole-star, or that the different positions of the sun among the fixed stars in the course of the year form a circle. For astronomical calculations it was found necessary to determine the arc of a circle by means of its chord. The notion is as old as Hipparchus, a work of whom is referred to as consisting of twelve books on the chords of circular arcs. We have (A.D. 125) Ptolemy's 'Almagest,' the first book of which contains a table of arcs and chords, with the method of construction; and among other theorems on the subject, he gives there the theorem, afterwards inserted in Euclid (book vi. prop. D), relating to the rectangle contained by the diagonals of a quadrilateral inscribed in a circle. The Arabians made the improvement of using, in place of the chord of an arc, the sine, or half-chord of double the arc, and so brought the theory into the form in which it is used in modern trigonometry. The before-mentioned theorem of Ptolemy, — or, rather, a particular case of it, — translated into the notation of sines, gives the expression for the sine of the sum of two arcs in terms of the sines and cosines of the component arcs, and it is thus the fundamental theorem on the subject. We have in the fifteenth and sixteenth centuries a series of mathematicians, who, with wonderful enthusiasm and perseverance, calculated tables of the trigonometrical or circular functions, — Purbach, Müller or Regiomontanus,

[1] Address of Professor CAYLEY before the British association. Concluded from No. 35.

Copernicus, Reinhold, Maurolycus, Vieta, and many others. The tabulations of the functions tangent and secant are due to Reinhold and Maurolycus respectively.

Logarithms were invented, not exclusively with reference to the calculation of trigonometrical tables, but in order to facilitate numerical calculations generally. The invention is due to John Napier of Merchiston, who died in 1618, at sixty-seven years of age. The notion was based upon refined mathematical reasoning on the comparison of the spaces described by two points; the one moving with a uniform velocity, the other with a velocity varying according to a given law. It is to be observed that Napier's logarithms were nearly, but not exactly, those which are now called, sometimes Napierian, but more usually hyperbolic logarithms, those to the base e; and that the change to the base 10 (the great step by which the invention was perfected for the object in view) was indicated by Napier, but actually made by Henry Briggs, afterwards Savilian professor at Oxford (d. 1630). But it is the hyperbolic logarithm which is mathematically important. The direct function e^x, or exp. x, which has for its inverse the hyperbolic logarithm, presented itself, but not in a prominent way. Tables were calculated of the logarithms of numbers, and of those of the trigonometrical functions.

The circular function and the logarithm were thus invented each for a practical purpose, separately, and without any proper connection with each other. The functions are connected through the theory of imaginaries, and form together a group of the utmost importance throughout mathematics: but this is mathematical theory; the obligation of mathematics is for the discovery of the functions.

Forms of spirals presented themselves in Greek architecture, and the curves were considered mathematically by Archimedes. The Greek geometers invented some other curves more or less interesting, but recondite enough in their origin. A curve which might have presented itself to anybody, that described by a point in the circumference of a rolling carriage-wheel, was first noticed by Mersenne in 1615, and is the curve afterwards considered by Roberval, Pascal, and others, under the name of the roulette, otherwise the cycloid. Pascal (1623–62) wrote, at the age of seventeen, his 'Essais pour les coniques' in seven short pages, full of new views on these curves, and in which he gives, in a paragraph of eight lines, his theory of the inscribed hexagon.

Kepler (1571–1630), by his empirical determination of the laws of planetary motion, brought into connection with astronomy one of the forms of conic, the ellipse, and established a foundation for the theory of gravitation. Contemporary with him for most of his life, we have Galileo (1564–1642), the founder of the science of dynamics; and closely following upon Galileo, we have Isaac Newton (1643–1727). The 'Philosophiae naturalis principia mathematica,' known as the 'Principia,' was first published in 1687.

The physical, statical, or dynamical questions which presented themselves before the publication of the 'Principia' were of no particular mathematical difficulty; but it is quite otherwise with the crowd of interesting questions arising out of the theory of gravitation, and which, in becoming the subject of mathematical investigation, have contributed very much to the advance of mathematics. We have the problem of two bodies, or, what is the same thing, that of the motion of a particle about a fixed centre of force, for any law of force; we have also the problem (mathematically very interesting) of the motion of a body attracted to two or more fixed centres of force; then, next preceding that of the actual solar system, the problem of three bodies. This has ever been and is far beyond the power of mathematics; and it is in the lunar and planetary theories replaced by what is mathematically a different problem, — that of the motion of a body under the action of a principal central force and a disturbing force, — or, in one mode of treatment, by the problem of disturbed elliptic motion. I would remark that we have here an instance in which an astronomical fact, the observed slow variation of the orbit of a planet, has directly suggested a mathematical method, applied to other dynamical problems, and which is the basis of very extensive modern investigations in regard to systems of differential equations. Again: immediately arising out of the theory of gravitation, we have the problem of finding the attraction of a solid body of any given form upon a particle, solved by Newton in the case of a homogeneous sphere, but which is far more difficult in the next succeeding cases of the spheroid of revolution (very ably treated by Maclaurin), and of the ellipsoid of three unequal axes. There is, perhaps, no problem of mathematics which has been treated by so great a variety of methods, or has given rise to so much interesting investigation, as this last problem of the attraction of an ellipsoid upon an interior or exterior point. It was a dynamical problem, that of vibrating strings, by which Lagrange was led to the theory of the representation of a function as the sum of a series of multiple sines and cosines; and connected with this we have the expansions in terms of Legendre's functions P_n, suggested to him by the question, just referred to, of the attraction of an ellipsoid. The subsequent investigations of Laplace, on the attractions of bodies differing slightly from the sphere, led to the functions of two variables called Laplace's functions. I have been speaking of ellipsoids; but the general theory is that of attractions, which has become a very wide branch of modern mathematics. Associated with it, we have in particular the names of Gauss, Lejeune-Dirichlet, and Green; and I must not omit to mention that the theory is now one relating to n-dimensional space. Another great problem of celestial mechanics, that of the motion of the earth about its centre of gravity (in the most simple case, that of a body not acted upon by any forces), is a very interesting one in the mathematical point of view.

I may mention a few other instances where a practical or physical question has connected itself with the development of mathematical theory. I have spoken of two map projections, — the stereographic, dating from Ptolemy; and Mercator's projection, invented by Edward Wright about the year 1600. Each of these, as a particular case of the orthomorphic projection, belongs to the theory of the geometrical representation of an imaginary variable. I have spoken also of perspective, and (in an omitted paragraph) of the representation of solid figures employed in Monge's descriptive geometry. Monge, it is well known, is the author of the geometrical theory of the curvature of surfaces, and of curves of curvature. He was led to this theory by a problem of earthwork, — from a given area, covered with earth of uniform thickness, to carry the earth and distribute it over an equal given area with the least amount of cartage. For the solution of the corresponding problem in solid geometry, he had to consider the intersecting normals of a surface, and so arrived at the curves of curvature (see his 'Mémoire sur les déblais et les remblais,' *Mém. de l'acad.*, 1781). The normals of a surface are, again, a particular case of a doubly infinite system of lines, and are so connected with the modern theories of congruences and complexes.

The undulatory theory of light led to Fresnel's wave-surface, — a surface of the fourth order, by far the most interesting one which had then presented itself. A geometrical property of this surface, that of having tangent planes, each touching it along a plane curve (in fact, a circle), gave to Sir W. R. Hamilton the theory of conical refraction. The wave-surface is now regarded in geometry as a particular case of Kummer's quartic surface, with sixteen conical points and sixteen singular tangent planes.

My imperfect acquaintance, as well with the mathematics as the physics, prevents me from speaking of the benefits which the theory of partial differential equations has received from the hydrodynamical theory of vortex motion, and from the great physical theories of electricity, magnetism, and energy.

It is difficult to give an idea of the vast extent of modern mathematics. This word 'extent' is not the right one: I mean extent crowded with beautiful detail, — not an extent of mere uniformity, such as an objectless plain, but of a tract of beautiful country seen at first in the distance, but which will bear to be rambled through, and studied in every detail of hillside and valley, stream, rock, wood, and flower. But as for any thing else, so for a mathematical theory, — beauty can be perceived, but not explained. As for mere extent, I might illustrate this by speaking of the dates at which some of the great extensions have been made in several branches of mathematical science.

And, in fact, in the address as written, I speak at considerable length of the extensions in geometry since the time of Descartes, and in other specified subjects since the commencement of the century. These subjects are the general theory of the function of an imaginary variable; the leading known functions, viz., the elliptic and single theta-functions and the Abelian and multiple theta-functions; the theory of equations and the theory of numbers. I refer also to some theories outside of ordinary mathematics, — the multiple algebra, or linear associative algebra, of the late Benjamin Peirce; the theory of Argand, Warren, and Peacock, in regard to imaginaries in plane geometry; Sir W. R. Hamilton's quaternions; Clifford's biquaternions; the theories developed in Grassmann's 'Ausdehnungslehre,' with recent extensions thereof to non-Euclidian space by Mr. Homersham Cox; also Boole's 'Mathematical logic,' and a work connected with logic, but primarily mathematical and of the highest importance, Shubert's 'Abzählende geometrie' (1878). I remark that all this in regard to theories outside of ordinary mathematics is still on the text of the vast extent of modern mathematics.

In conclusion, I would say that mathematics have steadily advanced from the time of the Greek geometers. Nothing is lost or wasted. The achievements of Euclid, Archimedes, and Apollonius, are as admirable now as they were in their own days. Descartes' method of co-ordinates is a possession forever. But mathematics has never been cultivated more zealously and diligently, or with greater success, than in this century, — in the last half of it, or at the present time. The advances made have been enormous. The actual field is boundless, the future full of hope. In regard to pure mathematics we may most confidently say, —

> "Yet I doubt not through the ages one increasing purpose runs,
> And the thoughts of men are widened with the process of the suns."

THE ENDOWMENT OF BIOLOGICAL RESEARCH.[1]

It has become the custom for the presidents of the various sections of this association to open the proceedings of the departments with the chairmanship of which they are charged by formal addresses. In reflecting on the topics which it might be desirable for me to bring under your notice, as your president, on the present occasion, it has occurred to me that I might use this opportunity most fitly by departing somewhat from the prevailing custom of reviewing the progress of science in some special direction during the past year, and that, instead of placing before you a summary of the results recently obtained by the investigations of biologists in this or that line of inquiry, I might ask your attention, and that of the external public (who are wont to give some kindly consideration to the opinions expressed on these occasions) to a matter which is even more directly connected with the avowed object of our association; namely, 'the advancement of science.' I propose to place before you a few observations upon the provision which exists in this country for the advancement of that branch of science to which section D is dedicated; namely, biology.

I am aware that it is usual for those who speak of men of science and their pursuits to ignore altogether such sordid topics as the one which I have chosen to bring forward. A certain pride, on the one hand, and a willing acquiescence, on the other hand, usually prevent those who are professionally concerned with

[1] An address to the biological section of the British association. By Prof. E. Ray Lankester, M.A., F.R.S., F.L.S., president of the section. From advance copy kindly furnished by the editor of *Nature*.

scientific pursuits from exposing to the public the pecuniary destitution, and the consequent crippling and languor, of scientific research in this country. Those Englishmen who take an interest in the progress of science are apt to suppose, that, in some way which they have never clearly understood, the pursuit of scientific truth is not only its own reward, but also a sufficient source of food, drink, and clothing. Whilst they are interested and amused by the remarkable discoveries of scientific men, they are astonished whenever a proposal is mentioned to assign salaries to a few such persons, sufficient to enable them to live decently whilst devoting their time and strength to investigation. The public are becoming more and more anxious to have the opinion or report of scientific men upon matters of commercial importance, or in relation to the public health: and yet, in ninty-nine cases out of a hundred, they expect to have that opinion for the asking, although accustomed to pay other professional men handsomely for similar service. There is, it appears, in the public mind, a vague belief that men who occupy their time with the endeavor to add to knowledge in this or that branch of science are mysteriously supported by the state exchequer. and are thus fair game for attacking with all sorts of demands for gratuitous service; or, on the other hand, the notion at work appears sometimes to be, that the making of new knowledge — in fact, scientific discovery — is an agreeable pastime, in which some ingenious gentlemen, whose business in other directions takes up their best hours, find relaxation after dinner or on the spare hours of Sunday. Such mistaken views ought to be dispelled with all possible celerity and determination. It is in part owing to the fact that the real state of the case is not widely and persistently made known to the public, that no attempt is made in this country to raise scientific research, and especially biological research, from the condition of destitution and neglect under which it suffers, — a condition which is far below that of these same interests in France and Germany, and even in Holland, Belgium, Italy, and Russia, and is discreditable to England in proportion as she is richer than other states.

It appears to me, that, in placing this matter before you, I may remove myself from any suggestion of self-interest by at once stating that the great defect to which I shall draw your attention is, *not* that the few existing public positions which are open in this country to men who intend to devote their chief energies to biological research are endowed with insufficient salaries, but that there is not any thing like *a sufficiently large number* of those posts, and that there is in that respect, from a national point of view, a pecuniary starvation of biology, a withholding of money, which (to use another metaphor) is no less the sinews of the war of science against ignorance than of other less glorious campaigns. Surely, men engaged in the scientific profession may advocate the claim of science to maintenance and needful pecuniary provision. It seems to me that we should, if necessary, swallow, rather than be controlled by, that pride which tempts us to paint the scientific career as one far above and independent of pecuniary considerations: whereas all the while we know that knowledge is languishing, that able men are drawn off from scientific research into other careers, that important discoveries are approached and their final grasp relinquished, that great men depart, and leave no disciples or successors, simply for want of that which is largely given in other countries, — of that which is most abundant in this country, and is so lavishly expended on armies and navies, on the development of commercial resources, on a hundred injurious or meaningless charities, — viz., money.

I have no doubt that I have the sympathy of all my hearers in wishing for more extensive provision in this country for the prosecution of scientific research, and especially of biological research. I need hardly remind this audience of the almost romantic history of some of the great discoveries which have been made in reference to the nature and history of living things during the past century. The microscope, which was a drawing-room toy a hundred years ago, has, in the hands of devoted and gifted students of nature, been the means of giving us knowledge which, on the one hand, has saved thousands of surgical patients from terrible pain and death, and, on the other hand, has laid the foundation of that new philosophy with which the name of Darwin will forever be associated. When Ehrenberg, and, later, Dujardin, described and figured the various forms of Monas, Vibrio, Spirillum, and Bacterium, which their microscopes revealed to them, no one could predict that fifty years later these organisms would be recognized as the cause of that dangerous suppuration of wounds which so often defeated the beneficent efforts of the surgeon, and made an operation in a hospital-ward as dangerous to the patient as residence in a plague-stricken city. Yet this is the result which the assiduous studies of the biologists, provided with laboratories and maintenance by continental states, have in due time brought to light. Theodore Schwann, professor at Liége, first showed that these bacteria are the cause of the putrefaction of organic substances; and subsequently, the French chemist Pasteur, professor in the École normale of Paris, confirmed and extended Schwann's discovery, so as to establish the belief that all putrefactive changes are due to such minute organisms, and that, if these organisms can be kept at bay, no putrefaction can occur in any given substance.

It was reserved for our countryman, Joseph Lister, to apply this result to the treatment of wounds, and, by his famous antiseptic method, to destroy by means of special poisons the putrefactive organisms which necessarily find their way into the neighborhood of a wound, or of the surgeon's knife and dressings, and to ward off by similar means the access of such organisms to the wounded surface. The amount of death, not to speak of the suffering short of death, which the knowledge of bacteria gained by the microscope has thus averted, is incalculable.

Yet, further, the discoveries of Ehrenberg, Schwann, and Pasteur, are bearing fruit of a similar kind in other directions. It seems in the highest degree probable that the terrible scourge known as tubercular consumption, or phthisis, is due to a parasitic bacterium (Bacillus) discovered two years since by Koch of Berlin as the immediate result of investigations which he was commissioned to carry on at the public expense, in the specially erected laboratory of public health, by the German imperial government. The diseases known as erysipelas and glanders (or farcy) have similarly, within the past few months in German state-supported laboratories, been shown to be due to the attacks of special kinds of bacteria. At present this knowledge has not led to a successful method of combating those diseases, but we can hardly doubt that it will ultimately do so. We are warranted in this belief by the fact that the disease known as 'splenic fever' in cattle, and 'malignant pustule,' or anthrax, in man, has likewise been shown to be due to the action of a special kind of bacterium, and that this knowledge has, in the hands of MM. Toussaint and Pasteur, led to a treatment, in relation to this disease, similar to that of vaccination in relation to small-pox. By cultivation a modified growth of the anthrax parasite is obtained, which is then used in order to inoculate cattle and sheep with a mild form of the disease, such inoculation having the result of rendering the cattle and sheep free from the attacks of the severe form of disease, just as vaccination or innoculation with cow-pox protects man from the attack of the deadly small-pox. One other case I may call to mind, in which knowledge of the presence of bacteria as the cause of disease has led to successful curative treatment. A not uncommon affliction is inflammation of the bladder, accompanied by ammoniacal decomposition of the urine. Microscopical investigation has shown that this ammoniacal decomposition is entirely due to the activity of a bacterium. Fortunately, this bacterium is at once killed by weak solutions of quinine, which can be injected into the bladder without causing any injury or irritation. This example appears to have great importance; because it is the fact that many kinds of bacteria are not killed by solutions of quinine, but require other and much more irritant poisons to destroy their life, which could not be injected into the bladder without causing disastrous effects. Since some bacteria are killed by one poison, and some by another, it becomes a matter of the keenest interest to find out all such poisons; and possibly among them may be some which can be applied so as to kill the bacteria which produce phthisis, erysipelas, glanders, anthrax, and other scourges of humanity, whilst not acting injuriously upon the body of the victim in which these infinitesimal parasites are doing their deadly work. In such ways as this, biology has turned the toy 'magnifying-glass' of the last century into a saver of life and health.

No less has the same agency revolutionized the thoughts of men in every branch of philosophy and speculation. The knowledge of the growth of the chick from the egg, and of other organisms from similarly constituted beginnings, has been slowly and continuously gained by prodigious labor, extending over generation after generation of students who have occupied the laboratories, and lived on the stipends, provided by the governments of European states, — not English, but chiefly German. It is this history of the development of the individual animal and plant from a simple homogeneous beginning to a complex heterogeneous adult, which has furnished the starting-point for the wide-reaching doctrine of evolution. It is this knowledge, coupled with the knowledge of the myriad details of structure of all kinds of animals and plants, which the faithful occupants of laboratories, and the guardians of biological collections, have, in the past hundred years, laboriously searched out, and recorded. It is this which enabled Darwin to propound, to test, and to firmly establish his theory of the origin of species by natural selection, and finally to bring the origin, development, and progress of man also into the area of physical science. I have said enough, in referring only to two very diverse examples of the far-reaching consequences flowing from the discoveries of single-minded investigators in biological science, to remind my hearers that in the domain of biology, as in other sciences, the results attained by those who have labored simply to extend our knowledge of the structure and properties of living things, in the faith that every increase of knowledge will ultimately bring its blessing to humanity, have, in fact, led with astonishing rapidity to conclusions affecting most profoundly both the bodily and the mental welfare of the community.

We who know the beneficent results which must flow more and more from the labors of those who are able to create new knowledge of living things, or, in other words, are able to aid in the growth of biological science, must feel something more than regret, — even indignation, — that England should do so small a proportion of the laborious investigation which is necessary, and is being carried on for our profit by other nationalities. It must not be supposed, because we have had our Harvey and our Darwin, our Hunter and our Lister, that therefore we have done, and are doing, all that is needful in the increase of biological science. The position of this country in relation to the progress of science is not to be decided by the citation of great names.

We require to look more fully into the matter than this. The question is, not whether England has produced some great discoverers, or as many as any other nationality, but whether we might not, with advantage to our own community and that of the civilized world generally, do far more in the field of scientific investigation than we do.

It may be laid down as a general proposition, to which I know of no important exception, that scientific discovery has only been made by one of two classes of men; namely, (1) those whose time could be devoted to it in virtue of their possessing inherited fortunes; (2) those whose time could be devoted to it in virtue of their possessing a stipend or endowment especially assigned to them for that purpose.

Now, it is a very remarkable fact that in England, far more than in any other country, the possessors of private fortunes have devoted themselves to scientific investigation. Not only have we, in all parts of the country, numerous *dilettanti*,[1] who, especially in various branches of biology, do valuable work in continually adding to knowledge, quietly pursuing their favorite study without seeking to reach to any great eminence, but it is the fact that many of the greatest names of English discoverers in science are those of men who held no professional position designed to maintain an investigator, but owed their opportunity simply to the fact that they enjoyed a more or less ample income by inheritance. Thus, Harvey possessed a private fortune, Darwin also, and Lyell. Such, also, is true of some of the English naturalists, who more recently have most successfully devoted their energies to research. Those who wish to defend the present neglect of the government and of public institutions to provide means for the carrying on of scientific research in this country are accustomed to declare as a justification for this neglect, that we do very well without such provision, inasmuch as the cultivation of science here flourishes in the hands of those who are in a position of pecuniary independence. The reply to this is obvious. If those few of our countrymen who by accident are placed in an independent position show such ability in the prosecution of scientific research, how much more would be effected in the same direction, were the machinery provided to enable those also who are *not* accidentally favored by fortune to enter upon the same kind of work! The number of wealthy men who have distinguished themselves in scientific research in England is simply evidence that there is a natural ability and liking for such work in the English character, and is a distinct encouragement to those who have it in their power to do so, to offer the opportunity of devoting themselves to research to a larger number of the members of the community. It is impossible to doubt that there are hundreds of men amongst us who have as great capacity for scientific discovery as those whom fortune has favored with leisure and opportunity. It cannot be doubted, that, were the means provided to enable even a proportion of such men to give themselves up to scientific investigation, great discoveries, of no less importance to the world than those relative to the causes of disease, and the development of living things from the egg, — which I have cited, — would be made as a direct consequence of their activity; whereas now we must wait until, in due course of time, these discoveries shall be made for us in the laboratories of Germany, France, or Russia.

It should further be pointed out, that it is altogether a mistake to suppose that the existence amongst us of a few very eminent men is any evidence that we are contributing largely to the hard work of careful study and observation, which really forms the material upon which the conclusions of eminent discoverers are based. You will find in every department of biological knowledge, that the hard work of investigation is being carried on by the well-trained army of German observers. Whether you ask the zoölogist, the botanist, the physiologist, or the anthropologist, you will get the same answer: it is to German sources that he looks for new information; it is in German workshops that discoveries, each small in itself, but gradually leading up to great conclusions, are daily being made. To a very large extent, the business of those who are occupied with teaching or applying biological science in this country consists in making known what has been done in German laboratories. Our English students flock to Germany to learn the methods of scientific research; and to such a state of weakness is English science reduced, for want of proper nurture and support, that, even on some of the rare occasions when a capable investigator of biological problems has been required for the public service, it has been necessary to obtain the assistance of a foreigner trained in the laboratories of Germany.

Let me now briefly explain what are the arrangements, in number and in kind, which exist in other countries, for the purpose of promoting the advancement of biological science, which are wanting in this country.

In the German empire, with a population of 45,000,000, there are twenty-one universities. These universities are very different from any thing which goes by the name in this country. Amongst its other arrangements, devoted to the study and teaching of all branches of learning and science, each university has five institutes, or establishments, devoted to the prosecution of researches in biological science. These are respectively the physiological, the zoölogical, the anatomical, the pathological, and the botanical. In one of these universities of average size, each of the institutes named consists of a spacious building containing many rooms fitted as workshops, provided with instruments, a museum, and, in the last instance, with an experimental garden. All this is provided and maintained by the state. At the head of each institute is the university professor respectively of physiology, of zoölogy, of anatomy, of pathology, or of botany. He is paid a stipend by the state, which, in the smallest university, is as low as £120, but may be in others as much as £700, and averages, say, £400 a year. Considering the relative expenditure of the professional classes in the two countries, this average may be taken as equal to £800 a year in England.[1] Besides the professor, each institute has attached to it, with salaries paid by the state, two qualified assistants, who, in course of time, will succeed to independent positions. A liberal allowance is also made to each institute, by the state, for the purchase of instruments, material for study, and for the pay of servants; so that the total expenditure on professor, assistants, laboratory service, and

[1] I use this word in its best and truest sense, and would refer those who have been accustomed to associate with it some implication of contempt to the wise and appreciative remarks of Goethe on 'dilettanti.'

[1] From the fact that the salaries of judges, civil servants, military and naval officers, parsons, and schoolmasters, as also the fees of physicians and lawyers, are in Germany even less than half what is paid to their representatives in England, I think that we are justified in making this estimate.

maintenance, averages £800 a year for each institute, reaching as much as £2,000 or £3,000 a year in the larger universities. It is the business of the professor, in conjunction with his assistants and the advanced students, who are admitted to work in the laboratories free of charge, to carry on investigations, *to create new knowledge* in the several domains of physiology, zoölogy, anatomy, pathology, and botany. It is for this that the professor receives his stipend, and it is on his success in this field of labor that his promotion to a more important or better paid post in another university depends. In addition to and irrespective of this part of his duties, each professor is charged with the delivery of courses of lectures, and of elementary instruction to the general students of the university; and for this he is allowed to charge a certain fee to each student, which he receives himself. The total of such fees may, in the case of a largely attended university and a popular subject, form a very important addition to the professorial income; but it is distinctly to be understood that such payment by fees is only an *addition* to the professor's income, quite independent of his stipend, and of his regular occupation in the laboratory: it is paid from a separate source, and for a separate object. There are thus in the German empire more than 100 such institutes devoted to the prosecution of biological discovery, carried on at an annual cost to the state of about £80,000, equal to about £160,000 in England, providing posts of graduated value for 300 investigators, some of small value, sufficient to carry the young student through the earlier portion of his career, whilst he is being trained and acting as the assistant of more experienced men; others forming the sufficient but not too valuable prizes which are the rewards of continuous and successful labor.

In addition to these university institutes, there are in Germany such special laboratories of research, with duly salaried staff of investigators, as the Imperial sanitary institute of Berlin, and the large museums of Berlin, Bremen, and other large towns, corresponding to our own British museum of natural history.

Moreover, we must be careful to note, in making any comparison with the arrangements existing in England, that there are, in addition to the universities in Germany, a number of other educational institutions, at least equal in number, which are known as polytechnic schools, technical colleges, and agricultural colleges. These furnish posts of emolument to a limited number of biological students, who give courses of instruction to their pupils; but they have not the same arrangements for research as the universities, and are closely similar to those colleges which have been founded of late years in the provincial towns of England, such as Bristol, Nottingham, and Leeds. The latter are sometimes quoted by sanguine persons, who are satisfied with the neglected condition of scientific training and research in this country, as really sufficient and adequate representatives of the German universities. As a matter of fact, the excellent English colleges in question do not present any thing at all comparable to the arrangements of a German university, and are, in respect of the amount of money which is expended upon them, the number of their teaching-staff, and the efficiency of their laboratories, inferior not merely to the smallest German university, but inferior to many of the technical schools of that country.

Passing from Germany, I would now ask your attention for a moment to an institution which is supported by the French government, and which — quite irrespective of the French university system, which is not, on the whole, superior to our own — constitutes one of the most effective arrangements, in any European state, for the production of new knowledge. The institution to which I allude is the Collége de France in Paris, — co-existing there with the Sorbonne, the École de médecine, the École normale, the Jardin des plantes, and other state-supported institutions, — in which opportunity is provided for those Frenchmen who have the requisite talent to pursue scientific discovery in the department of biology, and in other branches of science. I particularly mention the Collége de France, because it appears to me that the foundation of such a college in London would be one of the simplest and most direct steps that could be taken towards filling, in some degree, the void from which English science suffers. The Collége de France is divided into a literary and a scientific faculty. Each faculty consists of some twenty professors. Each professor in the scientific faculty is provided with a laboratory and assistants (as many as four assistants in some cases), and with a considerable allowance for the expenses of the instruments and materials required in research. The personal stipend of each professor is £400, which has been increased by an additional £100 a year in some cases from the government department charged with the promotion of higher studies. The professors in this institution, as in the German universities, when a vacancy occurs, have the right of nominating their future colleague, their recommendation being accepted by the government. The professors are not expected to give any elementary instruction, but are directed to carry on original investigations, in prosecuting which, they may associate with themselves pupils who are sufficiently advanced to join in such work; and it is further the duty of each professor to give a course of forty lectures in each year, upon the results of the researches in which he is engaged. There are at present, among the professors of the Collége de France, four of the most distinguished among contemporary students of biological science, — Professor Brown-Sequard, Professor Marey, Professor Balbiani, and Professor Ranvier. Every one who is acquainted with the progress of discovery in physiology, minute anatomy, and embryology, will admit that the opportunities afforded to these men have not been wasted. They have, as the result of the position in which they have been placed, produced abundant and most valuable work, and have, in addition, trained younger men to carry on the same line of activity. It was here, too, in the Collége de France, that the great genius of Claude Bernard found the necessary conditions for its development.

Let us now see how many and what kind of institutions there are in England devised so as to promote the making of new knowledge in biological science. Most persons are apt to be deceived in this matter by the fact that the terms 'university,' 'professorship,' and 'college' are used very freely in England in reference to institutions which have no pecuniary resources whatever, and which, instead of corresponding to the German arrangements which go by these names, are empty titles, neither backed by adequate subsidy of the state nor by endowment from private sources.

In England, with its 25,000,000 inhabitants, there are only four universities which possess endowments and professoriates; viz., Oxford, Cambridge, Durham, and the Victoria (Owens college). Besides these, which are variously and specially organized each in its own way, there are the London colleges (University and King's), the Normal school of science at South Kensington, and various provincial colleges, which are, to a small and varying extent, in possession of funds which could be or are used to promote scientific research. Amongst all these variously arranged institutions, there is an extraordinarily small amount of provision for biological research. In London there is one professorship only, that at the Normal school of science, which is maintained by a stipend paid by the state, and has a laboratory and salaried assistants similarly maintained, in connection with it. The only other posts in London which are provided with stipends intended to enable their holders to pursue researches in the domain of biological science, are the two chairs of physiology and of zoölogy at University college, which, through the munificence of a private individual,[1] have been endowed to the extent of £300 a year each. To these should be added, in our calculation, certain posts in connection with the British museum of natural history and the Royal gardens at Kew, maintained by the state; though it must be remembered that a large part of the expenditure in those institutions is necessarily taken up in the preservation of great national collections, and is not applicable to the subvention of investigators. We may, however, reckon about six posts, great and small, in the British museum, and four at Kew, as coming into the category which we have in view. In London, then, we may reckon approximately some fourteen or fifteen subsidized posts for biological research. In Oxford there fall under this category the professorship of anatomy and his assistant, that of physiology, that of zoölogy, that of botany. The Oxford professorships are well supported by endowment, averaging £700 or £800 a year; but they are inadequately provided with assistants, as compared with corresponding German positions. Whilst Oxford has thus five posts, Cambridge has at present the same number, though the stipends are of less average value. In regard to Durham, it does not appear that the biological professorships (which have their seat in the Newcastle college of science) are supported by stipends derived from endowment: they fall under another category, to which allusion will be made below, of purely teaching positions, supported by the fees paid for such teaching by pupils. The Victoria university (Owens college, Manchester) supports its professors of physiology, anatomy, zoölogy, botany, and pathology, by means partly of endowment, partly of pupils' fees. By the provision of adequate laboratories, and of salaries for assistants to each professor, and of student-fellowships, Owens college gives direct support to orginal investigation. We may reckon five major and eight minor posts as dedicated to biological research in this college. Altogether, then, we have fifteen positions in London and twenty-three in the provinces (taking assistantships and professorships and curatorships together), — a total of thirty-eight in all England, with its 25,000,000 inhabitants, as against the three hundred in Germany, with 45,000,000 inhabitants. In proportion to its population (leaving aside the consideration of its greater wealth), England has only about one-fourth of the provision for the advancement of biological research which exists in Germany.

[1] Mr. Jodrell.

It would not be fair to reckon in this comparison the various biological professorships in small colleges recently created, and paid to a small extent by stipends derived from endowments in the provincial towns of England: for the holders of these chairs are called upon to teach a variety of subjects; for instance, zoölogy, botany, and geology combined. And not only is the devotion of the energies of their teaching-staff to scientific discovery not contemplated in the arrangement of these institutions, but, as a matter of fact, the large demands made on the professors in the way of teaching must deprive them of the time necessary for any serious investigation. Such posts, in the fact that neither time, assistants, nor proper laboratories are provided to enable their holders to engage in scientific research, are schoolmasterships rather than professorships, as the word is used in German universities.

One result of the exceedingly small provision of positions in England, similar to those furnished by the German university system, and of the irregular, uncertain character of many of those which do exist, is, that there is an insufficient supply of young men willing to enter upon the career of zoölogist, botanist, physiologist, or pathologist, as a profession. The number of posts is too small to create a profession, i.e., an avenue of success; and consequently, whereas in Germany there is always a large body of new men ready to fill up the vacancies as they occur in the professorial organization, in England it very naturally does not appear to our university students as a reasonable thing to enter upon research as a profession, when the chances of employment are so few, and far between.

Before stating, as I propose to do, what appears to me a reasonable and proper method of removing, to some extent, the defect in our national life due to the want of provision for scientific research, I will endeavor to meet some of the objections which are usually raised to such views as those which I am advocating. The endowment of research by the state, or from public funds of any kind, is opposed on various grounds. One is, that such action on the part of the government is well enough in continental states, but is contrary to the spirit of English statecraft, which leaves scientific as well as other *enterprise* to the individual initiative of the people. This objection is based on error, both as to fact and theory. It is well enough to leave to individual effort the conduct of such enterprises as are remunerative to the parties who conduct them; but it is a mistake to speak of scientific research as an 'enterprise' at all. The mistake arises from the extraordinary pertinacity with which so-called 'invention' is confounded with the discovery of scientific truth. New knowledge in biological or other branches of science cannot be sold: it has no marketable value. Koch could not have sold the discovery of the bacterium of phthisis for as much as sixpence, had he wished to do so. Accordingly, we find that there is not, and never has been, any tendency among the citizens of this country to provide for themselves institutions for the manufacture of an article of so little pecuniary value to the individual who turns it out as is new knowledge. On the other hand, as a matter of fact, the providing of means for the manufacture of that article is not only not foreign to English statecraft, but is largely, though not largely enough, undertaken by the English state. The Royal observatories, the British museum, the Royal gardens at Kew, the Geological survey, the government grant of £4,000 a year to the Royal society, the £300 or £400 a year (not a large sum) expended through the medical officer of the privy council upon the experimental investigation of disease, are ample evidence that such providing of means for creating new knowledge forms part of the natural and recognized responsibilities of the British government. Such a responsibility clearly is recognized in this country, and does fall, according to the present arrangement of things, upon the central government. What we have to regret is, that those who temporarily hold the reins of government fail to perceive the lamentable inadequacy of the mode in which this responsibility is met.

A second objection which is made to the endowment of research by public funds, or by other means, such as voluntary contributions, is this: it is stated that men engaged in scientific research ought to *teach*, and thus gain their livelihood. It is argued, in fact, that there is no need whatever to provide stipends or laboratories for researchers, since they have only to stand up and teach in order to make income sufficient to keep them and their families, and to provide themselves with laboratories. This is a very plausible statement, because it is the fact that some investigators have also been excellent lecturers, and have been able to make an income by teaching, whilst carrying on a limited amount of scientific investigation. But neither by teaching in the form of popular lectures, nor by teaching university or professional students who desire, as a result, to pass some examination-test, is it possible, where there is a fair field and no favor, for a man to gain a reasonable income, and at the same time to leave himself time and energy to carry on original investigations in science.

In some universities, such as those of Scotland, the privilege of conferring degrees of pecuniary value to their possessors becomes a source of income to the professors of the university. They are, in fact, able to make considerable incomes, independently of endowment, by compelling the candidates for degrees to pay a fee to each professor in the faculty for the right of attending his lectures, and of presentation to the degree: consequently teaching here appears to be producing an income which may support a researcher. In reality, it is the acquisition of the university degree, and not necessarily the teaching, for which the pupil pays his fee. Where the teacher is unprotected by any compulsory regulations (such as that which requires attendance on his lectures, and fee-payment on the part of the pupils), it is *impossible* for him to obtain such an income, by teaching for one hour a day, as will enable him to devote the rest of the day to unremunerative study and investigation, for the following reason. Other teachers, equally satisfactory as teachers, will enter into competition with him, without having the same intention of teaching for one hour only, and of carrying on researches for the rest of the day. They will contemplate teaching for six hours a day, and they will accordingly offer to those who require to be taught, either six hours' teaching for the same fee which the researcher charges for one, or one hour for a sixth part of that fee: consequently the unprotected researcher will find his lecture-room deserted. Pupils will naturally go to the equally good teacher who gives more teaching for the same fee, or the same teaching for a less cost. And no one can say that this is not as it should be. The university pupil requires a certain course of instruction, which he ought to be able to buy at the cheapest rate. It does not seem to be doing justice to the pupil, to compel him to form one of a class consisting of some hundreds of hearers, where he can obtain but little personal supervision or attention from the teacher, whereas, if he had the free disposal of his fee, he might obtain six times the amount of attention from another teacher. This arrangement does not seem to be justifiable, even for the purpose of providing the university professor with an income, and leisure to pursue scientific research. The student's fee should pay for a given amount of teaching at the market value; and he has just cause of complaint, if, by compulsory enactments, he is taxed to provide the country with scientific investigation.

Teaching must, in all fairness, ultimately be paid for as teaching; and scientific research must be provided for out of other funds than those extracted from the pockets of needy students, who have a reasonable right to demand, in return for their fees, a full modicum of instruction and direction in study.

In the German universities, the professor receives a stipend which provides for him as an investigator. He also gives lectures, for which he charges a fee;

but no student is compelled to attend those lectures as a condition of obtaining his degree. Accordingly, independent teachers can and do compete with the professor in providing for the students' requirements in the matter of instruction. As a consequence, the fees charged for teaching are exceedingly small, and the student can feel assured that he is obtaining his money's worth for his money. He is not compelled to pay any fee to any teacher as a condition of his promotion to the university degree. In a German university, if the professor in a given subject is incompetent, or the class overcrowded, the student can take his fee to a private teacher, and get better teaching. All that is required of the candidate, as a condition of his promotion to the doctor's degree, is that he shall satisfy the examination-tests imposed by the faculty, and produce an original thesis.

Unless there be some such compelling influence as that obtaining in the Scotch universities, enabling the would-be researcher to gather to him pupils and fees without fear of competition, it seems impossible that he should gain an income by teaching, whilst reserving to himself time and energy for the pursuit of scientific inquiry. It is thus seen that the necessity of endowment, in some form or another, to make provision for scientific research, is a reality, in spite of the suggestion that teaching affords a means whereby the researcher may readily provide for himself. The simple fact is, that a teacher can only make a sufficient income by teaching, on the condition that he devotes his whole time and energy to that occupation.

Whilst I feel called upon to emphatically distinguish the two functions, — viz., that of *creating new knowledge*, and that of *distributing existing knowledge*, — and to maintain that it is only by arbitrary and undesirable arrangements not likely to be tolerated, or, at any rate, extended, at the present day, that the latter can be made to serve as the support of the former, I must be careful to point out that I agree most cordially with those who hold that it is an excellent thing for a man who is engaged in the one to give a certain amount of time to the other. It is a matter of experience, that the best teachers of a subject are, *ceteris paribus*, those who are actually engaged in the advancement of that subject, and who have shown such a thorough understanding of that subject as is necessary for making new knowledge in connection with it. It is also, in most cases, a good thing for the man engaged in research to have a certain small amount of change of occupation, and to be called upon to take such a survey of the subject in connection with which his researches are made, as is involved in the delivery of a course of lectures, and other details of teaching. Though it is not a thing to be contemplated, that the researcher shall sell his instruction at a price sufficiently high to enable him to live by teaching, yet it is a good thing to make teaching an additional and subsidiary part of his life's work. This end is effected in Germany by making it a duty of the professor (already supported by a stipend) to give some five or six lectures a week during the academical session, for which he is paid by the fees of his hearers. The fees are low, but are sufficient to be an inducement; and, inasmuch as the attendance of the students is not compulsory, the professor is stimulated to produce good and effective lectures at a reasonable charge, so as to attract pupils who would seek instruction from some one else, if the lectures were not good, or the fees too high. Indeed, in Germany this system works so much to the advantage of the students, that the private teachers of the universities at one time obtained the creation of a regulation forbidding the professors to reduce their fees below a certain minimum; since, with so low a fee as some professors were charging, it was impossible for a private teacher to compete. This state of things may be compared with much advantage with the condition of British universities. In these we hear, from one direction, complaints of the high fees charged, and of the ineffective teaching given by the professoriate; and in other universities, where no adequate fees are allowed to the professors as a stimulus to them to offer useful and efficient teaching, we find that the teaching has passed entirely out of their hands into those of college tutors and lecturers. The fact is, that a satisfactory relation between teaching and research is one which will not naturally and spontaneously arrange itself. It can hardly be said to exist in any British university or college, but the method has been thought out and carried into practice in Germany. It consists in giving a competent researcher a stipend, and a laboratory for his research work, and then requiring him to do a small amount of teaching, remunerated by fees proportionate to his ability and the pains which he may take in his teaching. If you pay him a fixed sum as a teacher, or artificially insure the attendance of his class, instead of letting this part of his income vary simply and directly with the attractiveness of his teaching, you will find as the result that (with rare exceptions) he will not give effective and useful teaching. He will naturally tend to do the minimum required of him in a perfunctory way. On the other hand, if you leave him without stipend as a researcher, dependent on the fees of pupils for an income, he will give all his time and energies to teaching: he will cease to do any research, and become, *pro tanto*, an inferior teacher.

A third objection which is sometimes made to the proposition that scientific research must be supported and paid for as such, is the following: it is believed by many persons that a man who occupies his best energies in scientific research can always, if he choose, make an income by writing popular books or newspaper articles in his spare hours; and, accordingly, it is gravely maintained that there is no need to provide stipends, and the means of carrying on their work, for researchers. To do so, according to this view, would be to encourage them in an exclusive reticence, and to remove from them the inducement to address the public on the subject of their researches, by which the public would lose valuable instruction.

This view has been seriously urged, or I should not here notice it. Any one who is acquainted with the sale of scientific books, and the profits which either author or publisher makes by them, knows that the suggestion which I have quoted is ludicrous. The writing of a good book is not a thing to be done in leisure moments; and such as have been the result of original research have cost their authors often years of labor, apart from the mere writing. Mr. Darwin's books, no doubt, have had a large sale; but that is due to the fact, apart from the exceptional genius of the man who wrote them, that they represent some thirty or more years of hard work, during which he was silent. There is not a sufficiently large public interested in the progress of science to enable a researcher to gain an income by writing books, however great his literary facility. A schoolbook or classbook may now and then add more or less to the income of a scientific investigator; but he who becomes the popular exponent of scientific ideas, except in a very moderate and limited degree, must abandon the work of creating new knowledge. The professional *littérateur* of science is as much removed by his occupation from all opportunity of serious investigation as is the professional teacher who has to consume all his time in teaching. Any other profession — such as the bar, medicine, or the church — is more likely to leave one of its followers time and means for scientific research than is that of either the popular writer or the successful teacher.

We have, then, seen that there is no escape from the necessity of providing stipends and laboratories for the purpose of creating new knowledge, as is done in continental states, if we are agreed that more of this new knowledge is needed, and is among the products which a civilized community is bound to turn out, both for its own benefit and for that of the community of states, which give to and take from one another in such matters.

There are some who would finally attack our contention by denying that new knowledge is a good thing, and by refusing to recognize any obligation, on the part of England, to contribute her share to that common stock of increasing knowledge by which she necessarily profits. Among such persons are those who would prohibit altogether the pursuit of experimental physiology in England, and yet would not and do not hesitate to avail themselves of the services of medical men whose power of rendering those services depends on the fact that they have learned the results obtained by the experiments of physiologists in other countries or in former times. In reference to this strange contempt and even hatred of science, which undoubtedly has an existence among some persons of consideration even at the present day, I shall have a few words to say before concluding this address. I have now to ask you to listen to what seems to me to be the demand which we should make, as members of a British association for the advancement of science, in respect of adequate provision for the creation of new knowledge in the field of biology in England.

Taking England alone, as distinct from Scotland and Ireland, we require, in order to be approximately on a level with Germany, forty new biological institutes, distributed among the five branches of physiology, zoölogy, anatomy, pathology, and botany, — forty, in addition to the fifteen which we may reckon (taking one place with another) as already existing. The average cost of the buildings required would be about £4,000 for each, giving a total initial expenditure of £160,000; the average cost of stipends for the director, assistants, and maintenance, we may calculate at £1,500 annually for each, or £60,000 for the forty, — equal to a capital sum of £2,000,000. These institutes should be distributed in groups of five — eight groups in all — throughout the country. One such group would be placed in London (which is at present almost totally destitute of such arrangements), one in Bristol, one in Birmingham, one in Nottingham, one in Leeds, one in Newcastle, one in Ipswich, one in Cardiff, one in Plymouth, — in fact, one in each of the great towns of the kingdom where there is at present, or where there might be with advantage, a centre of professional education and higher study. The first and the most liberally arranged of these biological institutes — embracing its five branches, each with its special laboratory and staff — should be in London. If we can have nothing else, surely we may demand, with some hope that our request will eventually obtain compliance, the formation in London of a College of scientific research similar to that of Paris (the Collége de France). It is one of the misfortunes and disgraces of London, that, alone amongst the capitals of Europe, with the exception of Constantinople, it is destitute of any institution corresponding to the universities and colleges of research which exist elsewhere.

Either in connection with a properly organized teaching university, or as an independent institution, it seems to me a primary need of the day that the government should establish in London laboratories for scientific research. Two hundred and fifty years ago Sir Thomas Gresham founded an institution for scientific research in the city of London. The property which he left for this purpose is now estimated to be worth three millions sterling. This property was deliberately appropriated to other uses, by the Corporation of the city of London and the Mercers' company, about a hundred years since, with the consent of both Houses of Parliament. By this outrageous act of spoliation these corporations, who were the trustees of Gresham, have incurred the curse which he quaintly inserted in his will in the hope of restraining them from attempts to divert his property from the uses to which he destined it. 'Gresham's curse' runs as follows: "And that I do require and charge the said Corporations and chief governors thereof, with circumspect Diligence and without long Delay, to procure and see to be done and obtained, as they will answer the same before Almighty God; (for if they or any of them should neglect the obtaining of such Licenses or Warrants, which I trust cannot be difficult, nor so chargeable, but that the overplus of my Rents and Profits of the Premisses hereinbefore to them disposed, will soon recompense the same; because to soe good Purpose in the Commonwealth, no Prince nor Council in any Age, will deny or defeat the same. And if conveniently by my Will or other Convenience, I might assure it, I would not leave it to be done after my death, then the same shall revert to my heirs, whereas I do mean the same to the Commonwealth, and then THE DEFAULT THEREOF SHALL BE TO THE REPROACH AND CONDEMNATION OF THE SAID CORPORATIONS AFORE GOD"). I confess that I find it difficult to see how the present representatives of the corporations who perverted Gresham's trust are to escape from justly deserving the curse pronounced against those corporations, unless they conscientiously take steps to restore Gresham's money to its proper uses. Let us hope that Gresham's curse may be realized in no more deadly form than that of an act of parliament repealing the former one which sanctioned the perversion of Gresham's money. Such a sequel to the report of the commission which has recently inquired into the proceedings of the corporation and companies of the city of London is not unlikely.

Whilst we should, I think, especially press upon public attention the need for an institute of scientific research in London, and indicate the source from which its funds may be fitly derived, we must also urge the foundation of other institutes in the provinces, upon the scale already sketched; because it is only by the existence of numerous posts, and of a series of such posts, — some of greater and some of less value, the latter more numerous than the former, — that any thing like a professional career for scientific workers can be constructed. It is especially necessary to constitute what I have termed 'assistantships,' that is, junior posts, in which younger men assist, and are trained by, more experienced men. Even in the few institutions which do already exist, additional provision of this kind is what is wanted more than any thing else, so that there may be a progressive career open to the young student, and a sufficient field of trained investigators from which to select in filling up the vacancies in more valuable positions.

I am well aware that it will be said that the scheme which I have proposed to you is gigantic and almost alarming in respect of the amount of money which it demands. One hundred and sixty thousand pounds a year for biology alone must seem, not to my hearers, but to those who regard biology as an amusing speculation, — that is to say, who know little or nothing about it, — an extravagant suggestion. Unfortunately, it is also true that such persons are very numerous, — in fact, constitute an overwhelming majority of the community; but they are becoming less numerous every day. The time will come, it seems possible, when there will be more than one member of the government who will understand and appreciate the value of scientific research. There are already a few members of the House of Commons who are fully alive to its significance and importance.

We may have to wait for the expenditure of such a sum as I have named, and possibly it may be derived ultimately from local rather than imperial sources, though I do not see why it should be; yet I think it is a good thing to realize *now* that this is what we ought to expend in order to be on a level with Germany. This apparently extravagant and unheard of appropriation of public money *is actually made every year in Germany.*

I think it is well to put the matter before you in this definite manner; because I have reason to believe that even those whom we might expect to be well informed in regard to such matters are not so, and, as a consequence, there is not that keen sense of the inferiority and inadequacy of English arrangements in these matters which one would gladly see actuating the conduct of English statesmen. For instance: only a few years ago, when speaking at Nottingham, the present prime-minister, who has taken an active part in re-arranging our universities, and has, it is well known, much interest in science and learning, stated that £27,000, the capital sum expended on the Nottingham college of science, was a very important contribution to the support of learning in this country, amounting, as he said he was able to state from the perusal of official documents, to as much as one-third of what was spent in Germany during the past year upon her numerous universities, which were so often held up to England as an example of a well-supported academical system. Now, I do not think that Mr. Gladstone can ever have had the opportunity of considering the actual facts with regard to German universities: for he was in this instance misled by the official return of expenditure on a single university, namely, that of Strasburg; the total annual expenditure on the twenty-one German universities being, in reality, about £800,000, by the side of which a capital sum of £27,000 looks very small indeed. I cannot but believe, that if the facts were known to public men, in reference to the expenditure incurred by foreign states in support of scientific inquiry, they would be willing to do something in this country of a sufficient and statesmanlike character. As it is, the concessions which have been made in this direction appear to me to be in some instances not based upon a really comprehensive knowledge of the situation. Thus, the tentative grant of £4,000 a year from the treasury to the Royal society of London appears to me not to be a well-devised experiment in the promotion of scientific research by means of grants of money; because it is on too small a scale to produce any definite effect, and because the money cannot be relied upon from year to year as a permanent source of support to any serious undertaking.

The Royal society most laboriously and conscientiously does its best to use this money to the satisfaction of the country, but the task thus assigned to it is one of almost insurmountable difficulty. In fact, no such miniature experiments are needed. The experiment has been made on a large scale in Germany, and satisfactory results have been obtained. The reasonable course to pursue is to benefit by the experience, as to details and methods of administration, obtained in the course of the last sixty years in Germany, and to apply that experience to our own case.

It is quite clear that 'the voluntary principle' can do little towards the adequate endowment of scientific research. Ancient endowments belonging to the country must be applied thereto, or else local or imperial taxes must be the source of the necessary support.

Seeing that the results of research are distinctly of imperial and not of local value, it would seem appropriate that a portion of the imperial revenue should be devoted to their achievement. In fact, as I have before mentioned, the principle of such an application of public money has long been admitted, and is in operation.

Whilst voluntary donations on the part of private persons can do little to constitute a fund which shall provide the requisite endowment for the scheme of biological institutes which I have sketched (not to mention those required for other branches of science), yet those who are interested in the progress of scientific investigation may, by individual effort, do something, however little, towards placing research in a more advantageous position in this country. Supposing it were possible, as I am sanguine enough to believe that it is, to collect in the course of a year or two, from private sources, a sum of £20,000 for the maintenance of a biological laboratory and staff: it would be necessary, in expending so limited a sum, to aim at the provision of something which would be likely to produce the largest and most obvious results in return for the outlay, and to benefit the largest number of scientific observers in this department.

I believe that it is the general opinion among biologists, that there could be no more generally useful institution thus set in operation than a biological laboratory upon the seacoast, which, besides its own permanent staff of officers, would throw open its resources to such naturalists as might from time to time be able to devote themselves to researches within its precincts. There is no such laboratory on the whole of the long line of British coast. At Naples there is Dr. Dohrn's celebrated and invaluable laboratory, which is frequented by naturalists from all parts of the world; at Trieste, the Austrian government supports such a laboratory; at Concarneau, Roscoff, and Villefranche, the French government has such institutions; at Beaufort, in North Carolina, the Johns Hopkins university has its marine laboratory; and at Newport Professor Alexander Agassiz has arranged a very perfect institution also for the study of marine life. In spite of the great interest which English naturalists have always taken in the exploration of the sea and marine organisms; in spite of the fact that the success, and even the existence, of our fisheries industries, to a large extent depend upon our gaining the knowledge which a well-organized laboratory of marine biology would help us to gain, — there is actually no such institution in existence.

This is not the occasion on which to explain precisely how, and to what extent, a laboratory of marine zoölogy might be of national importance. I hope to see that matter brought before the section during the course of our meeting. But I may point out now, that though it appears to me that the great need for biological institutes, to which I have drawn your attention, can *not* be met by private munificence, and must, in the end, be arranged for by the continued action of the government in carrying out a policy to which it has for many years been committed, and which has been approved by conservatives and liberals alike, yet such a special institution as a laboratory of marine biology, serving as a temporary workshop to any and all of our numerous students of the important problems connected with the life of marine plants and animals, might very well be undertaken from private funds. Should it be possible, on the occasion of this meeting of the British association in Southport, to obtain some promise of assistance towards the realization of this project, I think we shall be able to congratulate ourselves on having done something, though small, perhaps, in amount, towards making better provision for biological research, and therefore something towards the advancement of science.

In conclusion, let me say, that, in advocating to-day the claim of biological science to a far greater measure of support than it receives at present from the public funds, I have endeavored to press that claim chiefly on the ground of the obvious utility to the community of that kind of knowledge which is called biology. I have endeavored to meet the opposition of those who object to the interference of the state, wherever it may be possible to attain the end in view without such interference, but who profess themselves willing to see public money expended in promoting objects which are of real importance to the country, and which cannot be trusted to the voluntary enterprise arising from the operation of the laws of self-preservation, and the struggle for wealth. There are, however, it seems to me, further reasons for desiring a thorough and practical recognition by the state of the value of scientific research. There are not wanting persons of some cultivation, who have perceived and fully realized the value of that knowledge which is called science, and of its methods, and yet are anxious to restrain rather than to aid the growth of that knowledge. They find in science something inimical to their own interests, and accordingly either condemn it as dangerous and untrustworthy, or encourage themselves to treat it with contempt by asserting, that, 'after all, science counts for very little,' — a statement which is unhappily true in one sense, though totally untrue when it is intended to signify that the progress of science is not a matter which profoundly influences every factor in the well-being of the community. Amongst such people there is a positive hatred of science, which finds expression in their exclusion of it, even at this day, from the ordinary curriculum of public-school education, and in the baseless, though oft-repeated calumny, that science is hostile to art, and is responsible for all that is harsh, ugly, and repulsive in modern life. To such opponents of the advancement of science it is of little use to offer explanations and arguments. But we may, when we reflect on their instinctive hostility, and the misrepresentations of science and the scientific spirit which it leads them to disseminate, console ourselves by bringing to mind what science really is, and what truly is the nature of that calling in which a man who makes new knowledge is engaged.

They mock at the botanist as a pedant, and the zoölogist as a monomaniac; they execrate the physiologist as a monster of cruelty, and brand the geologist as a blasphemer; chemistry is held responsible for the abomination of aniline dyes and the pollution of rivers, and physics for the dirt and misery of great factory towns. By these unbelievers, science is declared responsible for individual eccentricities of character, as well as for the sins of the commercial utilizers of new knowledge. The pursuit of science is said to produce a dearth of imagination, incapability of enjoying the beauty either of nature or of art, scorn of literary culture, arrogance, irreverence, vanity, and the ambition of personal glorification.

Such are the charges, from time to time, made by those who dislike science; and for such reasons they would withhold, and persuade others to withhold, the fair measure of support for scientific research which this country owes to the community of civilized states. Not in reply to these misrepresentations, but by way of contrast, I would here state what science seems to be to those who are on the other side, and how, therefore, it seems to them wrong to delay in doing all that the wealth and power of the state can do to promote its progress.

Science is not a name applicable to any one branch of knowledge, but includes all knowledge which is of a certain order or scale of completeness. All knowledge which is deep enough to touch the causes of things is science: all inquiry into the causes of things is scientific inquiry. It is not only co-extensive with the area of human knowledge, but no branch of it can advance far, without reacting upon other branches: no department of science can be neglected, without sooner or later causing a check to other departments. No man can truly say this branch of science is useful, and shall be cultivated, whilst this is worthless, and shall be let alone: for all are necessary; and one grows by the aid of another, and in turn furnishes methods and results assisting in the progress of that from which it lately borrowed.

We desire the increase and the support and the acceptance of science, not only because it has a certain material value, and enables men to battle with the forces of nature, and to turn them to account so as to increase both the intensity and the extension of healthy human life: that is a good reason, and for some persons, it may be, the only reason. But there is something to be said beyond this.

The pursuit of scientific discovery, the making of new knowledge, gratifies an appetite, which, from whatever cause it may arise, is deeply seated in man's nature, and, indeed, is the most distinctive of his properties. Man owes this intense desire to know the nature of things, smothered though it often be by other cravings which he shares with the brutes, to an inherited race-perception, stronger than the reasoning faculty of the individual. When once aroused, and in a measure gratified, this desire becomes a guiding passion. The instinctive tendency to search out the causes of things, gradually strengthening as generation after generation of men have stumbled and struggled in ignorance, has at last become an active and widely extending force: it has given rise to a new faith.

To obey this instinct — that is, to aid in the production of new knowledge — is the keenest and the purest pleasure of which man is capable, greater than that derived from the exercise of his animal faculties in proportion as man's mind is something greater and further developed than the mind of brutes. It is in itself an unmixed good, the one thing which commends itself as still 'worth while' when all other employments and delights prove themselves stale and unprofitable.

Arrogant and foolish as those men have appeared, who, in times of persecution, and in the midst of a contemptuous society, have, with an ardor proportioned to the prevailing neglect, pursued some special line of scientific inquiry, it is nevertheless true that in itself, apart from special social conditions, science must develop, in a community which honors and desires it before all things, qualities and characteristics which are the highest, the most human of human attributes. These are, firstly, the fearless love and unflinching acceptance of truth; hopeful patience; that true humility which is content not to know what cannot be known, yet labors and waits; love of Nature, who is not less, but more worshipped by those who know her best; love of the human brotherhood, for whom and with whom the growth of science is desired and effected.

No one can trace the limits of science, nor the possibilities of happiness, both of mind and body, which it may bring in the future to mankind. Boundless though the prospect is, yet the minutest contribution to the onward growth has its absolute and unassailable value, — once made, it can never be lost: its effect is forever in the history of man.

Arts perish, and the noblest works which artists give to the world. Art, though the source of great and noble delights, cannot create nor perpetuate: it embodies only that which already exists in human experience, whilst the results of its highest flights are doomed to decay and sterility. A vain regret, a constant effort to emulate or to imitate the past, is the fitting and laudable characteristic of art at the present day. There is, indeed, no truth in the popular partition of human affairs between science and art as between two antagonistic or even comparable interests; but the contrast which they present in points such as those just mentioned is forcible. Science is essentially creative: new knowledge — the experience and understanding of things which were *previously non-existent for man's intelligence* — is its constant achievement. And these creations never perish: the new is built on, and incorporates, the old; there is no turning back to recover what has lapsed through age; the oldest discovery is even fresher than the new, yielding in ever-increasing number new results, in which it is itself reproduced and perpetuated, as the parent in the child.

This, then, is the faith which has taken shape in proportion as the innate desire of man for more knowledge has asserted itself: namely, that there is no greater good than the increase of science: that through it all other good will follow. Good as science is in itself, the desire and search for it is even better, raising men above vile things and worthless competitions, to a fuller life and keener enjoyments. Through it we believe that man will be saved from misery and degradation, not merely acquiring new material powers, but learning to use and to guide his life with understanding. Through science he will be freed from the fetters of superstition. Through faith in science he will acquire a new and enduring delight in the exercise of his capacities: he will gain a zest and interest in life such as the present phase of culture fails to supply.

In opposition to the view that the pursuit of science can obtain a strong hold upon human life, it may be argued, that on no reasonable ground can it appear a necessary or advantageous thing to the individual man to concern himself with the growth and progress of that which is merely likely to benefit the distant posterity of the human race. Our reply is, let those who contend for the reasonableness of human motives develop, if they can, any theory of human conduct in which reasonable self-interest shall be man's guide. We do not contend for any such theory. By reasoning we may explain and trace the development of human nature, but we cannot change it by any such process. It is demonstrably unreasonable for the individual man, guided by self-interest, to share the dangers and privations of his brother-man; and yet, in common with many lower animals, he has an inherited quality which makes it a pleasure to him to do so. It is unreasonable for the mother to protect her offspring, and yet it is the natural and inherited quality of mothers to derive pleasure from doing so. It is unreasonable for the half-starved poor to aid their wholly-starving brethren; and yet such compassion is natural and pleasurable to those who show it, and is the constant rule of life. Unreasonable though these things are, from the point of view of individual self-interest, yet they are done because to do them is pleasurable, to leave them undone a pain. The race has, as it were, in these respects, befooled the individual, and, in the course of evolution, has planted in him, in its own interests, an irrational capacity for taking pleasure in doing that which no reasoning in regard to self-interest could justify. As with these lower and more widely distributed instincts, shared by man with some lower social animals, so is it with this higher and more peculiar instinct, — the tendency to pursue new knowledge. Whether reasonable or not, it has, by the laws of heredity and selection, become part of us, and exists. Its operation is beneficial to the race. Its gratification is a source of keen pleasure to the individual, — an end in itself. We may safely count upon it as a factor in human nature. It is in our power to cultivate and develop it, or, on the other hand, to starve and distort it for a while, though to do so is to waste time in opposing the irresistible.

As day by day the old-fashioned stimulus to the higher life loses the dread control which it once exercised over the thoughts of men, the pursuit of wealth, and the indulgence in fruitless gratifications of sense, become to an increasing number the chief concerns of their mental life. Such occupations fail to satisfy the deep desires of humanity: they become wearisome and meaningless, so that we hear men questioning whether life be worth living. When the dreams and aspirations of the youthful world have lost their old significance, and their strong power to raise men's lives, it will be well for that community which has organized in time a following of and a reverence for an ideal good, which may serve to lift the national mind above the level of sensuality, and to insure a belief in the hopefulness and worth of life. The faith in science can fill this place. The progress of science is an ideal good, sufficient to exert this great influence.

It is for this reason, more than any other (as it seems to those who hold this faith), that the progress and diffusion of scientific research, its encouragement and reverential nurture, should be a chief business of the community, whether collectively or individually, at the present day.

NOTES AND NEWS.

Pursuant to the invitation already noted in Science, a number of gentlemen met in the library of the American museum of natural history in New-York City, on the 26th to 28th of September, and founded the American ornithologists' union. The membership consists of active, foreign, corresponding, and associate members. The active membership is limited to fifty residents of the United States and Canada; the foreign, to twenty-five non-residents of the United States and Canada; the corresponding, to one hundred residents of any country; the associate being composed of any number of residents of the United States and Canada. The officers of the union for the current year are, Mr. J. A. Allen, president; Dr. Elliott Coues and Mr. Robert Ridgway, vice-presidents; Dr. C. Hart Merriam, secretary and treasurer; Messrs. S. F. Baird, George N. Lawrence, H. W. Henshaw, and Montagu Chamberlain, councillors, — these nine officers constituting the council of the union. Dr. Coues presided over the convention, and continued in the chair in the absence of the president. Mr. Allen and Professor Baird, who were unable to be present, were added to the list of founders. After the discussion and adoption of a constitution, submitted by the committee of organization, and the election of officers, a large number of members were elected, raising the active and foreign membership nearly to the limit. The work of the union for the present year was laid out by the formation of committees, appointed by the chair, on the subjects of classification and nomenclature, of the distribution and migration of birds, of avian anatomy, of oölogy, and on the question of the eligibility or ineligibility of the European sparrow in America. The first-named committee, besides revising the current lists of North-American birds, is expected to consider the subject of zoölogical nomenclature at large; and its labors may result in the formation of a code of nomenclature applicable to other departments of zoölogy, as well as to ornithology. It consists of Messrs. Ridgway, Allen, Brewster, Henshaw, and Coues.

— Mr. Charles F. Parker, the curator in charge of the Academy of natural sciences of Philadelphia, died Sept. 7, after an illness of several months. Mr. Parker became a member of the academy in 1865, and was elected a curator in 1873. Shortly afterward he was appointed by the council curator in charge,— a position which he filled with singular efficiency until last March, when he was compelled to avail himself of leave of absence, granted by the council in the hope that he would soon be able to return. Mr. Parker had paid special attention to the botany of New Jersey; and, both in the completeness of his herbarium and the accuracy of his knowledge of it, he had few, if any, equals. Even before his connection with the academy, he was well known to the leading botanists of America, and his collection was frequently referred to by specialists for illustrative material. The many students who have visited the academy during his term of office will remember the alacrity with which he rendered them assistance in their investigations. Although he may be succeeded by one having a more general knowledge of natural history in its several departments, or a more profound knowledge of a specialty, the academy will probably not be able to secure the services of any one person able and willing to perform the same work so economically and efficiently.

— We copy from the daily press the following telegram from Lieut. Ray, commanding the Point-Barrow expedition, concerning whose safety there were reasonable grounds for anxiety:—

"San Francisco, Oct. 7, 1883. — I report my safe arrival here to-day with party. Also brought down Lieut. Schwatka and party from St. Michaels. All work accomplished as ordered by chief signal-officer. Pendulum observation not made. Leo reached Ooglaamie Aug. 22; was driven away by ice the same night; returned on the 24th; again driven away and damaged on the 25th; returned on the 27th, when party and stores were embarked; sailed on the 29th, vessel leaking badly; put into Unalaska, where she was beached and repaired."

— A large and exceptionally fine collection of fossil plants from the Fort-Union group (Laramie) is now on its way to Washington, collected in the valley of the Yellowstone River, within thirty miles of Glendive, Montana, by Mr. Lester F. Ward, assisted by Mr. Richard Foster. Mention has already been made (Science, i. 559) of a small but interesting collection from this locality, which was partially elaborated last spring. The same stations were revisited and thoroughly worked. The expedition was very successful, and the collection is one of the largest and best ever made in the country. Fifty-seven boxes of fossils, aggregating nearly four tons in gross weight, were obtained. The material was carefully assorted, and scarcely any but cabinet specimens were taken. In the very large number of genera and species represented, there can scarcely fail to be some new to science. The localities examined embrace several distinct horizons within the group, each possessing a special facies. Nearly all the old forms described by Dr. Newberry appear in abundance,— Populus, Platanus, Viburnum, Rhamnites, Tilia, etc.,— but varied by additional species; while such new genera as Trapa, Rhamnus, Ilex, Eleodendron, Asarum, Ficus, etc., are present, often in great profusion, and beautifully preserved. Special pains were taken to secure as large and complete a representation as possible of those forms whose affinities are less obvious or wholly unknown. Mr. Ward intends to commence work on this collection as soon as it arrives.

— The 13th of August, 1883, was the hundredth anniversary of the successful attempt of the brothers Montgolfier to cause their hot-air balloon to rise. On that day a monument commemorative of the

event was unveiled at Annonay, where the Montgolfiers lived and worked. Joseph, the older, is represented as holding the balloon, while his younger brother, Étienne, fills it with heated air by means of a lighted torch. For the three days the streets of Annonay were filled with the crowds gathered to honor the memory of the great inventors. In the addresses stress was laid upon the aids which the use of the balloon may be to the sciences, especially meteorology, and in military operations. Joseph Montgolfier was born at Vidalon-les-Annonay, Aug. 26, 1740, and Etienne at the same place, the 7th of January, 1745. The younger brother died Aug. 2, 1799, at Serrière; and Joseph, after a stroke of paralysis in 1809, died at Balaruc-les-Bains on the 26th of June, 1810.

— A notable event of the present season's field-work has been the descent of the Missouri River in a 'Mackinaw' (a sort of flat boat) from Fort Benton to Bismarck by a party of geologists, consisting of Dr. C. A. White, Mr. J. B. Marcou, and Mr. Lester F. Ward, with one assistant, for the express purpose of geological and paleontological study.

The distance, according to steamboat schedule, is 1,059 miles; and thirty days (Aug. 22 to Sept. 20) were consumed in the journey. A large part of the territory passed through is occupied by Indian reservations; and there is no white population between Benton and Poplar Creek Agency, the first post-office, — a distance of 567 miles. The river is very low at this season of the year; and the current was correspondingly sluggish, though still quite rapid enough in some places. Progress was farther impeded by shoals, bars, and head winds; and considerable time was, of course, occupied in climbing and examining the adjacent bluffs and mountains.

The geology of this region, as all know, is very interesting; and the trip is believed to have thrown much light upon some of its leading problems. The results of the expedition will, of course, be officially made known in due time by the several parties participating, who have brought with them ample data, both in the form of notes and specimens.

— Mr. G. Brown Goode arrived in Washington on the 2d inst. from London.

— Representatives of nearly all the branches of the western surveys have returned to Washington. Dr. C. A. White reports having explored a great number of miles of the upper Missouri in a row-boat, being engaged in extending and confirming his previous observations of the formations.

— The winter session of the Philosophical society of Washington opens on the 13th inst. A considerable number of communications on widely different topics are in readiness. Biological papers are not numerous. The Biological society will probably begin its session on the 19th inst. It is possible that negotiations for the formation of a Washington academy of sciences will be opened for a second time this winter, but with what success it is impossible at present to say. It seems to be generally considered that an academy would be desirable, but there is little agreement relative to the proper basis of union between the existing societies.

— Prof. K. A. Zittel of Munich is visiting this country, and will probably be in Washington early in this month.

— At the first autumn meeting of the Boston society of natural history, Oct. 3, Mr. F. W. Putnam gave an account of the great serpent-mound in Adams county, O., and of some other ancient works in Wisconsin and Ohio examined during the past summer.

— The Appalachian mountain-club commenced its Boston meetings on the 10th, when papers were read on the Route Salvan, by Selah Howell; on a trip over Osceola, the Twin Mountain range, and Garfield, by W. L. Hooper; and on an exploration of the Traveller Mountain, and the head waters of Mattagamon River, by G. H. Witherle.

SCIENCE.

FRIDAY, OCTOBER 19, 1883.

PRECISION OF OBSERVATION AS A BRANCH OF INSTRUCTION.

We sometimes find the philosopher envying the physicist because the results sought by the latter can be expressed *exactly*. In so doing, he doubtless overlooks the fact that all quantitative work has to be regarded as giving merely an approximation to the truth. Numerous and refined as are the precautions adopted, the careful experimenter must admit that his measurements contain errors whose sources are more or less hidden. Success will lie, not in ignoring this, but in recognizing it, and studiously avoiding any unwarranted claim to accuracy. His investigation may establish some law beyond a reasonable doubt. This law may be expressible in exact terms; but, so far as the direct quantitative results are concerned, he must give up, once for all, the popular notion of exactness. He must admit that the work merely shows it to be reasonable to assume the truth to lie somewhere between two limits, respectively greater and less than the one magnitude which he names. Desiring that these limits shall fall as near together as practicable, he will study the observations for internal evidence of the precision attained; but any appearance of accuracy greater than might reasonably be expected will often cause him more uneasiness than would a greater apparent error. Until the extent of the error is recognized, and found to be in harmony with experience derived from other similar observations, a cautious observer will not be confident of the result reached.

As the scientific professions are currently taught, it is possible to get a fair training (as a chemist, engineer, or electrician, for example) without properly appreciating the practical limitations to precision. He may instinctively acquire correct notions of the performances of the instruments he most frequently uses; but let a new operation, with a different instrument, be required, and he will too often develop the wildest notions as to the great accuracy attainable by the use of sufficient care. What is needed in our professional courses is systematic instruction in the general science of planning, conducting, and discussing observations, accompanied with adequate practice. This should be given as early as the student is fitted to profit by it, in order that the subsequent practical training in special branches may have a firm foundation.

The field for such instruction is ample. A good routine observer is one who, being informed of the accuracy desired at each step, is able to take just care enough to attain it, without wasting time and energy in uselessly perfecting certain parts of the work. Our professional observer must add to this the good judgment which is able to discover the relative accuracy required in different parts of a complex observation, and to decide how accurate to aim to make a single performance of the whole. In general, he will seek to avoid errors which usually occur in a single direction; but he will not always take the greatest care to avoid errors which are as liable to be negative as positive. Life is short. Time, to most, is money; and the ability to repeat an observation will often depend upon the ability to do it quickly. Moreover, in many cases, mere lapse of time allows additional errors to enter. Having avoided the larger errors, he will therefore seek to eliminate the effect of the smaller by repeatedly performing the work. Recognizing, then, the importance of reasonable speed, he will allow rough measures of certain quantities, provided the final error of the complex operation is not thereby appreciably affected. All this calls for a clear understanding of the causes of error, and an ability to reason out their effect upon the result. The knowledge of the differential calculus required is indeed elementary; but it must be a *tool* which can be applied as readily, for instance, as the knowledge of the properties of logarithms. All the principles are covered by the customary courses in physics and mathematics; but additional special practice in their employment is very desirable.

In the planning of observations, the theory of maxima and minima gives important aid; but this theory has so many other applications, that we can hardly ask of the regular course in differential calculus such attention to this one point as would insure the required facility. In the absence of such a course of instruction as is recommended in this paper, the matter is left to slow acquisition through practical experience. Knowledge is often thus bought at a high cost.

A general understanding of instruments of precision, so necessary to successful planning of observations, is also within the field of instruction proposed. Instrumental errors should be treated systematically: their preliminary adjustment to zero, their elimination from the mean of pairs of observations properly taken to that end, their determination in such manner that corrections may be duly applied, and the cost in time of variously managing them, should come to be understood through suitable practice. Here, particularly, each professional course is liable to inculcate its own narrow view.

An examination of the proceedings of the leading learned societies will convince one of the importance of good method in the discussion of results. It will also develop the fact that there exist numerous valuable, analytical, and graphical processes, which at present are not likely to be brought to the attention of the professional student.

The theory of probabilities as applied to observation would naturally be treated in the course proposed. If it were previously given to the student as a branch of pure mathematics, the attention could here be riveted upon its use, which calls for the exercise of much practical good judgment. It furnishes an important means of studying the precision attained, but just here is a great abuse. Its results, demonstrated for a very large number, are applied to very limited series of measurements. Again: its assumption of equal probability for equal positive and negative errors is allowed, in face of the fact that a preponderance of error in one direction is unavoidable. The rising generation of experimenters in every field of applied science should therefore be taught the many limitations which surround its application, and they should learn to avoid that indiscriminate use of its principles which has led to so many unfounded claims to accuracy.

We have outlined a subject the successful teaching of which requires qualifications not to be found in every scientific professor, and the successful study of which requires a concentration of the attention not likely to be given to it as a subordinate part of some other course. Already the appearance of treatises on probabilities, errors of observation, and least squares, has enabled writers on astronomy, geodesy, physics, and engineering, to devote their attention to special applications, and has saved the waste of space which would otherwise be given to the general theory. Similarly, we should avoid that distraction of the student's attention from the main subject of a professional course which results from the necessity of frequently pausing to give additional information about the subject of this article.

Although the first object of establishing a course of instruction in any branch of applied science is to put the students into possession of the best methods already reached by workers in that field, the end attained is often something more. The instructor's attention is speedily called to conspicuous omissions, and his energies are consequently bent upon supplying the defect by demonstrating and testing some theorem or method which meets the want. Thus the schools come to the aid of the professions. Are they yet doing their whole duty in regard to the science and art of observation?

A SYSTEM OF LOCAL WARNINGS AGAINST TORNADOES.

I have lately examined with some care the excellent compilation by Sergeant Finley of the signal-service, 'Characteristics of six hundred tornadoes,' with reference to the question of devising a simple apparatus for saving human life.

Saving property seems to be out of the question, as no structure can withstand the force of the tornado-wind. Life may be saved by recourse to underground shelters, cellars, etc., such as actually have been built in many places for this end.

Two facts may be quoted from the work named, — 1°. Three hundred and forty-seven out of three hundred and ninety-three tornadoes (that is eighty-eight per cent) originated between the west and the south-south-west points; 2°. The average velocity of progression was about one mile in two minutes.

From what we already know of the atmospheric conditions necessary to the production of tornadoes, it seems probable that in the future it may be practicable for the general weather service in Washington to send out warnings a day in advance to large regions of country within which tornadoes are likely to occur. These warnings would necessarily be of a very general nature. They would simply state that the conditions were such on two sides of a large region (like the state of Wisconsin, for example) as to make it probable that tornadoes would occur somewhere inside that region within twenty-four hours. The local weather services of states like Ohio and Iowa could, perhaps, make these predictions a little more specific; but there is no prospect whatever that warnings of any particular tornado can be given in the immediate future. It can be said, that, within a district five hundred miles square, tornadoes are likely to occur within twenty-four hours. and such a warning would be of value; but it does not seem to be probable that it can be said that a particular thirty miles square of this region is in particular danger. Under these circumstances, it is of interest and importance to inquire whether some efficient method of local warnings cannot be devised. If five minutes' warning could have been given at any of the late tornadoes, many lives might have been saved. If each household could be warned by the continuous ringing of a bell, for example, that a wind of destructive force (say, seventy miles per hour and upwards) was approaching, and that five minutes were available in which to seek shelter, this would be well worth doing.

A wind of seventy miles an hour is sufficient to blow down chimneys and to unroof houses, unless they are well built. Ordinary trees will not stand under it. The pressure on a square foot is in the neighborhood of fifty pounds. There might be occasions where seventy miles would be the maximum wind-velocity; and the person who had taken refuge in the cellar might be inclined, after the gust had blown over, to find fault with the indicator which had predicted a tornado, when only a violent gale occurred. But such storms do not occur as often as once a year: and it would seem that one could afford to be frightened as frequently as this for the sake of immunity from an occasional tornado, which might be following in the track of such a violent gale.

I have found that it is practicable to erect, at a moderate expense (less than five hundred dollars), an apparatus which would give from three to five minutes' warning to all the inhabitants of a small town, by the firing of a cannon, for instance; and in addition, and without any increased expense, this apparatus could ring a bell in every house. The additional expense to each house would be less than ten dollars, the cost of maintenance would be less than a hundred dollars a year, and the work could be done by any intelligent person. The system, for a small town, would be something like the following: suppose a circle described about the town with a radius of from two to two and one-half miles. The only serious danger from tornadoes is to be feared from the part of this circle between the west point and the south-south-west point. Along the circumference of this circle, between the south-south-west and west points, run a line of single telegraph-wire on twenty posts to the mile, and from the west point bring the wire into the town, letting it end at the telegraph-office. It is grounded at each end of the line, and at the telegraph-office it is connected with a battery, which sends a constant current over the line. Within the town, connection is made in various houses with magnets. Each magnet holds a detent, which prevents a bell from being rung by the action of a cheap clock-work governed by a coiled spring. If the circuit is broken anywhere in the line, each bell begins to ring, and continues to sound till its spring is run down; for four or five minutes, for example. A cannon could be fired by a simple device, which would warn persons in the fields, etc., to seek shelter. In a large town the circuit might end in one of the engine-houses of the fire-department, and ring a bell there. This would be the signal for the man on watch to repeat the warnings simultaneously through as many local circuits as desirable.

It remains to indicate the way in which the circuit is to be broken by the wind. The circle of telegraph-poles from the south-south-west to the west points would contain about fifty poles. On every one of these the wire would run first to an insulator, then to an iron horizontal axis screwed into the side of the post. On this axis a piece of board one foot square can revolve freely. An iron rod projects below this board, and from the lower end of it a small wire goes to a pin in the telegraph-pole. This pin is connected by wire to a second insulator. From this the line goes to the next pole, and so on. The circuit ordinarily passes to the first insulator, thence to the iron rod, thence down the iron rod to the thin wire, through the pin and to the second insulator, and so to the next telegraph-pole. The thin wire is a necessary part of the circuit. It is so made that it will break when the pressure of the wind on the square board is fifty pounds. The apparatus for each post is tested practically before it is set up. This can be done at any time in a simple manner. Whenever any single one of these boards is subjected to the pressure of fifty pounds, its wire will be ruptured, and the circuit will be broken, thus sending the necessary warning along the whole line.

I have made one such indicator, which is connected with a small bell in this observatory. The wire is arranged so that it breaks at a wind-velocity of about ten miles per hour, and it works in a perfectly successful manner. The extension of the system for the protection of a small town is a simple matter. For a large city a more expensive system would have to be provided, as the wires between poles should be carried underground to protect them from the chance of disturbance.

I need not enlarge on the details of the scheme, since they can be worked out by any one who is at all familiar with electrical constructions. I believe that I have considered all the practical difficulties, and that there are none of any importance. It is a very simple matter to provide for the inspection of the line, bells, etc., so as not to interfere with the working of the system, and so that false alarms will not be given.

The point I wish to emphasize is, that a practical and cheap system of local warnings can be had, and that it ought to be considered by those who live in districts subject to tornadoes. The particular manner in which the above-described device is to be employed is a question to be settled by the particular circumstances of each case. I have only described the simplest and cheapest form, but this has been proved by trial to be efficient.

I may just mention, that, by employing a spring balance to hold the board in position, it is possible to provide an indicator which will break the circuit at any desired velocity of wind.

To any one who has seen the effects of a tornado, or even to one who has simply read that in this year alone several hundreds of lives have been lost from their violence, it will appear that the question of erecting systems for local warnings ought to be seriously considered by persons living in exposed regions.

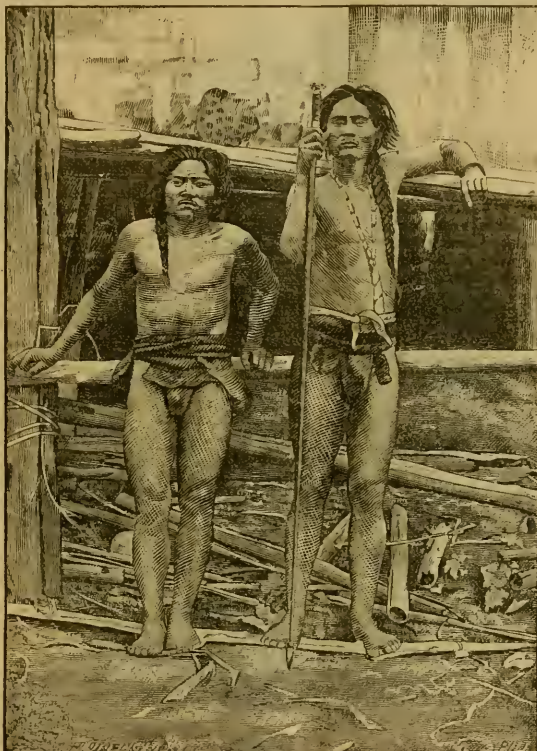
Edward S. Holden.

THE WILD TRIBES OF LUZON.

When the Malays took possession of the Philippines, they either found there, or were soon joined by, Japanese, Chinese, Siamese, Javanese, and Dyaks from Borneo and Celebes, all waging war against the Papuans, who had gone there from the south-east, if they were not aborigines. Under these circumstances, we should expect to find the present natives a very mixed race, who have received different names, according to the predominating characters in each locality. There is no unanimity of opinion among those who have studied the people in their own homes, and I think it impossible wholly to unravel the tangled skein of races. The following is what, from my observation and reading, I think a fair approximation to the truth.

The name of *Igorrote* has been applied to almost every wild tribe except the Negritos. I agree with Dr. Semper that it should be restricted to those of northern Luzon, who are hybrids of Japanese and Chinese with the Indians, differing somewhat in features and customs, according to the principal admixture.

In the Igorrote the stature is small, with well-developed form, indicating great strength with little symmetry; color very dark; eyes oblique; hair long, and, in the women, combed in Chinese fashion; nose flat, lips thick, mouth large, and cheeks wide. Houses mere huts, on the ground or raised on posts, shaped like a beehive, with furniture of the rudest description, — arms, hatchets, lances, daggers, bows and arrows, frequently poisoned, of bamboo, and shields. Their presence would be accounted for as the descendants of the army of the Chinese pirate, Li Mahon, whose fleet was destroyed after his attack on Manila in 1574. The fugitives escaped to the mountains; and for more than three centuries these wild hybrids between Chinese and Indian have defied the power of Spain. They have many dialects, but the Igorrote proper is spoken by over ten habit northern Ilocos. They are of finer shape, lighter color, with less oblique eyes, and more aquiline nose. In their habits, music, and love for porcelain vases, they resemble the Japanese, and have probably descended from the union of crews of junks, driven to Luzon by the northern monsoon, and the neighboring tribes.



IGORROTES OF LUZON.

thousand people. They are not wholly savage, except in the remote mountainous districts. Their customs are simple and patriarchal. It is only of late years that they have consented to bury their dead, instead of exposing them to decay in the air.

The name of *Tinguians* has been given to the hybrids of Japanese and Indians who in-

They number over nine thousand in twenty villages. Their dress and arms are much like those of the Igorrotes, but they have borrowed from their enemies the Gaddans the custom of preserving as trophies the heads of those killed in battle. They are said to mummify their dead by heat.

The *Gaddans* and *Ifuagos*, numbering about ten thousand, resemble in their appearance and customs the Dyaks of Borneo. Many dwell in the provinces of the Camarines, where they have preserved their independence. They have traditions of great antiquity, and speak the Vicol dialect as well as their own. They were evidently here before the Mahometan Malays, by whom they have been driven to the mountains. They are hostile to all foreigners. Their mode of life is patriarchal, the head of a family recognizing no superior authority. From the resemblance of the skulls of some of these wild tribes to those of the people of Sunda, Borneo, and Celebes, and the occurrence of similar ones in the long disused caverns, it seems undeniable that there is among them a considerable Dyak mixture, and that from a very remote period.

The above-mentioned races are what the Spanish writers call the *infidels*, and may or may not be Igorrotes. SAMUEL KNEELAND.

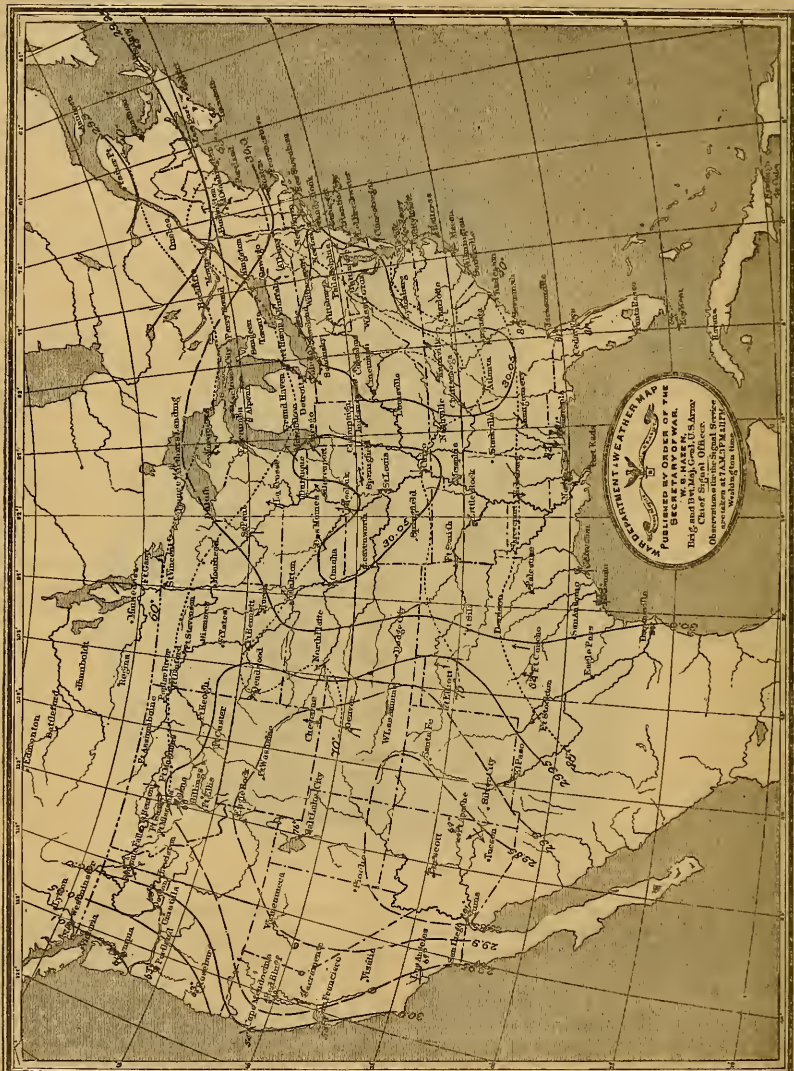
GADDAN OF LUZON.

THE WEATHER IN AUGUST, 1883.

THE monthly review of the U. S. signal-service shows that in August there were two features of special note. These are, 1°, the low temperatures which prevailed over nearly the whole country; 2°, the small rainfall, which was below the average in nearly every district. Other important features were a few destructive storms, and the opening of the hurricane season, as will be referred to below.

The pressure has been above the normal, except on the Atlantic coast; the greatest excess, 0.08 inch, occurring in the upper Mississippi and Missouri valleys, where, also, the lowest temperature departures were recorded. Six barometric depressions were charted in their progress, and a seventh begun, as the month closed. Of these, one only visited the southern states: this developed in Mississippi, passed off the Virginia coast, and across the Atlantic to the Irish coast, being a severe storm all along its passage. Of the other depressions, one developed in the Rocky Mountains, and was traced to the British coast, and another entered the country in the extreme south-west, moved south-easterly to the North Carolina coast, and in the ocean probably united with a tropical hurricane which was then moving up the Atlantic. None of the storms were traced from the Pacific coast over the Rocky Mountains. The storms left no disastrous effects in the United States; but there were violent gales on the upper lakes on the 22d, and remarkably heavy rains on the North Carolina coast on the 16th. The storms on the Atlantic were especially prominent, and the general character of the weather on the ocean during the whole month was stormy. Five depressions were traced nearly across the Atlantic, two of which were genuine hurricanes. The first moved north-westward at a considerable distance from the Atlantic coast, between the 19th and 24th, when it curved to the north-eastward near the Bermudas. Reaching the Banks on the 26th, it caused great damage to the fishing-fleet, the reports showing a loss of eighty lives and one hundred dories, while many fishing-vessels were swamped or disabled. Vessels on the Atlantic report severe gales during its further passage, but its severity decreased as it approached the Irish coast on the 29th. The lowest pressure

GADDAN WOMAN.



MONTHLY MEAN ISOBARS, ISOTHERMS, AND WIND-DIRECTIONS, AUGUST, 1883. REPRINTED IN REDUCED FORM BY PERMISSION OF THE CHIEF SIGNAL-OFFICER.

noted was 28.9 inches. The second hurricane came from the West Indies about the 24th, and reached the Banks on the 29th, only three days after the passage of the former hurricane, repeating the disasters to the fishing-vessels. Its violence was great as it continued across the Atlantic, and approached the British coasts early in September. As this storm passed up the Atlantic, very high tides were experienced on the coast, much damage being thereby inflicted on the New Jersey shore on the 29th. Very few icebergs were reported during the month.

The average temperatures were above the normal only in Florida, the Rio Grande valley, and in the middle and southern portions of the Rocky Mountain region, the departures being within a degree, except at Salt Lake City (2°). In other districts the departures ranged from 0°.1, in the eastern Gulf states, to 4°.4, in the upper Mississippi valley. Yuma, Arizona, reports a mean temperature of 91°, and a maximum of 111°. Frosts were reported from the northern states, especially at the end of the month.

Average precipitation for August, 1883.

Districts.	Average for August. Signal-service observations.		Comparison of August, 1883, with the average for several years.
	For several years.	For 1883.	
	Inches.	Inches.	Inches.
New England	4.33	1.53	2.80 deficiency.
Middle Atlantic states .	4.95	3.20	1.75 deficiency.
South Atlantic states . .	6.43	7.51	0.72 deficiency.
Florida peninsula . . .	7.67	5.69	1.98 deficiency.
Eastern gulf	6.33	4.39	1.94 deficiency.
Western gulf	4.27	1.62	2.65 deficiency.
Tennessee	3.92	3.51	0.41 deficiency.
Ohio valley	3.70	1.94	1.76 deficiency.
Lower lakes	2.91	2.30	0.61 deficiency.
Upper lakes	3.12	1.25	1.87 deficiency.
Extreme north-west . .	2.50	2.70	0.20 excess.
Upper Mississippi valley,	3.40	1.87	1.53 deficiency.
Missouri valley	2.81	2.52	0.29 deficiency.
Northern slope	1.39	1.83	0.44 excess.
Middle slope	1.42	3.65	2.23 excess.
Southern slope	2.99	1.95	1.04 deficiency.
Southern plateau . . .	3.16	2.26	0.90 deficiency.
North Pacific coast . . .	0.78	0.08	0.70 deficiency.
Middle Pacific coast . .	0.02	0.00	0.02 deficiency.
South Pacific coast . . .	0.22	0.07	0.15 deficiency.
Mt. Washington, N.H. .	7.67	6.06	1.61 deficiency.
Pike's Peak, Col. . . .	4.81	2.22	2.59 deficiency.
Salt Lake City, Utah . .	0.88	0.62	0.26 deficiency.
Brownsville, Tex. . . .	5.94	1.97	3.97 deficiency.

The rainfall record can be best shown by the above table, which shows the unusual deficiency of the month in almost every section, which especially affected the crops in the south. Remarkably heavy rains were recorded in a few instances, — 10.38 inches at Griffin, Ga., in eight hours; and 8.14 inches at Kittyhawk, N.C., in four hours. In the cotton region the rainfall was much less than in August of last year, the amount at New Orleans being 2.70 inches, against 8.38 inches a year ago.

Local storms were not numerous, but were quite severe, especially in Iowa, on the 7th and 8th. On the 21st there was a veritable tornado in Minnesota, which devastated the town of Rochester, causing a loss of over thirty lives, and much damage to property.

Seven auroral displays occurred, but none were of especial note. The following electrical phenomenon is reported from Pike's Peak: —

"The observer on the summit of Pike's Peak, Col., reported that during a sleet and thunder storm, on the evening of the 4th, the anemometer cups revolved in circles of electric light. After a flash of lightning, the light encircling the cups became dim, but would soon regain its former brilliancy. The observer states, that, by holding up his hands, electric sparks would form on the ends of his fingers, and that his hair and clothing were full of them. A peculiar crackling noise was heard about the anemometer cups; and at the corners of the office building there were continuous sparks of bright light."

Earthquake-shocks occurred at Oakland, Cal., Carson City, Nev., St. Thomas, W.I. At the last-named place a tidal wave occurred on the 27th, and at San Francisco on the 27th and 28th. Earthquake waves, whose height was one foot, and time between crests forty minutes, were recorded on the Saucelito tide-gauge. It is supposed they were caused by the earthquake in Java on the 27th.

A dense smoke, due to forest-fires in Oregon and Washington, Idaho and Montana territories, prevailed during a greater part of the month, and extended on the Pacific coast as far south as Cape Mendocino, and thence eastward to eastern Montana, Dakota, and Minnesota.

The accompanying chart exhibits the mean pressure, temperature, and wind-direction, for the month.

THE INVENTION AND SPREAD OF BRONZE.

AT the thirteenth session of the German anthropological congress, held at Trier early in August, Professor Rudolph Virchow, the president, gave an address, the substance of which we quote from the *Frankfurter zeitung* of Aug. 11.

In beginning the president remarked, that, in the choice of Trier as the place of assembly for this year's congress, it was considered that the city and its surroundings were especially suited by their situation for the solution of the often-broached question of celts. The speaker then reviewed in a general way the present condition of anthropological research, paying especial attention to the first appearance of bronze in Europe. The question, when did the metal first come into use in our part of the world, is certainly one of the most important which anthropological science has to consider, and in order to provide the necessary material for its solution, wherever individual investigators or scientific societies are active, the territorial relations should be first examined, and, without drawing general conclusions, the localities or the strata in which the discoveries are made should be determined; for, however many investigations have already been undertaken in this branch of anthropology, the boundary where the stone age ceases and the metal age begins has not yet been definitely decided for any locality. A difficulty which arises in answering the question, does this or that settlement, this or that discovery, belong to the stone or bronze age, must not be passed in silence, since neglect of it has frequently led to mistakes. The difficulty is, that at one time, when metal was already common, stone implements were used both by poorer people, who were not able to obtain the expensive tools, and for ritualistic purposes. A circumstance which next comes into consideration, and which renders difficult in no little degree the determination of the epoch to which certain discoveries belong, is that the river-sand, silt, etc., in which the objects were found, often change their positions.

Passing to a general consideration of the bronze age, the speaker said that the answer to the question, where did the invention of this alloy originate, is one of the most important problems for anthropological research. There are two widely differing views on this subject: 1°, that of investigators who assume that bronze was invented at different times and in different places, independently of each other; and, 2°, that of those who assert that the invention was made at one place, and thence the use of the metal spread. In opposition to the first-mentioned assumption, is the fact that the bronze objects scattered over many regions show in their composition a considerable agreement, and, almost without exception, are composed of a mixture of nine parts copper and one part tin, as are by far the majority of those which are found in the countries lying between the Caucasus and Portugal. Even if the moisture of the earth and atmospheric influences affect the various components of the alloy in various ways, and a part of the copper is destroyed or altered, the bronze objects, as a whole, are affected in the same way; and the appearance of a very similar composition, in regions far removed from each other, points with convincing force to the conclusion that the invention of this mixture was made in one place, and its use was thence spread. Further, as to how bronze was introduced into Europe, we find also various opinions not very harmonious with each other. Some investigators naturally claim that it was through the Phoenicians, of whom we know that in ancient time they carried on a trade extending over the whole Mediterranean, and that while Cyprus, one of the chief centres for copper ore, — from this island copper (Latin, *cuprum*) received its name, — lay in their immediate neighborhood, they passed in their voyages the Pillars of Hercules, and visited the 'tin-island' (Great Britain). From the Phoenician trade-stations on the coast of the Mediterranean, among which the Massilian colony (Marseilles) played an important part, trade-roads into the interior were probably built. Many investigators suppose the spread of bronze was through commercial activity. Whether this view is true, is not easy to determine; since trade-settlements, which, as a rule, exert no, or at most only a transient, influence over the majority of the colonies and customs with which they come in contact, as soon as they cease to exist, can seldom be traced. The speaker, in his researches in Sicily, where, as is well known, the Carthaginians, also a people of Phoenician origin, were for a long time settled, could find no traces which indicated this settlement. Further, it is also well known that the trade supremacy which Pisa on the Mediterranean, and Genoa on the Black Sea, once exercised, has left on the coasts bordering these seas no traces worth mentioning. But, supposing that bronze was scattered by the commerce of the Phoenicians, it by no means proves that they were the inventors of this alloy. The speaker, on the whole, was much more inclined, with reservation of his decision, to place this invention farther to the east, in central Asia.

Besides the view just mentioned, which considers the commercial activity of the Phoenicians as the agent by which that advance in culture signalized by the use of metal implements was brought about, there is a theory lately advanced by Hochstetter, which deserves mention because it completely abandons the views formerly held. Hochstetter bases his assumptions on the discoveries in the graves at Hallstadt (first described by Sacken), and on certain discoveries at Watsch (Carniola), which show an interesting similarity to the former.[1] From these data, Hochstetter traces the identity of bronze manufacture in Hallstadt and upper Italy, and comes to the conclusion that this manufacture originated with the Aryans, and that the use of bronze for weapons and vessels had been common among this people a long time before the Aryan races wandered from their Asiatic home to Europe; while, at the same time, he denies the Etruscan origin of the findings at Hallstadt, Watsch, and Este, and assumes that the bronzes found in Italy, so far as they were not brought there by the Aryans inhabiting Italy, were imported from Greece.

Against these conclusions, surprising by their novelty, Virchow asserts, that in case the Aryans, in their wanderings to the west, had taken bronze with them, we must expect to find traces of its use on the highways, which they presumably followed in their

[1] A situla dug up at Watsch exhibits the same decoration as those found at Hallstadt, and contains, among other things, a representation of warriors, who are equipped with four different kinds of helmets, such as may be reconstructed from the discoveries at Hallstadt. Objects corresponding to the Watsch bronzes were found also in Este (North Italy).

advance; for example, in the valley of the Donau. Especially in regard to the Caucasus, his investigations in the region convinced him that no people already sufficiently civilized to employ metals could have passed over this range; and, on account of the geographical relations, we must assume that the Aryan peoples first divided in central Asia, and separated widely along the northern coast of the Aral and Caspian seas, and then proceeded through modern Russia, where the characteristic bronzes are not found, or westward through Asia Minor. Once in Greece, it is highly probable that Italy was their next step. A fact brought forward by Hochstetter in support of his theory — viz., the lack of ribbed bronzes, Mestea dicordoni — has proved a mistake. A point of attack is presented by the same investigator, in his assertion that the discoveries at Hallstadt do not date back of the second millenary before the Christian era, and immediately preceded the Roman civilization; and that, at the time of the subjugation of Noricum by Rome, the manufacture of bronze already existed.

At the close of his address, Virchow merely touched upon other anthropological questions, and pointed out that philology and archeology alone were not in condition to relieve the darkness which still concealed the invention and spread of bronze; and that somatic anthropology, i.e., the investigation of the physical constitution of the peoples under consideration, as seen from the bones preserved to us, may here have a final word to say, and may, perhaps, answer the important question, whether the cultivation of central Europe is to be traced to the influence of two different families, or to only one, the Aryan.

THE VEGETATION OF THE CARBONIFEROUS AGE.[1]

MUCH of the second decade of my life was spent in the practical pursuit of geology in the field; and throughout most of that period I enjoyed almost daily intercourse with William Smith, the father of English geology. But, in later years, circumstances restricted my studies to the paleontological side of the science: hence I was anxious that the council of the British association should place in this chair some one more familiar than myself with the later developments of geographical geology. But my friend, Professor Bonney, failing to recognize the force of my objections, intimated to me that I might render some service to the association by placing before you a sketch of the present state of our knowledge of the vegetation of the carboniferous age.

This being a subject respecting which I have formed some definite opinions, I am going to act upon the suggestion. To some this may savor of 'shop-talk;' but such is often the only talk which a man can indulge in intelligently: and to close his mouth on his special themes may compel him either to talk nonsense or to be silent.

Whilst undertaking this task, I am alive to the difficulties which surround it, especially those arising from the wide differences of opinion amongst paleobotanists on some fundamental points. On some of the most important of these there is a substantial agreement between the English and German paleontologists. The dissentients are chiefly, though not entirely, to be found amongst those of France, who have, in my humble opinion, been unduly influenced by what is in itself a noble motive; viz., a strong reverence for the views of their illustrious teacher, the late Adolphe Brongniart. Such a tendency speaks well for their hearts; though it may, in these days of rapid scientific progress, seriously mislead their heads. I shall, however, endeavor to put before you faithfully the views entertained by my distinguished French friends, M. Renault, M. Grand-Eury, and the Marquis of Saporta, giving, at the same time, what I deem to be good reasons for not agreeing with them. I believe that many of our disagreements arise from geological differences between the French carboniferous strata and those in our own islands. There are some important types of carboniferous plants that appear to be much better represented amongst us than in France: hence we have, I believe, more abundant material than the French paleontologists possess, for arriving at sound conclusions respecting these plants. We have rich sources, supplying specimens in which the internal organization is preserved, in eastern Lancashire and western Yorkshire, Arran, Burntisland, and other scattered localities: France has equally rich localities at Autun and at St. Étienne. But some important difference exists between these localities. The French objects are preserved in an impracticable siliceous matrix, extremely troublesome to work, except in specimens of small size: ours, on the other hand, are chiefly embedded in a calcareous material, which, whilst it preserves the objects in an exquisite manner, does not prevent our dissecting examples of considerable magnitude. But, besides this, we are much richer in huge Lepidodendroid and Sigillarian trees, with their Stigmarian roots, than the French are: hence we have a vast mass of material illustrating the history of these types of vegetation, in which they seem to be seriously deficient. This fact alone appears to me sufficient to account for many of the wide differences of opinion that exist between us, respecting these trees. My second difficulty springs out of the imperfect state of our knowledge of the subject. One prominent cause of this imperfection lies in the state in which our specimens are found. They are not only too frequently fragmentary, but most of those fragments only present the external forms of the objects. Now, mere external forms of fossil plants are somewhat like similarities of sound in the comparative study of languages: they are too often unsafe guides. On the other hand, microscopic internal organizations in the former subjects are like grammatical indentities in the latter one: they indicate deep affinities that promise to guide the student safely to philosophical

[1] Opening address before the section of geology of the British association for the advancement of science. By Prof. W. C. WILLIAMSON, LL.D., F.R.S., president of the section. From advance sheets kindly furnished by the editor of *Nature*.

conclusions. But the common state in which our fossil plants are preserved presents a source of error that is positive as well as negative. Most of those from our coal-measures consist of inorganic shale, sandstone, or ironstone, invested by a very thin layer of structureless coal. The surface of the inorganic substance is moulded into some special form, dependent upon structural peculiarities of the living plants; which structures were sometimes external, sometimes internal, and sometimes intermediate ones. Upon this inorganic cast we find the thin film of structureless coal, which, though of organic origin, is practically as inorganic as the clay or sandstone which it invests; but its surface displays specific sculpturings, which are apt to be regarded as always representing the outermost surface of the plant when living, whereas this is not always the case. That the coaly film is a relic of the carbonaceous substance of the living plant is unquestionable; but the thinnest of these films are often the sole remaining representatives of structures that must originally have been many inches, and in some instances even many feet, in thickness. In such cases most of the organic material has been dissipated, and what little remains has often been consolidated in such a way that it is merely moulded upon the sculptured inorganic substance which it covers, and hence affords no information respecting the exterior of the fossil when a living organism. It is, in my opinion, from specimens like these, that the smooth bark of the Calamite has been credited with a fluted surface, and the Trigonocarpons with a merely triangular exterior and a misleading name, as it long caused the inorganic casts known as Sternbergiae to be deemed a strange form of plant, that had no representative amongst living types. In other cases the outermost surface of the bark is brought into close contact with the surface of the vascular cylinder. I have a Stigmaria in which the bases of the rootlets appear to be planted directly upon that cylinder, the whole of the thick intermediate bark having disappeared. In other examples, that vascular zone has also gone. Thus the innermost and outermost surfaces of a cylinder, originally many inches apart, are, through the disappearance of the intermediate structures, brought into close approximation. In such cases, leaves and other external appendages appear to spring directly from what is merely an inorganic cast of the interior of the pith. I believe that many of our Calamites are in this condition. Such examples have suggested the erroneous idea that the characteristic longitudinal flutings belong to the exterior of the bark.

Fungi. — Entering upon a more detailed review of our knowledge of the carboniferous plants, and commencing at the bottom of the scale, we come to the lowly group of the fungi, which are unquestionably represented by the Peronosporites antiquarius[1] of Worthington Smith. There seems little reason for doubting that this is one of the phycomycetous fungi, possibly somewhat allied to the Saprolegnieae; but since we have, as yet, no evidence respecting its fructification, these closer relationships must for the present remain undetermined. So far as I know, this is the only fungus satisfactorily proved to exist in the carboniferous rocks, unless the Excipulites Neesii of Goeppert, and one or two allied forms, belong to the fungoid group. The Polyporites Bowmanni is unquestionably a scale of a holoptychian fish.

Algae. — Numerous objects supposed to belong to this family have been discovered in much older rocks than carboniferous ones. The subject is a thorny one. That marine plants of some kind must have existed simultaneously with the molluscous and other plant-eating animals of paleozoic times, is obviously indisputable; but what those plants were is another question. The widest differences of opinion exist in reference to many of them. A considerable number of those recognized by Schimper, Saporta, and other paleobotanists, are declared by Nathorst to be merely inorganic tracks of marine animals; and, in the case of many of these, I have little doubt that the Swedish geologist is right. Others have been shown to be imperfectly preserved fragments of plants of much higher organization than algae, branches of conifers even being included amongst them. I have, as yet, seen none of carboniferous age that could be indisputably identified with the family of algae, though there are many that look like and may probably be such. The microscope alone can settle this question, though even this instrument fails to secure unity of opinion in the case of Dawson's Prototaxites; and no other of the supposed seaweeds hitherto discovered have been sufficiently well preserved to bear the microscopic test: hence I think that their existence in carboniferous rocks can only be regarded as an unproven probability. Mere superficial resemblances do not satisfy the severe demands of modern science, and probabilities are an insufficient foundation upon which to build evolutionary theories.

Seeing what extremely delicate cell-structures *are* preserved in the carboniferous beds, it cannot appear other than strange that the few imperfect fungoid relics just referred to constitute the only terrestrial cellular cryptogams that have been discovered in the carboniferous strata. The Darwinian doctrine would suggest that these lower forms of plant-life ought to have abounded in that primeval age; and that they were capable of being preserved is proved by the numerous specimens met with in tertiary deposits. Why we do not find such in the paleozoic beds is still an unsolved problem.

Vascular cryptogams. — The vascular cryptogams, next to be considered, burst upon us almost suddenly, and in rich profusion, during the Devonian age. They are equally silent in the Devonian and carboniferous strata as to their ancestral descent.

Ferns. — The older taxonomic literature of paleozoic fern-life is, with few exceptions, of little scientific value. Hooker and others have uttered in vain wise protests against the system that has been pursued. Small fragments have had generic and specific names assigned to them, with supreme indifference to the study of morphological variability amongst living types. The undifferentiated tip of a terminal

[1] Memoir xi. p. 299.

pinnule has had its special name, whilst the more developed structures forming the lower part of a frond have supplied two or three more species. Then the distinct forms of the fertile fronds may have furnished additional ones, whilst a further cause of confusion is seen in the wide difference existing between a young, half-developed seedling and the same plant at an advanced stage of its growth. Any one who has watched the development of a young Polypodium aureum can appreciate this difference. Yet, in the early stages of paleontological research, observers could scarcely have acted otherwise than as they did, in assigning names to these fragments, if only for temporary working purposes. Our error lies in misunderstanding the true value of such names. At present the study of fossil ferns is affording some promise of a newer and healthier condition. We are slowly learning a little about the fructification of some species, and the internal organization of others. Facts of these kinds, cautiously interpreted, are surer guides than mere external contours. Unfortunately, such facts are, as yet, but few in number; and, when we have them, we are too often unable to identify our detached sporangia, stems, and petioles, with the fronds of the plants to which they primarily belonged.

That all the carboniferous plants included in the genera Pecopteris, Neuropteris, and Sphenopteris, are ferns, appears to be most probable; but what the true affinities of the objects included in these ill-defined genera may be, is very doubtful. Here and there we obtain glimpses of a more definite kind. That the Devonian Palaeopteris hibernica is an hymenophyllous form appears to be almost certain; and, on corresponding grounds, we may conclude that the carboniferous forms, Sphenopteris trichomanoides, S. Humboldtii,[1] and Hymenophyllum Weissii,[2] belong to the same group. The fructification of the two latter leaves little room for doubting their position, whilst the foliage of some other species of Sphenopteris is suggestive of similar conclusions; but, until their fructification is discovered, this cannot be determined. An elegant form of Sphenopteris (S. tenella, Brong.; S. lanceolata of Gutbier), recently described by Mr. Kidson of Stirling, abundantly justifies caution in dealing with these Sphenopterides. This plant possesses a true sphenopteroid foliage, but its fructification is that of a marattiaceous danaid. The sporangia are elongated vertically, and have the round terminal aperture of both the recent and fossil Danaiae, — a group of plants far removed from the hymenophyllaceous type of sphenopterid already referred to.

Whether or not this Sphenopteris was really marattiaceous in other features than in its fructification, is uncertain; but I think that we have indisputably got stems and petioles of Marattiaceae from the carboniferous strata. My friend M. Renault, and I, without being aware of the fact, simultaneously studied the Medullosa elegans of Cotta. This plant was long regarded as the stem of a true monocotyledon, — a decision the accuracy of which was doubted first by Brongniart, and afterwards by Binney. M. Renault's

[1] Schimper, vol. I. p. 408. [2] *Ibid.*, p. 415.

memoir, and my part vii., appeared almost simultaneously. We then found that we had alike determined the supposed monocotyledon to be not only a fern, but to belong to the peculiarly aberrant group of the Marattiaceae. As yet we know nothing of its foliage and fructification.

M. Grand-Eury has figured [1] a remarkable series of ferns from the coal-measures of the basin of the Loire, the sporangia of which exhibit marked resemblances to those of the Marattiaceae. This is especially the case with his specimens of Asterotheca and Scolecopteris,[2] as also with his Pecopteris Marattiaetheca, P. Angiotheca, and P. Danaeaetheca; but there is some doubt as to the dehiscence of the sporangia of these plants: hence their marattiaecous character is not absolutely established.

That the coal-measures contain the remains of arborescent ferns has long been known, especially from their abundance at Autun. In Lancashire I have only met with the stems or petioles of one species preserving their internal organization.[3] The Rev. H. H. Higgins obtained stems that appear to have been tree-ferns from Ravenhead, in Lancashire; and it is probable that most of the plants included in the genera Psaronius, Caulopteris, and Protopteris, are also tree-ferns.

There yet remains another remarkable group of ferns, the sporangia of which are known to us through the researches of M. Renault. In these the fertile pinnules are more or less completely transmuted into small clusters of oblong sporangia. In one case, M. Renault believes that he has identified these organs with a stem or petiole of a type not uncommon at Oldham and Halifax, belonging to Corda's genus Zygopteris. Renault has combined this with some others to constitute his group of Botryopteridées, an altogether extinct and generalized type. This review shows, that whilst forms identifiable with the Hymenophyllaceae and Marattiaceae existed in the carboniferous epoch, and we find here and there traces of affinities with some other more recent types, most of the carboniferous ferns are generalized primeval forms, which only become differentiated into later ones in the slow progress of time.

Equisetaceae and Asterophylliteae (*Brongniart*), *Calamariae* (*Endlicher*), *Equisetineae* (*Schimper*). — Confusion culminates in the history of this variously named group: hence the subject is a most difficult one to treat in a concise way. The confusion began when Brongniart separated the plants contained in the group into two divisions, one of which (Équisétacés) he identified with the living equisetums, and the other (Astérophyllitées) he regarded as being gymnospermous dicotyledons. To Schimper belongs the merit, as I believe it to be, of steadily resisting this division; nevertheless, paleobotanists are still

[3] Psaronius Renaultii, Memoir vii., p. 10; and Memoir xii., pl. iv., fig. 16. These and other similar references are to my series of memoirs on the organization of the fossil plants of the coal-measures, published in the Philosophical transactions.

separated into two schools on the subject. Dawson, Renault, Grand-Eury, and Saporta adhere to the Brongniartian idea; whilst the British and German paleontologists have always adopted the opposite view, rejecting the idea that any of these plants were other than cryptogams.

A fundamental feature of the entire group is in the fact that their foliar appendages, however morphologically and physiologically modified, are arranged in nodal verticils. This appears to be the only characteristic which the plants possess in common.

Calamites and Calamodendron.— In his 'Prodrome' (1828), and in his later 'Végétaux fossiles,' Brongniart adopted the former of these generic names as previously employed by Suckow, Schlotheim, Sternberg, and Artis. It was only in his 'Tableau des genres de végétaux fossiles' (Dictionnaire universel d'histoire naturelle, 1849) that he divided the genus, introducing the second name to represent what he believed to be the gymnospermous division of the group. A long series of investigations, extending over many years, has convinced me that no such gymnospermous type exists.[1] The same conclusion has more recently been arrived at by Vom c. M. D. Stur,[2] after studying many continental examples in which structure is preserved. What I regard as *an* error appears to have had an intelligible origin, — the fertile source of similar errors in other groups.

Nearly all the Calamitean fossils found in shales and sandstones consist of an inorganic, superficially fluted substance, coated over with a thin film of structureless coal (see 'Histoire des végétaux fossiles,' vol. i. pl. 22); *the latter being exactly moulded upon and following the outlines of the inorganic fluted cast that underlies it.* Brongniart, and those who adopt his views, believe that the external surface of this coal-film exactly represents the corresponding external surface of the original plant: hence the conclusion was arrived at, that the plant had a very large central fistular cavity, surrounded by a very thin layer of cellular and vascular tissues, as in some living equisetums. On the other hand, Brongniart also obtained some specimens of what he primarily believed to be Calamites, in which the central pith was surrounded by a thick layer of woody tissue arranged in radiating laminated wedges, separated by medullary rays. The exogenous structure of this woody zone was too obvious to escape his practised eye. But, not supposing it possible that any cryptogam could possess a cambium-layer and an exogenous mode of development, Brongniart came to the conclusion that the thin-walled specimens found in the shales and sandstones were true Equisetaceae, those with the thick, woody cylinders being mere exogens of another type. His conclusion that they were gymnosperms was a purely hypothetical one, since justified by no one feature of their organization.

My researches, based upon a vast number of specimens of all sizes, from minute twigs little more than the thirtieth of an inch in diameter to thick stems

[1] Memoirs i., ix., and xii.

[2] Zur morphologie der calamarien.

at least thirteen inches across, led me to the conclusion that we have but one type of calamite, and that the differences which misled Brongniart are merely due to variations in the mode of their preservation.[1] It became clear to me that the outer surface of the coaly film in the specimens preserved in the shales and sandstones did *not* represent the outer surface of the living plant, but was only a fractional remnant of the carbon of that plant, which had undergone a complete metamorphosis. The greater part of what originally existed had disappeared, probably in a gaseous state; and the little that remained, displaying no organic structure, *had been moulded upon the underlying inorganic cast of the medullary cavity.* This cast is always fluted longitudinally, and constructed transversely at intervals of varying lengths. Both these features were due to impressions made by the organism upon the inorganic sand or mud filling the medullary cavity whilst it was in a plastic state, and which subsequently became more or less hardened; the longitudinal grooves being caused by the pressure of the inner angles of the numerous longitudinally vascular wedges, and the transverse ones partly by the remains of a cellular nodal diaphragm which crossed the fistular medullary cavity, and partly by a centripetal encroachment of the vascular zone at each of the same points.[2]

My cabinets contain an enormous number of sections of these plants, in which the minutest details of their organization are exquisitely preserved. These specimens, as already observed, show their structure in every stage of their growth, — from the minutest twigs, to stems more than a foot in diameter. Yet these various examples are all, without a solitary exception, constructed upon one common plan. That plan is an extremely complicated one, — far too complex to make it in the slightest degree probable that it could co-exist in two such very different orders of plants as the Equisetaceae and the Gymnospermae. Yet, though very complex, it is, even in many of its minuter details, unmistakably the plan upon which the living equisetums are constructed. The resemblances are too clear, as well as too remarkable, in my mind, to leave room for any doubt on this point. The great differences are only such as necessarily resulted from the gradual attainment of the arborescent form so unlike the lowly herbaceous one of their living representatives. On the other hand, no living gymnosperm possesses an organization that *in any solitary feature* resembles that of the so-called Calamodendra. The two have absolutely nothing in common: hence the conclusion that these Calamodendra were gymnospermous plants is as arbitrary an assumption as could possibly be forced upon science, — an assumption that no arguments derived from the merely external aspects of structureless specimens could ever induce me to accept.

These Calamites exhibit a remarkable morphological characteristic, which presents itself to us here for the first time, but which we shall find recurs in other paleozoic forms. Some of our French botani-

[1] Memoirs i. and ix.

[2] See Memoir i., pl. xxiv., fig. 10; and pl. xxvi., fig. 24.

cal friends group the various structures contained in plants into several 'appareils,'[1] distinguished by the functions which those structures have to perform. Amongst others, we find the 'appareil de soutiens,' embracing those hard, woody tissues which may be regarded as the supporting skeleton of the plant, and the 'appareil conducteur,' which M. van Tieghem describes as composed of two tissues, — "le tissu criblé qui transporte essentiellement les matières insolubles, et le tissu vasculaire qui conduit l'eau et les substances dissoutes." Without discussing the scientific limits of this definition, it suffices for my present purpose. In nearly all flowering plants these two 'appareils' are more or less blended. The supporting wood-cells are intermingled in varying degrees with the sap-conducting vessels. It is so, even in the lower gymnosperms; and in the higher ones these wood-cells almost entirely replace the vessels. It is altogether otherwise with the fossil cryptogams. The vascular cylinder in the interior of the Calamites, for example, consists wholly of *barred* vessels, a slight modification of the scalariform type so common in all cryptogams. No trace of the 'appareil de soutiens' is to be found amongst them. The vessels are, in the most definite sense, the 'appareils conducteurs' of these plants. No such absolutely undifferentiated unity of tissue is to be found in any living plants other than cryptogams.

But these Calamites, when living, towered high into the air. My friend and colleague, Professor Boyd Dawkins, recently assisted me in measuring one found in the roof of the Moorside colliery, near Ashton-under-Lyne, by Mr. George Wild, the very intelligent manager of that and some neighboring collieries. The flattened specimen ran obliquely along the roof, each of its two extremities passing out of sight, burying themselves in the opposite sides of the mine. Yet the portion which we measured was thirty feet long; its diameter being six inches at one end, and four inches and a half at the other. The mean length of its internodes at its broader end was three inches, and at its narrower one an inch and a half. What the real thickness of this specimen was when all its tissues were present, we have no means of judging; but the true diameter of the cylinder represented by the fossil when uncompressed has been only four inches at one end of the thirty feet, and two inches and a half at the other. Whatever its entire diameter when living, the vascular cylinder of this stem must have been at once tall and slender, and consequently must have required some 'appareil de soutien' such as its exogenous vascular zone did not supply. This was provided in a very early stage of growth by the introduction of a second cambium-layer into the bark; which, though reminding us of the cork-cambium in ordinary exogenous stems, produced, not cork, but prosenchymatous cells.[2] In its youngest state, the bark of the Calamites was a very loose cellular parenchyma; but in the older stems much of this parenchyma became enclosed in the prosenchymatous tissue referred to, and which appears to have constituted the greater portion of the matured bark. The sustaining skeleton of the plant, therefore, was a hollow cylinder, developed centrifugally on the inner side of an enclosing cambium-zone. That this cambium-zone must have had some protective periderm external to *it*, is obvious; but I have not yet discovered what it was like. We shall find a similar cortical provision for supporting lofty cryptogamous stems in the Lepidodendra and Sigillariae.

[1] Van Tieghem, Traité de botanique, p. 679.

[2] Memoir ix., pl. xx., figs. 14, 15, 18, 19, and 20.

The carboniferous rocks have furnished a large number of plants having their foliage arranged in verticils, and which have had a variety of generic names assigned to them. Such are Asterophyllites, Sphenophyllum, Annularia, Bechera, Hippurites, and Schizoneura. Of these genera, Sphenophyllum is distinguished by the small number of its wedge-shaped leaves; and the structure of its stems has been described by M. Renault. Annularia is a peculiar form, in which the leaves forming each verticil, instead of being all planted at the same angle upon the central stem, are flattened obliquely nearly in the plane of the stem itself. Asterophyllites differs from Sphenophyllum chiefly in the larger number and in the linear form of its leaves. Some stems of this type have virtually the same structure[1] as those of Sphenophyllum, — a structure which differs widely from that of the Calamites, and of which, consequently, these plants cannot constitute the leaf-bearing branches. But there is little doubt that true calamitean branches have been included in the genus Asterophyllites. I have specimens, for which I am indebted to Dr. Dawson, which I should unhesitatingly have designated Asterophyllites but for my friend's positive statement that he detached them from stems of a calamite. Of the internal organization of the stems of the other genera named, we know nothing.

It is a remarkable fact, that notwithstanding the number of young calamitean shoots that we have obtained from Oldham and Halifax, in which the structure is preserved, we have not met with one with the leaves attached. This is apparently due to the fact that most of the specimens are decorticated ones. We have a sufficient number of corticated specimens to show us what the bark was, but such specimens are not common. They clearly prove, however, that their bark had a smooth, and not a furrowed, external surface.

There yet remains for consideration the numerous reproductive strobili, generally regarded as belonging to plants of this class, Equisetinae. We find some of these strobili associated with stems and foliage of known types, as in Sphenophyllum;[2] but we know nothing of the internal organization of these sphenophylloid strobili. We have strobili connected with stems and foliage of Annularia,[3] but we are equally ignorant of the organization of these. So far as that

[1] Memoir, part v., pl. i.–v.; and part ix., pl. xxi., fig. 32.

[2] Lesquereux, Coal flora of Pennsylvania, pl. ii., fig. 687.

[3] Ueber die fruchtähren von Annularia sphenophylloides. Von T. Sterzel. Zeitschr. d. deutschen geolog. gesellschaft, Jahrg. 1882.

organization can be ascertained from Sterzel's specimen, it seems to have alternating sterile and fertile bracts, with the sporangia of the latter arranged in fours, as in Calamostachys.[1] On the other hand, we are now very familiar with the structure of the Calamostachys Binneana, the prevalent strobilus in the calcareous nodules found in the lower coal-measures of Lancashire and Yorkshire. It has evidently been a sessile spike, the axial structures of which were trimerous[2] (rarely tetramerous), having a cellular medulla in its centre. Its appendages were exact multiples of those numbers. Of the plant to which it belonged we know nothing. On the other hand, we have examples supposed to be of the same genus, as C. paniculata[3] and C. polystachya,[4] united to stems with asterophyllitean leaves; but whether or not these fruits have the organization of C. Binneana, we are unable to say.

We are also acquainted with the structure of the two fruits belonging to the genera Bruckmannia[5] and Volkmannia.[6] This latter term has long been very vaguely applied.

There still remain the genera Stachannularia, Palaeostachya, Macrostachya, Cingularia, Huttonia, and Calamitina, all of which have the phyllomes of their strobili fertile and sterile, arranged in verticils, and some of them display asterophyllitean foliage. But these plants are only known from structureless impressions. That all these curious spore-bearing organisms have close affinities with the large group of the equisetums cannot be regarded as certain; but several of them undoubtedly have peculiarities of structure suggestive of relations with the Calamites. This is especially observable in the longitudinal canals found in the central axis of each type, apparently identical with what I have designated the internodal canals of the Calamites.[7] The position and structure of their vascular bundles suggest the same relationship, whilst in many the position of the sporangia and sporangiophores is eminently equisetiform. Renault's Bruckmannia Grand-Euryi and B. Decaisnei, and a strobilus which I described in 1870,[8] exhibit these calamitean affinities very distinctly.

One strobilus which I described in 1880[9] must not be overlooked. As is well known, all the living forms of esquisetaceous plants are isosporous. We only discover heterosporous vascular cryptogams amongst the Lycopodiaceae and the Rhizocarpae. My strobilus is identical, in every detailed feature of its organization, with the common Calamostachys Binneana, excepting that it is heterosporous; having microspores in its upper, and macrospores in its lower part, — a state of things suggestive of some link between the Equisetinae and the heterosporous Lycopodiaceae.

Lycopodiaceae. — This branch of my subject suggests memories of a long conflict, which, though it is virtually over, still leaves here and there the groundswell of a stormy past. At the meeting of the British association at Liverpool, in 1870, I first announced that a thick, secondary, exogenous growth of vascular tissue existed in the stems of many carboniferous cryptogamic plants, especially in the calamitean and lepidodendroid forms. But at that time the ideas of M. Brongniart were so entirely in the ascendant, that my notions were rejected by every botanist present. Though the illustrious French paleontologist knew that such growths existed in Sigillariae and in what he designated Calamodendra, he concluded, that, *de facto*, such plants could not be cryptogams. Time, however, works wonders. Evidence has gradually accumulated, proving, that, with the conspicuous exception of the ferns, nearly every carboniferous cryptogam was capable of developing such zones of secondary growth. The exceptional position of the ferns still appears to be as true as it was when I first proclaimed their exceptional character at Liverpool. At that time I was under the impression that the secondary wood was only developed in such plants as attained to arboreal dimensions; but I soon afterwards discovered that it occurred equally in many small plants like Sphenophyllum, Asterophyllites, and other diminutive types.

After thirteen years of persevering demonstration, these views, at first so strongly opposed, have found almost universal acceptance; nevertheless, there still remain some few who believe them to be erroneous ones. In the later stages of this discussion the botanical relations subsisting between Lepidodendron, Sigillaria, and Stigmaria, have been the chief themes of debate. In this country we regard the conclusion, that Stigmaria is not only a root, but the root alike of Lepidodendron and Sigillaria, as settled beyond all dispute. Nevertheless, M. Renault and M. Grand-Eury believe that it is frequently a leaf-bearing rhizome, from which aerial stems are sent upwards. I am satisfied that there is not a shadow of foundation for such a belief. The same authors, along with their distinguished countryman the Marquis de Saporta, believe with Brongniart that it is possible to separate Sigillaria widely from Lepidodendron. They leave the latter plant amongst the lycopods, and elevate the former to the rank of a gymnospermous exogen. I have in vain demonstrated the existence of a large series of specimens of the same species of plant, young states of which display all the essential features of structure which they believe to characterize Lepidodendron; whilst, in its progress to maturity, every stage in the development of the secondary wood, regarded by them as characteristic of a Sigillaria, can be followed step by step.[1] Nay, more. My cabinet contains specimens of young dichotomously branching twigs, on

[1] M. Renault has described a strobilus under the name of Annularia longifolia, but which appears to me very distinct from that genus.

[2] It is an interesting fact, that transverse sections of the strobili of Lycopodium alpinum exhibit a similar trimerous arrangement, though differing widely in the positions of its sporangia.

[1] Memoir xi., plates xlvii.–lii.

which one of the two diverging branches has only the centripetal cylinder of the Lepidodendron, whilst the other has begun to develop the secondary wood of the Sigillaria.[1]

The distinguished botanist of the Institut, Ph. van Tieghem, has recently paid some attention to the conclusions adopted by his three countrymen in this controversy, and has made an important advance upon those conclusions, in what I believe to be the right direction. He recognizes the lycopodiaceous character of the Sigillariae, and their close relations to the Lepidodendra;[2] and he also accepts my demonstration of the unipolar, and consequently lycopodiaceous, character of the fibro-vascular bundle of the stigmarian rootlet, — a peculiarity of structure of which M. Renault has hitherto denied the existence. But along with these recognitions of the accuracy of my conclusions, he gives fresh currency to several of the old errors relating to parts of the subject to which he has not yet given personal attention. Thus he considers that the Sigillariae, though closely allied to the Lepidodendra, are distinguished from them by possessing the power of developing the centrifugal or exogenous zone of vascular tissue already referred to. He characterizes the Lepidodendra as having '*un seul bois centripète*,' notwithstanding the absolute demonstrations to the contrary contained in my Memoir xi. Dealing with the root of Sigillaria, which in Great Britain, at least, is the well-known Stigmaria ficoides, following Renault, he designates it a 'rhizome,' limiting the term 'root' to what we designate the rootlets. He says, "Le rhizome des sigillaires a la même structure que la tige aérienne, avec des bois primaires tantôt isolés à la périphérie de la moelle, tantôt confluents au centre et en un ax plein; seulement les fasceaux libéro-ligneux secondaires y sont séparés par de plus larges rayons," etc.

Now, Stigmaria, being a root, and not a rhizome, contains no representative of the primary wood of the stem. This latter is, as even M. Brongniart so correctly pointed out long ago, the representative of the medullary sheath; and the fibro-vascular bundles which it gives off are all foliar ones, as is the case with the bundles given off by this sheath in all exogenous plants. But in the Lepidodendra and Sigillariae, as in all living exogens, it is not prolonged into the root. In the latter, as might be expected *a priori*, we only find the secondary or exogenous vascular zone. Having probably the largest collection of sections of Stigmariae in the world, I speak unhesitatingly on these points. M. van Tieghem further says, "La tige aérienne part d'un rhizome rameux très-développé nommé Stigmaria, sur lequel s'insèrent à la fois de petites feuilles et des racines parfois dichotomées." I have yet to see a solitary fact justifying the statement that leaves are intermingled with the rootlets of Stigmaria. The statement rests upon an entire misinterpretation of sections of the fibro-vascular bundles supplying those rootlets, and an ignorance of the nature and positions of the rootlets themselves. More than forty years have elapsed since John Eddowes Bowman first demonstrated that the Stigmariae were true roots; and every subsequent British student has confirmed Bowman's accurate determination.

[1] Memoir xi., pl. xlix., fig. 8. [2] Traité de botanique, p. 304.

M. Lesquereux informs me that his American experiences have convinced him that Sigillaria is lycopodiaceous. Dr. Dawson has now progressed so far in the same direction as to believe that there exists a series of sigillarian forms which link the Lepidodendra on the one hand with the gymnospermous exogens on the other. As an evolutionist, I am prepared to accept the possibility that such links may exist. They certainly do, so far as the union of Lepidodendron with Sigillaria is concerned. I have not yet seen any from the higher part of the chain that are absolutely satisfactory to me, but Dr. Dawson thinks that he has found such. I may add, that Schimper and the younger German school have always associated Sigillaria with the Lycopodiaceae; but there are yet other points under discussion connected with these fossil lycopods.

M. Renault affirms that some forms of Halonia are subterranean rhizomes, and the late Mr. Binney believed that Haloniae were the roots of Lepidodendron. I am not acquainted with a solitary fact justifying either of these suppositions, and unhesitatingly reject them. We have the clearest evidence that some Haloniae, at least, are true terminal, and, as I believe, strobilus-bearing, branches of various lepidodendroid plants; and I see no reason whatever for separating Halonia regularis from those whose fruit-bearing character is absolutely determined. Its branches, like the others, are covered throughout their entire circumference, and in the most regularly symmetrical manner, with leaf-scars, — a feature wholly incompatible with the idea of the plant being either a root or a rhizome. M. Renault has been partly led astray in this matter by misinterpreting a figure of a specimen published by the late Mr. Binney. That specimen being now in the museum of Owens college, we are able to demonstrate that it has none of the features which M. Renault assigns to it.

The large, round or oval, distichously arranged scars of Ulodendron have long stimulated discussion as to their nature. This, too, is now a well-understood matter. Lindley and Hutton long ago suggested that they were scars whence cones had been detached, — a conclusion which was subsequently sustained by Dr. Dawson and Schimper,[1] and which structural evidence led me also to support. The matter was set at rest by Mr. d'Arcy Thompson's discovery of specimens with the strobili *in situ*. Only a small central part of the conspicuous cicatrix characterizing the genus represented the area of organic union of the cone to the stem. The greater part of that cicatrix has been covered with foliage, which, owing to the shortness of the cone-bearing branch, was compressed by the base of the cone. The large size of many of these biserial cicatrices on old stems has been due to the considerable growth of the stem subsequently to the fall of the cone.

Our knowledge of the terminal branches of the

[1] Memoir ii., p. 222.

large-ribbed Sigillariae is still very imperfect. Paleontologists who have urged the separation of the Sigillariae from the Lepidodendra have attached weight to the difference between the longitudinally ridged and furrowed external bark of the former plants, along which ridges the leaf-scars are disposed in vertical lines, and the diagonally arranged scars of Lepidodendron. They have also dwelt upon the alleged absence of branches from the sigillarian stems. I think that their mistake, so far as the branching is concerned, has arisen from their expectation that the branches must necessarily have had the same vertically grooved appearance and longitudinal arrangement of the leaf-scars as they observed in the more aged trunks: hence they have probably *seen* the branches of Sigillariae without *recognizing* them. Personally, I believe this to have been the case. I further entertain the belief, that the transition from the *vertical* phyllotaxis, or leaf-arrangement, of the sigillarian leaf-scars, to the *diagonal* one of the Lepidodendra, will ultimately be found to be effected through the subgenus Favularia, in many of which the diagonal arrangement becomes quite as conspicuous as the vertical one. This is the case even in Brongniart's classic specimen of Sigillaria elegans, long the only fragment of that genus known, which preserved its internal structure. The fact is, the shape of the leaf-scars, as well as their proximity to each other, underwent great changes as lepidodendroid and sigillarian stems advanced from youth to age. Thus Presl's genus Bergeria was based on forms of lepidodendroid scars which we now find on the terminal branches of unmistakable lepidodendra.[1] The phyllotaxis of Sigillaria, of the type of S. occulata, passes by imperceptible gradations into that of Favularia. In many young branches the leaves were densely crowded together; but the exogenous development of the interior of the stem, and its consequent growth both in length and thickness, pushed these scars apart at the same time that it increased their size and altered their shape. We see precisely the same effects produced upon the large fruit-scars of Ulodendron by the same causes. The carboniferous lycopods were mostly arborescent; but some few dwarf forms, apparently like the modern Selaginellae, have been found in the Saarbrücken coal-fields. Many, if not all, the arborescent forms produced secondary wood by means of a cambium-layer, as they increased in age. In the case of some of them,[2] this was done in a very rudimentary manner; nevertheless, sufficiently so to demonstrate what is essential to the matter, viz., the existence of a cambium-layer producing 'centrifugal growth of secondary vascular tissue.'

As already pointed out in the case of the Calamites, the vascular axis of these Lepidodendra was purely an 'appareil conducteur,' unmixed with any wood-cells: hence the 'appareil de soutien' had to be supplied elsewhere. This was done as in the Calamites: a thick, persistent, hypodermal zone of meristem[3] developed a layer of prismatic prosenchyma of enormous thickness,[1] which incased the softer structures in a strong cylinder of self-supporting tissue. We have positive evidence that the fructification of many of these plants was in the form of heterosporous strobili. Whether or not such was the case with all the Lepidostrobi, we are yet unable to determine; but the incalculable myriads of their macrospores, seen in so many coals, afford clear evidence that the heterosporous types must have preponderated vastly over all others.

Gymnosperms. — Our knowledge of this part of the carboniferous vegetation has made great progress during the last thirty years. This progress began with my own discovery[2] that all our British Dadoxylons possessed what is termed a discoid pith, such as we see in the white jasmine, some of the American hickories, and several other plants. At the same time. I demonstrated that most of our objects hitherto known as Artisias and Sternbergias were merely inorganic casts of these discoid medullary cavities. Further knowledge of this genus seems to suggest that it was not only the oldest of the true conifers in point of time, but also one of the lowest of the coniferous types.

Cycads. — The combined labors of Grand-Eury, Brongniart, and Renault, have revealed the unexpected predominance in some localities of a primitive but varied type of cycadean vegetation. Observers have long been familiar with certain seeds known as Trigonocarpons and Cardiocarpons, and with large leaves to which the name of Noeggerathia was given by Sternberg. All these seeds and leaves have been tossed from family to family at the caprice of different classifiers, but, in all cases, without much knowledge on which to base their determinations. The rich mass of material disinterred by M. Grand-Eury at St. Étienne, and studied by Brongniart and M. Renault, has thrown a flood of light upon some of these objects, which now prove to be primeval types of cycadean vegetation.

Mr. Peach's discovery of a specimen demonstrating that the Antholithes Pitcairniae[3] of Lindley and Hutton was not only, as these authors anticipated, 'the inflorescence of some plant,' but that its seeds were the well-known Cardiocarpons, was the first link in an important chain of new evidence. Then followed the rich discoveries at St. Étienne, where a profusion of seeds, displaying wonderfully their internal organization, was brought to light by the energy of M. Grand-Eury; which seeds M. Brongniart soon pronounced to be cycadean. At the same time I was obtaining many similar seeds from Oldham and Burntisland, in which, also, the minute organiza-

[2] On the structure and affinities of the plants hitherto known as Sternbergias. Memoirs of the literary and philosophical society of Manchester, 1851. M. Renault, in his Structure comparée de quelques tiges de la flore carbonifère, p. 285, has erroneously attributed this discovery to Mr. Dawes, including my illustration from the jasmine and juglans. Mr. Dawes' explanation was a very different one.

[3] Fossil flora. p. 82.

tion was preserved. Dawson, Newberry, and Lesquereux have also shown that many species of similar seeds, though with no traces of internal structure, occur in the coal-measures of North America.

Equally important was the further discovery by M. Grand-Eury, that the Antholithes, with their cardiocarpoid seeds, were but one form of the monoclinous catkin-like inflorescences of the Noeggerathiae, now better known by Unger's name of Cordaites. These investigations suggest some important conclusions. 1°. The vast number and variety of these cycadean seeds, as well as the enormous size of some of them, are remarkable, showing the existence of an abundant and important carboniferous vegetation, of most of which no trace has yet been discovered other than these isolated seeds. 2°. Most of the seeds exhibit the morphological peculiarity of having a large cavity (the 'cavité pollinique' of Brongniart) between the upper end of the nucelle and its investing episperm, and immediately below the micropile of the seed. That this cavity was destined to have the pollen-grains drawn into it, and be thus brought into direct connection with the apex of the nucelle, is shown by the various examples in which such grains are still found in that cavity.[1] 3°. M. Grand-Eury has shown that some of his forms of Cordaites possessed the discoid or Sternbergian pith which I had previously found in Dadoxylon. And, lastly, these Cordaites prove that a diclinous form of vegetation existed at this early period in the history of the flowering plants, but whether in a monoecious or a dioecious form we have as yet no means of determining. Their reproductive structures differ widely from the true cones borne by most cycads at the present day.

Conifers. — It has long been remarked that few real cones of conifers have hitherto been found in the carboniferous rocks, and I doubt if any such have yet been met with. Large quantities of the woody stems now known as Dadoxylons have been found, both in Europe and America. These stems present a true coniferous structure, both in the pith, medullary, sheath-wood, and bark.[2] The wood presents one very peculiar feature: its foliar bundles, though in most other respects exactly like those of ordinary conifers, are given off, not singly, but in pairs.[3] I have only found this arrangement of double foliar bundles in the Chinese gingko (Salisburia adiantifolia).[4] This fact is not unimportant when connected with another one. Sir Joseph Hooker long ago expressed his opinion that the well-known Trigonocarpons[5] of the coal-measures were the seeds of a conifer allied to this Salisburia. The abundance of the fragments of Dadoxylon, combined with the readiness with which cones and seeds are preserved in a fossil state, makes it probable that the fruits belonging to these woody stems would be so preserved; but of cones we find no trace, and, as we discover no other plant in the carboniferous strata to which the Trigonocarpons could with any probability have belonged, these facts afford grounds for associating them with the Dadoxylons. These combined reasons — viz., the structure of the stems with their characteristic foliar bundles, and the gingko-like character of the seeds — suggest the probability that these Dadoxylons, the earliest of known conifers, belonged to the Taxineae, the lowest of these coniferous types, and of which the living Salisburia may perhaps be regarded as the least advanced form.

Thus far our attention has been directed only to plants whose affinities have been ascertained with such a degree of probability as to make them available witnesses, so far as they go, when the question of vegetable evolution is *sub judice*. But there remain others, and probably equally important ones, respecting which we have yet much to learn. In most cases we have only met with detached portions of these plants, such as stems or reproductive structures, which we are unable to connect with their other organs. The minute tissues of these plants are preserved in an exquisite degree of perfection: hence we are able to affirm, that, whatever they may be, they differ widely from every type that we are acquainted with amongst living ones. The exogenous stems or branches from Oldham and Halifax which I described under the name of Astromyelon,[1] and of which a much fuller description will be found in my forthcoming Memoir xii., belong to a plant of this description. The remarkable conformation of its bark obviously indicates a plant of more or less aquatic habits, since it closely resembles those of Myriophyllum, Marsilea, and a number of other aquatic plants belonging to various classes. But its general features suggest nearer affinities to the latter genus than to any other. Another very characteristic stem is the Heterangium Grievii,[2] only found in any quantity at Burntisland, but of which we have recently obtained one or two small specimens at Halifax. This plant displays an abundant supply of primary, isolated, vascular bundles, surrounded by a very feeble development of secondary vascular tissue. Still more remarkable is the Lyginodendron Oldhamium,[3] a stem not uncommon at Oldham, and not unfrequently found at Halifax. Unlike the Heterangium, its primary vascular elements are feeble, but its tendency to develop secondary zylem is very characteristic of the plant. An equally peculiar feature is seen in the outermost layer of its cellular bark, which is penetrated by innumerable longitudinal laminae of prosenchymatous tissue, which is arranged in precisely the same way as is the hard bast in the lime and similar trees, affording another example of the introduction into the outer bark of the 'appareil de soutien.' As might have been anticipated from this addition to the bark, this plant attained arborescent dimensions, very large

[2] Memoir iii. *Ibid.*

fragments of sandstone casts of the exterior surface of the bark[1] being very abundant in most of the leading English coal-fields. Corda also figured it[2] from Radnitz, confounding it, however, with his lepidodendroid Sagenaria fusiformis, with which it has no true affinity. Of the smaller plants of which we know the structure, but not the systematic position, I may mention the beautiful little Kaloxylons.[3] We have also obtained a remarkable series of small spherical bodies, to which I have given the provisional generic name of Sporocarpon.[4] Their external wall is multicellular: hence they cannot be spores. Becoming filled with free cells, which display various stages of development as they advance to maturity, we may infer that they are reproductive structures. Dr. Dawson informs me that he has recently obtained some similar bodies, also containing cells, from the Devonian beds of North and South America. Except in calling attention to some slight resemblance existing between my objects and the sporangiocarps of Pilularia,[5] I have formed no opinion respecting their nature. Dr. Dawson has pointed out that his specimens, also, are suggestive of relations with the Rhizocarpae.

I am unwilling to close this address without making a brief reference to the bearing of our subject upon the question of evolution. Various attempts have been made to construct a genealogical tree of the vegetable kingdom. That the cryptogams and the gymnosperms made their appearance, and continued to flourish on this earth, long prior to the appearance of the monocotyledonous and dicotyledonous flowering plants, is, at all events, a conclusion justified by our present knowledge, so far as it goes. Every one of the supposed palms, aroids, and other monocotyledons, has now been ejected from the lists of carboniferous plants, and the Devonian rocks are equally devoid of them. The generic relations of the carboniferous vegetation to the higher flowering plants found in the newer strata have no light thrown upon them by these paleozoic forms. These latter do afford us a few plausible hints respecting some of their cryptogamic and gymnospermous descendants, and we know that the immediate ancestors of many of them flourished during the Devonian age; but here our knowledge practically ceases. Of their still older genealogies, scarcely any records remain. When the registries disappeared, not only had the grandest forms of cryptogamic life that ever lived attained their highest development, but even the yet more lordly gymnosperms had become a widely diffused and flourishing race. If there is any truth in the doctrine of evolution, and especially if long periods of time were necessary for a world-wide development of lower into higher races, a terrestrial vegetation must have existed during a vast succession of epochs, ere the noble lycopods began their prolonged career. Long prior to the carboniferous age they had not only made this beginning, but during that age they had diffused themselves over the entire earth. We find them equally in the old world and in the new. We discover them from amid the ice-clad rocks of Bear Island and Spitzbergen to Brazil and New South Wales. Unless we are prepared to concede that they were simultaneously developed at these remote centres, we must recognize the incalculable amount of time requisite to spread them thus from their birthplace, wherever that may have been, to the ends of the earth. Whatever may have been the case with the southern hemisphere, we have also clear evidence that in the northern one much of this wide distribution must have been accomplished prior to the Devonian age. What has become of this pre-Devonian flora? Some contend that the lower cellular forms of plant-life were not preserved, because their delicate tissues were incapable of preservation. But why should this be the case? Such plants are abundantly preserved in tertiary strata: why not equally in paleozoic ones? The explanation must surely be sought, not in their incapability of being preserved, but in the operation of other causes. But the carboniferous rocks throw another impediment in the way of constructors of these genealogical trees. Whilst carboniferous plants are found at hundreds of separate localities, widely distributed over the globe, the number of spots at which these plants are found displaying any internal structure is extremely few. It would be difficult to enumerate a score of such spots; yet each of those favored localities has revealed to us forms of plant-life of which the ordinary plant-bearing shales and sandstones of the same localities show no traces. It seems, therefore, that, whilst there was a general resemblance in the more conspicuous forms of carboniferous vegetation from the arctic circle to the extremities of the southern hemisphere, each locality had special forms that flourished in it either exclusively, or at least abundantly, whilst rare elsewhere. It would be easy, did time allow, to give many proofs of the truth of this statement. Our experiences at Oldham and Halifax, at Arran and Burntisland, at St. Étienne and Autun, tell us that such is the case. If these few spots which admit of being searched by the aid of the microscope have recently revealed so many hitherto unknown treasures, is it not fair to conclude that corresponding novelties would have been furnished by all the other plant-producing localities, if these plants had been preserved in a state capable of being similarly investigated? I have no doubt about this matter: hence I conclude that there is a vast variety of carboniferous plants of which we have as yet seen no traces, but every one of which must have played some part, however humble, in the development of the plant races of later ages. We can only hope that time will bring these now hidden witnesses into the hands of future paleontologists. Meanwhile, though far from wishing to check the construction of any legitimate hypothesis calculated to aid scientific inquiry, I would remind every too ambitious student that there is a haste that retards rather than promotes progress, that arouses opposition rather than produces conviction, and that injures the cause of science by discrediting its advocates.

LETTERS TO THE EDITOR.

Greenland geology.

IN the seventh volume of Heer's Flora fossilis arctica, just issued, my distinguished colleagues, Professor Heer of Zurich, and Herr K. F. V. Steenstrup of Copenhagen, seem to be at cross purposes with me, regarding the positions and Eskimo names of the localities where the collections of fossil plants discovered by us were obtained; Mr. Steenstrup giving the spot one name, and I another, while, owing to this misapprehension, the exact latitude of at least one place is differently entered in our respective papers. For instance: we apply the name of 'Kudlisact' (Kitludsat) to spots at considerable distances from each other, and do not quite understand the same place by the word 'Unartok.' Heer, who has, however, never been in Greenland, notes (p. 203) that "nach Steenstrup fällt Ujarasuksumitok von R. Brown (Flora foss. arct., ii. p. 452) mit Unartok zusammen und der Name beruht auf missverständniss." Again: Steenstrup, in the admirable memoir appended to Heer's work, mentions that "Brown zufolge *l. c.* [*Philosophical transactions*, 1869, p. 445, and *Transactions of the geological society of Glasgow*, vol. v. p. 36], war es hier [at Unartok], dass er und Whymper im jahr 1867 versteinerungen sammelten. Meines erachtens rüht der name Browns 'Uiarasuksumitok' von dem umstande her, dass der Grönlander ihn missverstanden und geglaubt hat, dass er gefragt würde, woher er (der Grönlander) wäre, worauf er eine antwort gab, die ungefähr bedeutet 'Ich bin aus Ujaragsugsuk'" (p. 247). I do not doubt for a moment that Mr. Steenstrup may be right; and his general accuracy forbids me to assert that he is wrong. My acquaintance with Danish was in 1867 (as it is still) trifling, while of Eskimo I was all but ignorant. And even with the greatest care, it is always difficult to arrive at the exact designation of localities in Greenland. However, Mr. Tegner, who accompanied us, was familiar with Eskimo, and of course, as a Dane, with Danish; and the names attached to my map and paper referred to were arrived at, after repeated cross-questioning of our native boatmen, and of Paulus, the intelligent Eskimo catechist at Ounartok (Unartok), who wrote them down in a note-book, at present before me. Curiously enough, in a note in the hand-writing of the late Chevalier Olrick, so many years governor of North Greenland, the place is called 'Ujarasaksumitok,' which naturally led me to believe that this was a synonyme of Ujaragsugsuk, under which name it is also designated by Dr. Rink, in my edition of Danish Greenland (p. 349). 'Ritenbenks Kolbroff' I regarded as the same place as Unartok, for there coal was being mined; while Steenstrup seems to consider it the same as Kudlisaet. The latter spot, after a series of very careful, and, I am certain, accurate, meridian altitudes, I place in Lat. 70° 5′ 35″ N., while Nares puts the Ritenbenk coal-mine, so called (Kudlisaet), in Lat. 70° 3′ 4″, which convinces me that this spot is what I took to be Unartok. At my Kudlisaet there was, in 1867, no coal being dug. Anyhow, in the 'Geological notes on the Noursoak Peninsula, Disco Island, etc.' (*Trans. geol. soc. Glasgow*, vol. v. p. 55), I have so fully described these localities, that no future explorer can mistake them. But as many may see Heer's work who may not be able to consult my humbler brochure, I ask permission to make these explanations in the columns of a scientific journal, which, as the mouthpiece of American geologists, takes cognizance of far-away Greenland also. Moreover, as one might suppose, from Mr. Steenstrup's (inadvertently, no doubt) mentioning that Nares and I differed two minutes and thirty-one seconds (2′ 31″) in our latitudes of 'Ritenbenks Kohlenbruch,' that there was some *inexcusable roughness* in the use of the sextant and artificial horizon, while in reality we observed *at two totally different places*, the matter is, though not of great scientific or geographical importance, in a manner personal to myself, if not to Sir George Nares.

ROBERT BROWN.

Streatham, London, Eng.,
Sept. 24, 1883.

Human proportion.

In a review of my lecture on 'Human proportion in art and anthropometry' (SCIENCE, ii. 354), the accuracy of certain statements contained therein is questioned. Permit me space for a brief reply.

The critic says that the implement in the hand of the Egyptian figure is a *crux ansata*, the symbol of eternity, and not 'a key.' But M. Charles Blanc, whose description I was quoting, says 'la personnage tient *une clef* de la main droite;' and the expression is warranted, as it is, in its symbolical sense, spoken of by Egyptologists as 'a key.'

His next assertion is, that the Doryphorus of Polykleitus was not, as I stated, 'a beautiful youth in the act of throwing a spear,' but a spear-bearer of the body-guard of the Persian king. The latter functionary, however, wore a long robe, termed the 'candys,' extending from the neck to the mid-leg, and could not have been selected for a model, which necessarily required a naked figure. Pliny (Hist. nat., xxxiv. 8) says, 'Idem et Doryphorum *viriliter puerum* fecit,' etc.; and many other allusions in classical writers confirm this view.

The last and most surprising criticism is the statement that my assertion that prior to the time of Phidias, the face, hands, feet, etc., were carved in marble, and were fastened to a wooden block, is "a complete misunderstanding of the nature of the archaic *ξόανα*, or wooden statues, which in Greece preceded those made of stone or metal." Now, the *ξόανον* was simply a wooden statue. (Cf. Pausanias, vii., 17, 2, *τοσάδε ἦν ἀφ' ὧν τὰ ξόανα*, etc.) It was succeeded by a more elaborate invention, known as an *acrolith*, from *ἄκρος* and *λίθος*, *stone-ends*. Pausanias describes one of them (ix. 4): "The statue of the goddess [the Plataean Athena of Phidias] is made of wood, and is gilt, except the face, and the ends of the hands and feet, which are of Pentelican stone." See also Quatremère de Quincy, Monuments et ouvrages d'art antiques, vol. ii., Restitution de la Minerve en or et ivoire de Phidias au Parthenon, pp. 63–123; also Müller, Handbuch d. archaeol. d. kunst, § 84. Dr. William Smith states the case concisely (Dict. Gr. and Rom. mythol., vol. iii. p. 250): "Up to his [Phidias's] time, colossal statues, when not of bronze, were *acroliths*; that is, only the face, hands, and feet were of marble, the body being of wood, which was concealed by real drapery." ROBERT FLETCHER.

Washington, Oct. 8, 1883.

[The most common of all the Egyptian symbols is an emblem in the form of 'a handled cross,' symbolical of 'life;' but both the nature of the object represented, and the reason of the symbolism, are equally unknown. To call it 'a key' is certainly wrong, as the Egyptians had none; and by archeologists it is usually designated by the conventional term '*crux ansata*.'

That the word 'Doryphoros,' *ex vi termini*, cannot mean 'a youth in the act of *throwing* a spear,' as Mr.

Fletcher says, but simply a 'spear-bearer,' is what our criticism was intended to convey.

Although it may be true enough that 'prior to the time of Phidias, *colossal* statues, when not of bronze, were *acroliths*, our criticism was directed to the author's broad assertion, which entirely ignored the existence of *ξόανα*.]

Geology of Philadelphia.

Will Professor Henry Carvill Lewis state where the term 'hydro-mica slate' is used by H. D. Rogers, or in that portion of the report on Chester county written by the undersigned?

The word occurs seven times in the Lancaster county report; but in every case except the italics on p. 10, which the reference on the ninth line below shows to be a misprint, it is used in the sense defined in my criticism, and not as an equivalent for hydro-mica-schist. As his defence of the use of the other terms alluded to does not meet the objections, no further remark is necessary.

Sept. 28, 1883.

The chinch-bug in New York.

We have the chinch-bug (Blissus leucopterus Say) in New York in formidable numbers. Its appearance with us is of great interest, as hitherto the only record of its occurrence is that of Dr. Fitch, who, several years ago, saw three individuals of it upon willows in the spring. I had never before met with it in our state. Dr. Harris, you will remember, mentions having seen one example in Massachusetts. By some manner it has been introduced here, and I can think of no way so probable as that it has been brought in a freight-car from the west.

The locality of its occurrence is in St. Lawrence county, the most western of our northern counties. As it was for some time thought that the insect could not live north of 40° of latitude, this seems a strange locality for its first appearance.

Its operations were first noticed in a field of timothy-grass last summer, but the depredator was not then discovered. This summer the infested area had largely extended, and, upon a more thorough search being made, it was found in myriads — could be scooped up, it is stated, by handfuls — among the roots of the living grass bordering the killed area. In the fields infested, the timothy, June, and 'wire grass' are completely killed, so that they are succeeded the following season by thistles, weeds, and patches of clover. So far, it has not attacked wheat or corn, of which, however, very little is grown in St. Lawrence county.

I have just visited the infested locality, and I find it to be a very serious attack. It is rapidly extending to other than the two farms upon which it was observed last year, and it in all probability exists in many places where it has not yet been detected. Great alarm is felt throughout the district invaded, as the timothy-grass is the foundation of the grazing interests of that region. Clover, owing to the severity of the winters, cannot be grown to any extent. The most threatening feature of the attack is, that it has continued to increase, notwithstanding that this year and the preceding have both been unusually wet in northern New York. Garden-crops were killed by the heavy and continued rains; grass is lying in the meadows, which could not be secured; and so cold has the season been, that fields of oats are still unharvested. All writers have concurred in stating that the chinch-bug could not endure cold and wet seasons, and that heavy rains were invariably fatal to it. It really seems as if the new-comer was destined to be a permanent institution in the state.

The farmers are aroused to the importance of doing what they can to arrest and repel the invasion. I have recommended that it be fought with that valuable insecticide, kerosene-oil, emulsified and diluted; and, if generally used the ensuing spring, I have great faith in its proving efficient.

Ziphius on the New-Jersey coast.

A telegram was received at the Smithsonian institution on the 3d inst. from the keeper of the life-saving station at Barnegat City, N.J., announcing the stranding of a large cetaceau at that place. Professor Baird immediately despatched the writer and a preparator from the museum to take charge of the specimen. On arriving at Barnegat City, I immediately perceived that we had to do with an example of an aged female of an interesting ziphioid whale; and, when the skull was cut out, it became evident that the animal was of the genus Ziphius. The specimen measures 19 feet 4 inches in length, and was apparently of a light stone-gray color, darkest on the belly. This disposition of color is unusual in cetaceans. The species is probably Z. cavisortris.

Mr. Palmer and myself succeeded in making a plaster mould of half the exterior, and in cutting out the complete skeleton.

The genus Ziphius has not, I believe, been hitherto recorded as occurring in the north-western Atlantic.

THE DE LONG RECORDS.[1]

The voyage of the Jeannette. The ship and ice journals of George W. De Long, Lieut.-commander U.S.N., and commander of the polar expedition of 1879-81. Edited by his wife, Emma [Jane Wotton] De Long. 2 vols. Boston, *Houghton, Mifflin, & Co.*, 1883. 12+911 p., illustr. 8°.

The voyage of the Jeannette, owing to its connection with a great newspaper, has become, in its general features, familiar to all. The courage, endurance, and patience with which the members of the party met pain, peril, privation, and even death, will always remain a conspicuous example of manly quality. This expedition, however, was unique in several of its features, which should be taken into account in any judgment rendered upon its results. It was not an expedition for scientific research in the arctic regions. It was not scientifically planned. It had, so far as can be learned from the documents, no programme. Of its members, but two, a civilian and a seaman, had had any experience of an arctic winter; none had made any serious study of the physical conditions of the polar area; and, without

[1] For the woodcuts illustrating this article, the editor is indebted to the publishers of the work, Messrs. Houghton, Mifflin, & Co.

disrespect, it may be said, that, with the possible exception of two civilians, there was no one on board whose scientific acquirements rose above the daily needs of the intelligent practice of his profession. The object of the expedition, as far as may be surmised from the circumstances made public, seems to have been to determine what would be the result of a set-to between the arctic pack, cold and starvation on the one hand, and a shipful of inexperience and 'pure grit' on the other. The result is now known; and the innocent confidence with which both promoter and explorer undertook the task is one of the extraordinary features of this melancholy history. Under the circumstances, it is well that Mrs. De Long has made public her husband's records of the story, already twice told elsewhere. The account of the voyage is preceded by some details of the previous life of De Long, who, from an early age, showed evidence of great force of will and audacity, and who preserved until his death the religious convictions instilled by a fond and pious mother. There seems to have been no special turn for study in the lad, whose energy, nevertheless, carried him through the Naval academy with credit. The introduction to that friendship with Mr. Bennett which finally led to De Long's selection as commander of the arctic expedition, is left untold. It is evident that these two had a strong and well-founded friendship, and perfect mutual confidence. The voyage once determined upon, Mr. Bennett providing the vessel and the means, the government lending its naval organization and prestige, De Long had only to choose his party, and organize his plans. The first was soon, and, all must admit, remarkably well done. Certainly, no body of men ever stood harder test of fidelity to their commander than that little party, and with less flinching.

The vessel, it is now generally admitted, was tolerably well adapted to her purpose, and endured from the ice all that could be expected in like circumstances. The provisions, on the whole, turned out well; and the equipment, in the course of the expedition, showed no serious deficiencies. On the whole, then, well provided, and with much popular approbation and sympathy, the expedition departed on the 8th of July, 1879, from San Francisco. A *rendezvous* was had Aug. 2, at Unalaska, — that cosey little harbor which has received so many expeditions, and bravely borne up the barks of Kotzebue, of Lütke, of Levasheff, of Kruzenstern, of Sarycheff, and many more masters of exploration. Ten days afterward they anchored at St. Michael's, Norton Sound. Here dogs, furs, and coal were shipped; and then the Asiatic coast of Bering Strait was reached, and some time spent in endeavoring to determine the fate of Nordenskiöld. Here several

UNALASKA.

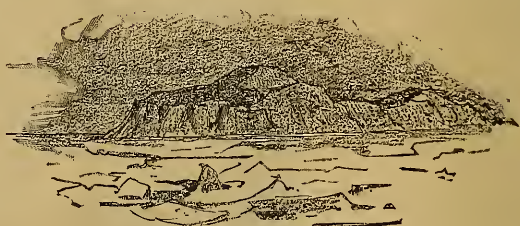
curious bone implements were collected, which are figured, but not referred to in the text. One of these we reproduce.

Pushing into the Arctic on Sept. 6, the vessel was beset in the pack north-eastward of Herald Island. From its rigid embrace she was never released, except to sink, a shattered wreck, beneath its surface, nearly two years later.

On Jan. 19, 1880, she received a wrench from an under-running tongue of ice, creating a leak, which remained a more or less constant source of anxiety. From this time until the 16th of May, 1881, the time passed uneventfully; the ship fast in the ice, which occasionally groaned, shrieked, crunched, or thundered, with the various motions imparted to it by wind and tide, threatening instant destruction to ship and party. A few bear and seal hunts, ordinary

BONE SHOVEL.

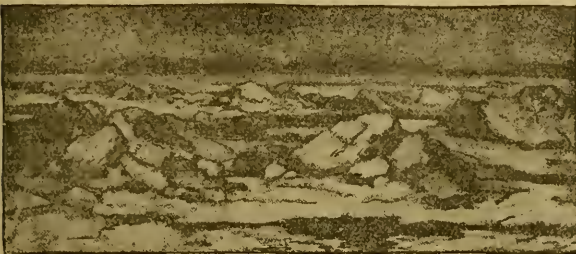
meteorological observations, the quarrels of the Eskimo dogs, innumerable devices for saving coal, pumping the ship dry, or preventing condensation of moisture within the living-rooms,—these things, and such as these, made up the characteristics of a life which eventually became almost unendurable in its monotony. Good health in general prevailed, owing to the extraordinary precautions planned by Dr. Ambler, and energetically put in force by the commander. No extreme temperatures (rated by the experience of other arctic voyages) were noted: indeed, the mildness, arctically speaking, of the temperatures experienced, is somewhat remarkable. The auroras do not seem to have been sufficiently brilliant to call for especial comment. The ice reached about six feet in thickness, and all parts of it contained more or less salt; while the precipitation of snow was insufficient to afford a supply of drinking-water by melting. On this account, water had to be distilled most of the time,—a process which used much invaluable fuel. Many of their experiences were such as had already been recorded by those who drifted with the Germania's crew, the Tegethoff, or the floating Polaris' party, of which the indefatigable Nindeman had been a member. Payer's conclusion that the motions of the arctic pack result from the friction upon its surface of the prevailing winds, was fully confirmed, and placed upon an impregnable basis, by the drift of the Jeannette. This is perhaps the most important generalization the history of the voyage affords. Another fact of value is the determination of the shallow character of this part of the arctic basin, which nowhere reached one hundred fathoms in depth, and was usually less than fifty fathoms. From the constant though moderate motion of the pack which held the vessel, tidal observations were impracticable; and the disturbances of the surface so occasioned, also prevented the permanent occupation of an observatory away from the ship. Polar bears, seals, a fox or two, walrus, and a small number of birds, comprise the air-breathing vertebrates obtained. Some fish-bones were found on the ice, but it does not appear that any fishing was attempted. Vignettes from the pencil of Mr. Newcomb, who acted as naturalist of the expedition, are scattered through the text, and illustrate the scanty fauna in a neat and artistic way. On the 16th of May, 1881, land was seen bearing nearly west, which was named Jeannette Island. It proved to be a small rocky island with bold shores, and was situated in latitude 76° 47′, and east longitude 158° 56′. On the 24th another island was observed more to the north and west, which



JEANNETTE ISLAND (FROM A SKETCH BY MR. MELVILLE).

A POLAR BEAR.

was named Henrietta Island. This was visited by Melville, with a small party, ten days later. After great difficulties, caused by the hummocky ice, they succeeded in landing upon it, and found it to be a desolate rock, surmounted by a snow-cap which discharged in several glaciers on the east side. Dovekies nesting on the face of the rock were the only sign of life about it other than a little stunted vegetation. But a great change was at hand. Motions and fractures of the ice increased; and the ship was evidently in serious danger, which was accordingly provided for. On June 12, 1881, the Jeannette yielded to the irresistible pressure, and at four o'clock the next morning she sank. The retreat was then organized and begun, with several men on the sick-list in addition to the usual difficulties offered by rough, broken, and fissured ice. After a little, De Long made the painful discovery that the ice was drifting northward faster than they were able to travel in a southerly direction. The course was therefore altered to cross the drift in a south-westerly direction, in the hope of escaping from the moving area. About the middle of July more land was observed, and on the 28th the party succeeded in landing upon it after almost incredible exertions. This land, the loom of which had been reported by Russian explorers on the New Siberian Islands many years ago, but which had never been definitely verified or charted, was named Bennett Island; and we observe that in the map accompanying the work, this and the others are very appropriately included under the name of the De Long Islands. Coal, hematite, fossiliferous limestone, clay, and lavas were observed on this island, and, more important for the party, myriads of sea-fowl breeding in the rocky cliffs. There were several glaciers, and, to one hundred feet above the sea, masses of drift-wood embedded in the soil, indicating tolerably recent elevation of the land. Hence by way of the New Siberian Islands, touching at Thaddeieff, Kotelnoi, Semeonoffski, the party made their way, but became separated in a gale of wind on the 12th of September, after which the smallest boat, with its crew, was never heard from; and finally the two remaining boats reached the shores of the Lena delta. De Long landed on the north Sept. 17, and Melville the previous day reached the south-eastern angle, and entered a branch of the river. It is not necessary to recapitulate the circumstances which attended the retreat, — the heroic journey of Nindeman and Noros, the indefatigable search of Melville, the final recovery of the remains, and their temporary interment on Monument Hill, looking out upon the flat stretches



BENNETT ISLAND AS SEEN IN THE DISTANCE, JULY 19.

MONUMENT HILL, LENA DELTA.

of the delta. These facts are the property of the public, which has not failed to appreciate the heroic qualities exhibited, nor to observe that the disastrous result of this unfortunate expedition offers in great part its own explanation. If it teach the aspiring that mere uninstructed courage cannot take the place of science, De Long and his people will not have died in vain. That this lesson should be especially emphasized, from recent events in another part of the arctic regions, will occur to most of our readers. Perhaps it would be well to permit future candidates for such work to convince themselves by trial, that the most exalted bravery will not enable the inexperienced to milk a fractious cow; and that, if so simple a matter requires knowledge and experience, it may be well to hesitate before assuming the fearful responsibility of hazarding the lives of even willing subordinates, without reasonable preparation for the problems offered by all serious arctic work, whether of exploration or retreat. Tenderness toward the dead should not be for an instant permitted to befog this self-evident truth, the statement of which is a duty owed, not merely to those who may hereafter attempt arctic exploration, but on behalf of scientific training everywhere.

STEP'S PLANT-LIFE.

Plant-life: popular papers on the phenomena of botany. By Edward Step. With 148 illustrations drawn by the author, and engraved by W. M. R. Quick. New York, *Holt & Co.*, 1883. 12+218 p. 12°.

Year by year there is what may be termed a noticeable amelioration in the character of the botanical literature which appears in this country. By this we mean no discourtesy to the authors of the many excellent works which have appeared from time to time. In certain scientific lines, the botanical literature of the United States has been both voluminous and of a high order of excellence. In systematic botany, the publications of Torrey, Gray, Eaton, and Watson (to mention only a few of the later workers) have not been excelled anywhere. We may justly feel a national pride in such magnificent books as the two volumes of the Botany of California, the Botany of the Clarence King reports and of the Wheeler reports, the Ferns of North America, etc. Then, too, our school and college books have been worthy of their authors. What country was ever supplied with better field-manuals than Gray's or Wood's? and where can one find as good a treatise on the morphology of the phanerogams as Dr. Gray has given us in the latest edition of his Structural botany?

All these, however, are for students and botanists proper. They were not designed for the general reader, — the man who does not take botany in such dreadful earnest as do the botanists, but who asks of the gentle science that it shall please and amuse him. Our scientific botanists have been too busy with the serious matter of instructing their classes of young people in school and college, to turn aside and furnish entertaining reading for the unbotanical. We can scarcely blame them for thus neglecting the great outside world, when the small world of the classroom required all their time and strength; and yet we cannot help feeling that it would have been better for the botanists, as well as for botany itself, had they compelled themselves to find time for those lighter works which have, in other countries, been at once the recreation of the scientific man and the pleasure of the general reader.

In the work before us we have an example of what may be done in the way of putting the main facts of biological botany before the unbotanical in plain and easy English, and in such a way as to be attractive and interesting. We wish its English author were an American; but, that being an impossibility, it is most gratifying that the Messrs. Holt have brought out so neat an American edition.

It is, of course, to be expected that there is nothing new botanically in such a book; so that those who are fairly well equipped with a knowledge of recent botanical literature need not take it up in the hope of gleaning any new facts. It is only what its titlepage indicates, — an aggregation of popular papers on some of the phenomena of botany. They are not profound, nor are they so arranged as to present themselves as a series of connected lessons. They are rather like lightly drawn sketches, — now of this interesting view of a portion of the plant-world, and now of that. Thus we have a chapter on microscopic plants, another on plant structure and growth, one on the fertilization of flowers, followed by others on predatory plants, remarkable flowers and leaves, and about a fern. Then we have the folk-lore of plants, plants and animals, mosses and lichens, etc. So the chapters (fourteen in all) run on through the book, there being a delightful alternation of the structural with those which deal with sentimental or poetical considerations.

Considering the nature of the book, the errors are remarkably few. Here and there, however, are statements which ought to be changed in a second edition. The Zygnemae are erroneously described as producing zoospores (p. 5), — a statement true enough of their relatives the Confervae, but not of any of the Zygnemae. Of roots it is said positively (in italics, p. 29) that 'they are never green,' which, to say the least, is a strong statement. On p. 34 we find that "in some plants the calyx or corolla is entirely wanting, in which case the floral covering is called the *perianth*," which is certainly not in accordance with ordinary usage. On the same page the stigma is curiously described as 'the surface of the style.' The Equiseta are not leafless, as they are said to be on p. 164. Their leaves are small, it is true; but certainly the whorls of united leaves at each joint are evident enough to even the casual observer. The formation of the zygospore in Mucor is not correctly given on p. 184, where it is described as resulting from the union of two aerial hyphae. On p. 192, in describing the fly fungus, the reader is given the impression that a mycelium upon a surface (as a window-pane) attacks its hapless victim, the fly, which, when dead, is said to be "standing upon a mat of delicate silk threads spread upon the glass."

Fig. 21 (repeated in fig. 143) is erroneous in showing the hyphae of the potato fungus to be septated. Fig. 104 is said to show the antheridia of a moss; but certainly no such organs are visible in the cut given.

In spite of the slips noted above, and others which we may well pass over, the little book is a pleasant one to read, and we feel sure that it will receive a hearty welcome from plant-lovers everywhere.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Saturn's rings. — Encke's division in the outer ring of Saturn has been examined by M. Schiaparelli, who finds that the position and lack of symmetry are the same as previously noticed, but the line is broader, and more diffused than in 1881. He thinks the phenomenon is variable, and accounts for it by supposing the middle of the ring to be thinner, and by the change of orbit of the particles composing it. He also examined carefully the region about the inner bright ring and the dark ring. At times O. Struve's division was seen very distinctly, and on other occasions very faintly. More observations are necessary to determine whether the phenomenon is variable. — (*Observ.*, Aug.; *Astr. nachr.*, 2,521.) M. McN. [289

The great comet of 1882. — Mr. Maxwell Hall shows the possible identity of the great comet of 1882, the comets of 1880, 1843, and 1668, with a comet which appeared B.C. 370, and which was said to have separated into two parts. The orbits of all are nearly identical. Taking a period not greatly different from that given by Prof. Frisby for the comet of 1882, he identifies the comets of B.C. 370 and A.D. 1843 with one which was seen in 1106. No comet is recorded for A.D. 368. The comets of 1880 and 1882 may possibly be identical with two which appeared in 1131 and 1132, and with the second part of the comet of B.C. 370. If this is the case, this comet also probably separated into two parts at its unrecorded appearance in A.D. 381 or 382. We already have an instance of this separation in Biela's comet; and the comet of 1882 gave evidence, to a certain extent, that a process of disintegration was going on. — (*Observ.*, Aug.) M. McN. [290

PHYSICS.

Electricity.

Atmospheric electricity. — Dr. L. J. Blake has found that no convection of electricity takes place by the rising vapor from a charged liquid surface, to which he gave a potential due to from four to five hundred Daniells cells. The plate placed in the track of the vapors was, in the different experiments, either colder than the vapor, or of the same temperature. By connecting the liquid with the electrometer, he finds a small negative charge, increasing during the fifteen minutes which each experiment lasted, but not sufficiently to justify the statement that electricity is generated by evaporation. In all the work, the lamp was removed before connecting with the electrometer; and the whole apparatus was within a metallic covering connected with the earth. Distilled water, sea-water from the North Sea, alcohol, dilute sulphuric acid, mercury, and solutions of a number of different salts, were tried. — (*Ann. phys. chem.*, xix. 518.) [291

ENGINEERING.

A new current-meter. — Mr. L. d'Auria proposes an apparatus for determining the mean velocity at any vertical in a stream, which apparatus consists of a scow, or pontoon, to be moored in the desired place; a pole with a pulley near each end, carrying an endless cord; a light ball; and a species of net, or grillage. The pole is thrust to the bottom alongside the scow, at the point where the velocity is to be gauged; and the ball is lightly attached to the cord by a string, so as to be disengaged by a moderate pull when it reaches the pulley at the bottom. The time of the disengaging pull is noted, and also the time of the appearance of the ball at the surface. As the floating grillage has previously been moored over this place, the ball is caught at the point of rising, and the horizontal distance of this point from the pole measured. Hence are known, upon measuring the depth, the two co-ordinates of the point at the surface from the bottom of the pole. The author proposes to weight the ball until it shall be one-half the heaviness of water. He deduces some equations to prove that the ball rises with a practically uniform velocity, and observes, that for a depth of 30 feet, from which such a ball would rise in about 11 seconds, and a mean velocity of current of 4 feet per second, the ball would travel horizontally about 44 feet.—(*Amer. eng.*, Aug. 24.) C. E. G. [292

CHEMISTRY.

(Physical.)

Determination of vapor density.—Br. Pawlewsky proposes a modification of Dumas' method in which he uses a globe of 20–30 cubic centimetres volume. After heating, the globe is closed by a rubber cap, which is fitted to a cylindrical tube of glass sealed at one end. The volume is therefore constant for different determinations, and the observations may be taken in a room of nearly constant temperature. In the formula of Dumas,—

$$m = \frac{0.0012932 \,.\, V \,.\, B_0}{(1 + a t)\ 760}, \qquad \text{(I.)}$$

where m is equal to the weight of air, the product $0.0012932 \,.\, V = K$ would be constant. The value $(1 + a t) = N$ is constant, and may be obtained from a table. If, then, the constant, K, is divided by 760, a new constant, D, results, and (I.) becomes

$$m = \frac{K \,.\, B_0}{N \,.\, 760} = \frac{D \,.\, B_0}{N}. \qquad \text{(II.)}$$

In a determination at any temperature, t'_0, and any pressure, B'_0, if the weight of air in the apparatus is represented by n, its weight is shown in the formula

$$n = \frac{0.0012932\ V\ (1 + \kappa t')\ B'_0}{(1 + a t)\ 760}, \qquad \text{(III.)}$$

in which κ represents the coefficient of expansion of the apparatus. If the temperature is constant, and the same apparatus is used in different determinations, the product $0.0012932\ V\ (1 + \kappa\, t')$, and the whole denominator, become constant. Representing the denominator by R, and the product $0.0012932\ V\ (1 + \kappa t')$ by M, the fraction $\frac{M}{R} = C$ is constant, and formula (III.) will take the form

$$n = \frac{M B'_0}{R} = C \,.\, B'_0. \qquad \text{(IV.)}$$

The volume of air may therefore be obtained by multiplying the constant, C, by B' reduced to B'_0; and when the weight, a, of the vapor, and that of the air, n, under the same conditions, are known, the vapor density may be found by the formula

$$D = \frac{a}{n}. \qquad \text{(V.)}$$

The apparatus may be heated in a beaker of medium size, containing water, oil, or paraffine. For a complete description of the apparatus, reference must be made to the original article. A series of determinations are given, which indicate a high degree of accuracy.—(*Berichte deutsch. chem. gesellsch.*, xvi. 1293.) C. F. M. [293

GEOLOGY.

Evidences of modern geological changes in Alaska.—Mr. T. Meehan exhibited a piece of wood taken from a prostrate tree which had been covered with glacial drift on a peninsula of Hood's Bay, Alaska, formed by the junction of Glacier Bay and Lynn Channel. The trunk, which lay under a block of granite estimated to measure 2,214 cubic feet, was quite sound, and exhibited no evidence of great age since it became covered. The shores are strewn with rocks and stones of various kinds, as usual in cases of glacial deposits. All the surroundings indicated that there had been a sudden subsidence of the land, accompanied by a flow of water with icebergs and huge bowlders, which crushed and tore off the trees. The whole surface was afterwards covered to a great depth with drift. Since that time, there must have been an elevation of the land bringing the remains of trees to their original surface, but with a deep deposit above them. A study of the existing vegetation might afford an approximation to the time when these events occurred. The living forest indicated clearly that it could not have been, at the farthest, more than a few hundred years since the elevation occurred. The trees in the immediate vicinity, indeed, were not more than fifty years old; but unless the original parent trees, which furnished the seed for the uplifted land, were near by, it might take some years for the seed to scatter from bearing trees, grow to maturity, again seed, and, in this way, be spread to where we now find them. But, as original forests were evidently not far distant, two or three hundred years ought to cover all the time required. The Indians of the region have a tradition of a terrible flood about seven or eight generations ago, from which only a few of the natives had escaped in a large canoe. The probable identity of the sunken trees with the present species, and the freshness of the wood, indicate no very great date backwards at which the original subsidence occurred.

In connection with the subject of the comparatively recent occurrence of great geological changes, as indicated by botanical evidence, Mr. Meehan referred to an exposure of the remains of a large forest near the Muir glacier,—one of five huge ice-fields which form the head of Glacier Bay between Lat. 59° and 60°. This glacier is at least two miles wide at the mouth, and has an average depth of ice, at this spot, of perhaps five hundred feet. At the present time there is not a vestige of arboreal vegetation to be seen in the neighborhood. The river which flows under the glacier rushes out in a mighty torrent a few miles above the mouth, and has cut its way through mountains of drift, the gorge being many hundred feet in width, and the sides from two hundred to five hundred feet high. The torrent, though the bed is now comparatively level, carries with it an immense quantity of heavy stones, some of which must have contained six or eight cubic feet. Along the sides of this gorge were the exposed trunks referred to, all standing perfectly erect, and cut off at about the same level. Some were but a few feet high, and others as much as fifteen, the difference arising from the slope of the ground on which the trees grew. The trunks were of mature trees in the main, and were evidently Abies Sitkensis, with a few of either Thuja gigantea or Juniperus, perhaps J. occidentalis. These trees must have been filled in tightly by drift to a height of fifteen feet before being cut off: otherwise the trunks now standing would have been split down on the side opposite to that which received the blow. The facts seemed to indicate that the many feet of drift which had buried part of the trees in the first instance were the work of a single season, and that the subsequent total destruction of every vestige of these great forests was the work of another one, soon following. As in the case of the facts noted in Hood's Bay, the conclusion was justified, that the total destruction of the forests, the covering of their site by hundreds of feet of drift, and the subsequent exposal of their remains, were all the work of a few hundred years. — (*Acad. nat. sc. Philad.; meeting* Aug. 28.) [294

MINERALOGY.

Stibnite from Japan. — Within the last few months most remarkable specimens of stibnite from Mount Kosang, in southern Japan, have been received in America. For great size and beauty, as well as complexity of form, they rival all specimens of the same species from other localities, while the crystals have arrived at a degree of perfection rarely met with in metallic minerals. The crystals have been carefully studied and fully described by E. S. Dana. Their great complexity of form is of the highest scientific interest. There had previously been identified on stibnite forty-five crystal planes. Of these, thirty have been observed on the Japanese crystals, and, in addition, forty new ones. The habit of the crystals is quite constant, being prismatic, elongated in the direction of the vertical axis, single crystals obtaining often a length of over twenty inches and a width of two inches. The prismatic planes are deeply striated. The crystals are usually terminated by a few polished pyramidal faces. They are usually quite simple in form; very complicated, large crystals occurring only occasionally, while the more complicated ones are usually small. The planes in the zone between the brachypinacoid (010) and unit macrodome (101) are those which ordinarily terminate the crystal. Another remarkable zone is between the brachypinacoid (010) and macrodome (203), consisting of ten planes, all but one of which are new, and as many as nine of which have been observed on a single crystal. A bending in the direction of the macrodiagonal axis is a feature of the crystals, and seems to be characteristic of the species. In the Japanese crystals this bending seems to be confined to the termination. A corkscrew-like twist has been observed in slender crystals. The lustre of the crystals is very remarkable, and is to be compared to highly polished steel, while the perfect brachypinacoidal cleavage yields a cleavage-surface of remarkable beauty. — (*Amer. journ. sc.*, Sept., 1883.) S. L. P. [295

GEOGRAPHY.

(*Asia.*)

Railways in the Caspian region. — General Chernaieff, the governor of Turkestan, has recently gone over the route from Kungrad to the Caspian in person, and finds it well suited for vehicles. Even a railway between the delta of the Oxus and the Gulf Mertvi-kuttuk has been talked of. The connection of Tiflis and Baku by rail is completed, and the journey can now be made between the Black and Caspian seas in thirty hours without change. — (*Comptes rendus soc. géogr.*, June.) W. H. D. [296

Prjevalski's travels. — This indefatigable explorer has just started for Kiachta, on the Siberian border of China, in order to continue his researches in central Asia. On this occasion he will endeavor to penetrate the north-west part of Thibet, without giving up his original idea of reaching Lassa, or at least as far as Batang or Tziamdo. He will have a well-armed escort of some twenty men, fully equipped for two years' service. The publication of the third volume of his travels has just been finished. During these he has travelled 23,530 kilometres; topographically sketched over 12,000 kilometres along his line of travel, in countries previously quite unknown; determined the altitude of 212 points, and the latitude of 48 localities; and has collected ten or twelve thousand specimens of animals and plants belonging to over two thousand species. — (*Comptes rendus soc. géogr.*, June.) W. H. D. [297

(*Africa.*)

Notes. — C. Doelter has ascended the Rio Grande as far as Futa Djallun, but was prevented from going farther east by a war among the natives. He believes that the Rio Grande has been incorrectly mapped, and doubts its alleged identity with the Tomani River. —— The English have annexed the Guinea coast from the right bank of the Mannah River toward the Liberian boundary-line, — a distance of eight leagues in a north-westerly direction; and the Portuguese government has ceded to England the fort of St. John de Ajuda, situated on the Dahomey coast. Ajuda, or Whydah, is situated a short distance from the coast, on a shallow lagoon. The port is a poor one, like all those on the Guinea coast; and there are very few white residents. It is said that the cession was contingent on the recognition, by England, of the acquired rights of Portugal on the Congo. —— Robert Flegel, during the past season, has discovered the source of the Binué, an affluent from the east of the lower Niger, and also of the Logné, which discharges into Lake Chad. In this way he has been able to trace the watershed between the two basins, through a previously unexplored district. —— Hore has arrived at Ujiji on Lake Tanganyika, and proposes to establish a regular postal service on the lake, between the missionary and other stations. —— Dr. Baxter has attempted an exploration of the country of the Massai adjacent to Mpuapua.

These people are extremely hostile to strangers, and his success, therefore, is problematical. —— The Mahdi, or false prophet, who has been menacing Khartum, is reported to have captured the traveller, G. Roth, who was sent out by the Geographical society of St. Gall, Switzerland, to explore the upper Nile. —— Yunker has succeeded in passing from the basin of the Nile to that of the Congo, and continues his explorations, while one of his party has returned with the collections made in the Niam-Niam country. —— Paul Soleillet writes from Ankober of his safe arrival at Shoa, the success of his journey, and his favorable reception by King Menelik II., who governs all the population of Obok Shaffa and adjacent region with a firm rule. Menelik is favorable to trade with foreigners; and it is announced that he has been named by King John of Abyssinia as his successor, in default of direct heirs, to that kingdom. Soleillet has formed valuable collections, and has discovered wild coffee forming a dense undergrowth in the forest along the river Guébé, and indefinitely beyond. He reports the product of the wild plant to be of excellent quality. —— The abbé Trihidez, almoner of the army of occupation in Tunis, is reported to have discovered at Susa some Phoenician stelae engraved in a rather artistic manner, and in a good state of preservation. These records have been pronounced to be of great interest by such eminent specialists as Renan and Berger. —— M. Alphonse Aubry has forwarded to the Ministry of public instruction at Paris, reports on the geology of the English colony of Aden, which is situated in the horseshoe-shaped crater of an extinct volcano, and on the French colony of Obok on the opposite shore of the Gulf of Aden. —— Gold has been found on the Kaap River in the Transvaal. Nuggets of half a pound in weight are reported. —— Oil has been 'struck' in Natal, near Dundee, and also large deposits of magnetic iron. A company has been formed at Pietermaritzberg to investigate these minerals. — W. H. D. [298

BOTANY.

Thermotropism. — Julius Wortmann has recently shown that radiant heat falling upon a growing organ can cause curvatures either toward or away from the source of energy, and that the phenomena are in general much like those produced by light. His experiments are interesting, but are, as yet, incomplete, leaving some questions which seem to us very important wholly unanswered. It is pretty clear, however, that hereafter we must add the words 'positive thermotropism' and 'negative thermotropism' to the already long list of new terms. — (*Bot. zeit.*, 1883, no. 29.) G. L. G. [299

On the growth of the epicotyl of Phaseolus multiflorus. — In a series of experiments published in 1878, Wiesner detected two maxima of growth characterizing the younger internodes of many plants, whereas Sachs (and more lately Wortmann) had recognized only one maximum. To satisfy himself of the correctness of his former observations, Wiesner has repeated and extended the experiments. His results, derived from more than one hundred cases, show that in the plant named there are two distinct maxima of growth. The measurements were made with Grisebach's auxanometer. — (*Bot. zeit.*, 1883, no. 27.) G. L. G. [300

VERTEBRATES.

Reptiles.

Organ of Jacobson in Ophidia. — Born regarded the cellular columns which form the greater part of the thickness of the roof of Jacobson's organ as "*die zellige ausfüllungsmasse einfacher drüsen von birnförmiger configuration. Sie dicht an einander gedrängt die ganze schleimhaut durchsetzen,*" while Leydig believed them to be largely of ganglionic nature. E. Ramsay Wright agrees with Leydig. He has studied the organ in Eutaenia (embryo and adult). In conclusion, he says, "From the above data I conclude that the cellular columns in the roof of Jacobson's organ are outgrowths of the nuclear stratum of its neuro-epithelium, the polygonal form of which has been determined by the meshes of the capillary plexus, through which the outgrowths have taken place, and that in the course of development more and more of the cells of the nuclear stratum have been pushed outside the boundary formed by the capillary plexus, till eventually little but the superficial stratum is left inside that boundary." — (*Zool. anz.*, vi. 389.) C. S. M. [301

Mammals.

The species of hogs. — M. Forsyth Major is convinced, from his study of the genus Sus, that the sixteen or seventeen species now recognized must be reduced to four; namely, Sus vittatus Müll. and Schleg., S. verrucosus M. and S., S. barbatus M. and S., and S. scrofa Linné. — (*Zool. anz.*, vi. (140), 1883, 295.) F. W. T. [302

Digestion of meats and milk. — Jessen has carried out a series of experiments to determine the time necessary for the digestion of equal quantities of different meats and of milk. Three different methods were employed in the investigation: 1. Artificial digestion; 2. Introduction of the meats into the stomach of a living dog by means of a fistula; 3. Upon a healthy man, allowing him to swallow the foods used, and ascertaining the time of digestion by means of the stomach-pump. The results obtained by the different methods are, on the whole, uniform, as far as the relative time necessary for digestion in each case is concerned, and may be stated as follows: raw beef and mutton are digested most quickly; for half-boiled beef and raw veal, a longer time is necessary; thoroughly boiled and half-roasted beef, raw pork, and sour cow's-milk follow next; fresh cow's milk, skimmed milk, and goat's milk are still less easily digested; while the longest time is required for thoroughly roasted meats and boiled milk. — (*Zeitsch. f. biol.*, xix. 129.) W. H. H. [303

ANTHROPOLOGY.

Iron in the mounds. — F. W. Putnam has had occasion to review some of the statements of the older writers on American archeology, — notably, Mr.

Atwater and Dr. Hildreth, — with reference to the occurrence of iron implements in the mounds. From these statements, such inferences as the following have been drawn: —

The mound-builders understood working iron; they had intercourse with civilized peoples; the mounds were built since the arrival of the whites, or these iron objects belong to intrusive burials. Now, Mr. Putnam demolishes all these deductions at a single blow, by showing that none of the objects are iron. In other words, Mr. Atwater's "handle of either a small sword or a large knife" was an antler, in one end of which a hole had been bored, and around this part was a band of silver. The blade was evidently of native, cold-hammered copper. Dr. Hildreth's silver-plated ear-ornament is duplicated in some of our museums by a kind of plating, first described by Mr. Putnam. In this discussion, some light is thrown upon the spool-shaped copper objects that have been so long a puzzle to archeologists, by the finding of pieces of 'leather' between the plates, very closely resembling the skin from the ear of a Peruvian mummy. Important discoveries made during the last year, in mounds in Ohio, by Dr. C. L. Metz and Mr. Putnam, have brought to light a number of copper ornaments, some of which are covered, or plated, with thin layers of silver. The investigation shows us quite conclusively that we are no longer safe in our archeological deductions, except in the hands of a skilful guide. — (*Proc. Amer. antiq. soc.*, ii. 349.) O. T. M. [304

Aztec music. — Mr. H. T. Cresson has been studying the musical instruments of the ancient Mexicans. The *huehuetl*, or large drum of the great temple, at the ancient pueblo of Tenochtitlan, was covered with the skins of serpents, and when beaten could be heard at a distance of several miles. Clay balls were placed inside of their grotesque clay images, also within the handles attached to their earthenware vessels, which are generally hollow. Some of these rattles in the Poinsett collection resemble the head of Crotalus horridus, and give forth a rattling sound. In this connection Mr. Cresson makes a very suggestive observation which we do not remember to have seen before: "It may therefore be supposed that these children of nature noticed and strove to reproduce sounds, which, however harsh and unmusical to us, to them were pleasing, because they recalled familiar objects." The author thinks he can recognize the Mexican Hyladae, macaws, parrots, and other bird-calls. A musical vase is spoken of. Mr. Barber's assertion that the fourth and seventh are wanting from the diatonic scale is denied, since, in the Poinsett collection, there exist Aztec flageolets capable of producing not only the fourth and seventh of the diatonic scale, but also the entire chromatic scale. This subject is elaborated at great length. Mr. Cresson thinks that the musicians of our day have arrived at a somewhat hasty decision in regard to the music of these ancient people, and its confinement within the narrow limits of a pentatonic scale. — (*Proc. acad. nat. sc. Philad.*, 86.) J. W. P. [305

NOTES AND NEWS.

The resolution of the American association, offering all the privileges of membership for next year's meeting to the members of the British association, was received by the latter with much enthusiasm; and the council of the British association, with which such matters lie, will, it is said, extend a similar invitation to the American association. The Canadian authorities have arranged for such members of the British association as may desire, to take the longer excursions planned for them *before* their meeting on Aug. 27, and thus allow them to attend the meeting of the American association in Philadelphia, Sept. 3, without losing their excursions. It is hoped that at least five hundred members of the British association, including many leading scientific men, will attend the Montreal meeting; while there seems to be a very general wish, more especially on the part of the younger scientific men, to attend the Philadelphia meeting as well.

— The following is the list of grants of money, which, according to *Nature*, the British association has granted for scientific purposes for the coming year; amounting, in all, to seven thousand dollars. When may we hope for even the beginning of such a list from the American association, with its two thousand members?

— Lieut. Ray returned to San Francisco, Oct. 7, by the schooner Leo. He left that port on July 18, 1881, under instructions from the signal-service bureau to establish a permanent signal-station at Point Barrow, and to remain there until the summer of 1884, unless otherwise ordered. The order for the party to return created great surprise, as the work was successfully carried on. Lieut. Ray stated, that, apart from the scientific importance of the station, it was a necessity, as a refuge for the crews of whaling-vessels. Every year, in the Arctic Ocean, there are, on an average, forty vessels, worth, with their cargoes, four million dollars, and employing sixteen hundred men. Out of eighty-seven vessels, fifty have been lost within a hundred miles of Point Barrow, in one year alone. In 1877 twelve were lost, with all on board. The crews would not abandon their vessels, knowing there was nothing on the shore. Had the station then existed, it is probable that all their lives would have been saved. Since the station was established, two years ago, over fifty lives have been saved. Lieut. Ray states, that all the party lived comfortably, and enjoyed good health, the climate being particularly beneficial to those suffering from malaria. Besides their regular provisions, the party had seal, walrus, and white whale meat; the last being the best, as it was sweeter and more nutritious. Lieut. Ray expressed regret at his recall.

— Lieut. Schwatka, who, with his party, was picked up by Lieut. Ray at St. Michael's, speaking of his trip up the Yukon River, Alaska, says they started from Fort Vancouver, W.T., on May 21, and travelled twenty-eight hundred miles overland, reaching the head waters of the river, where they constructed a raft of logs to navigate the stream to its mouth. They procured a crew of six Indians, and proceeded down the gradually increasing stream within two hundred and fifty miles of Fort Chilcat, where rapids were encountered. Down these the Indians refused to go, and attempted to force the raft ashore. Schwatka succeeded in suppressing the mutiny, and the rapids were run. The voyage on the raft was eighteen hundred and twenty-nine miles. From the mouth of the Yukon they proceeded to St. Michael's, where they boarded the Leo for this port. Signal-service officer Leavitt, who has been stationed at St. Michael's, and who also came down on the Leo, says he has ascended the Yukon to Fort Selkirk two thousand miles from its mouth. He describes the river as being one of the largest in the world, discharging fifty per cent more water than the Mississippi, and as being in places seven miles in breadth.

— Professor Oswald Heer, of the university and federal polytechnic school of Zurich, the celebrated Swiss paleontologist, died at Lausanne, Canton de Vaud, the 27th of September. Heer has done more for fossil botany and fossil insects than any one else during the last forty years, and his death will leave a place in science which it will be difficult to fill.

SCIENCE.

FRIDAY, OCTOBER 26, 1883.

THE VIVISECTION QUESTION.

The book we take as the basis of our remarks,[1] originally published in England, is one of several recent signs that British physiologists are at last coming to their senses; and, instead of attempting to conceal the fact that they experiment on animals, have decided to explain to the general public what a vivisection is, and why vivisections are necessary. Philanthropos, who is evidently well informed, discusses without passion or prejudice such topics as, 'What is pain?' 'What is cruelty?' 'Our rights over animals,' 'What is vivisection?' 'The relation of experiment to physiology,' 'The relation of medicine to experiment,' and so forth. If our colleagues across the water had, some seven or eight years ago, shown sufficient courage to trust to the common sense of the majority of their countrymen, and had endeavored to inform the laity by securing the publication and distribution of some such book as this, the anti-vivisection legislation could hardly have been enacted. Its passage, and the still-continued agitation for an act of Parliament totally forbidding all experiment on living animals, prove that the public did not and does not know enough about the matter to save itself from being misled by the reckless misstatements of irresponsible fanatics, and of certain seekers after notoriety or salary.

People in general do not read official blue-books: so, in spite of the fact that the royal commission appointed to investigate the matter reported, that, after prolonged and careful inquiry, it could find no evidence that English physiologists were guilty of cruelty, it has been possible for certain anti-vivisectors, by a persistent course of malignant vituperation and brazen mendacity, to produce a wide-spread belief that vivisection essentially consists in torturing an animal for the object of seeing how much it can suffer without dying. That such is the actual conviction of many worthy men and women in England, we know to be the case. The physiologists kept silent, and left the field to their enemies, with disastrous result; no one, not a brute, who believed half the stories circulated, could fail to hate physiology and physiologists. When the railroad-stations of England were placarded with large figures of dissections of dead animals, accompanied by printed words designed to entrap the general public into the belief that they represented vivisections of living creatures; when a text-book of practical physiology, designed only for special students of physiology, was represented far and wide as intended for use by every crude medical student; when the fact that the words 'first give an anaesthetic' were omitted (as they are in text-books of surgery, the administration of an anaesthetic being, of course, assumed in cases where very special reasons for its omission do not exist) in the directions for the performance of certain operations, was used as proof that physiologists never thought of employing means to prevent or minimize pain; when a law was passed which allows any one to torture a frog in the most brutal manner if he says he does it just because he likes it, but subjects a university professor to fine and imprisonment if he draws a drop of blood from the animal's toe for a scientific purpose, — then it had certainly become time for the physicians and physiologists of the British Isles to endeavor to inform the public on the vivisection question.

The anti-vivisection craze has now spread to Germany, and there are premonitory symptoms in the United States. Our people in general are too well informed, and have too great confidence in scientific men, to be so easily led

[1] Physiological cruelty; or, fact *v.* fancy: an inquiry into the vivisection question. By Philanthropos. New York, *John Wiley & Sons*, 1883. 156 p. 8°.

astray as the English have been. We shall, moreover, be free from the pressure of a royal court which dislikes biological science, and from the influence of the personal prejudices of the sovereign, still powerful enough in England to have much weight in legislation on questions outside of Whig and Tory politics. Still, American physiology is by no means secure, unless its leaders take warning by the English disaster. They have, in consequence of British legislation, an opportunity to make the United States the chief seat of physiological research among the English-speaking peoples; and it will be a lasting disgrace to them if they let it slip. If, while freely admitting that they believe it their duty to experiment on living animals, they will be on the alert to correct at once the falsehoods and exaggerations of the fanatics; to take pains to teach the public how much the scientific treatment of disease depends on physiological, therapeutical, and pathological research; and to make it widely known how very small a percentage of vivisections involve more pain than that felt by a man on receiving a hypodermic of morphia, — then there is little doubt they will be allowed to carry on without hindrance their beneficent work. The only danger lies in the ignorance of the great majority of ordinarily well-informed people regarding such subjects. Secrecy, not publicity, is what American physiology has to fear.

A HEARING OF BIRDS' EARS.[1] — II.

Let us next confine attention to the ossicles of the ear. Those familiar with these little bones, only as they occur in man or any other mammal, need to be cautioned that their anatomical arrangement, and to a great extent their physiological characters, are very different in birds and other reptile-like vertebrates. Presuming, of course, upon the reader's thorough knowlege of the human case, we will demonstrate these bones in their proper relations and offices in birds, as elements of the lower jaw and hyoid bones (mandibular and hyoidean arches).

The malleus is the proximal element of the meckelian cartilage (figs. 1, 2, *mk*), a gristly rod about which the lower jaw-bone is developed in membrane. Becoming segmented off from the rest of the meckelian rod, it is in mammals withdrawn into the tympanic cavity, disconnected from the jaw-bone, and connected with the incus, its *processus gracilis* lying in the glaserian fissure. The jaw-bone then articulates directly with the glenoid cavity of the squamosal, forming the temporo-maxillary articulation. In any bird the malleus remains outside the ear, and acquires comparatively enormous dimensions, with the peculiar shape shown in fig. 1, *q* (see also fig. 2, *q*). This

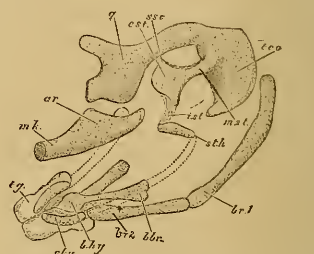

Fig. 2. — The post-oral arches of the house-martin, at middle of period of incubation, lateral view, × 20 diameters. *Mk*, stump of meckelian or mandibular rod, its articular part, *ar*, already shapen; *q*, quadrate bone, or suspensorium of lower jaw, with a free anterior orbital process and long posterior otic process articulating with the ear-capsule, of which *teo*, tympanic wing of occipital, is a part; *mst*, *est*, *sst*, *ist*, *sth*, parts of the suspensorium of the third post-oral arch, not completed to *chy*: *mst*, medio-stapedial, to come away from *teo*, bringing a piece with it, the true stapes, or *columella auris*, the oval base of the stapes fitting into the future *fenestra ovalis*, or oval window, looking into the cochlea, or inner ear; *sst*, supra-stapedial; *est*, extra-stapedial; *ist*, infra-stapedial, which will unite with *sth*, the stylo-hyal; *chy* and *bhy*, cerato-hyal and basi-hyal, distal parts of the same arch; *bbr*, *br*1, *br*2, basi-branchial, epi-branchial, and cerato-branchial pieces of the third arch, composing the rest of the hyoid bone. (After Parker.)

quadrate bone, as it is called in birds, looks something like an anvil, and has often been mistaken for the incus: on the other hand, from its function in supporting the *membrana tympani* in part, it has been malidentified with the tympanic bone (external auditory process). It is very freely articulated at both ends, rocking back and forth with the movements of the jaws. It normally has articulation with five separate bones: 1. By its lower end, which is bituberculur, with the articular piece of the mandible (lower jaw), forming the true temporo-maxillary articulation; 2. By the outer extremity of its lower end with the quadrato-jugal bone (fig. 1, *qj*), which is the posterior element of the zygomatic arch, continued forward by the jugal or malar bone (fig. 1, *j*) to the superior maxillary (fig. 1, *mx*); 3. By the inner extremity of its lower end with the ptery-

[1] Continued from No. 34.

goid bone (fig. 1, *pg*), and so with the palate-bone (fig. 1, *pa*) and superior maxillary (*mx*), 4, 5. The head of the bone normally articulates both with the squamosal (fig. 1, *sq*) and with the pro-otic (fig. 1, *po*, here seen inside the cranial cavity). A long spur of the quadrate, its orbital process, projects freely into the orbital cavity, as shown in fig. 1, where the still cartilaginous tip of the orbital process reaches to the round white hole marked 2 (*optic foramen*). Now, the osseous articulations and muscular tractions are such, that, when the mouth is opened, the malleus rocks forward upon its squamosa-petrosal articulation (4, 5, of above enumeration), and pushes upon the zygomatic and pterygo-palatal bars, causing the upper mandible to rise as the lower jaw is depressed; the upper jaw hinging upon elasticity of, or a joint at, the bones of the forehead. Thus the malleus-quadrate is here seen in its proper relation to the jaw-parts as nothing at all of an *ossiculum auditus*, except in so far as it hinges upon parts of the temporal bone, and helps to support the ear-drum. It has no direct connection whatever with the rest of the ossicles.

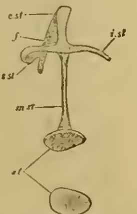

Fig. 3. — Mature stapes of fowl, about × 4. (After Parker.) *st*, its foot, fitting *fenestra ovalis*; *mst*, main shaft, or medio-stapedial element; *sst*, supra-stapedial; *est*, extra-stapedial; *ist*, infra-stapedial, its end representing a rudimentary stylohyal; *f*, a fenestra in the extra-stapedial. (See *st*, *in situ*, fig. 1, and its embryonic formation, fig. 2.)

It will be best to take the stapes next. Fig. 3 shows the mature stapes of the domestic fowl, enlarged about four times, and indicates its several elements which have received special names. It is practically the same bone so named in man, but includes incudial as well as some other elements. In form it is not at all stirrup-like, being trumpet-shaped, with a slender cylindrical shaft, expanded oval foot, and a crossbar and other pieces at the distal end. It is therefore oftener called the *columella auris*, or sounding-post of the ear. In skulls prepared with sufficient care, the stapes may be seen *in situ*, as in fig. 1, *st*, — an extremely delicate rod, stepped into the *fenestra ovalis* by its foot, the other end protruding into the tympanum, and bearing the additional hammer-like or claw-like elements. A stapes I have just picked out of an eagle's ear is a fourth of an inch long, with a stem as fine as a thread of sewing-silk, but a stout foot, and, at the tympanic extremity, a still finer hair-like process half as long as the main stem, from which it stands out at right angles: while there appears to have been another similar claw, which has broken off from such a cross-like object as *st* in fig. 1.

Embryological study is required to demonstrate the stapes as the proximal element of the hyoidean apparatus, quite as the malleus is of the mandibular arch. Reference to fig. 2 should make this clear. Here the malleus, *q*, extends from *teo*, the tympanic wing of the exoccipital, to *ar*, the articular element of *mk*, the meckelian rod whence *q* has been segmented off, leaving the 'temporo-maxillary articulation' between *q* and *ar*. This chain of bones, including others to be developed about and beyond the stump of *mk*, is the lower jaw, or mandibular arch. Now, quite a similar arrangement is shown in the chain of bones in the tongue or hyoidean arch. From *teo* stands off a rod of bone, *m st*, the medio-stapedial element, or main shaft of the stapes, to be segmented away from *teo*, the place of this segmentation to become the fenestra ovalis. The medio-stapedial rod expands at its end; the upper part of the expansion, never separating from the rest, is the supra-stapedial element = mammalian incus, *s st* in figs. 2, 3. An infra-stapedial element, just forming in fig. 2, *ist*, completed in fig. 3, *ist*, connects with the piece marked *st h* in fig. 2. This *st h* is the stylohyal = human 'styloid process of the temporal,' which connects in man by the 'stylo-hyoid ligament,' with the 'lesser cornu of the hyoid bone,' which is the cerato-hyal, *c hy*. In birds, the distal parts of the hyoid arch (composed of the numerous pieces lettered in fig. 2, but which need not longer detain us) become entirely separated from the proximal, the tongue-bones being quite otherwise affixed to the skull; while the proximal parts of the same arch are shut up in the tympanic cavity, where they extend from the *membrana tympani* to the *fenestra ovalis*, constitute all there is of *ossicula auditus*, and consist of the stapes itself (including the several elements specified).

So, therefore, avian malleus or quadrate-bone = human malleus as proximal element of mandibular arch, retaining articular connection with its own arch, but not acquiring character or connections of a human *ossiculum auditus*.

So, therefore, avian stapes or columella = human stapes + incus, as proximal elements of hyoidean arch, not retaining connection with its own arch, but acquiring characters and connections of *ossicula auditus*.

These are the reasons why a bird's lower jaw does not articulate directly with the squamosal, why the hyoid bones do not articulate at all with the skull, why the malleus is outside the ear, and why there is apparently but one ossicle in the tympanum, of the particular shape shown in fig. 3.

(*To be continued.*)

THE PSYCHOLOGICAL MECHANISM OF DIRECTION.

Were it admissible that one person should add to the work of a living author, I might call this paper a supplement to Mr. Francis Galton's Human faculty. My object is to explain the subjective mechanism by which I preserve the consciousness of direction. How far others adopt the same mechanism, I am not fully aware, but am inclined to think that what is fundamentally the same system is employed by nearly every one; but I doubt whether the details are always the same, and the matter appears of sufficient interest to be discussed.

To be conscious which way he is going, one must keep in mind some system of directions. It is true, that, so far as finding one's way about in a place with which he is fully acquainted is concerned, no attention to direction is necessary. One knows that he must turn here to the right, and there to the left, and must follow certain familiar paths, all of which he can do without attending to direction. It is probable that most animals, and possible that some men, have no system except this. Regarding such a limitation as exceptional, we must suppose that in general, men, in going about, have constantly in mind an idea that they are going in a certain definable direction. A direction can, however, be defined only by reference to the direction of some line taken as a standard of reference; and it is this standard of reference, as I have always employed it, which I shall now describe.

I. I continually carry around with me a conception of four horizontal lines, which I shall call co-ordinates, going out in four cardinal directions. I shall call these directions east, west, north, and south; but it must be understood that they have no necessary relation to the actual points of the compass, being purely subjective. This system of co-ordinates is employed, I think, by most or all men.

II. These four cardinal directions are conceived of as *absolute* directions, and not as defined relatively to any particular line on the earth's surface. They have remained unchanged since the earliest memories of childhood. To be more explicit, the ideal or subjective west is the direction in which I was facing, when, as a child, my father explained to me which was the right hand, and which the left; the ideal north is the direction towards which my right side was then turned; the ideal south, that towards which the left side was turned: while east was behind my back.

I have always since imagined myself as conscious of these four absolute directions, and therefore at any moment can face as I imagine myself to have been facing on the occasion referred to. I do not know whether the co-ordinates have the same absolute character with other men, but think it highly probable that they do, since absolute directions must be more easily thought of than relative ones.

III. With some limitations, to be soon referred to, the system of directions is quite independent of the will. Once fixed in a place, a street, or a house, they are an inseparable component of the situation, and forever unalterable so long as the identity of the place is recognized. Once in a room of which I conceive a certain side to be the absolute west, by no act of the will, and by no consciousness that some other side is the west, can I change the subjective impression. Of course, however, one is liable on going into a strange place, or on walking about without sufficient attention, to be mistaken as to his direction; and thus I am subject to a kind of trouble or confusion which I never heard any one else describe, and which, therefore, I can hardly suppose to be universal. Some instances will illustrate the matter better than general statements.

I recently went to a hotel in Paris, where I had stopped eight years before. While driving into the court, and just as the carriage was stopping, my attention was momentarily occupied in speaking to one of the attendants. Getting out of the carriage, I remarked, as I supposed, that the offices of the hotel had all been moved from the north to the west side of the court. I may anticipate by saying that this was an illusion arising from the very minute circumstance that the carriage, during the moment that I was speaking to the attendant, had turned at a right angle from facing north to facing east; but being unconscious of this change, and not looking around the court, I supposed that the carriage was still directed towards the ideal north. I entered the elevator, was carried to an upper story, shown through several long passages, and into a room, preserving the changed system of co-ordinates of which I was entirely unconscious. Had it been my first visit to the hotel, no confusion would have resulted, since every thing around it would have been referred to this same system; but I entertained a distinct idea of the orientation of the rooms around the court as they existed in my mind during my former visit. The result was, that when I went down to dinner I found my co-ordinates 90° wrong. But I was absolutely powerless to refer the two parts of the hotel to the same system. During the week that I remained, whenever I went from my room down-stairs, to the court, the reading-room, or the dining-room, there was a momentary confusion on reaching the point where I saw that the system was wrong. Momentary glances around, and the co-ordinates changed 90°. On returning to my room, the co-ordinates below were carried up-stairs with me, because there was nothing on the stairway with which I had become sufficiently familiar to fix either set of co-ordinates; and thus one system obliterated the other, as it were. In consequence, I could carry one set all the way down, and another set all the way up; the change occurring at the bottom of the stairway in one case, and at the top in the other. The result was, that during my stay I got no clear idea where my room was situated, or what buildings I saw through the window.

To mention another instance: I lived for a number of years in a house in which I must have made a similar mistake the first time I entered it; since, during my whole stay, the orientation inside the building was 90° different from that outside. In the case of such an inconsistency as this, I find that the orientation corresponds to that of the place to which the attention is directed. So long as I was inside a room, or so long as my attention was directed to things inside the house, there was one orientation. On raising the window, and taking a good view of the street, I would perceive that this orientation was 90° in error; and after a momentary confusion the street would assume its right direction. The reverse change would recur on turning back to the room.

I find this occasional inconsistency of orientation, to which I am very liable when I pay no attention to directions on first entering a house, to be really troublesome. It has twice happened quite recently, that, on going upstairs in a hotel on my first arrival, I got the co-ordinates reversed 180°. The result was, that unless I staid long enough to go right by mere habit, without thinking about the direction, I was continually in doubt about which way I should go to find the room I wanted.

IV. I find that this fixity of co-ordinates holds in any kind of a building, and in a ship, but not at all in a carriage, and not absolutely in a railway-car. If I am conscious, by looking at surrounding objects, that a railway-car turns 90°, I can change its relation to the system of co-ordinates accordingly. It appears, therefore, that it is only in fixed structures that the co-ordinates inure in my conceptions of enclosed space; yet I feel perfectly sure, that, if a house in which I lived be turned through 90° or 180°, the system would turn with it, in spite of any thing I could think to the contrary.

V. I now come to the modifications of fixity to which I have already referred. The imaginary sense of direction is not absolutely always present. In travelling over a new road to a new place, the sense of direction is, for the time being, apt to be lost. In this case, and in this alone, it is to a certain extent under control of the will; but, if the will fails to act promptly on arriving at a place, the co-ordinates fix themselves, as it were, and that quite arbitrarily, so far as I have been able to perceive. Once fixed, they stay. But, while under control of the will, I am in the habit of so directing them that the ideal directions shall correspond to the points of the compass, in case I know them.

VI. I have recently noticed that it is not necessary that I should actually have seen a place, in order that the co-ordinates should be fixed in it. If I study on a map a place which I am to visit, I unconsciously fix the co-ordinates to correspond to the points of the compass. Thus, on arrival, I readily find my way about. But it may happen, that, when I arrive, I am mistaken as to the direction in which the railway-station stands. Then, take what pains I will, the same confusion arises when I arrive at a street or hotel which I have studied on the map, and find the co-ordinates to be wrong. The directions change to those in which I have thought of the house or street.

Of this fixing of the co-ordinates in advance, I recently had a curious example. I got on board a steamship at Liverpool, resolving that the ideal and real west on board ship should correspond. I went down to seek out my state-room, and, on returning to the deck, I was chagrined to find that the co-ordinates had got changed 180°. In consequence, I had to think before knowing which side of the ship I looked at. For some time I was puzzled to imagine how the mistake could have occurred. I finally traced it to the fact, that, on studying the position of my state-room on the plan of the ship a month before, I had held up the plan with the stern in the direction in which west is on the map. I constructed the orientation of the passageway and of the stateroom accordingly. It happened, that, when I joined the ship, her stern was towards the east; but, on descending into the cabin for the first time, I fixed the orientation to correspond to the one previously formed from the plan, forgetting at the moment that I was thus making a change of 180°.

VII. A universal law of the four cardinal directions is, that they always arrange themselves along visible lines, such as roads, boundaries of a room, etc.: in other words, the directions never subdivide themselves. In going along a new road which I know ought to bisect the angle between two directions, I can, by an effort of the will, imagine it to do so; but, the moment attention is relaxed, one cardinal direction is sure to take possession of the road, and of course, once in possession, keeps it: so, no matter how well I may know that the walls of a room are at an angle of 90° with the other walls of a building, the directions are sure to arrange themselves parallel to the walls.

It may be asked, How does this system work, in case of a number of rooms radiating like a fan from a central space? I answer, that in such a case my ideas of direction simply get unutterably confused, and only by long habit can I get the relations of the different rooms to each other. SIMON NEWCOMB.

THE ARAGO LABORATORY AT BANYULS.

AMONG the zoölogical stations or laboratories along the coast of France, none is more widely known or more firmly established than the laboratory at Roscoff,[1] in Finisterre, organized in 1872 by Professor Lacaze-Duthiers as an adjunct of his zoölogical laboratory of the Sorbonne at Paris. Encouraged by the success of his laboratory at Roscoff, which during August, 1881, had twenty-five workers, but which, owing to its exposed position at the north-west extremity of France, was only available for work from March until October, at the most, Professor Lacaze-Duthiers sought to establish a winter laboratory on the Mediterranean, to furnish seaside work the remaining months of the year. After careful examination of the French coast of the Mediterranean, a location was chosen for the laboratory at the base of the rocky promontory of Fontaulé, at the entrance of the little harbor of Banyuls-sur-mer, within a few miles of the Spanish frontier in the department of Pyrénées-Orientales.

The municipal council of Banyuls, through the mayor, M. Pascal, who took much interest in the establishment of the laboratory, offered a site for building, twelve hundred francs for immediate use, and an income of five hundred francs annually for twenty years; M. Thomas, a wealthy gentleman of Banyuls, offered two hundred and fifty francs annually for ten years, and a boat; the council of the department of Pyrénées-Orientales voted twenty thousand francs toward the construction of the laboratory; and subscriptions were received from the citizens of this rich wine-producing neighborhood. These were some of the means employed to induce Professor Lacaze-Duthiers to locate at Banyuls. Port Vendrès, a neighboring village, offered inducements to locate there; but the great number of fishermen in Banyuls, its nearness to the open Mediterranean, and its freedom from the distractions due to commercial and other activities, together with the earnest interest taken by its inhabitants in the laboratory, won the choice of that village. What a novel sight it would be, here in America, to see villages contesting for the honor of possessing a scientific laboratory! The Academy of sciences at Paris took the laboratory under its protection; and the establishment was called 'Laboratoire Arago,' to honor the name of the most distinguished *savant* of the Pyrénées-Orientales, a former member of the academy.

It is, of course, impossible to speak of much work already accomplished at the Arago laboratory, as one might describe studies completed at Roscoff; for the laboratory at Banyuls was scarcely finished in the winter of 1881–82, when, with another American and a French student, I had the pleasure of being one of the first to work within its walls: so I will write only of the region and of the laboratory.

The eastern end of the Pyrenees descends suddenly upon a north and south coast by a series of radiating ridges, between which are small indentations of the sea, forming harbors, with rocky promontories at each side of their entrances, and a sandy beach within. This kind of coast offers numerous advantages to those searching for marine animals. On each of the larger of the beaches are villages, most of which date back to Roman times. These villages were recently connected by a railroad which follows the coast, passing through tunnels between them.

Banyuls is situated upon one of these beaches, at the head of a small harbor, which is partly

[1] For a detailed account of the laboratory at Roscoff, with maps and plans, see *Revue scientifique*, Nov. 26, 1881, xxviii. 673–680.

protected from the open sea by a breakwater (seen in the middle of the first picture at the left of the laboratory), which extends from the promontory, at the base of which the laboratory is built, to a rocky island in the middle the entrance to the harbor. The village of Banyuls itself (seen in the other illustration, looking from the laboratory into the harbor) has about four thousand inhabitants. Behind the village the hills are clothed with vineyards, olive-groves, and cork-oak trees, nearly to their tops. To crown the view is the middle-age tower of Madeloth, or *Tour du Diable*, on a mountain six hundred and sixty-eight metres high. The village has two hotels, which are crowded with bathers during midsummer. In winter there are few amusements, and the hotels are then nearly empty. For a good concise description and history of this region, in which the Catalan dialect still prevails to a considerable extent, and the history of which is extremely interesting, I refer to Pierre Vidal's *Guide historique et pittoresque dans le département des Pyrénées-Orientales*, Perpignan, 1879. M. Vidal is the assistant librarian of the town of Perpignan, capital of the department.

The climate of Banyuls is sufficiently moderate to make a winter's stay very agreeable. Oranges, figs, cactuses, almonds, and even the date-palm with poorly developed fruit, are cultivated in the valleys. In the latter part of February, 1882, I waded along the beaches in search of mollusks, without finding the cold inconvenient. Snow rarely falls. The climate can be shown best by quoting a table for 1882, from Martinet,[1] as follows (*degrees in Centigrade*) : —

Month.	Temperature.					Number of days of	
	Extremes.		Means.				
	Minimum.	Maximum.	Minimum.	Maximum.	Total.	Rain.	Wind.
January	2.0	15.0	5.0	11.7	8.4	3	1
February . . .	1.5	19.5	6.4	13.1	9.7	3	7
March	4.0	23.0	9.3	16 9	13.1	5	9
April	7.5	26.0	10.6	18.6	14.6	8	7
May	10.0	27.5	14.7	22.7	18.7	3	3
June	13.5	34.5	17.6	26.5	22.1	4	9
July	16.0	38.5	19.3	28 3	23.8	3	11
August	13.0	35.0	19.9	28.1	24.0	7	6
September . . .	10.5	28 0	12.9	20.4	17.1	13	2
October	9.5	27.0	13 3	19.8	16.5	6	8
November . . .	5.0	19.0	8.7	15.5	12.1	4	8
December . . .	1.0	16.0	6.7	11.6	9.2	8	3
Means of the year,	–	–	12.1	19.4	15.8	67	74

[1] L. Martinet, Banyuls sur mer (*Rev. géogr. internat.*, April, 1883, 8e ann., 67).

The lowest temperature of which I find data was − 6° C., in January, 1871. The cold winds which sometimes descend from the mountains, blowing with considerable severity for one or two days at a time, are the only unpleasant climatological feature of the region.

I have been unable to find sufficient data in regard to the temperature of the sea-water at Banyuls. Martinet writes (*l. c.*, May, 1883, p. 85), "From the month of May the temperature of the sea is 18° ; that of the air, in the shade, from 30° to 35°. In July and August the temperature of the water reaches 24° to 26° ; then in September and October it descends from 22° to 18°."

The marine fauna at Banyuls is very rich. Several species of corals and of actinias, and numerous species of interesting mollusca, such as Chiton and Haliotus, can be taken on the rocks within a few metres of the laboratory. Besides these, the janitor in charge regularly transplants new species to the vicinity of the laboratory. Siphonophores, ctenophores, and tunicates swarm in the waters. It would be useless to mention here the numerous forms which are found on every side without the aid of the dredge ; and, when the dredge is used, the result is almost incredible. Add to this the habit already acquired by the fishermen of bringing to the laboratory all curious animals which they find in their nets, and we have a place where unsurpassed opportunities are offered for obtaining material in quantity for study, an opportunity of which I availed myself, in order to study the parasites of fishes and crustaceans. The fishing at Banyuls, excepting that for sardines and anchovies, is carried on by the use of a large funnel-shaped net, held open, and drawn through the water by two boats, which stand a distance apart. Numerous sharks and cephalopods, — both eaten by the people at Banyuls, — and sometimes sunfishes (Orthagoriscus) and other large fishes, are taken in these nets, besides smaller fishes by thousands.

About fifty fishing-boats, like those seen in the second illustration, leave Banyuls early every pleasant morning, returning about five o'clock in the afternoon, when the fish are spread out for sale along the beach. This mode of sale is a convenience for the naturalists as well as for the townspeople : on the contrary, in fishing-places near large cities, the fish are hurried aboard the trains, leaving no opportunity for their examination. The fresh entrails of fishes can be examined by thousands on the beach at Banyuls, for parasites or for anatomical purposes.

The terrestrial and aerial fauna offers abundance of water-birds, lizards, geckoes and insects, scolopendra and scorpions.

The Arago laboratory is a brick and stone building, about forty metres long and ten metres wide, facing nearly northward. The illustration is a view of the laboratory looking nearly southward from the village. The ground-floor of the laboratory is devoted to a small room for the janitor, another for apparatus, and to a large room for aquaria. In the centre of the last room is a large oval aquarium, and about the room are smaller aquaria to be devoted to special purposes. The water from these aquaria passes out of the front of the building, and supplies other aquaria in the open air. It is, however, upon the first floor that the arrangements made by Professor Lacaze-Duthiers attain the maximum of convenience. A hall runs lengthwise through the middle of the laboratory; and from this hall open out at each side the separate rooms, consisting of a store-room for glassware, a lecture-room, a library, a room for the director, and nine rooms for work. Instead of having a table, as is the usual mode in laboratories, each worker has a room (four metres square) to himself, wherein he can carry on researches undisturbed by his neighbors. As the laboratory is intended for advanced students pursuing original investigations, this provision is of special importance. Sitting on a revolving-chair in the middle of his room, the worker has upon his right a table for drawing; in front, toward the large window, — which, with the climate of Banyuls, can be open much of the time, — is a table for his microscope and apparatus; at his left, a table for specimens. Turning to his right, the investigator can write his notes and draw, free from the danger of water from his larger specimens. This arrangement of tables in three sides of a square, with a revolving-chair at the centre, is an idea original, as far as zoölogical laboratories are concerned, with Professor Lacaze-Duthiers; and, after having used for a time tables thus arranged, one never is exactly at ease when they are placed otherwise. As if these were too meagre furnishings for each room, another table, a bookcase with drawers, and shelves, are added. A flowing supply of salt water will be, or probably is already, available for small aquaria in each of these work-rooms. Three of the rooms have chimneys, and are more especially desirable for physiological researches. The second floor is not yet used, but probably will be ultimately partitioned into sleeping-rooms for those who work in the laboratory.[1]

ARAGO LABORATORY, SEEN FROM BANYULS.

The laboratory possesses already, besides two rowboats for collecting along the indentations of the coast, a new boat of the same general construction as are the fishing-boats of

[1] For a detailed description and plans of the Arago laboratory, see the *Revue scientifique*, Dec. 3, 1881, xxviii. 705–715.

the region, with a lateen-sail, but considerably larger for long voyages. This boat is commanded by an experienced fisherman of Banyuls, who is conversant with the whole neighboring coast.

The almost entire absence of rise and fall of the water at Banyuls at first puzzles a collector of marine animals accustomed to searching the rocks bared by the receding tide: but one soon finds other and equally productive modes of shore-collecting; while the very absence of great variation in the level of the water enables one to moor boxes of embryos along the inside of the breakwater, and watch their development at leisure.

The expenses of living in Banyuls are about what they would be in a village of the same size on the New-England coast; but the laboratory, like that at Roscoff, is free, requiring for its use only the permission of Professor Lacaze-Duthiers. Reagents, microscopes, mounted dissecting-lenses, glassware, and all other necessary apparatus, are furnished free, the only cost being a small fee paid to the janitor for the care of rooms. While, in all probability, preference would be rightly given to Frenchmen, in case there were more applicants for places than there were rooms, yet foreign investigators will undoubtedly play an important part in the laboratory at Banyuls, as they have already done in that at Roscoff, and will return to their native countries vividly impressed with the liberality and devotion to science shown by Professor Lacaze-Duthiers.

GEO. DIMMOCK.

BANYULS AS SEEN FROM THE LABORATORY.

AUGUST REPORTS OF STATE WEATHER-SERVICES.

THE states in which organized weather-services exist have issued reports for August which give in some detail the results of the observations. The special feature of the month in the majority of states seems to have been the lack of rain, and the consequent drought.

Georgia. — The temperatures ranged from 47° to 98°: the mean was 79°.3. The rainfall ranged from 1.01 inches in the south-west to 9.15 inches in the south-east. The general drought of the summer was unbroken. The cotton and corn crops do not average 75 % of the usual yield.

Indiana. — Thunder and lightning were unusually prevalent, but the rainfall was at least one inch less than the average. The temperatures were lower than usual, and light frosts were reported on the 24th and 25th. The pressure was nearly normal, with a small range.

Iowa. — "The month was cold, clear, dry, with north-westerly and south-easterly winds equally frequent, and calms numerous." The low mean temperature, 2°.5 below the normal, is mainly due to the first decade; but in this period the sunshine was especially intense. The number of fine days, and the dry, sunny weather, have been favorable to the crops. Frosts were recorded on the 22d, 23d, and 24th. There was a very severe hail-storm on the 7th, extending from Sac to Cass counties.

Missouri. — The mean temperature was below the normal, at St. Louis 2°.3 lower. The rainfall was less than the average, the amount at the central station in St. Louis being not much more than half the usual quantity. The heaviest rainfall was on the southern border of the state. In consequence of the continued drought, the crops have suffered much. A few wind and hail storms were reported.

Nebraska. — There are thirty-one observers, from whose reports it is found that the temperature and rainfall were about normal. The average mean temperature was 75°.4; average rainfall, 3.43 inches. The highest of the maximum temperatures was 93°; the lowest of the minimum, 47°. A violent hailstorm occurred on the 8th, at Lincoln; and a wind of forty four miles per hour, from the east, was noted at North Platte.

Ohio. — The barometric pressure was unusually steady, the small range of 0.542 inches being noted. The mean temperature, 68°.2, is more than four degrees below the average. A minimum of 39° was noted. Rain fell on seven days only. The average rainfall was only 1.88 inches, the usual amount being 3.47 inches. At Lebanon 4.60 inches fell, and at Granville 0.70 inch. A violent storm of wind and hail visited Wooster and vicinity on the 28th.

Tennessee. — The reports are from thirty-five stations. The highest of the maximum temperatures noted was 94°, and the lowest of the minimum 43°. The ranges of temperature were generally uniform throughout the state; but the precipitation, which ranged from 1.03 to 6.38 inches, was quite unevenly distributed. The weather presented no remarkable features. There was a marked absence of high winds or severe electrical disturbances. The crop reports are excellent, but the average condition is a little below that of last year.

THE GEOGRAPHIC CONTROL OF MARINE SEDIMENTS.

M. A. Rutot, conservator in the Royal museum of natural history of Belgium, who, in connection with M. E. Van den Broeck, has been studying the tertiary strata of his country, has lately taken up (*Bull. mus. roy. hist. nat. Belg.*, ii. 1883, 41) the fruitful subject of the immediate dependence of fragmental marine deposits on geographic conditions, such as distance and form of shore-line, depth of water, currents, etc., and the consequent changes in these deposits following changes in the controlling geographic surroundings. The matter is properly treated deductively, and so far as concerns vertical oscillations of the earth's crust, which determine advance and retreat of the shore-line, it is examined with much detail. The conclusion is reached, that the frequent changes from gravels, through sands to clays, and back again to gravels, that characterize the Belgian tertiaries, can be fully explained by simple, assignable, and slow geographic causes. We have only to regret, that, in the forty pages devoted to the subject, more room was not found for mention of what others have done in the same direction. The method of investigation may be outlined as follows: —

There is first given the familiar illustration of the varied deposits forming off shore at any single time, showing that the texture, and, in part, the composition of the deposits, are functions of the distance from the shore-line, as in fig. 1. Now, let a general depression slowly take place, by which the sea will advance over the land: the whole set of deposits shifts with the shore, until sands, and at last clays, are laid down over the first gravels, as in fig. 2. Then, if elevation replace the depression, the set of strata shifts seaward, and the sands, and at last the shore-gravels, lie above the clays, as in fig. 3. It is generally noted that the upper gravels are finer than the lower, as the later deposits are made, in part, by working over the older during the time of emergence.

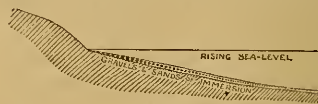

Fig. 1.

The complete set of deposits formed during such a double oscillation of sea-level is to be considered in two ways, — first, with regard to the vertical sequence of the strata; second, with regard to their horizontal equivalence. The vertical sequence is seen in fig. 4: it is made up of the gravels and sands of immersion, the central layer of clay, and the sands and gravels

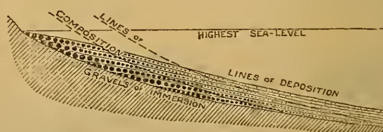

Fig. 2.

of emersion, each stratum having its appropriate fossils. Such 'circles of deposition,' enlarged by the addition of a limestone at the time of greatest distance of the old shore-line, occur several times in our Appalachian sections; and the recognition of their meaning, especially in Professor Newberry's luminous writings, has thrown much light on the evolution of our country. M. Rutot gives the accompanying figure (5) to illustrate the succession of unequal or incomplete oscillations: it shows, I., a large and complete

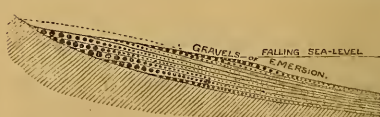

Fig. 3.

oscillation, partly eroded before II., a second depression, from which the elevation was incomplete; III., a great depression and complete elevation; IV., a moderate depression and elevation. This complicated succession represents perfectly the type of the Belgian tertiaries; and the deductions from its physical features are fully confirmed by the evidence from its fossils.

The second consideration, involving the horizontal equivalence of the different strata, is perhaps the most suggestive part of the paper. It is of much importance, and is seldom sufficiently treated. It involves the further examination of the dependence of a set of phenomena on their distance from some controlling condition, which can be called the directrix, and which may change its position. This is worthy of illustration. We find a simple case, in which the directrix is motionless, in the escape of

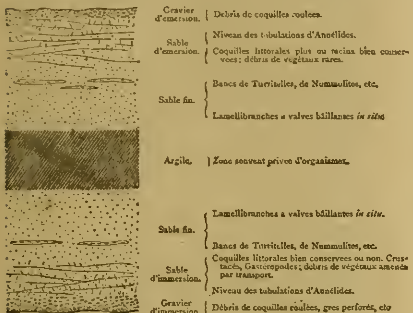

Fig. 4.

gases during a volcanic eruption. The eruptive vent is the directrix, and the various gases are successively given off from the lava when its temperature falls to that below which they cannot be occluded, the temperature depending largely on the distance of flow from the crater. An example in which the directrix moves continually in one direction is seen in the dependence of terrestrial day and night, with all their attendant changes, from warmth to cold, activity to rest, on the position of the sun. One in which the directrix moved for a time in one direction is seen in the relation of our drift-deposits to the

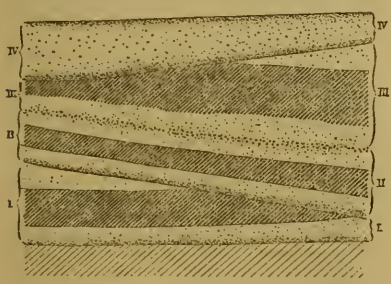

Fig. 5.

'retreating' margin of the continental ice. Far to the northward of the margin, where the ice was thickest and moved fastest, erosion was most active; at a less distance, the ground-moraine was accumulated at favorable points; at the margin, the Kame gravels were deposited; and farther south, the brick-clays settled where they found quiet water: hence all these may be chronologically equivalent in passing from south to north, although at a given point we should find a vertical sequence from scratched rock, through ground-moraine and Kame gravels to brick-clay. An effect of irregular motion of the directrix will be seen in the shifting of all those physical and chemical actions going on within the earth, and dependent for their proper temperatures and pressures on their depth below the surface; for this depth, or the distance from their directrix, is continually, though very slowly and irregularly, changing, — decreasing, while the superincumbent mass culminates in a land-surface that is losing ground by erosion; increasing, while it is receiving new material below the sea. A regular oscillation of the directrix is presented in the swinging of the sun north and south of the equator, carrying the seasons, the wind-systems, and the length of the day, in its train. Finally, the case in point shows us an irregular shifting of the shore-line directrix as the land slowly rises and falls. As a first result of the dependence of deposits on their distance from the shore-line, we shall find that those formations which are at any given moment contemporaneous, or horizontally equivalent, are the very ones already seen at any given point in vertical sequence. Secondly, when we view a broad set of deposits accumulated during a shifting of the shore-line, it will be seen, that while the band of conglomerate or sandstone is continuous for considerable distances, and apparently of contemporaneous formation throughout, it is not so in reality; for the lines of composition are not lines of deposition, and one part of the conglomerate is distinctly of later date than another, and really contemporaneous with the clay overlying the latter. This is illustrated in fig. 2, and shows the complete abandonment of the old ideas concerning universal formations. Instead of supposing that contemporaneous deposits are of uniform composition throughout, we must now admit that they necessarily vary.

M. Rutot's paper was prepared especially for the explanation of Belgian geology. Before it could serve as a guide to the meaning of our broad paleozoic strata, there should be added a consideration of the geographic conditions of limestone-making, and of the former greater strength of transporting agencies required by our old conglomerates. It would have been well to consider Phillips's suggestion concerning continuous subsidence at irregular rates, in which the shallowing is produced by deposition instead of by elevation; for, although this is quite inadequate to explain the changes in the heavy Appalachian sediments, where shallow-water sandstones sometimes quickly follow deep-water limestones or shales, it may serve in certain cases of smaller measure, which M. Rutot has interpreted as the effects of oscillations. On the other hand, the occurrence of elevation after and in spite of deposition might be emphasized to show the rather one-sided aspect of the conclusions lately discussed by the English geologists, who too often consider erosion and deposition as almost the chief causes of change of level.

THE DEVONSHIRE CAVERNS, AND THEIR CONTENTS.[1]

Anthropology, on one of its numerous sides, marches with geology; and hence it is, no doubt, that I, for many years a laborer very near this somewhat ill-defined border, have been invited to assist my friends and neighbors in the work which lies before them during the association week. I have the more cheerfully accepted the invitation, from a vivid recollection, that, when on a few occasions I have come uninvited into this department, my reception has been so very cordial as to lead me to ask myself whether the reports which for many years (1864 to 1880) I laid annually before my geological brethren did not derive their chief interest from their anthropological bearings and teachings.

In 1858, a quarter of a century ago, I had the pleasure of reading to the geological section of the association the first public communication on the exploration, then in progress, of Brixham Cavern (more correctly, Brixham Windmill-hill Cavern); and as any interest connected with that paper lay entirely in the evidence it contained of the inosculation and contemporaneity of human industrial relics of a rude character, with remains of certain extinct mammals, I purpose on this occasion to lay before the department a few thoughts, retrospective and prospective, which may be said to radiate from that exploration, confining myself mainly to South Devon.

Probably nothing will better show the apparent apathy and scepticism with which, up to 1858, all geological evidence of the antiquity of man was received by British geologists generally, than the following statement of facts: —

About the beginning of the second quarter of the present century, the late Rev. J. MacEnery made Kent's Cavern, or Kent's Hole, near Torquay, famous by his researches and discoveries there. He not only found flint implements beneath a thick continuous sheet of stalagmite, but, after a most careful and painstaking investigation in the presence of witnesses, arrived at the conclusion that the flints "were deposited in their deep position before the creation of the stalagmite" (*Trans. Devon. assoc.*, iii. 330); and when it was suggested by the Rev. Dr. Buckland, to whom he at once and without reservation communicated all his discoveries, that "the ancient Britons had scooped out ovens in the stalagmite, and that through them the knives got admission to the 'diluvium,'" he replied, "I am bold to say that in no instance have I discovered evidence of breaches or ovens in the floor, but one continuous plate of stalagmite diffused uniformly over the loam" (*Ibid.*, p. 334). He added, "It is painful to dissent from so high an authority, and more particularly so from my concurrence generally in his views of the phenomena of these caves, which three years' personal observation has in almost every instance enabled me to verify" (*Ibid.*, p. 338).

It is perhaps not surprising that Dr. Buckland, one of the leading geologists of his day, should be too tenacious of his opinion, and feel too secure in his position to yield to the statements and arguments of his comparatively young friend, MacEnery, then scarcely known to the scientific world.

That the position taken by Buckland retarded the progress of truth, and was calculated to check the ardor of research, is apparently certain, and much to be regretted. But it should be remembered, that, at least as early as 1819, he taught that "the two great points . . . of the low antiquity of the human race, and the universality of a recent deluge, are most satisfactorily confirmed by every thing that has yet been brought to light by geological investigations" (Vindiciae geologicae, p. 24); that early in 1822 he reiterated and emphasized these opinions in his famous Kirkdale paper (*Phil. trans.* for 1822, pp. 171–236), which the Royal society 'crowned with the Copley medal' (*Quart. journ. geol. soc.*, vol. xiii. p. xxxiii.); that in 1823, having amplified and revised this paper, he published it as an independent quarto volume under the attractive title of 'Reliquiae diluvianae,' of which he issued a second edition in 1824; and that though his acquaintance with Kent's Cavern was much less intimate than that of MacEnery, he nevertheless was, of the two, the earlier worker there, and, in fact, had discovered a flint implement in it before MacEnery had ever seen that or any other cavern, — the first tool of the kind found in any cavern, it is believed, and which in all probability was met with under circumstances not in conflict with his published opinion on the low antiquity of man. I confess that under such circumstances, human nature being what it is, the line followed by Dr. Buckland seems to me to have been that which most men would have pursued.

It was, at any rate, the line to which he adhered as late, at least, as 1837; for in his well-known 'Bridgewater treatise,' published that year, after describing his visit to the caverns near Liége, famous through the discoveries of Dr. Schmerling, he said, "The human bones found in these caverns are in a state of less decay than those of the extinct species of beasts: they are accompanied by rude flint knives, and other instruments of flint and bone, and are probably derived from uncivilized tribes that inhabited the caves. Some of the human bones may also be the remains of individuals, who, in more recent times, have been buried in such convenient repositories. M. Schmerling . . . expresses his opinion that these human bones are coeval with those of the quadrupeds of extinct species, found with them, — an opinion from which the author, after a careful examination of M. Schmerling's collection, entirely dissents" (*Op. cit.*, i. 602).

It may be doubted, however, whether his faith in these his early convictions remained unshaken to the end. I have frequently been told by one of his contemporary professors at Oxford, who knew him intimately, that Buckland shrank from the task of preparing for the press new editions of his 'Reliquiae diluvianae' and his 'Bridgewater treatise.' 'The work,' he said, 'would be, not editing, but re-writing.'

[1] Address by William Pengelly, F.R.S., F.G.S., vice-president of the section of anthropology of the British association for the advancement of science. From *Nature*.

Mr. MacEnery intended to publish his 'Cavern researches' in one volume quarto, illustrated with thirty plates. In what appears to have been his second prospectus, unfortunately not dated, he said, "The limited circulation of works of this nature being by no means equal to the expenses attendant on the execution of so large a series [of plates], the author is obliged to depart from his original plan, and to solicit the support of those who may feel an interest in the result of his researches."

There is reason to believe that at least twenty-one of the plates were ready, and that the rough copy of much of his manuscript was written, but that, the support he solicited not being forthcoming, the idea of publishing had to be abandoned (see *Trans. Devon. assoc.*, iii. 198–201).

In 1840 Mr. R. A. C. Austen, F.G.S. (now Godwin-Austen), read to the Geological society of London a paper on the bone-caves of Devonshire, which, with some amplifications, was incorporated in his memoir on the geology of the south-east of Devonshire, printed in the transactions of the society in 1842 (2d ser. vi. 433–489). Speaking of his own researches in Kent's Cavern, he said, "Human remains, and works of art, such as arrow-heads and knives of flint, occur in all parts of the cave, and throughout the entire thickness of the clay; and no distinction founded on condition, distribution, or relative position, can be observed whereby the human can be separated from the other reliquiae" (*Ibid.*, p. 444).

He added, "My own researches were constantly conducted in parts of the cave which had never been disturbed, and in every instance the bones were procured from beneath a thick covering of stalagmite. So far, then, the bones and works of man must have been introduced into the cave before the flooring of stalagmite had been formed" (*Ibid.*, p. 446).

Though these important and emphatic statements were so fortunate as to be committed to the safe keeping of print with but little delay, and under the most favorable circumstances, they appear neither to have excited any interest, nor, indeed, to have received much, if any, attention.

In 1846 the Torquay natural history society appointed a committee, consisting of Dr. Battersby, Mr. Vivian, and myself, — all tolerably familiar with the statements of Mr. MacEnery and Mr. Austen, — to make a few diggings in Kent's Cavern for the purpose of obtaining specimens for their museum. The work, though more or less desultory and unsystematic, was by no means carelessly done; and the committee were unanimously and perfectly satisfied that the objects they met with had been deposited at the same time as the matrix in which they were inhumed. At the close of their investigation they drew up a report, which was printed in the Torquay directory for Nov. 6, 1846 (see *Trans. Devon. assoc.*, x. 162). Its substance, embodied in a paper by Mr. Vivian, was read to the Geological society of London on May 12, 1847, as well as to the British association in the succeeding June; and the following abstract was printed in the Report of the association for that year (p. 73): —

"The important point that we have established is, that relics of human art are found *beneath* the unbroken floor of stalagmite. After taking every precaution by sweeping the surface, and examining most minutely whether there were any traces of the floor having been previously disturbed, we broke through the solid stalagmite in three different parts of the cavern, and in each instance found flint knives. . . . In the spot where the most highly finished specimen was found, the passage was so low that it was extremely difficult, with quarrymen's tools and good workmen, to break through the crust; and the supposition that it had been previously disturbed is impossible."

It will be borne in mind that the same paper was read the month before to the Geological society. The council of that body, being apparently unprepared to print in their *Quarterly journal* the statements it contained, contented themselves with the following notice, given here in its entirety (*Op. cit.*, iii. 353): —

"'On Kent's Cavern, near Torquay,' by Mr. Edward Vivian. — In this paper an account was given of some recent researches in that cavern by a committee of the Torquay natural history society, during which the bones of various extinct species of animals were found in several situations."

It will be observed that the 'flint knives' were utterly ignored, — a fact rendered the more significant by the following announcement on the wrapper of the journal: "The editor of the *Quarterly journal* is directed to make it known to the public that the authors alone are responsible for the facts and opinions contained in their respective papers."

Such, briefly, were the principal researches in Kent's Cavern, at intervals from 1825 to 1847. Their reception was by no means encouraging: Mr. MacEnery, after incurring very considerable expense, was under the necessity of abandoning the intention of publishing his 'Cavern researches;' Mr. Austen's paper, though printed unabridged, was given to an apathetic, unbelieving world, and was apparently without effect; and Mr. Vivian's paper, virtually the report by a committee of which he was a member, was cut down to four lines of a harmless, unexciting character.

For some years nothing occurred to break the quietude, which, but for an unexpected discovery on the southern shore of Torbay, would probably have remained to this day.

Early in 1858 the workmen engaged in a limestone-quarry on Windmill Hill, overhanging the fishing town of Brixham in South Devon, broke unexpectedly a hole through what proved to be the roof of an unknown and unsuspected cavern. I visited it very soon after the discovery, and secured to myself the refusal of a lease, to include the right of exploration. As the story of this cavern has been told at some length elsewhere (see *Phil. trans.*, clxiii. 471–572; or *Trans. Devon. assoc.*, vi. 775–856), it will here suffice to say, that at the instance of the late Dr. H. Falconer, the eminent paleontologist, the subject was taken up very cordially by the Royal and geological societies of London, a committee was appointed by the latter body, the exploration was placed under the superintendence of Mr. (now Professor) Prestwich and myself, and, being the only resident member of the committee, the actual superintendence fell of necessity to me.

The following facts connected with this cavern were, no doubt, influential in leading to the decision to have it explored: —

1. It was a virgin cave which had been hermetically sealed during an incalculably long period, the last previous event in its history being the introduction of a reindeer antler, found attached to the upper surface of the stalagmitic floor. It was therefore free from the objection, urged sometimes against Kent's Cavern, that having been known from time immemorial, and up to 1825 always open to all comers, it had perhaps been ransacked again and again.

2. It was believed, and it proved, to be a comparatively very small cavern; so that its complete exploration was not likely to require a large expenditure of time or of money.

It will be seen that the exploration was placed under circumstances much more likely to command attention than any of those which had preceded it. It was to be carried on under the auspices of the Royal and Geological societies by a committee consisting of Mr S. H. Beckles, Mr. G. Busk, Rev. R. Everest, Dr. H. Falconer, Mr. Godwin-Austen, Sir C. Lyell, Professor Owen, Dr. J. Percy, Mr. J. Prestwich, Professor (now Sir A. C.) Ramsay, and myself, — all fellows of the Geological society, and almost all of them of the Royal society also.

It was impossible not to feel, however, that the mode of exploration must be such as would not merely satisfy those actually engaged in the work, but such as would command for the results which might be obtained the acceptance of the scientific world generally. Hence I resolved to have nothing whatever to do with 'trial pits' here and there, or with shafts to be sunk in selected places, but first to examine and remove the stalagmite floor, then the entire bed immediately below (if not of inconvenient depth), horizontally throughout the entire length of the cavern, or so far as practicable; this accomplished, to proceed in like manner with the next lower bed; and so on until all the deposits had been removed.

This method, uniformly followed, was preferable to any other, because it would reveal the general stratigraphical order of the deposits, with the amount and direction of such 'dip' as they might have, as well as any variations in the thickness of the beds; it would afford the only chance of securing all the fossils, and of thus ascertaining, not only the different kinds of animals represented in the cave, but also the ratios which the numbers of individuals of the various species bore to one another, as well as all peculiar or noteworthy collocations; it would disclose the extent, character, and general features of the cavern itself; it was undoubtedly the least expensive mode of exploration; and it would render it almost impossible to refer bones, or indications of human existence, to wrong beds, depths, or associations.

The work was begun in July, 1858, and closed at the end of twelve months, when the cavern had practically been completely emptied. An official report was printed in the *Philosophical transactions* for 1873, and all the specimens have been handed over to the British museum.

The paper on the subject mentioned at the beginning of this address was read in September, 1858, during the meeting of the association at Leeds, when I had the pleasure of stating that eight flint tools had already been found in various parts of the cavern, all of them inosculating with bones of mammalia, at depths varying from nine to forty-two inches in the cave-earth, on which lay a sheet of stalagmite from three to eight inches thick, and having *within* it and *on* it relics of lion, hyena, bear, mammoth, rhinoceros, and reindeer.

It soon became obvious that the geological apathy previously spoken of had been rather apparent than real. In fact, geologists were found to have been not so much disinclined to entertain the question of human antiquity as to doubt the trustworthiness of the evidence which had previously been offered to them on the subject. It was felt, moreover, that the Brixham evidence made it worth while, and indeed a duty, to re-examine that from Kent's Cavern, as well as that said to have been met with in river-deposits in the valley of the Somme and elsewhere.

The first-fruits, I believe, of this awakening, was a paper by Mr. Prestwich, read to the Royal society, May 26, 1859, on the occurrence of flint implements, associated with the remains of animals of extinct species in beds of a late geological period, — in France at Amiens and Abbeville, and in England at Hoxne (*Phil. trans.* for 1860, pp. 277–317). This paper contains explicit evidence that Brixham Cavern had had no small share in disposing its author to undertake the investigation, which added to his own great reputation, and rescued M. Boucher de Perthes from undeserved neglect. "It was not," says Mr. Prestwich, "until I had myself witnessed the conditions under which these flint implements had been found at Brixham, that I became fully impressed with the validity of the doubts thrown upon the previously prevailing opinions with respect to such remains in caves" (*Op. cit.*, 280).

Sir C. Lyell, too, in his address to the geological section of the British association, at Aberdeen, in September, 1859, said, "The facts recently brought to light during the systematic investigation, as reported on by Dr. Falconer, of the Brixham Cave, must, I think, have prepared you to admit that scepticism in regard to the cave evidence in favor of the antiquity of man had previously been pushed to an extreme" (*Report Brit. assoc.*, 1859, *trans. sects.*, p. 93).

It is probably unnecessary to quote further to show how very large a share the exploration at Brixham had in impressing the scientific world generally with the value and importance of the geological evidence of man's antiquity. That impression, begun, as we have seen, in 1858, has not only lasted to the present day, but has probably not yet culminated. It has produced numerous volumes, crowds of papers, countless articles in reviews and magazines, in various countries; and perhaps, in order to show how very popular the subject became almost immediately, it is only necessary to state that Sir C. Lyell's great work on the 'Antiquity of man' was published in February, 1863; the second edition appeared in the following April; and the third followed in the succeeding November, — three editions of a bulky scientific work in less than ten months! A fourth edition was published in May, 1873.

Few, it may be presumed, can now doubt that those who before 1858 believed that our fathers had under-estimated human antiquity, and fought for their belief, have at length obtained a victory. Nevertheless, every anthropologist has doubtless, from time to time,

"Heard the distant and random gun
That the foe was sullenly firing."

The 'foe,' to speak metaphorically, seems to consist of very irregular forces, occasionally unfair but never dangerous, sometimes very amusing, and frequently but badly armed, or without *any* real armor. The Spartan law which fined a citizen heavily for going into battle unarmed was probably a very wise one.

For example, and dropping a metaphor, a pamphlet published in 1877 contains the following passage: "With regard to all these supposed flint implements and spear- and arrow-heads found in various places, it may be well to mention here the frank confession of Dr. Carpenter. He has told us from the presidential chair of the Royal academy that 'no logical proof can be adduced that the peculiar shapes of these flints were given them by human hands'" (see 'Is the book wrong? a question for sceptics,' by Hely H. A. Smith, p. 26). The words ascribed to Dr. Carpenter are put within inverted commas, and are the whole of the quotation from him. I was a good deal mystified on first reading them; for while it seemed likely that the president spoken of was the well-known member of this association, Dr. W. B. Carpenter, it was difficult to account for his being in the presidential chair of the Royal academy, and not easy to understand what the Royal academy had to do with flint implements. A little search, however, showed that the address which Dr. W. B. Carpenter delivered in 1872 from the presidential chair of, not the Royal academy, but the British association, contained the actual words quoted, followed immediately by others which the author of the pamphlet found it inconvenient to include in his quotation. Dr. Carpenter, speaking of 'common sense,' referred, by way of illustration, to the 'flint implements' of the Abbeville and Amiens gravel-beds, and remarked, "No logical proof can be adduced that the peculiar shapes of these flints were given to them by human hands; but does any unprejudiced person now doubt it?" (*Report Brit. assoc.*, 1872, p. lxxv.) Dr. Carpenter, after some further remarks on the 'flint implements,' concluded his paragraph respecting them with the following words: "Thus what was in the first instance a matter of discussion, has now become one of those 'self-evident' propositions which claim the unhesitating assent of all whose opinion on the subject is entitled to the least weight."

It cannot be doubted, that, taken in its entirety (that is to say, taken as every lover of truth and fairness should and would take it), Dr. Carpenter's paragraph would produce on the mind of the reader a very different effect from that likely, and no doubt intended, to be produced by the mutilated version of it given in the pamphlet.

A second edition of the pamphlet has been given to the world. Dr. Carpenter is still in the presidential chair of the Royal academy, and the quotation from his address is as conveniently short as before.

It would be easy to bring together a large number of similar modes of 'defending the cause of truth,' to use the words of the pamphlet just noticed; but space and time forbid.

I cannot, however, forego the pleasure of introducing the following recent and probably novel explanation of cavern phenomena. In 1882 my attention was directed to two articles by one and the same writer, on 'Bone-cave phenomena.' The writer's theme was professedly the Victoria Cave, near Settle, Yorkshire, which he says was an old Roman lead-mine; but his remarks are intended to apply to bone-caves in general. He takes a very early opportunity, in the second article, of stating that "we shall have to take care to distinguish between what is truly indicated in the 'science' view from what are purely imaginary exaggerations of its natural and historical phenomena;" and he no doubt believes that he has taken this care.

"We have now," he says, "to present our own view of the Victoria Cave and the phenomena connected with it, premising that a great many of the old mines in Europe were opened by Phoenician colonists and metal-workers a thousand years before the Romans had set foot in Britain, which accounts for the various floors of stalagmite found in most caves, and also for the variety of groups of bones embedded in them. The animals represented by them, when living, were not running wild about the hills, devouring each other, as science men suppose, but the useful auxiliaries and trained drudges of the miners in their work. Some of them, as the bear, had simply been hunted, and used for food; and others of a fierce character, as the hyena, to frighten and keep in awe the native Britons. The larger species of mammalia, as the elephant, the rhinoceros, and hippopotamus, and beasts foreign to the country, the Romans, no less than the Phoenicians, had every facility in bringing with them in their ships of commerce from Carthage, or other of the African ports. These, with the native horse, ox, and stag, which are always found in larger numbers in the caves than the remains of foreign animals, all worked peacefully together in the various operations of the mines. . . . The hippopotamus, although amphibious, is a grand beast for heavy work, such as mining, quarrying, or road-making; and his keeper would take care that he was comfortably lodged in a tank of water during the night. . . . The phenomena of the Victoria Cave lead-mine differ in no material respect from those of hundreds of others, whether of lead, copper, silver, or iron, worked in Roman and pre-Roman times in all parts of Europe. Its tunnels have all been regularly quarried and mined, *not by ancient seas*, but by the hands of historic man. Double openings have been made in every case for convenient ingress and egress during the process of excavation. Its roadways had been levelled, and holes made up with breccia, gravel, sand, and bones of beasts that had succumbed to toil, on which sledges, trolleys, and wagons could glide or run. . . . Near the entrance inside Victoria Cave were found the usual beds of charcoal, and the hearths for refining the metal; while close by, on the hillside, may still be seen the old kilns in which the men 'roasted' the metallic ores, and burned lime."

Should any one be disposed to ascribe these articles to some master of the art of joking, it need only be replied that they appeared in a religious journal (*The champion of the faith against current infidelity* for April 20 and May 11, 1882, vol. i. pp. 5 and 26), with the writer's name appended, and that I have reason to believe they were written seriously and in earnest.

It has been already intimated that Brixham Cavern has secured a somewhat prominent place in literature; and it can scarcely be needful to add that some of the printed statements respecting it are not quite correct. The following instances of inaccuracy may be taken as samples: —

The late Professor Ansted, describing Brixham Cavern in 1861, said, "In the middle of the cavern, under stalagmite itself, and actually entangled with an antler of a reindeer and the bones of the great cavern-bear, were found rude sculptured flints, such as are known to have been used by savages in most parts of the world" ('Geological gossip,' p. 209).

To be 'entangled' with one another, the antler, the bones of the cave-bear, and the flints, must have been all lying together. As a matter of fact, however, the antler was *on* the upper surface of the sheet of stalagmite, while all the relics of the cave-bear, and all the flints, were in detrital beds below that sheet. Again: the flints nearest the bear's bones in question were two in number: they were twelve feet south of the bones, and fifteen inches less deep in the bed. There was no approach to entanglement.

Should it be suggested that it is scarcely necessary to correct errors on scientific questions in works like 'Geological gossip,' professedly popular and intended for the million, I should venture to express the opinion that the strictest accuracy is specially required in such books, as the great majority of their readers are entirely at the mercy of the compilers. Those who read scientific books of a higher class are much more capable of taking care of themselves.

Professor Ansted's slip found its way into a scientific journal, where it was made the basis of a speculation (see *Geologist*, 1861, p. 246).

The most recent noteworthy inaccuracies connected with this famous cavern are, so far as I am aware, two in the English edition of Prof. N. Joly's 'Man before metals' (1883).

According to the first, "an entire left hind-leg of Ursus spelaeus was found lying above the incrustation of stalagmite which covered the bones of other extinct species and the carved flints" (p. 52).

It is only necessary, in reply to this, to repeat what has been already stated: all the bones of cave-bear found in the cavern were in beds *below* the stalagmite.

The following quotation from the same work contains the second inaccuracy, or, more correctly, group of inaccuracies, mentioned above: "We may mention, among others, the cave at Brixham, where, associated with fragments of rude pottery, and bones of extinct species, heaps of oyster-shells and other salt-water mollusks occur, as well as fish-bones of the genus Scarus" (p. 104).

I am afraid there is no way of dealing with this paragraph except that of meeting all its statements with unqualified denials. In short, Brixham Windmill-hill Cavern contained no pottery of any kind whatever, not a single oyster-shell, nor even a solitary bone of any species of fish. One common limpet-shell was the only relic of a marine organism met with in the cavern.

As already intimated, the result of the researches at Brixham quickened a desire to re-examine the Kent's Cavern evidence; and this received a considerable stimulus from the publication of Sir C. Lyell's 'Antiquity of man' in 1863. Having in the mean time made a careful survey of the cavern, and ascertained that there was a very large area in which the deposits were certainly intact, to say nothing of unsuspected branches which in all probability would be discovered during a thorough and systematic exploration, I had arrived at the conclusion, that, taking the cavern at its known dimensions merely, the cost of an investigation as complete as that at Brixham would not be less than £1,000.

Early in 1864 I suggested to Sir C. Lyell that an application should be made to the British association, during the meeting to be held at Bath that year, for the appointment of a committee, with a grant of money, to make an exploration of Kent's Cavern; and it was decided that I should take the necessary steps in the matter. The proposal being cordially received by the committee of the Geological section, and well supported in the committee of recommendations, a committee — consisting of Sir C. Lyell, Mr. J. Evans, Mr. (now Sir) J. Lubbock, Prof. J. Phillips, Mr. E. Vivian, and myself (honorable secretary and reporter) — was appointed, with £100 placed at its disposal. Mr. G. Busk was added to the committee in 1866, Mr. W. Boyd Dawkins in 1868, Mr. W. Ayshford Sanford in 1869, and Mr. J. E. Lee in 1873. The late Sir L. Palk (afterwards Lord Haldon), the proprietor, placed the cavern entirely under the control of the committee during the continuance of the work. The investigation was begun on March 28, 1865, and continued without intermission to June 19, 1880, the committee being annually re-appointed, with fresh grants of money, which in the aggregate amounted to £1,900, besides £63 received from various private sources.

The mode of exploration was essentially the same as that followed at Windmill Hill, Brixham; but as Kent's Cavern, instead of being a series of narrow galleries, contained a considerable number of capacious chambers, and as the aim of the explorers was to ascertain not merely what objects the deposits contained, but their exact position, their distribution, their condition, their collocation, and their relative abundance, the details had to be considerably more elaborate, while they remained so perfectly simple that the workmen had not the least difficulty in carrying them out, under my daily superintendence. The process being fully described in the First annual report by the committee (see *Report Brit. assoc.*, 1865, pp. 19, 20), it is unnecessary to repeat it here.

Mr. Godwin-Austen, while agreeing with Mr. MacEnery that flint implements occurred under the stalagmite, contended that they were found throughout the entire thickness of the cave-earth. MacEnery, on the other hand, was of opinion that in most cases their situation was intermediate between the bottom of the stalagmite and the upper surface of the cave-earth; and while admitting that occasionally, though rarely, they had been met with somewhat lower, he stated that the greatest depth to which he had been able to trace them was not more than a few inches below the surface of the cave-earth (*Trans. Devon. assoc.*, iii. 326, 327). The committee soon found themselves in a position to confirm Mr. Godwin-Austen's statement, and to say with him that "no distinction founded on condition, distribution, or relative position, can be observed whereby the human can be separated from the other reliquiae" (*Trans. geol. soc.*, 2d ser. vi. 444).

Mr. MacEnery's 'Plate F' contains seven figures of three remarkable canine teeth, and the following statement respecting them: "Teeth of Ursus cultridens, found in the cave of Kent's Hole, near Torquay, Devon, by Rev. Mr. MacEnery, January, 1826, in Diluvial Mud mix'd with Teeth and Gnaw'd Bones of Rhinoceros, Elephant, Horse, Ox, Elk, and Deer, with Teeth and Bones of Hyaenas, Bears, Wolves, Foxes, etc."

It is worthy of note, that no other plate in the entire series names the date on which the specimens were found, or the mammals with whose remains they were commingled. This arose probably from the fact, well known to MacEnery, that no such specimens had been found elsewhere in Britain; and possibly also to emphasize the statements in his text, should any doubt be thrown on his discovery.

It is, no doubt, unnecessary to say here that the teeth belonged to a large species of carnivore, to which, in 1846, Professor Owen gave the name of Machairodus latidens. MacEnery states that the total number of teeth he found were five upper canines and one incisor, and the six museums in which they are now lodged are well known.

A considerable amount of scepticism existed for many years in some minds, as to whether the relics just mentioned were really found in Kent's Cavern, it being contended, that, from its zoölogical affinities, Machairodus latidens must have belonged to an earlier fauna than that represented by the ordinary cave-mammals; and various hypotheses were invented to explain away the difficulty, most of them, at least, being more ingenious than ingenuous. Be this as it may, it was naturally hoped that the re-exploration of the cavern would set the question at rest forever; and it was not without a feeling of disappointment that I had to write seven successive annual reports without being able to announce the discovery of a single relic of Machairodus. Indeed, the greater part of the eighth report was written, with no better prospect, when, while engaged in washing a 'find' met with on July 29, 1872, I found that it consisted of a well-marked incisor of Machairodus latidens, with a left ramus of lower jaw of a bear, in which was one molar tooth. They were lying together in the first or uppermost foot-level of cave-earth, having over it a continuous sheet of granular stalagmite 2.5 feet thick. There was no longer any doubt of MacEnery's accuracy; no doubt that Machairodus latidens was a member of the cave-earth fauna, whatever the zoölogical affinities might say to the contrary; nor was there any doubt that man and Machairodus were contemporaries in Devonshire.

I cannot pass from this case without directing attention to its bearing on negative evidence. Had the exploration ceased on July 28, 1872, — the day before the discovery, — those who had always declined to believe that Machairodus had ever been found in the cavern would have been able to urge, as an additional and apparently conclusive argument, that the consecutive, systematic, and careful daily labor of seven years and four months had failed to show that their scepticism was unwarranted. Nay, more: had the incisor been overlooked, — and, being but a small object, this might very easily have occurred, — they might finally have said '15.25 years' labor;' for, so far as is known, no other relic of the species was met with during the entire investigation. In all probability, had either of these by no means improbable hypotheses occurred, geologists and paleontologists generally would have joined the sceptics; MacEnery's reputation would have been held in very light esteem, and, to say the least, his researches regarded with suspicion.

When its exploration began, and for some time after, the committee had no reason to believe or to suspect that the cavern contained any thing older than the cave-earth: but, at the end of five months, facts pointing apparently to earlier deposits began to present themselves; and, at intervals more or less protracted, additional phenomena, requiring apparently the same interpretation, were observed and recorded. But it was not until the end of three full years that a vertical section was cut, showing in undisturbed and clear succession, not only the cave-earth with the granular stalagmite lying on it, but, under and supporting the cave-earth, another, thicker and continuous, sheet of stalagmite (appropriately termed crystalline), and below this, again, an older detrital accumulation, known as the breccia, made up of materials utterly unlike those of the cave-earth.

The breccia was just as rich as the cave-earth in osseous remains, but the lists of species represented by the two deposits were very different. It will be sufficient to state here, that while remains of the hyena prevailed numerically very far above those of any other mammal in the cave-earth, and while his presence there was also attested by his teeth-marks on a vast number of bones; by lower jaws (including those of his own kith and kin), of which he had eaten off the lower borders as well as the condyles; by long bones broken obliquely, just as hyenas of the present day break them; and by surprising quantities of his coprolites, — there was not a single indication of any kind of his presence in the breccia, where the crowd of bones and teeth belonged almost entirely to bears.

No trace of the existence of man was found in the breccia until March, 1869, — that is, about twelve months after the discovery of the deposit itself, — when a flint flake was met with in the third foot-level, and was believed not only to be a tool, but to bear evidence of having been used as such (see *Report Brit. assoc.*, 1869, pp 201, 202). Two massive flint implements were discovered in the same deposit in May, 1872; and at various subsequent times other tools were found, until, at the close of the exploration, the breccia had yielded upwards of seventy implements of flint and chert.

While all the stone tools of both the cave-earth and the breccia were paleolithic, and were found inosculating with remains of extinct mammals, a mere inspection shows that they belong to two distinct categories. Those found in the breccia — that is, the more ancient series — were formed by chipping a flint nodule or pebble into a tool; while those from the cave-earth, the less ancient series, were fashioned by first detatching a suitable flake from the nodule or pebble, and then trimming the flake, not the nodule, into a tool.

It must be unnecessary to say that the making of nodule-tools necessitated the production of flakes and chips, some of which were no doubt utilized. Such flakes, however, must be regarded as accidents, and not the final objects the workers had in view.

It is worthy of remark, that in one part of the cavern, upwards of a hundred and thirty feet in length, the excavation was carried to a depth of nine feet, instead of the usual four feet, below the bottom of the stalagmite; and that, while no bone of any kind occurred in the breccia below the seventh foot-level, three fine flint nodule-tools were found in the eighth, and several flint chips in the ninth or lowest foot-level.

It may be added that the same fact presented itself in the lowest or corresponding bed in Brixham Windmill-hill Cavern. In short, in each of the two famous Devonshire caverns the archeological zone reached a lower level than the paleontological.

That the breccia is of higher antiquity than the cave-earth, is proved by the unquestionable evidence of clear, undisturbed superposition; that they represent two distinct chapters and eras in the cavern history, is shown by the decided dissimilarity of the materials composing them, the marked difference in the osseous remains they contained, and the strongly contrasted characters of the stone implements they yielded; and that they were separated by a wide interval of time, may be safely inferred from the thickness of the bed of stalagmite between them.

It is probable, however, that the fact most significant of time and physical change is the presence of the hyena in the cave-earth or less ancient, but not in the breccia or more ancient, of the two deposits. I called attention to this fact in a paper read to this department ten years ago (see *Report Brit. assoc.*, 1873, pp. 209–214), and at greater length elsewhere in 1875 (see *Trans. Plym. inst.*, v. 360–375). Bearing in mind the cave-haunting habits of the hyena, the great preponderance of his remains in the cave-earth, and their absence in the breccia, it seems impossible to avoid the conclusion that he was not an occupant of Britain during the earlier period.

The acceptance of this conclusion, however, necessitates the belief, 1°, that man was resident in Britain long before the hyena was; 2°, that it was possible for the hyena to reach Britain between the deposition of the breccia and the deposition of the cave-earth; in other words, that Britain was a part of the continent during this interval.

Sir C. Lyell, it will be remembered, recognized the following geographical changes within the British area between the newer pliocene and historical times (see 'Antiquity of man,' edition 1873, pp. 331, 332): —

Firstly, A pre-glacial continental period, towards the close of which the Forest of Cromer flourished, and the climate was somewhat milder than at present.

Secondly, A period of submergence, when the land north of the Thames and Bristol Channel, and that of Ireland, was reduced to an archipelago. This was a part of the glacial age, and icebergs floated in our waters.

Thirdly, A second continental period, when there were glaciers in the higher mountains of Scotland and Wales.

Fourthly, The breaking-up of the land through submergence, and a gradual change of temperature, resulting in the present geographical and climatal conditions.

It is obvious, that if, as I venture to think, the Kent's Cavern breccia was deposited during the first continental period, the list of mammalian remains found in it should not clash with the list of such remains from the Forest of Cromer, which, as we have just seen, flourished at that time. I called attention to these lists in 1874, pointing out, that, according to Professor Boyd Dawkins ('Cave-hunting,' p. 418), the forest-bed had at that time yielded twenty-six species of mammals, sixteen of them being extinct and ten recent; that both the breccia and the forest-bed had yielded remains of the cave-bear, but that in neither of them had any relic or trace of hyena been found. A monograph on the 'Vertebrata of the forest-bed series' was published in 1882 by Mr. E. T. Newton, F.G.S., who, including many additional species found somewhat recently, but eliminating all those about which there was any uncertainty, said, "We still have forty-nine species left, of which thirty are still living and nineteen are extinct" (p. 135). Though the number of the species has thus been almost doubled, and the presence of the cave-bear remains undoubted, it continues to be the fact that no trace of the hyena has been found in the forest-bed, and no suspicion exists as to his probable presence amongst the eliminated uncertain species.

It should be added, that no relic or indication of hyena was met with in the 'fourth bed' of Brixham Windmill-hill Cavern, believed to be the equivalent of the Kent's Hole breccia.

I am not unmindful of the fact that my evidence is negative only, and that raising a structure on it may be building on a sandy foundation. Nevertheless, it appears to me, as it did ten years ago, strong enough to bear the following inferences: —

1. That the hyena did not reach Britain until its last continental period.

2. That the men who made the paleolithic nodule-tools found in the oldest known deposit in Kent's Cavern arrived during the previous great submergence, or, what is more probable, — indeed, what alone seems possible, unless they were navigators, — during the first continental period. In short, I have little or no doubt that the earliest Devonians we have sighted were either of glacial, or, more probably, of pre-glacial age.

It cannot be necessary to add, that while the discovery of remains of hyena in the forest-bed of Cromer, or any other contemporary deposit, would be utterly fatal to my argument, it would leave intact all other evidence in support of the doctrine of British glacial or pre-glacial man.

Some of my friends accepted the foregoing inferences in 1873; while others, whose judgment I value, declined them. Since that date no adverse fact or thought has presented itself to me; but through the researches and discoveries of others in comparatively distant parts of our island, and especially in East Anglia, the belief in British pre-glacial man appears to have risen above the stage of ridicule, and to have a decided prospect of general scientific acceptance at no distant time.

I must, before closing, devote a few words to a class of workers who are 'more plague than profit.'

The exuberant enthusiasm of some would-be pioneers in the question of human antiquity results occasionally in supposed 'discoveries,' having an amusing side; and not unfrequently some of the pioneers, though utter strangers, are so good as to send me descriptions of their 'finds,' and of their views respecting them. The following case may be taken as a sample: in 1881 a gentleman of whom I had never heard wrote, stating that he was one of those who felt deeply interested in the antiquity of man, and that he had read all the books he could command on the subject. He was aware that it had been said by one paleontologist to be "unreasonable to suppose that man had lived during the eocene and miocene periods," but he had an indistinct recollection that another eminent man had somewhere said that "man had probably existed in England during a tropical carboniferous flora and fauna." He then went on to say, "I have got that which I cannot but look upon as a fossil human skull. I have endeavored to examine it from every conceivable stand-point, and it seems to stand the test. The angles seem perfect; the contour, the same, but smaller in size than the average human head: but that, in my opinion, is only what should be expected, if we assume that man lived during the carboniferous period, in spite of what Herodotus says about the body of Orestes." Finally he requested to be allowed to send me the specimen. On its arrival, it proved, of course, to be merely a stone; and nothing but a strong 'unscientific use of the imagination' could lead any one to believe that it had ever been a skull, human or infrahuman.

It may be added, that a few years ago a gentleman brought me what he called, and believed to be, 'three human skulls, and as many elephants' teeth,' found from time to time during his researches in a limestone-quarry. They proved to be nothing more than six oddly-shaped lumps of Devonian limestone.

So far as Britain is concerned, cave-hunting is a science of Devonshire birth. The limestone-caverns of Oreston, near Plymouth, were examined with some care, in the interests of paleontology, as early as 1816, and subsequently as they were successively discovered. The two most famous caverns of the same county — one on the northern, the other on the southern, shore of Torbay — have been anthropological as well as paleontological studies, and, as we have seen, have had the lion's share in enlarging our estimate of human antiquity. The researches have, no doubt, absorbed a great amount of time and labor, and demanded the exercise of much care and patience; but they have been replete with interest of a high order, which would be greatly enhanced if I could feel sure that your time has not been wasted, nor your patience exhausted, in listening to this address respecting them.

LETTERS TO THE EDITOR.

Tree-growth.

THE 'influence of winds upon tree-growth,' causing the asymmetry to which Mr. Kennedy calls attention in SCIENCE for Oct. 5, is noticeable to a remarkable degree among conifers in the mountains of the western half of the United States. The stunted, ground-hugging evergreens, which advance a little way above the limit of ordinary timber-growth on lofty mountains, are pressed to the earth by the steady gales as much as by overbearing snows, if not more. Evidence of this is found in the fact, that, where a cleft or little hollow occurs at or in advance of timber-line, the trees will stand straight and shapely within it as high as its rim (although in such nooks the snows lie longest and most deeply), above which they will be deformed, or unable to grow at all. This bending of the trees, the whole skirt of a forest, away from the edge of a precipice, or on a hilltop over which the wind sucks through the funnel of a cañon, is so common as to be seen every day by one travelling through the Rockies or the Sierra Nevada. It is particularly true in the Sierra San Joan, where the radiation of the vast adjacent sage-plains produces an extraordinary suction upward, toward the chilly crests of that lofty range. I remember noticing it nowhere more strongly than on the coast of Sonoma county, Cal., swept by a constant indraught from the Pacific.

This was the locality of my article in *Harper's magazine* for January, 1883, styled 'In a redwood logging-camp.' In that article (p. 194), after speaking of the stiff, erect trunks of the Sequoia, as seen inland, I say, "In windy places, like the exposed sea-front, all the boughs are twisted into a single plane landward, and great picturesqueness results." As you look at these trees from a distance, you cannot resist the impression (however quiet the sea and the air) that a furious gale is at that moment straining every branch to leeward, as a March day does the garments of pedestrians, or the flags of the shipping in a harbor. The seashore parks of Victoria or Vancouver, and of San Francisco, give other examples of this same appearance. A conspicuous instance of this same thing is to be seen in the Salinas valley, which extends for over a hundred miles southward from Monterey. There a high point of view shows that every tree and bush (save large clusters) in the whole valley leans toward the south-east (approximately), urged by the terrific wind that never ceases to rush up the long valley from the sea to the hills.

It is needless, however, to seek examples so far away. A line of evergreens along the Greenwich River, in eastern Connecticut, shows the asymmetry produced by wind very plainly; and the shore-trees all along Montauk Point, and the low islands on that coast, are bent away from the sea. On any ocean coast (or equally along the Great Lakes), on wide plains, or in any lofty mountain-range, according to my pretty wide observation in the United States, one might tell the course of the prevailing winds as accurately as fifty years of signal-service observation, by a glance at exposed trees, which, nurtured in steady gales, bend in age as their sapling twigs were inclined.

Snow is another factor to be considered in regarding the growth of trees in mountain regions. The flattened thickets of spruce just above timber-line, of the same species which, in sheltered spots no lower down, assumes an erect and lofty attitude, are matted close to the ground by long weight of snow, as well as bowed beneath fierce gales. Many and varied examples of its effect might be adduced; but I will refer to one only. On the road to the anthracite mine above Crested Butte, in the Elk Mountains of Colorado, you pass through a large grove of aspens, some eighteen inches or more in diameter, standing thickly on the hillside, at an elevation of about nine thousand feet. That region is famous for its deep snows, which might be inferred from the fact that every tree in this broad aspen-grove is bent far out of the vertical, many of them thirty or forty degrees, and all uniformly as to direction. The only explanation of this is the snow, which weights them down through so many months of the year. The sturdier trunks rise vertically in many cases, but their tops arch over almost in a semicircle; while the saplings are bowed nearly to the ground. In many parts of the mountains, great swaths lie open in the woods, and can never (or at least do not) become forested on account of snow-slides; while the opposition of wind and snow together are the only conceivable reasons why many bare plateaus are not tree-grown; that, for example, between the Lake Fork of the Gunnison and Cochetopa Creek.

Ernest Ingersoll.

New Haven, Oct. 10, 1883.

Standard railroad time.

Though the subject of standard and uniform railway time has for some years been under consideration by various scientific and practical bodies, it does not appear in any way to have been exhausted, even in its main features. Besides, a certain bias has shown itself in favor of the adoption of a series of certain hourly meridians, and thus keeping Greenwich minutes and seconds, when contrasted with the practicability of a more simple proposition. There is also a feature in the discussion of the subject which bears to have more light thrown upon it; namely, what necessary connection there is between the railway companies' uniform time and the mean local time of the people, or the time necessarily used in all transactions of common life. Directly or by implication, certain time-reformers evidently aim at a standard time, which shall be alike binding on railway traffic as well as on the business community; and to this great error much of the complexity of the subject is to be attributed, and it has directly retarded the much-needed reform in the time-management of our roads.

We say all ordinary business everywhere must forever be conducted on local mean solar time, the slight difference between apparent and mean time having produced no inconvenience; and we may rightly ask the railway companies to give in their time-tables for *public* use everywhere and always, the mean *local* time of the departure and of the arrival of trains. It is the departure from this almost self-evident statement, and the substitution and mixing-up in the time-tables of times referred to various local standards, which has in no small measure contributed to the confusion and perplexity of the present system. The people at large do not care to know by what time-system any railroad manages its trains, any more than they care what the steam-pressure is, or what is the number of the locomotive All the traveller is interested in is regularity and safety of travel: hence it was to be desired, that, whatever the standard or standards of time adopted, the companies would refrain from troubling him with a matter which only concerns their internal organization, or which is entirely administrative. We look upon the publication of the railway time-tables, by local time everywhere, as a *sine quâ non* for the satisfactory settlement of the time question, so far as the public at large is concerned; and it would seem equally plain that the best system for the administration of railroads would be the adoption of a uniform time, this time to be known only to the managers and employees of the roads.

We are informed in Science of Oct. 12, that the solution of the problem of standard railway time is near at hand, and probably has already been consummated by the adoption of four or more regions, each having uniform minutes and seconds of Greenwich time, but the local hour of the middle meridian. To have come down from several dozen of distinct time-systems to a very few and uniform ones, except as to the hour, is certainly a step forward, and, so far, gratifying; but why not adopt Greenwich time, pure and simple, and have absolute uniformity? Probably this will be felt before long. The counting of twenty-four hours to the day, in the place of twice twelve, and the obliteration from time-tables of the obnoxious A.M. and P.M. numbers, would seem to be generally acknowledged as an improvement and simplification, and perhaps can best be dealt with by adopting it at once, accompanied by a simple explanatory statement.

C. A. Schott.

Washington, Oct. 18, 1883.

PACKARD'S PHYLLOPOD CRUSTACEA.

A monograph of the phyllopod Crustacea of North America, with remarks on the order Phyllocarida. By A. S. Packard, Jun. Author's edition, extracted from the twelfth annual report of the U. S. geological and geographical survey. Washington, 1883. 298 p., 39 pl., map. 8°.

Although Professor Packard began publishing upon the Phyllopoda long ago, and has for several years been well known to be engaged upon a monograph of the North-American species, the bulk of the work just published, and the profusion of its illustrations, are a great surprise. It is the most extensive, and in many ways the most important, monographic contribution to American carcinology; and, however we may criticise the execution of the work, every student of the American fauna must feel grateful to the author for undertaking and accomplishing it.

The work is much more than a systematic monograph of North-American Phyllopoda, as the following table of contents will show: I. Classification of the living Phyllopoda, which includes the systematic description of the North-American species; II. Geological succession, including descriptions of the North-American fossil species; III. Geographical distribution; IV. Morphology and anatomy; V. Development, metamorphoses, and genealogy; VI. Miscellaneous notes on the reproductive habits of Branchipodidae, by Carl F. Gissler; VII. The order Phyllocarida, and its systematic position; VIII. Bibliography; Appendix, consisting of translations or abstracts by Gissler, of papers by C. T. von Siebold, on Artemia fertilis from Great Salt Lake, and on parthenogenesis in Artemia salina; and by Schmankewitsch, on the relation of Artemia salina to Artemia Muehlhausenii and to the genus Branchipus, and on the influence of external conditions of life upon the organization of animals. There is some confusion between the titles of the principal divisions, which are given above, and the table of contents in the work itself. Scarcely any of the titles are the same; and, in place of 'Miscellaneous notes on the reproductive habits of Branchipodidae,' we have, in the table of contents, 'Relation to their environment; habits,' — subjects nowhere treated under a separate heading; and all reference to the long appendix is omitted.

About a fourth of the entire work is devoted to the systematic account of the species and higher groups of Phyllopoda, regarded by Professor Packard as a sub-order of Branchiopoda, which is made to include Cladocera and Ostracoda also. The Phyllopoda are divided as follows into families and sub-families, which include the number of recognized North-American genera and species nearly as indicated: —

Limnadiidae:
 Limnetinae (1 genus, 4 species).
 Estheriinae (3 genera, 11 species).
Apodidae (2 genera, 9 species).
Branchipodidae:
 Branchipodinae (5 genera, 12 species).
 Thamnocephalinae (1 genus, 1 species).

All the groups are described; nearly all the species are figured, many of them very fully; and important notes on variability and habits are given for some of the species. Artemia gracilis is treated more at length than any other species, and is made to include all the described North-American species; but, in regard to its relation to the European A. salina, there is certainly confusion, as the following paragraphs show.

"Upon comparing our species with the European, it is difficult to find good differential characters, as the portions of the body where specific differences would be expected to occur are liable to considerable variation. Upon comparing a number of females from Great Salt Lake with a number of females of the maleless generation from Trieste, Austria, received from Professor Siebold, there are really no differences of importance. Our A. gracilis (Verrill's fertilis) is slighter, with a smaller head; and perhaps the second antennae are a little slighter in build; I see no essential difference in the form of the ovisac, while the shape of the legs, especially the sixth endite, is essentially the same" (p. 331).

"On comparing a number of Salt Lake females with individuals of the same sex of the European Artemia salina, our species was found to be undoubtedly specifically distinct; the Utah specimens are slenderer, smaller, and the sixth endite of all the feet considerably slenderer and longer in proportion than in A. salina. The ovisacs were of the same proportion but slenderer, and the head is slighter and smaller in our American species" (p. 333).

Different conclusions on neighboring pages, in regard to the specific identity of closely allied forms, might be accounted for in a careless author; but differences like these in statements of observation betray inexplicable carelessness.

In the chapter on geological succession, a table of the geological and geographical distribution of the known fossil species is given, and also a diagram indicating the geological history of the orders of Crustacea, the sub-orders of Branchiopoda, and the families of Phyllopoda. It is said that this diagram "may also serve as a genealogical tree, showing the probable origin of the main divisions of the Crustacea:" but the genealogical part of the diagram consists simply of dotted lines connecting the points of first appearance in geological history of the Branchipodidae, Apodidae, and Cladocera, with the point of appearance of the Limnadiidae in the Silurian; the common stem from this point with the Ostracoda in the upper Laurentian; and the branchiopod stem thus formed, and continued to a hypothetical Protonauplius in the lower Laurentian, with the points of appearance of the Malacostraca, Phyllocarida, and Cirripedia. On what conceivable theory of evolution this would represent a possible, much less the probable, origin of the main divisions of the Crustacea, it is hard to imagine, and was probably not seriously considered by the author himself; for it is far less like a probable genealogical tree than the diagram on p. 448, illustrating the relations of the Phyllocarida to other Crustacea.

In the chapter on morphology and anatomy, Professor Packard discusses at length the morphology of the regions of the body and the appendages of Arthropoda in general, and of the crustacean limb in particular, and gives some account of the anatomy of the phyllopods, but adds very little to our previous knowledge of the anatomy of the group. The morphological discussion is an interesting contribution to the subject, and, with the numerous figures with which it is illustrated, will prove very useful, although most of the new nomenclature proposed for the regions of the body and appendages is very objectionable. Professor Packard says, "For the primary regions of the head (*sic*), the only scientific terms as yet in use are those proposed by Prof. J. O. Westwood, in Bate and Westwood's History of British sessile-eyed Crustacea (vol. i. p. 3). These are *cephalon* for the head, *pereion* for the thorax, and *pleon* for the abdomen; while the thoracic feet are termed *pereiopoda*, and the abdominal legs *pleopoda;* the three terminal pairs being called *uropoda*. As the names applied to the thorax and abdomen have no especial morphological significance, the Greek περαιον, simply meaning ulterior, and πλεον, more, we would suggest that the head be termed the *cephalosome*, the cephalic segments, *cephalomeres*, and the cephalic appendages in general, *protopoda*, the term 'cephalopoda' being otherwise in use. The thorax of insects and of most Crustacea might be designated the *baenosome* (βαινω, to walk, locomotion), and the thoracic appendages, *baenopoda*, the segments being called *baenomeres;* while *urosome* might be applied to the abdomen, the abdominal segments being called *uromeres*. Westwood's term *uropoda* might be extended so as to include all the abdominal appendages." If mere names of parts are to be rejected, simply for want of 'morphological significance,' the language of the morphologist would soon become a meaningless jargon, to which it is near enough already; but, even as to 'morphological significance,' there appears to be little choice between the new and old terms. Bate, when first proposing the terms 'pereion'[1] and 'pleon,' expressly states that he derives the terms from περαιόω (*'to walk about'*) and πλέω (*navigo*). The proposed term 'protopoda' is quite as unfortunate as 'cephalopoda,' since 'protopodite' and 'protopod' are already in use for parts of crustacean appendages, the former even in the present work. The extension of the term 'uropoda' so as to make it synonymous with 'pleopoda' would also be unfortunate, since, as now employed, it is a very useful term to designate the modified caudal pleopoda, whether one, two, or three pairs.

In the chapter on development, metamorphoses, and genealogy, Professor Packard gives a short account of the nauplius form in Phyllopoda as an introduction to Dr. Gissler's interesting notes in the following chapter, and then briefly discusses the phylogeny of the group, in which he appears to find but one difficulty. He says, —

"The difficulty is (and this is a point apparently overlooked by Fritz Müller, Dohrn, Claus, and Balfour) to account for the origination of the phyllopods at all from any marine forms. The only explanation we can suggest, is that the phyllopods have arisen through Limnetis directly from some orginally marine cladocerous type like the marine forms now existing, such as Evadne. We imagine that when a permanent body of fresh water became established, as, for example, in perhaps early Silurian times, the marine forms carried into it in the egg-condition, possibly by birds or by high winds, hatched young, which, under favorable conditions, changed into Sida, Moina, and Daphnia-like forms."

Professor Packard appears to have overlooked the difficulty of the eggs of any marine cladocerous type of animals surviving a sudden transfer from salt to fresh water, and the

[1] According to either Bate's or Packard's derivation, this would be more properly written *peraeon*, as has sometimes been done, or even *pereon*.

absence of birds in the Silurian, which might well deter the boldest speculator from offering such an explanation; but when we consider that permanent bodies of fresh water were undoubtedly formed by the gradual freshening of bodies of salt water cut off from the ocean, and that such bodies of fresh water usually had outlets connecting them with the sea, it is not surprising that Fritz Müller, Dohrn, and others should overlook a difficulty which is no greater for Phyllopoda than for other groups of fresh-water animals.

In the chapter on his new order, Phyllocarida, and its systematic position, Professor Packard describes the anatomy and development of Nebalia, and discusses its fossil allies. The appendages of Nebalia bipes are described and fully figured, but on the internal anatomy very little that is new is given. The figures and text intended to elucidate the histology, like most of Professor Packard's similar work, leave much to be desired.

The bibliography consists of a hundred and thirty-eight titles, divided into four sections, — one for living and one for fossil Phyllopoda, and the same for Phyllocarida. The titles of many of the works referred to are omitted in the bibliography, which is evidently very incomplete; but its incompleteness is not so annoying as the entire want of system in its arrangement, and the frequency of typographical errors.

Typographical errors are very numerous in all parts of the work; and many of them cannot properly be charged to the proof-reader, who, however, ought to have corrected blunders like 'Yahresbericht' (several times) and 'zoogloical,' and the inexplicable punctuation of most of the bibliographical references in the systematic parts of the work. Errors due to careless writing or careless compiling are more common than purely typographical errors, and far more confusing. On p. 313 we have the following: "It is difficult to say whether this is a Limnadia or Estheria, as the description is too brief and inexact to enable us to determine the genus or species. It cannot be a Limnadia, and seems to approximate more closely to Estheria; though it cannot belong to that genus." On p. 335 it is said that 'Schmankevitch' found 'Branchinecta ferox (Fischer sp.)' transform by artificial means into Artemia; but in reality he found an Artemia change into a Branchinecta, or into what he considered a Branchipus. On p. 337, 'Labrador examples' are said to have been taken 'on the north side of Hamilton Inlet, Northern Greenland.' On pp. 313 and 314 the species of Estheriinae not recognizable are inserted between two species of Eulimnadia instead of at the end of the sub-family. Two paragraphs at the bottom of p. 349, under Streptocephalus Sealii, should have been placed under Chirocephalus Holmani, on p. 352. On pp. 356 to 358 the genus Leaia is inserted between two species of Estheria.

The plates, perhaps the most valuable part of the work, are nearly all lithographs from the establishment of Thomas Sinclair & son, and are apparently accurate representations of the original drawings. The general figures, mostly drawn by Emerton and Burgess, are excellent. The figures of details, drawn by the author, are not always so satisfactory: the figures of the appendages of Apus and Lepidurus, for example, are very rudely drawn, and badly arranged on the plates. Unfortunately, the amount of enlargement of scarcely any of the figures is given.

S. I. SMITH.

SIR WILLIAM LOGAN.

Life of Sir William E. Logan, Kt., LL.D., F.R.S., F.G.S., etc., first director of the Geological survey of Canada. By BERNARD J. HARRINGTON, B A., Ph D., professor of mining in McGill university. Montreal, *Dawson Bros*, 1883. With steel portrait and numerous woodcuts. 432 p. 8°.

A LIFE of Logan will be greeted by all geologists as a fit companion for those which have recently appeared of his English colleagues, Lyell and Murchison. What they did for Great Britain, he did for his native Canada, and even more. He solved the most complicated geological problems in vast areas where no white man had ever trod before him. He forced his way through trackless forests, making his own surveys and maps as he proceeded, and, in spite of such difficulties, not only discovered the structure of a greater part of his own country, but gave to the world a new series of formations. The work of Murchison and Sedgwick he completed by carrying order and succession beyond the Silurian and Cambrian, into that chaos of still older rocks, thus rendering the soil of his beloved Canada forever classic in geological annals.

The author of the present memoir has given us Sir William's history almost in his own words. By means of judicious extracts from his voluminous correspondence and journals, chronologically arranged, we are presented with a charming picture of the man, as well as the *savant*, all the more faithful because it is unconsciously given. Here we see portrayed an indomitable will, the keenest power of observation, as well as the coolest judgment in drawing conclusions, rare tact in managing his fellow-men, a ready sense of humor, combined with those subtler qualities of heart which make a man *beloved* wherever he may be. The author has rendered his work doubly attractive by making it sort of an unintentional autobiography.

Sir William Edmond Logan was born in Montreal, April 20, 1798, and remained at home until he was sent to the Edinburgh high school, in 1814. He studied at the high school and university of this place until 1817, when he entered upon a mercantile life in London, which he continued during the following fourteen years. In 1831 he was placed in charge of a copper company, near Swansea, in Wales, where he exhibited for the first time his geological proclivities. This company mined its own coal, and it was through this fact that he was led to his first really scientific investigations. He prepared a map of the South Wales coal-district with a degree of accuracy which had hardly before been equalled by any geological workers. This map attracted much attention from De la Beche, and other of England's most prominent geologists, and secured him influential friends who ever remained true to him.

In 1840 Logan returned to his native land, and spent over a year in studying the coal formation in New Brunswick and Pennsylvania. The results of his investigations relating to the origin of coal *in situ* were published soon after he returned to England. The subject of a government geological survey had been for some time under discussion in Canada, when, in 1841, £1,500 was appropriated for this purpose; and in the following year Logan received, upon the recommendation of his friends De la Beche, Murchison, Buckland, and Sedgwick, the appointment of director. During the seasons of 1843–44 he devoted his attention to studying the peninsula of Gaspé, where coal had been reported, and, in an incredibly short time, unravelled the geological complexities of a vast wilderness. The coal was not found, but its absence from the Silurian and Devonian rocks which compose that region was placed beyond a doubt.

But notwithstanding the energy with which Logan's work was carried on, and the success which attended it, his efforts to awaken in his countrymen an interest in geological pursuits were for a long time not appreciated. Years of doubt and anxiety followed the opening of the survey; and it was only through the indomitable will and consummate tact of its director that the opposition of a short-sighted government was finally overcome, and its permanent existence assured.

Although nothing was more foreign to Sir William's character than a taste for display, or a desire for fame, he fully appreciated the advantages to the survey and to Canada which must arise from having the results of his work widely known. Thus it was that he willingly undertook the charge of the Canadian exhibit at three world's fairs, — London in 1851 and 1862, and Paris in 1855, — and was more than repaid for his untiring exertions by the success which attended them. He saw, largely through his own efforts, an active interest in his native land awakened in Europe, the knowledge of her resources extended, and her industries and wealth thereby increased; while these practical results of his own work secured to him the encouragement of his countrymen, and honors poured fast upon him from all quarters. His appropriations were increased year by year; the best specialists were associated with him in different departments, such names as Hunt, Murray, and Billings, adding no little lustre to the survey's name; the field of work was extended over all of Canada that was accessible; and ample opportunity was given for the publication of scientific results.

Into the details of Sir William's special work we have here no time to enter: suffice it to say, that the sphere of his labors was very varied, as the list of his memoirs appended to the present work will show, his discoveries numerous and important, and all that he accomplished most thoroughly and accurately done. But the survey was always his especial care; and he may well have considered his life's work performed, when, at his resignation from the directorship in 1869, he could leave it upon a permanent footing, provided with every facility for future activity and usefulness. To the close of his life, his interest in its work never abated; and his last thoughts were devoted to completing some of his investigations begun as its director.

In August, 1874, Sir William once more went to England, and died the following June, at his sister's house in Wales. As a geologist, he will always be honored in the scientific world; while, as a man and as a friend, he will long be remembered by those who were never able to appreciate his work.

A very valuable paper on the history of the rocks of the Quebec group, by Principal Dawson of McGill college, forms a most welcome addition to this, of itself, so interesting book.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

The divisions in Saturn's rings. — Professor Kirkwood, in 1868, accounted for the great division in Saturn's rings by the commensurability of the period of a body revolving at that distance from Saturn with the periods of the six inner satellites. Dr. William Meyer of Geneva has investigated every possible combination of the commensurabilities of the revolution periods of the satellites, and finds six other places where a perturbing influence is exercised. The divisions most strongly marked seem to be at places where the commensurabilities are the closest, and all the satellites take part. A faint division should be found in the inner bright ring, according to Dr. Meyer. Prof. Holden has noted a distinct point at which the shading-off begins, in the position indicated by Meyer's theory, — a fact which seemed to have escaped Meyer's notice. — (*Observ.*, Sept., trans. from *Astr. nachr.*, 2,527, with additions.) M. McN. [306

Saturn. — Dr. William Meyer of Geneva gives a new determination of the orbits of six of Saturn's satellites, — Enceladus, Tethys, Dione, Rhea, Titan, and Iapetus. From each of these he has determined the mass of Saturn, the reciprocal value of the combined result being $M = 3,482.9 \pm 5.5$. The original observations are to appear in the *Mémoires de la société de physique de Genève* during the present year. — (*Astr. nachr.*, 2,528.) M. McN. [307

MATHEMATICS.

Functions of a complex variable. — In the present paper, entitled 'Applications of Fourier's theorem to the theory of the functions of a complex variable,' M. Harnack first shows in what manner the Fourier series are to be employed in the discovery of a rigid basis for the Cauchy-Riemann theorem concerning the development of functions of a complex variable. A generalization is also given of the fundamental hypothesis involved in the C.-R. theorem, as follows: if w is a function of $x + iy$, which over a simply connected plane region is everywhere continuous, and which 'in general' satisfies the differential equation, —

$$\frac{dw}{dx} + i\frac{dw}{dy} = 0,$$

then the function w is with its derivatives everywhere finite and continuous, and will possess no singular points. The term 'in general' (*im allgemeinen*) means that the points which do not satisfy the above differential equation, together with the points for which the partial derivatives $\frac{dw}{dx}$ and $\frac{dw}{dy}$ are indeterminate between finite or infinite limits, or are discontinuous, shall make up simply a discrete system of curves. In the second part of the paper, the author has gone very briefly into the subject of the representation of an analytical function, without singularities, in the interior of a circle by aid of Dirichlet's principle. — (*Math. ann.*, xxi.) T. C. [308

ENGINEERING.

Heavy engines and American railroad-tracks. — Mr. O. Chanute states that heavy 'consolidation' engines do not injure the track more than the lighter engines formerly did. Trains have been lengthened from 22 cars in 1874 to 38 in 1883; and the weights hauled, from 106 to 228 tons. By strengthening draw-heads, links, and pins, accidents from breaking apart of trains have been diminished, and the cost of haulage has been reduced from one cent to a half-cent per ton per mile. — (*Mechanics*, July 28.) R. H. T. [309

The British institution of mechanical engineers. — This society held its summer meeting in Belgium. It was received by the Association of engineers of Liége university, and visited the principal engineering establishments of the country. President Westmacott, in his opening address, called attention to the progress recently made in the rapid production of good articles of manufacture, and to the fact that speed and excellence of work are not incompatible where machinery is used. The materials must be of the best quality, however, the machines well proportioned, and all working parts well balanced and well fitted. He referred to Thorneycroft's experience with torpedo-boats, and called attention to the fact, that, at high speeds, the difficulties of lubrication and the jar observed at lower speeds disappear. In the speed of railway-trains, no advance has been lately made, and the maximum speeds remain at the figures of earlier years. Some economy has been obtained by the use of the crude products of the distillation of petroleum in the fireboxes of locomotives, this economy sometimes amounting to fifty per cent. Cotton-machinery has been speeded up, until the spindles which formerly made 5,000 revolutions are now making from 8,500 to 10,000, on fine American cotton. The increase in speed of woollen-machinery has not been great. In gunnery, the weight of gun and projectile have increased, in twenty-five years, from 5 tons and 66 pounds to 100 tons and 2,000 pounds. The shot has an initial energy of nearly 50,000 foot-tons. High speed is the direction of change in all departments of engineering. — (*Nature.*) R. H. T. [310

Hardening soft limestones with fluosilicates. — The application of alkaline silicates to the exterior of buildings, in order to prevent the deterioration of the stone, has not been attended with satisfactory results. H. L. Kessler proposes to use a solution of fluosilicates of bases whose oxides and carbonates are insoluble in a free state. When soft limestone is saturated with a concentrated solution of a fluosilicate of magnesium, aluminum, zinc, or lead, a very considerable degree of induration is soon reached, and the resulting products, except the liberated carbonic anhydride, are less soluble than the stone itself. No varnish is formed, and therefore no danger arises from expansion of frost beneath it. The process has resisted the severe tests of winter. Colors may be introduced satisfactorily. — (*Les mondes; Amer. arch.*, Sept. 1.) C. E. G. [311

CHEMISTRY.

(General, physical, and inorganic.)

The yellow and red plumbic oxides. — A study of the formation and properties of the two forms of plumbic oxide, by A. Geuther, shows that it is dimorphous, the yellow modification crystallizing in rhombic forms, and the red in the tetragonal system. The yellow oxide is changed by pressure and by friction into the red form, which is again transformed into the yellow, when heated to its melting point. — (*Ann. chem.*, ccxix., 56.) C. F. M. [312

Artificial reproduction of barite, celestite, and anhydrite. — A. Gorgeu finds that the sulphates of barium, strontium, and calcium dissolve freely in the melted chlorides of various metals at a red heat. On cooling, they separate in well-defined crystals which resemble closely the natural sulphates. From the results of his experiments, M. Gorgeu concludes that the minerals barite, celestite, and anhydrite must have been deposited from a solution of their amorphous sulphates in some metallic chloride. — (*Comptes rendus*, xvi. 1734.) C. F. M. [313

A modification of V. Meyer's apparatus for vapor density determinations. — In order to obtain a uniform temperature, H. Schwarz surrounds the tube containing the substance with a jacket which serves as an air-bath. The required temperature is obtained by placing the apparatus in an ordinary combustion-furnace. — (*Berichte deutsch. chem. gesellsch.*, xvi. 1051.) C. F. M. [314

METEOROLOGY.

Barometric laws. — The weather review issued by the *Deutsche seewarte* contains not only summaries of the weather conditions in each month, and of the work of the bureau in connection with them, but also occasional articles of scientific value, based upon the observations. The number for the year 1882 contains a valuable paper entitled *Typische witterungserscheinungen*, the object of which is to discuss the laws governing the velocity and direction of the movement of areas of low pressure, and their attendant phenomena, deduced from European observations between 1876 and 1880. The low areas during this period are grouped into five classes, according to the directions of the paths which they pursued. The accompanying charts exhibit, for each of three positions of the storm-centre (the entrance, middle position, and departure, as regards the territory of western Europe), six attendant phenomena, — the distribution of pressure and temperature, barometric changes in the preceding twenty-four hours, temperature departures from the normal, amount of precipitation, and cloud-phenomena. Tables are also given showing the distribution of the storm-tracks, with respect to the time of year, the average depth of the depressions, and their velocity.

The discussion to which the charts and tables have been subjected brings out various empirical laws, which are of special aid to the officers of the *seewarte* in their weather forecasts, as well as of scientific interest. Several of these may be mentioned: 1°. The depressions usually advance in the direction of the strongest winds. 2°. The line of advance of the depression forms an angle with the line of greatest increase of temperature, which generally lies between 45° and 90°, the highest temperature lying at the right of the path of the minimum. In summer the angle is greater than in winter, often reaching 90°. Both of these laws conform to the principles laid down in 1872 by Ley. They may be combined into one as follows: "The onward movement of the depressions follows approximately in the direction of the preponderating movement of the whole mass of air in the vicinity of the depression." The importance of cloud-studies, especially of the upper clouds, consists in the fact that their direction of movement foreshadows, in a general way, the direction of movement of the depression. On the other hand, their distribution in advance of the depression is so irregular that their indications cannot be relied upon alone, but must be combined with the distribution of pressure and other meteorological conditions.

The most interesting part of the discussion relates to the distribution of pressure at the height of 2,500 metres. The barometric readings are reduced to this height (in addition to the usual reduction to sea-level) by means of Köppen's formula, published in 1882; the first use of this method which has yet been published, as far as known. At this height the minima are not so closely enclosed by the isobars as is indicated by the charts; and it is shown, that "the rotary motion is limited to the lower atmospheric strata, in which the axis of the vortex is inclined towards the left and apparently somewhat forward." It seems that an advance in our knowledge of barometric movements might be made by further attention to this method of research, which enables us to investigate the extent of a depression in a vertical direction as well as in the horizontal direction, to which investigation has hitherto been limited. — (*Monatl. übersicht witterung*, 1882.) W. U. [315

GEOGRAPHY.

(Arctic.)

Polar stations. — The Austrian steamer Pola reached Jan Mayen, Aug. 3, and found the party in excellent health and spirits. We have already announced their safe return to Vienna. Some account of the wintering is given in *Nature*, from which we learn, that, in 1882, the autumn storms began with a heavy snowfall about the end of August. September was fine and warm; October again stormy. The polar night began Nov. 12, and ended Jan. 30. Aurora was constant and of great brilliancy during the winter. The greatest cold (−63° F.) was observed in January, but March had the lowest average temperature. Terrible snow-storms occurred at intervals; the ice, which first formed around the island in December, being frequently broken up, and the salt spray carried a long distance inland. The ice disappeared by the end of June. There had been no illness, and the international programme had been perfectly carried out. —— In addition to the international stations, the physical laboratory at Upsala has made simultaneous observations for the year ending Aug. 15. —— The Swedish expedition arrived at Tromsö from Spitzbergen, Aug. 28. The year's observations were completed Aug. 23. No casualties had occurred among the members of the party, and the relieving vessel encountered no ice of consequence. —— The Dutch, party which wintered in the Varna, near Waigatz Strait, arrived at Hammerfest, Sept. 3. The Varna was nipped Dec. 24, 1882, but did not founder until July 24, 1883. One of the crew died during the winter. The observations, except those relating to magnetism, were carried on with success. After the vessel sank, the party was accommodated on the Dimfna, from which it was taken by the steamer Obi, and carried to Vardö. Hovgaard, in the Dimfna, was confident of getting into open water in August, but intended, if he did not succeed in doing so by Aug. 15, to despatch half the crew under Lieut. Olsen for Yalmal on the Siberian coast, while he remained on the vessel with the other half during the winter. The Dimfna has since arrived at Vardö. —— No attempt is to be made to reach Greely's party this year, as the season is considered too late. Several Eskimo stories have reached civilization, aud have been supposed to refer to that party. It is certain that they are entitled to no credence whatever, in the shape in which they are received, even if originally based on some actual fact, which is doubtful. —— The Point Barrow party under Ray has been successfully relieved, and reached San Francisco, Oct. 7. According to a telegram from Lieut. Ray, all work was accomplished except the pendulum observations. The relieving schooner Leo reached Point Barrow, Aug. 22, but was forced away by the ice the same night; returned on the 24th, but was again forced to retire, with some damage, the next day. On the 27th, however, the party and stores were embarked, and the vessel reached Unalashka, where she was beached and repaired. Lieut. Schwatka and party, who had descended the Yukon from the Chilkat country to the sea, and reached St. Michael's safely, were brought to San Francisco by the Leo. — W. H. D. [316

The whaling-season. — Reports from Bering Strait to latest dates still continue to characterize the season as the worst and most icy for many years. No serious casualties had occurred since the loss of the John Howland. — W. H. D. [317

Arctic notes. — The death of Admiral Sir Richard Collinson, at the age of seventy-two, is announced. He commanded the Franklin search expedition, 1850–54, on the Enterprise and Investigator, surveyed Minto Inlet and Prince Albert Sound in 1852. Part of his command under M'Clure, by walking from their vessel in Mercy Bay, over the ice to the Resolute at Dealy Island, and afterwards sailing for England on the North Star, made the north-east passage from the Pacific for the first and only time. Collinson received the gold medal of the Royal geographical society, the order of the Bath, and had been deputy-master of Trinity House since 1875. —— The latest news from the polar station at the Lena mouth was to the effect that all were well April 3, though the winter had been very trying. The lowest temperature observed was −52°.3 F., Feb. 9. The deviation of the magnetic needles was very great, especially during 'magnetic storms,' reaching 25° in azimuth in the declinometer, and 90° for the suspended magnet in observations for horizontal intensity. —— The newspaper accounts of Lieut. Schwatka's voyage are so confused, and contain so many absolute errors, that it is difficult to know exactly what they are intended to convey. The facts appear to be, that he crossed the portage from the Chilkat River to the Kussooa affluents of the Lewis River, as several parties of prospectors have done before him. The descent was then made to the Yukon, at Fort Selkirk, on rafts. Some of the Indians of the party becoming mutinous, it is reported that three of them were killed by Schwatka; and the party then descended the river from the site of Fort Selkirk to Fort Adams, just below Nüklükahyet', about longitude 152° 30′ west, where one of the river-boats used in trading was chartered to take them to the seacoast. It is to be hoped that astronomical observations have been made by the party, which, so far as merely traversing the country is concerned, has done no more than has been done by different parties of prospectors and explorers before; none of whom, however, obtained any observations of precision on the river above Fort Yukon. —— Lieut. Stoney, U.S.N., after delivering the presents to the Chukchi of St. Lawrence Bay, which were sent in return for their benevolence to the officers and men of the Jeannette search expedition, on the U.S.S. Rodgers, landed near Hotham Inlet, and, according to newspaper reports, attempted to explore one of the three large rivers which fall into this estuary. The information given by the daily press is not exact; but it appears that the chief work accomplished was the collection of some native reports in regard to one of these rivers, which, in the state they have been made public, are incompatible with the known geography of the region. Doubtless, in this as in the case of Lieut. Schwatka's party, when the official reports are received, they will be found to contain welcome additions to our knowledge of these regions. [318

BOTANY.

Color-changes of lungwort flowers. — Dr. Müller finds, that while occasionally insects visit the blue (older) flowers of Pulmonaria officinalis, but without benefit to themselves or the plant, the red (younger) flowers are much more frequently visited for pollen and nectar, being at the same time fertilized. One female of Anthophora pilipes, for example, was seen to visit only red flowers, or those just beginning to change. Another visited, at first, both red and blue flowers, but later, apparently learning by experience that the blue flowers contain no nectar, confined her visits to the red flowers. A third visited in the following order: sixteen red flowers of Pulmonaria, one blue Nepeta glechoma, twenty-three red Pulmonaria, one Nepeta, twenty-one red Pulmonaria, and one Nepeta. Coming, now, to a place where the ground-ivy prevailed, she visited sixty-one Nepeta flowers, then five red Pulmonaria flowers, after which she returned to her nest. Earlier observation has also shown that this bee is not constant in its visits to a given species. The visits of the second individual and of one or two other insects, watched but a short time, to the blue flowers, is attributed to their lack of experience on this species; while the promiscuous visits of others are believed to be due to a noticeable confusion which was manifested after one or two unsuccessful visits had been made to flowers drained by earlier comers. From his observations, the writer concludes that the blue color of the older flowers, like the final color of those of Ribes aureum and Lantana, is of twofold advantage to the plant, — on the one hand increasing the conspicuousness of the flower-cluster, while, on the other hand, it indicates to the more acute of the visiting insects the flowers to which their attentions should be confined for their own good and that of the plant. — (*Kosmos*, 1883, 214.) W. T. [319

Insects versus fertilization. — In some notes on Thripidae, Mr. Osborn discusses the food-habits of these minute insects, believing, from the structure and position of their mouth-parts, and such observations as he has been able to make, that the major part of the group are vegetable feeders, the few species considered by Walsh and Riley as insectivorous differing in this respect from most of their congeners. Even these are thought to possibly seek the honey-dew of aphides, etc., rather than to destroy them.

Of young apple-blossoms frequented by them, "eighty per cent were injured by punctures upon the styles and other parts, but particularly the styles; and all the evidence pointed to the thrips as the cause of injury," though they were never seen to actually puncture the tissue. — (*Canad. entom.*, Aug.) W. T. [320

ZOÖLOGY.

Origin of individuality in the higher animals. — H. Fol has published a very interesting note, in which he studies, not the historical or phylogenetic, but the physiological, origin of the individual. The questions proposed are, At what moment in the ontogeny is the individuality created and limited? What factors determine the development of one, two, or several embryos from a single vitellus? The cases of double monsters by union of two distinct eggs, and polymerism, being phenomena of a different order, do not come into consideration here.

Fol's new researches were made principally on the sea-urchin, Strongylocentrotus lividus, which is strictly individualized at all stages of its existence. He had previously reached the conclusion that normal fecundation demands only one spermatozoon for each egg. Selenka thinks that two or three do not involve the sequel of an irregular development. Fol has verified both points, and finds that normal fecundation may be effected by either one or two spermatozoa uniting with the egg-nucleus. Three seem to produce abnormalities. The spermatozoon, then, does not act as an individuality: it represents only a certain dose of nuclear substance; and the dose may be either single or double. Immature or injured eggs admit several spermatozoa. Very ingeniously Fol has produced such a condition temporarily by immersing the mature ova for a moment in water saturated with carbonic acid, then transferring them to well-aerated water, and impregnating. The half-asphixiated eggs admit each three or four spermatozoa, which unite with the female pronucleus, after which follows an abnormally long period of repose. When segmentation begins, there appears a complex caryolytic figure, with three or four poles instead of two, a triaster or tetraster, or two parallel amphiasters, separate or united. The number of segmentation-spheres formed is at least double the normal. The larvae have irregular forms, and often two or three gastrular cavities.

If the eggs are more completely under the influence of the carbonic acid, from five to ten spermatozoa may gain entrance. The earliest comers unite with the female pronucleus: the later ones remain in the periphery. The nucleus forms a tetraster or double amphiaster; and the peripheral male pronuclei form each an amphiaster, which usually join end to end, forming a rosary of asters and spindles. Each of these amphiasters seems to be a centre of development, for the surviving larvae are polygastric.

These facts lead to the conclusion that neither the egg, nor the female pronucleus, nor the spermatozoon, suffices, taken separately, to determine the individuality. The dose of nuclear substance resulting in the formation of an embryo may vary within considerable limits; and the number of amphiasters at the first cleavage is the first criterion which decides the number of individuals. Fol then considers the first amphiaster of segmentation as the first fact of individuality. [Fol does not appear to have demonstrated a strict correspondence between the number of amphiasters and of individuals. His view raises the question whether there is a fundamental difference between the bipolar (amphiasters) and multipolar asters in cell-division.] — (*Comptes rendus acad. Paris*, Aug. 13, 1883.) C. S. M. [321

VERTEBRATES.

Birds.

The white of birds' eggs. — Tarchanoff has discovered that the white of the eggs of those birds whose young are born unfeathered differs from ordinary albumen, its most striking peculiarity being that it remains transparent after coagulation by heat. He designates it as 'tata-eiweiss.' It differs from ordinary white of egg in many respects. When coagulated it is fluorescent. It has less polarizing power, and contains more water, than the white of hens' eggs. It gives no precipitate when abundantly diluted with water. It is at first strongly alkaline, but loses that reaction as the yolk develops. It is rapidly digested. It can be redissolved in water after drying at 40° C. It can be changed into what appears to be identical with ordinary albumen, *a*, by the addition of a few drops of concentrated solutions of neutral salts of alkaline bases, or, *b*, of concentrated acetic or lactic acid; c, under the influence of carbonic acid at a temperature near boiling; d, by incubation (owing to the action of the CO_2 excreted by the yolk? — *Rep.*). Experiments left it uncertain whether the ordinary albumen first passes through the 'tata' form. It seems probable that the 'tata-eiweiss' is a sodic or potassic albuminate. — (*Pflüger's arch. physiol.*, xxxi. 368.) C. S. M. [322

Yolkless artificial eggs. — Tarchanoff, in the course of his experiments, noticed in the preceding abstract, made fistulae of the oviduct in hens. They bear the operation well, but it causes atrophy of the glands of the oviduct, and apparently of the ovary also. The mature ova are discharged into the body-cavity. Under favorable circumstances, if a ball of amber is introduced into the upper end of the duct, the white with fully developed chalazae, and the membranous shell, are deposited, producing a normally formed egg, in which the yolk is replaced by the amber ball. A ligature prevented the descent of the egg, during the experiment, into that region of the oviduct which secretes the calcareous shell. — (*Pflüger's arch. physiol.*, xxi. 375.) C. S. M. [323

ANTHROPOLOGY.

Notes on New Guinea. — By degrees this unknown land is being brought before the scientific world. Mr. W. G. Lawes, writing from Port Moresby, describes a visit to the Rouna Falls, accompanied by his wife, the first lady to tread the unbeaten tracks of New Guinea. In the district of Sogere the travellers stopped at several native villages. The one where they camped consisted of seven houses and three tree-houses, which are really forts or castles. One was a hundred and twenty feet high. A native went up with an armful of spears, and threw them down at an imaginary enemy. When they have reason to expect an enemy, they take up a supply of big stones. These houses command the whole village, and could not easily be taken. The travellers saw much of the natives, who are good specimens of the average Koiarian. They are somewhat darker, shorter, and more hairy, than the coast people. When a man dies, it is always known whose spirit has bewitched him; and his tribe must pay in order to give the dead man rest. Whenever a man of the least consequence dies, there is fighting. Their mode of getting fire is peculiar. They take a dry stick of pithy wood, and split it a little way. In the cleft they put a piece of wood or a stone to keep it open; then, putting a little rubbish as tinder under the split part of the stick, they stand on the other end, and pass a strip of rattan, cane, or bamboo, under the cleft, drawing it rapidly up and down, when it soon begins to smoke, and sparks appear between the forks of the stick, which, with a little care, sets fire to the tinder, and a flame is soon obtained. — J. W. P. [324

The Toltecs. — Notwithstanding Dr. Brinton's consignment of the Toltecs to the Morgenland, M. E. T. Hamy has the courage to say, "The Toltecs play the most important part in the past history of North America. Their history commences with the fifth century of our era, and their migration to the south-east coincides in a striking manner with the great movement of peoples in the old world. When the Goths and Huns were annihilating the civilization of Europe, at the other end of the world other barbarians, travelling in the same direction, were destroying older nations." M. Hamy gives a brief review of the Toltec art, especially in clay, and then proceeds to enlarge upon the discoveries of M. Charnay, illustrating his remarks by means of specimens in the Lorillard collection. The first period of Toltec ceramic art is termed *pastillage*; the second, more advanced, may be called *poussage*. Tula, Teotihuacan, and Cholula contain the most imposing vestiges of Toltec grandeur. The remains of what was the first capital of the Toltecs are situated nineteen leagues north of Mexico, at the confluence of the Rio Grande de Tula and a small river from the mountains of Texas. M. Charnay visited the ruins of this place, and photographed the most important. The descriptions of the other two capitals are passed over briefly by M. Hamy; but of Cholula, fortunately, we have the very minute observations of Bandelier, to be published by the Archeological institute. — (*Assoc. sc. France*, Conférence 25 Mars, 1882.) J. W. P. [325

The perforated humerus. — Professor Henry W. Haynes, in exhibiting a perforated Indian humerus found at Concord, Mass., brings together some important references to the same phenomenon observed elsewhere. Mr. Henry Gilman found 50 % in the Michigan mounds; at Grenelle, Paris, M. Martin found 28 %; in the Furfooz race of the caves of Belgium, M. Dupont found 30 %; in the Dolmen of Argenteuil, near Paris, M. Leguay found 25 %; while Dr. Pruner Bey ascertained the average at Vaureal, near by, to be 26 %. He also reported that it is common in skeletons of the Guanches. In the cave of Orrouy, belonging to the bronze age, the average was ascertained by Dr. Broca to be 25 %. Among two thousand skeletons of the polished stone age, discovered by the Baron de Baye in Champagne, he reports it as very frequent. Prof. Ward also speaks of the broken state in which long bones are found, attributing it to design. With regard to percentages on small numbers, a very singular experience was that of the writer of this note last year. Wishing to know what races and nationalities supplied the criminals of his city, he consulted the census and the police records. The former reported one Persian in the community; the latter, five Persians, arrested and convicted. Startled by the fact that five hundred per cent of the Persians were criminals, he was about to warn the government against allowing any more to land. A few moments' study, however, set the matter right. The poor Persian on the census-roll had been 'sent down' five times during one year, for sixty days each time, on account of vagrancy. — (*Proc. Amer. antiq. soc.*, ii. 80.) O. T. M. [326

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

National museum.

Publications. — The publications of the museum are issued under two titles, — 'Bulletins' and 'Proceedings.' The bulletins consist of monographs of groups of animals, plants, or minerals; papers upon the fauna, flora, and minerals of different regions of the globe; and similar works. The proceedings contain shorter communications descriptive of new species, etc., or relating to novel phenomena. All papers are based on material in the museum. Five volumes of the proceedings, and twenty-two bulletins, have already been published, aggregating 7,396 octavo pages. The sixth volume of the proceedings, and several bulletins, are now in course of publication. The bulletins which will appear within a short period are the following: —

A bibliography of the writings of Professor Spencer Fullerton Baird, by G. Brown Goode, A.M.; Avifauna columbiana, by Elliott Coues and D. Webster Prentiss, M.D.; A contribution to the natural history of Bermuda, edited by G. Brown Goode, A.M.; A manual of herpetology, by Henry C. Yarrow, M.D.; Official catalogue of the collections exhibited by the U. S. national museum at the London fisheries exhibition, 1883.

The exhibition-halls. — Two very important objects are about to be placed on exhibition in the museum. The first of these is a group of orangs, mounted by Mr. William T. Hornaday. The group represents a fight in the treetop, in which are concerned two adult male orangs, and as spectators a female and baby, and a young male. The setting has been worked out with great care, especially as regards the nests of the orangs, the foliage, vines, orchids, etc. All the specimens were shot by Mr. Hornaday in Borneo, and are mounted from his notes upon the living and fresh specimens.

The second object of interest is an antique Roman mosaic derived from Carthage. It was exhibited at the Centennial exhibition in the Tunisian section, and was afterward presented to the museum by Sir Richard Wood, British consul-general at Tunis. The mosaic represents a lion of life-size, seizing an animal resembling a horse or ass. It is believed to date from the first century B.C.

Additions to the collections. — The museum has recently secured a very valuable collection of archeological objects from Missouri, comprising twenty-five specimens. Included among them are a digging-implement of peculiar shape, and about a foot long, and two hourglass-shaped ceremonial objects of pink quartz about four inches long. Among the recent accessions to the department of birds is a nest of Opornis agilis, with eggs, — the first specimen of which there is authentic record. The department of reptiles is at present negotiating for a specimen of the very rare North-American serpent, Ophthalmidium longissimum. The department of mammals has received a valuable accession in the form of partially complete skeletons of eleven sperm whales. They represent the remains of a small school of these cetaceans, which stranded near Cape Canaveral, Florida, in the winter of 1882-83.

Bureau of ethnology.

Pueblo of Tallyhogan. — Mr. James Stevenson reports that careful investigations in the vicinity of the abandoned pueblo of Tallyhogan, in the ancient province of Tusayan, Arizona territory, disclose the fact that the sand-dunes on the north and east of the village were used by the former inhabitants as burial-places. A very little digging exposed the remains of the interred, which were usually placed in a hole in a doubled-up, mummy-like attitude.

In many cases vases and bowls, which probably contained food, were inhumed with the dead, and in some instances trinkets were found.

A number of old specimens were secured, among them being small images of human beings (previously unknown to collectors in this region), curious in workmanship, and ancient in ornamentation.

NOTES AND NEWS.

Mr. G. K. Gilbert has recently given some rather disturbing suggestions to the people of Salt Lake City (*Salt Lake weekly tribune*, Sept. 20) concerning the probability of destructive earthquakes there. He describes the slow and still continuing growth of the ranges in the Great Basin by repeated dislocation along great fractures, the earth's crust on one side being elevated and tilted into mountain attitude by an upthrust that produces compression and distortion in the rocky mass, until the strain can no longer be borne, and something must give way. Suddenly and violently there is a slipping of one wall of the fissure on the other, far enough to relieve the strain, and this is felt as an earthquake; then follows a long period of quiet, during which the strain is gradually reimposed. Such a shock occurred in Owen's valley, along the eastern base of the Sierra Nevada, in 1872, when a fault-scarp five to twenty feet high and forty miles long was produced. A scarp thirty or forty feet high is known along the western foot of the Wahsatch range, south of Salt Lake, and other scarps of similar origin have been found at the bases of many of the Basin ranges. The date of their formation is not known; but it must be comparatively recent, because they are still so little worn away. Wherever they are fresh, and consequently of modern uplift, there is probable safety from earthquakes for ages to come, because a long time is needed for the accumulation of another strain sufficient to cause a slipping of one wall of the fissure on the other. Conversely, when they are old and worn down, the breaking strain may even now be almost reached, and an earthquake may be expected at any time. This is the case at Salt Lake; for, continuous as are the fault-scarps along the base of the Wahsatch, they are absent near this city. From the Warm Springs to

Emigration Cañon they have not been found, and the rational explanation of their absence is that a very long time has elapsed since their last renewal. In this period the earth-strain has been slowly increasing. Some day it will overcome the friction, lift the mountains a few feet, and re-enact on a fearful scale the catastrophe of Owen's valley.

— The president of the International committee Dr. H. Wild, by request of the governments concerned, has announced that the observations of the parties at the circumpolar observing stations were to cease, as was originally planned, in September, 1883, and the different expeditions will return as shortly thereafter as practicable.

— Violent solfataric disturbances were experienced in Iceland between the 12th and 21st of last March.

— The English government has decided to establish an astronomical and meteorological observatory at Hong Kong, and has appointed Dr. William Doberck director of the institution. Dr. Doberck has accepted the position, and removed to Hong Kong. He may be addressed through the Crown agents for the Colonies, Downing street, London.

— In the *Journal of chemical industry* of June 29, Mr. G. W. Wigner, F.C.S., F.T.C., gives an account of the damage done to delicate substances by the material in which they are packed, suitability being too often sacrificed to strength, lightness, or mere ornament. As president of the society of public analysts, Mr. Wigner has had many opportunities of studying the subject.

Oysters, he writes, have been imported into England in barrels made of wood containing a very large proportion of tannin, with results which can be better understood than appreciated. The iron contained in the liquor has produced a very noticeable proportion of ink, and the oysters themselves have become converted into a poor but certainly novel kind of leather. Tinned fish and tinned acid fruits have been packed in vessels in which lead predominated over tin to a very marked extent. He alluded to the loss in cargoes of essences and scents by the impossibility of making the stoppers of glass bottles absolutely air-tight, and the damage done to other parts of the cargo by those essences. Mr. Wigner then proceeds to describe the effects of evaporation in the hold of a ship: bilge-water can never be quite excluded, and change of temperature must produce evaporation; the dew thus produced settles on the top of the packing-cases, and in time corrodes the metal, or is absorbed, as the case may be, and, if the voyage be long enough, damages the goods. Canned goods, he writes, seldom remain good for a second season, even if apparently well packed: the tin, some of the iron, and the lead contained in the tin, are dissolved, and the contents of the can become contaminated with these metallic substances.

The greater part of Mr. Wigner's article is devoted to the effects produced on tea by the wood in which it is packed. The Chinese formerly used 'toon' wood only; but the forests have been so much cut down that the supply is running short, and in Assam, wood for packing-cases is cut at random. In one instance, a consignment of Assam tea had a distinctive odor of its own, resembling a new and excessively rank kid glove; some hundreds of chests being thus damaged. The inner lead coating of tea-chests used by the Chinese is much purer, and less liable to damage by acid, than the lighter lining used by the dealers in upper India.

— Professor Angelo Heilprin was elected one of the curators of the Academy of natural sciences of Philadelphia on Oct. 2, to supply the vacancy caused by the death of Mr. Charles F. Parker. At a meeting of the council, held Oct. 5, Professor Heilprin was appointed actuary to the curators or curator in charge. He has commenced the arrangement of a department of the museum to be devoted exclusively to the natural history of Pennsylvania and New Jersey. The geology and mineralogy, together with the fauna and flora, of the two states, will be represented as completely as possible, and will form a collection which cannot fail to be of special interest to local students.

— The papers read at the meeting of the Biological society of Washington, Oct. 19, were by Dr. Theodore Gill, The ichthyological results of the explorations of the U. S. fish-commission steamer Albatross in 1883; Dr. C. A. White, Character and function of the epiglottis of the bull-snake (Pityophis); Professor Lester F. Ward, Note on an interesting botanical relic of the District of Columbia; Dr. C. V. Riley, Manna in the United States.

— The Philosophical society of Washington, on Oct. 13, held its first session after the summer vacation. Since June it has lost three members by death. — Surgeon-Gen. C. H. Crane, who was one of its vice-presidents; Admiral B. F. Sands, one of the original founders of the society; and Dr. Josiah Curtis. The papers of the evening were by Mr. William B. Taylor, on the Rings of Saturn; by Dr. Swan M. Burnett, on the Character of the focal lines in astigmatism; and by Mr. H. A. Hazen, on Thermometer-exposure.

— A scientific session of the National academy of sciences will be held in New Haven, at Yale college, commencing on Tuesday, Nov. 13.

— Mr. F. W. Putnam, of the Peabody museum, Cambridge, announces his readiness to give lectures on American archeology, based upon the course delivered last year before the Lowell institute. His subjects cover such matters as the shell-heaps, caves, mounds and earthworks, stone graves, pueblos, and ancient arts and religious rites of our country, as well as general sketches of the archeology of North America, Mexico and Central America, South America, and Peru.

— At the meeting of the Engineers' club of Philadelphia, Oct. 6, Mr. Edward Thiange presented an illustrated description of a method of earthwork computation, by means of diagrams constructed from the proposition, 'The areas of similar figures are to each other as the squares of their homologous sides.' An idea may be had of their nature and uses by the following directions: to get the average volume in cubic yards of a station (in embankment), to the centre-fill at each end add the constant height of the 'grade triangle' (which is formed by the road-bed and the side-slopes produced); at the resultant heights on the diagram, measure, with the scale of cubic yards, the lengths of the ordinates terminated by the slope-lines at each station respectively; their sum, diminished by the 'grade prism,' is the average quantity for the station of one hundred feet.

—A paper upon Economy in highway bridges, by Prof. J. A. L. Waddell, was read. Its objects are to determine the most economical depth and number of panels for spans from forty to two hundred feet; the lengths at which it is better to change from pony truss to thorough bridge, and from single to double intersection; the exact dead loads, and the amounts of lumber and iron for each case.

— Mr. Lester F. Ward has published in the U. S. fish-commission bulletin a list of the marsh and aquatic plants of the northern United States, which will be useful to those interested in aquaria and fish-ponds. The list numbers a hundred and eighty-one species, sixty-one of which are strictly aquatic, the balance being found in marshy places. Three species are said by Dr. Hessel to be injurious to carp-ponds; viz., Nuphar advena, Nuphar sagittaefolium, and Bidens Beckii. The species recommended especially for carp-ponds are of the strictly aquatic genera, Utricularia and Potamogeton. Of the Compositae, only three species, all Bidens, are given as being marsh-loving, or aquatic.

—The director of the Imperial Japanese government laboratory at Yokohama, Dr. A. J. C. Geerts, died there Aug. 30, aged forty.

—We have just received intelligence of the death of the distinguished French paleontologist, Dr. Joachim Barrande.

SCIENCE.

FRIDAY, NOVEMBER 2, 1883.

OSWALD HEER.

Oswald Heer, whose death in his seventy-fifth year we announced a fortnight since, was born in Glarus, Switzerland, Aug. 31, 1809. In 1828 he went to Halle to study theology and natural history. He began his career as a pastor at Glarus; and certain habits and manners of a clergyman clung to him throughout life, and traces of them may even be seen in his special paleontological writings. He soon gave up the ministry, and devoted himself exclusively to natural history; and we next find him settled in Zurich, where, in 1835, he founded the botanic garden, and became its director. In the following year he was attached to the university as professor of botany and entomology, — the two studies which divided his time throughout his life. Later, about 1855, he transferred his allegiance to the Polytechnicum, an institution of world-wide fame, where he remained the rest of his life. In 1845 he founded and became president of the Zurich society of agriculture and horticulture. And for twenty years he was a Rathsherr, or member of the Grand council of Zurich.

It was not until 1840 that he turned his attention to paleontology, studying first of all the fossil insects of Oeningen. This task he undertook at the instance of his friend Escher von der Linth. Knowing him from his childhood, Escher quickly perceived that a mind so delicately adjusted to observation, which no detail escaped, was well prepared for the difficult work of determining and classifying the numerous plants and insects of Oeningen. It was a virgin field. Yielding to the solicitations of his friend, Heer bravely undertook the suggested work; and with scarcely an interruption, notwithstanding a constitution always delicate, he brought out the remarkable and numerous memoirs which have given him a place among the first paleontologists of our time.

Soon after his return to Switzerland, Heer associated himself with Froebel (since renowned for his reforms in pedagogy) in the publication of a magazine under the title of '*Mittheilungen aus dem gebiete der theoretischen erdkunde*,' of which only four numbers were ever issued. In the first of these, in 1834, Heer printed two memoirs on the geographical distribution of insects and plants in the Swiss Alps, drawing his material mainly from his native canton, — memoirs which show, especially the longer one on insects, that he must have gathered his facts through patient, diligent observations of many years. These two memoirs appear to have been his earliest essays. He afterwards expanded the first into a long and better known memoir on the Swiss Coleoptera. These studies on geographical distribution formed an excellent basis for the paleontological work to which he was shortly to devote himself, one great value of which lies in his careful studies of the relations which the extinct insects and plants investigated bear to living forms in the same or other parts of the world. From this time on, not a year has passed without some sign of activity from this indefatigable student; and his last volume was only last month reviewed in our columns. At first the memoirs concerned mainly the transformations or distribution of Swiss Coleoptera, and the distribution of alpine plants; but from 1847, when his first memoir on the tertiary beetles of Europe appeared, his attention was directed almost exclusively to fossil insects and plants, especially those of the tertiary epoch; and it is here he has won his renown. The volume upon tertiary insects, issued between 1847 and 1853, opened a new world to science, and will forever remain the classic work on fossil insects. He brought to it a painstaking and faithful investigation, which in many cases will bear the closest scrutiny at the present time, notwithstanding the advance of entomology in the generation since elapsed. Finding that the determination of fossil insects must depend largely upon a study of their wings, he made a special investigation of the neuration in living types, and proposed for the first time a uniform nomenclature for all orders of insects. From its burial in a memoir on fossil beetles, this scheme received little attention; but it remains to-day the most philosophical presentation of the subject.

Although his earlier paleontological papers were mainly devoted to insects, his attention was from the first attracted to the plants associated with them. And, the mass of insects from Oeningen disposed of, his memoirs now became more and more largely paleobotanical. To these he gave a living interest, from his discussions of the probable physical condition and climate of tertiary time, drawn from the data furnished by the plants. He was a strong believer in a miocene Atlantis. His first essay, dealing with ancient climates, was published in Giebel's *Zeitschrift* in 1859, and was afterwards expanded into a volume, which passed immediately through a much enlarged second edition (in French) by the assistance of his friend Gaudin.[1] Then followed that remarkable series of illustrated quarto memoirs, published in various countries and languages in London, Stockholm, St. Petersburg, Zurich, etc., in which the collections of various government expeditions are described and figured, and which he afterwards collected into the volumes which compose his 'Flora fossilis arctica' (7 vols.), companion volumes to his 'Flora tertiaria Helvetiae' (3 vols.) and 'Flora fossilis Helvetiae.' His studies upon past climates were also carried into wider geologic fields, and resulted in his 'Urwelt der Schweiz,' a living picture of the past of his native country, clothed in popular language. His imagination was here brought into play, and occasionally expressed itself in verse. This volume, issued in 1865, was translated into French by Gaudin (1875), and into English by Heywood (2 vols. 1876). To each of these editions he added supplementary matter,

[1] This last was also enriched by contributions from several naturalists, notably Matheron and Saporta.

and himself published a considerably enlarged German edition in 1878.

Heer, who, as we have said, was instigated to his paleontological studies by Escher, was glad to acknowledge his debt to his friend, whose most illustrious pupil he was. Rarely have such cordial relations existed between two men. He always spoke of Escher in terms of warm friendship and admiration, and always seemed to be asking, Did you ever know his equal? And, indeed, Escher merited his praise.

Without personal fortune, and very often obliged by illness not only to suspend his courses, but even to make expensive journeys to Madeira, Italy, etc., to regain his strength, Heer would have been greatly embarrassed but for his friend. Escher possessed a fair fortune, especially in the latter part of his life; and, being childless, he constantly sought opportunity to assist Heer, and, so far as possible, without his knowledge. Escher urged his gratuities with such delicacy and kindness that he seemed to be the one under obligation when his dear friend would accept his offerings. Escher recognized the worth of his *protégé*, appreciated the value of the services he was rendering to science, and welcomed with a beaming face every fresh memoir from Heer's pen.

Heer was a man of very retiring habits, being rarely seen in public, even on the street. His delicate health forbidding his travelling or making personal explorations, he lived in his study, where he received fossils from all parts of the world. Here he accumulated specimens from the arctic regions, from every country of Europe, from Asia, and from America. Here in the midst of cabinets, and with books piled up on every side, he passed all his time, yet always receiving his geological friends with manifest pleasure. Many a scientific man came here to visit the illustrious paleontologist, — Leopold von Buch, Sir Charles Lyell, von Hauer, Geinitz, Fraas, Oppel, Sismonda, Ramsay, Falconer, Pictet, Studer, Merian, Agassiz, de Zigno, Mojsisovics, Gumbel, Schimper, Zittel, Schmidt, Abich, etc. While he was associated with Heer in the Polytechnicum, Jules Marcou was a visitor almost daily, and relates how, with a pleased and contented smile, Heer always greeted him after his fashion, grasping his hand in both of his. Reclining on a sofa (for Heer could only work a brief time without seeking rest), he would gladly converse for an hour or two upon geological topics and the numerous problems still requiring solution.

We have said he undertook no explorations; yet, in the winter of 1854–55, he visited Madeira for his health, in company with Ziegler and Hartwig. Several memoirs resulted from that visit; and in 1861, with his friends Escher and Merian, he visited Paris, London, the Isle of Wight, and Holland. An unusual exception was his accompanying his friend Marcou on short journeys to Oeningen, Schambelen, Dürnsten and Utznach, and Hohe Rhonen, — favorable localities for fossil plants and insects.

Heer worked quite alone, unaided by others; and he never worked in collaboration with other men, unless we may except the late C. T. Gaudin of Lausanne, who translated several of his important works, and in one at least, that on the climate of the tertiary epoch, may be said to have been a collaborator. Heer so called him. Indeed, it is possible, that had Gaudin not died in the flower of his age, eighteen years ago, he would have worked still further in concert with Heer, and given his works a wider circulation. Heer also found an assistant, as excellent as devoted, in his daughter, especially during the last twelve years of his life, many of which, after the disease which attacked him in 1872, he passed upon his bed. She was ever ready to place before him specimens, books, plates, descriptions, manuscripts. Always by his side, all his wishes were cared for by her in the most assiduous and intelligent manner.

A man more lovable, more sympathetic, a life more laborious and pure, one could scarcely imagine. As a man, he possessed the same irresistible attraction to all who came under his influence as that which characterized the late Lady Lyell.

The portrait given here has been photo-engraved from a photograph taken in 1864 by Heer's brother, kindly lent for the purpose by Professor Jules Marcou. The signature is taken from a letter addressed to the writer, under date of Aug. 13, 1883.

A HEARING OF BIRDS' EARS.[1]—III.

SECTION of bone is required for further examination of the ear parts. There being no mastoid affair to be considered as such, we may proceed directly to the 'petrous part of the temporal' (the periotic or petrosal bone); the otocrane, or otic capsule, enclosing the essential organ of audition just as the eyeball does that of vision, or the ethmoid bone that of olfaction. None of this bone is ordinarily recognizable on the outside of the skull; though in the embryo that part which is in especial relation with the posterior semicircular canal appears to a slight extent upon the occiput. The foundation of the bone is laid very early in cartilage; traces of the cochlea and canals being visible in the chick at the fifth day of incubation, if not sooner, in the primitive cartilaginous *basis cranii*, — the parachordal plate of cartilage on each side of the notochord. On longitudinally bisecting the adult skull, or otherwise gaining access to the brain-cavity, the whole cerebral surface of the petrosal bone is brought into view, as in fig. 4, *po*, *op*, *ep*. In a skull of any size, as that of an eagle (from which my description will be mainly derived), there is no difficulty in making out the parts, although the periphery of the petrosal is completely consolidated with surrounding bones. The petrosal or periotic bone consists of three distinct bones, which in some animals may remain long or permanently separate, or be consolidated with surrounding bones and not with one another. To see them it is usually necessary to examine a young skull, like that figured. These are the *pro-otic*, *po*; the *opisthotic*, *op*; the *epiotic*, *ep*. In the present case of the adult eagle, they are absolutely fused with one another, as well as with contiguous bones. The consolidated petrosal appears as an irregular protuberance upon the inner wall of the brain-cavity, much as the human petrous bone protrudes between posterior and middle cerebral fossae. It appears to be much more extensive than it really is, because the superior semicircular canal, too large to be accommodated in the petrosal, invades the occipital bone, — the track of the canal being sculptured in bas-relief, — as at *asc*, fig. 4. Behind this semicircular trace, the deep groove of a venous sinus (*sc*) is engraved upon the bone, throwing the track of the canal into still stronger relief. The top of the petrosal and contiguous occipital surface floors a fossa which lodges the enormous optic lobes (*corpora bigemina*) of the brain; in the eagle partly divided from the general cavity for the cerebral hemisphere by a bony tentorium, like that which in some mammals separates the cerebellar from the cerebral fossae. On the vertical face of the petrosal, or on the corresponding occipital surface, is a large smooth-lipped orifice leading to a tongue-like excavation which lodges the flocculus of the cerebellum, and would therefore seem to correspond to that slight chink of the human petrous bone, near the *meatus internus*, which lodges a process of the *dura mater*. In front, between the petrosal and the alisphenoid (or in the apposed border of one or the other of these bones), is a considerable foramen, — the exit of the second and third divisions of the trifacial (figs. 1 and 4, the hole marked *5*). Below the petrosal, between opisthotic and exoccipital, near the *foramen magnum*, is a foramen (which may be subdivided into foramina) representing the human *foramen lacerum posterius*, for transmission of the pneumogastric, etc. (fig. 4, the hole marked *8*). Thus, as always, the bony auditory capsule lies between the exits of the third division of the trifacial and the pneumogastric. The general space under description is continued to the margin of the *foramen magnum* by the exoccipital bone (fig. 4, *eo*). Now, on the vertical face of the petrosal itself, and in the pro-otic part, far behind the foramen marked *5* in fig. 4, considerably above that marked *8*, will be seen the large smooth-lipped orifice of the *meatus auditorius internus*, marked *7* in the figure. Here enter, as usual, both *portio dura* and *portio mollis* of the old seventh pair of cranial nerves. At the bottom of the meatus are at least two openings, small, but separate from each other. A bristle passed through the upper (anterior) one of these traces the course of *portio dura* (the facial nerve) through the fallopian aqueduct ('nerviduct,' it would be better called), and emerges in the tympanic cavity near the eustachian orifice. This orifice of exit of the facial is virtually a 'stylomastoid' foramen, though within the tympanic; for the nerve burrows through no more bone in reaching the surface of the skull. A bristle passed through the other one of the two foramina at the bottom of the meatus practically traces the course of the *portio mollis*, or auditory nerve,

[1] Concluded from No. 38.

and can also be made to come out into the tympanum, either through the vestibular or cochlear opening (*fenestra ovalis* or *fenestra rotunda*). In the dry skull, either passage is easily made without breaking down, and apparently without meeting any bony obstacle.

If, now, the whole periotic mass be cut away from the rest of the skull with a fine saw, and then divided in any direction, the bony labyrinth and essential organ of hearing can be studied. It is best to make the section in some definite plane with regard to the axes of the skull, — the vertical longitudinal, or vertical transverse, or horizontal, — as the disposition and relations of the contained structures are then more readily made out. Four or five parallel cuts will make as many thin flat slices of bone, affording eight or ten surfaces for examination. The whole course of the labyrinthine structures can be seen in sections, which, put together in the mind's eye, or held in hand a little apart, and visibly threaded with bristles, afford the required picture very nicely. At first sight, the unpractised eye will recognize nothing but confusion, — a bewildering maze of bone. All this cancellated structure or net-work, however, is pneumatic; the open-work tissue of bone containing air derived from the tympanum, and having nothing to do with the auditory cavities proper. Parts of the bony labyrinth will soon be recognized by their smooth, firm walls and definite courses, as distinguished from the irregular interstices of bone-tissue. They are, as usual, a central vestibular cavity, with its utricular recess; three semicircular canals; and the cochlear cavity, projecting downward like a beak (see figs. 5 and 6, the membranous labyrinth, to which the incasing bony cavities closely conform). According as the sections have been made, numerous cross-cuts of the canals will be seen here and there as circular orifices; the canals themselves lying curled like worms in the petrosal and occipital substance, their ends converging to the central vestibular cavity. As compared with those of man, the parts are of great size in a bird: in the eagle, for example, the whole affair is as large as the end of one's thumb, the whole length of the superior canal is an inch or more, and its calibre, I should judge, is absolutely about as great as in man. The cochlea, though not comparatively diminutive, is in an undeveloped state, as far as complexity of structure is concerned, — ligulate or strap-shaped, a little curved on itself, but making no whorl. This is substantially as in all Sauropsida (birds and reptiles), for the cochlea does not coil into a helix until we reach Mammalia. The tongue-like affair is simply as if a part of the first whorl of a mammal's cochlea very incompletely divided into *scala vestibuli* and *scala tympani* by cartilaginous structures representing a modiolus and its lamina, proceeding from the bony bar or bridge between *fenestra ovalis* and *fenestra rotunda*. These are the external (*a*) and in-

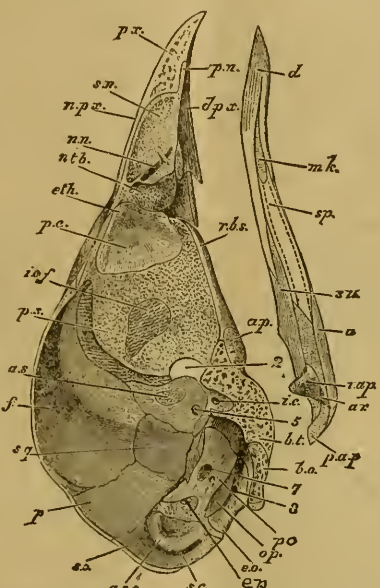

FIG. 4. — Ripe chick's skull, longitudinal section, viewed *inside*, × 3 diameters. (After Parker.) In the mandible are seen, — *mk*, remains of meckelian rod; *d*, dentary bone; *sp*, spleoial; *a*, angular; *su*, surangular; *ar*, articular; *iap*, internal articular process; *pap*, posterior articular process: in the skull, — *pn*, the original prenasal cartilage, upon which is moulded the premaxillary, *px*, with its nasal process, *npx*, and dentary process, *dpx*; *sn*, septo-nasal cartilage, in which is seen *nn*, nasal nerve; *ntb*, nasal turbinal; *eth*, ethmoid; *pe*, perpendicular plate of ethmoid; *iof*, inter-orbital foramen: *ps*, presphenoidal region; *2*, *optic foramen*; *as*, alisphenoid, with *5*, foramen for divisions of the fifth nerve; *f*, frootal; *p*, parietal; *so*, super-occipital; *asc*, superior semicircular canal; *sc*, a sinus (venous) canal; *ep*, epiotic; *eo*, exoccipital; *op*, opisthotic; *po*, pro-otic, with *7*, *meatus auditorius internus*, for entrance of seventh nerve; *8*, foramen for vagus nerve; *bo*, basi-occipital; *bt*, basi-temporal; *ic*, canal by which carotid artery enters brain-cavity; *ap*, basi-pterygoid process; *ap* to *rbs*, rostrum of the skull, being the parasphenoid bone underflooring the basi-sphenoid and future perpendicular plate of ethmoid.

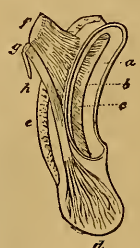
ternal (*b*) cartilaginous prisms shown in figs. 8 and 9. The cochlea ends with a saccular part, termed the 'lagena.' Details of the soft parts — membranous, vascular, and nervous — will readily be made out from Professor Ibsen's beautiful figures, here reproduced (figs. 5, 6, 8, 9), with ample explanatory text.

The vestibule hardly requires special description, after examination of figs. 5 and 6. In the eagle, if its irregularities of contour were smoothed out, it would about hold a pea. Its utricular recess (*g*) is well developed.

In the language of human anatomy, the three semicircular canals are the anterior or superior vertical, the posterior or inferior vertical, and the external or horizontal; and the planes of their respective loops are approximately perpendicular to one another in the three planes of any cubical figure. In birds, these terms do not apply so well to the situation of the canals with reference to the axes of the body, nor to the direction of their loops; neither is their mutual perpendicularity so nearly exhibited. The whole set is tilted over backward to some extent, so that the anterior (though still superior) canal, *d*, in figs. 5 and 6, loops back beyond either of the others; its anterior limb is also straightened out. The posterior (though still inferior) canal, *f*, loops behind and below the horizontal one, *e*, which tilts down backward. The verticality of the planes of *d* and *f* is preserved. The canals in birds might be better known as the superior (*d*) and inferior (*f*) vertical, and horizontal (*e*); though it is not probable, viewing the great variation in the axes of this part of the skull, that any terms descriptive of *direction* will apply perfectly to all birds. Whatever its inclination backward, there is no mistaking *d*, which is much the longest of the three, looping high over the rest, exc[illegible] the petrosal, and partly bedded in the o[illegible], with the upper limb bas-relieved upon the inner surface of the skull (fig. 4, *asc*). The one marked *f* loops lowest of all, though little, if any of it, reaches farther back than *d*; it is the second in size, and quite circular (rather more than a semicircle). Its upper limb joins the lower limb of *d* as in man, and the two open by one orifice in the vestibule; but, as far as the bony tubes are concerned, it is not simple union, for the two limbs, before forming a common tube, twine half around each other (like two fingers of one hand crossed). The loop of *f* reaches very near the back of the skull (outside). The horizontal canal, *e*, is the smallest, and, as it were, set within the loop of *f*; its plane, the opposite of that of *f*. The bony cavities of *e* and *f* intercommunicate where they cross, at or near the point of their



Figs. 5, 6. — Membranous labyrinth of *Haliaetus albicilla*, × 2. *a*, *b*, cochlea; *b*, its saccular extremity (or lagena); *c*, vestibule; *g*, its utricle; *d*, anterior or superior vertical semicircular canal; *e*, external or horizontal semicircular canal; *f*, posterior or inferior vertical semicircular canal; *h*, membranous canal leading into aqueduct of the vestibule; *k*, vascular membrane covering the *scala vestibuli*. Opposite this, at *i*, are seen the edges of the cartilaginous prisms in the *fenestra rotunda*: from the edges of these cartilages proceeds the delicate membrane closing the opening of the cochlea (not shown in the figure).

Fig. 7. — Part of the superior vertical semicircular canal, showing its ampulla, nerve of ampulla, artery, and connective tissue of the perilymph, × 3. *a*, that part of the vestibule (alveus) next to the ampulla; *b*, the dilatation of the ampulla at its vestibular opening; *c*, where it passes into the canal proper; *d*, the canal, furnished with connective tissue of the perilymph along its concave border and sides, as appears clearly at the sections *e* and *f*; *g*, nerve of the ampulla; *h*, artery of the connective tissue, running beneath it, remote from the wall of the duct.

Fig. 8. — Cochlea, × 3. *a*, external, *b*, internal, cartilaginous prism; *c*, membranous zone; *d*, saccular extremity of the cochlea, or lagena; *e*, vascular membrane; *f*, auditory nerve, its middle fascicle penetrating the internal cartilaginous prism, to reach the membranous zone by its terminal filaments; *g*, auditory nerve, its posterior fascicle running to the most posterior part of the lagena; *h*, filament to ampulla of posterior or inferior vertical semicircular canal.

Fig. 9. — Section of the cochlea. *a*, vestibular surface of external cartilaginous prism, extending into *d*, the lagena; *c*, section of the membranous zone; *e*, Huschke's process of the fenestra, which, with the margins of the cartilaginous prisms, affords attachment to the blind sac, *f*, occluding the fenestra of the cochlea; *g*, spongy vascular membrane of the *scala vestibuli*; *h*, auditory lamellae of Treviranus; *i*, canals in posterior wall of the lagena, by which the nervous filaments enter its cavity.

(From Ibsen's Anatomiske undersögelser over örets labyrinth. Kjöbenhavn, 1881, p. 17, pl. 1, figs. 13–17.)

greatest convexity, farthest away from the vestibule. This decussation of *e* and *f*, like the twining inosculation of *f* and *d*, is well known. It may not be so generally understood that there is (in the eagle; I do not know whether or not in birds generally) a *third* extra-vestibular communication of the bony canals. My sections show this perfectly. The great loop of *d*, sweeping past the decussation of *e* and *f*, is thrown into a cavity common to all three. Bristles threaded through [illegible] the three canals can all be seen in [illegible]t, crossing one another through this curious extra-vestibular chamber. I call it the *trivia*, or 'three-way place.' It is just where, in fig. 6, the three membranous canals [illegible]ussate, — midway between the letters *e*, *f*, and c. It does not, of course, follow, that the contained membranous canals intercommunicate here, and it appears from Ibsen's figures that they do not. The ampullar dilatations of the ends of the canals are well marked. The anatomy of associate soft parts is explained to some extent under fig. 7.

The endolymph may contain otoliths similar to those great concretions called 'earstones' in fishes. The equilibrating function of the labyrinth and its fluid appears to have been determined mainly from experiments upon birds. The apparatus may be likened to the glass tubes filled with water and a bubble of air, by a combination of which a surveyor, for example, is enabled to adjust his theodolite true; for a bird somehow knows how the liquid stands in these self-registering levelling tubes, and adjusts itself accordingly. Observations made upon pigeons show, that, "when the membranous canals are divided, very remarkable disturbances of equilibrium ensue, which vary in character according to the seat of the lesion. When the horizontal canals are divided, rapid movements of the head from side to side in a horizontal plane take place, along with oscillation of the eyeballs, and the animal tends to spin round on a vertical axis. When the posterior or inferior vertical canals are divided, the head is moved rapidly backwards and forwards, and the animal tends to execute a backward somersault, head over heels. When the superior vertical canals are divided, the head is moved rapidly forwards and backwards, and the animal tends to execute a forward somersault, heels over head. Combined section of the various canals causes the most bizarre contortions of the head and body." — (Ferrier, *Funct. of the brain*, 1876, p. 57.) Injury of the canals does not cause loss of hearing, nor does loss of equilibrium follow destruction of the cochlea. Two diverse though intimately connected functions are thus presided over by the acoustic nerve, — audition and equilibration.

The wonderful and endlessly varied songs of birds may acquire for us a new significance, now that we understand the mechanism by which these engaging creatures derive pleasure from their own music. Though no two things can well be conceived more different than an anatomical disquisition and a bird-song, either may be made to subserve the purpose of a truer appreciation of the other; and there may be physiological aspects of even a 'Christmas carol.' Elliott Coues.

Washington, Christmas, 1882.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1] — I.

The general circulation of the winds is at times interrupted by local and temporary disturbances of very varied size and strength, to which the general name of 'storms' is given. Their most constant features are, a more or less pronounced inward spiral whirling of the air near the ground, feeding an up-draught at the centre, and an outflow above; and a progressive motion from place to place, along a tolerably well-defined track. Clouds, and generally rain as well, accompany the larger storms.

It is our object to explain how these disturbances arise, to examine the causes and methods of their peculiar action, and to study their distribution in time and place. With this end in view, the small dust-whirlwinds that commonly arise in the hot dry air of deserts will be first considered. Next will come the great hurricanes and typhoons of the tropical seas, and the less violent rotary storms of our own latitudes, all of which may be grouped together as cyclones. The tornadoes and water-spouts, showing a peculiar concentration of power over a very limited area, will be discussed last.

The dry whirlwinds in flat desert regions suddenly interrupt the calmness of the air, and begin turning, catching up dust and sand, and carrying them upwards through the spiral vortex to a height of many hundred feet. They are therefore not at all like those whirls formed about our street-corners at the meeting of opposing currents of blustering wind, or the eddies of greater strength seen in windy mountain regions; for they arise in a time of quiet, and begin their motion without apparent cause. Hence we must, at the outset, inquire into the

[1] Based on a series of lectures delivered at the Lowell Institute, Boston, in January, 1883.

condition of the atmosphere when it lies at rest, examining it especially with regard to the kind of equilibrium that then exists, and the changes necessary to produce a tendency to motion.

When the air is at rest, it is normally densest and warmest next to the earth's surface, and becomes thinner and cooler at successive altitudes above it. It is denser below because the earth's attraction pulls it down, and compresses the lower layers by the weight of the upper ones. It is warmer below, mainly because the air gets nearly all of its heat by contact with, or radiation from, the warm earth, and not directly from the sun's rays, which pass through it with but little obstruction. The average rate of upward cooling, determined by many observations on mountains and in balloons, is about one degree F. for every three hundred feet of ascent. In this restful condition let us take a block of the dry air (the effect of the presence of water-vapor will be considered with the storms at sea) from the earth's surface, where the temperature is, say, 60° (fig. 1), and lift it up three hundred feet, to where the temperature is one degree less, or 59°. The block of lower air expands as it rises, because it is pressed on by less atmospheric weight, — less, at least, by the weight of three hundred feet of air; and, in thus expanding, it is cooled mechanically. It has been shown that this mechanical cooling of an ascending mass of dry air amounts to one degree F. in a hundred and eighty-three feet of ascent, whatever its initial temperature; so that in this special case the block is cooled by 1.6°, and its temperature is reduced to 58.4°. Now, let us compare it, when thus expanded and cooled, with an equal-sized block of air beside it, whose temperature is 59°. Evidently, of these two blocks of the same volume, and at the same pressure, the cooler will be the heavier. The block brought up from the surface, and now at a temperature of 58.4°, will weigh more than the air at 59° beside it, and hence it will tend to sink; and it must sink all the way down to its original level before it finds any air as heavy as itself. In this imaginary experiment we have disturbed the arrangement of the normal, quiet atmosphere; and the disturbed mass returns to its original position as soon as freed from the constraining force. Such an atmosphere is therefore in a condition of stable equilibrium, like a rod hung by its upper end, which is opposed to any change in its position, and, when displaced, tends to return to its original attitude.

Fig. 1.

Evidently, when a whirlwind springs up in the calm air of a desert, as is so often the case, the atmosphere cannot possess this normal stability: for then there would be no temptation to any such disturbance; the air would prefer to stand as it is. Before the whirlwind can arise, there must have been a change to a condition of unstable equilibrium, in which the air, like a rod balanced on its lower end, is ready to move on small provocation; and we have now to look for the cause of this change. To be guided properly in the search, the conditions necessary and antecedent to the formation of the whirls must be examined. They are, that the whirls occur generally in level, barren, warm regions, in quiet air, and only in the daytime after the sun has risen high enough to warm the sandy ground, and the air next to it, to a rather high temperature. As the first and second of these conditions may be present at night as well as by day, it must, without doubt, be the heat from the sun that disturbs the quiet equilibrium into which the air tends to settle, and, by warming the lower layers, causes a departure from the ordinary stable condition of rest.

Let a case be supposed: the sun has warmed the lower air of the first example to a temperature of 90° (fig. 2), while the air three hundred feet above the desert sands has, in virtue of its diathermance, risen only to 70°; so that there is now a difference of twenty degrees between these two layers. If we here repeat the experiment of carrying a block of surface-air to a height of three hundred feet, it is again mechanically cooled 1.6°, so that its temperature is reduced to 88.4°; and now, comparing it with an equal volume of adjoining air at 70°, the latter is evidently the heavier, and therefore the block of air brought up from the surface, instead of tending to sink, as in the first case, tends strongly to rise farther, and continue the motion given to it. In other words, the air is now in a condition of unstable equilibrium: it is ready to upset and re-arrange itself. The lower layer may be compared to a film of oil balanced beneath a quiet sheet of water: a little disturbance would cause the two liquids to change places, and the oil would rise through the water, draining itself upwards.

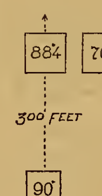


Fig. 2.

In such a condition as this, the desert-whirls may begin. It is clearly not necessary, in order to produce this result, that the vertical decrease of temperature should be as much as twenty degrees in three hundred feet, as in the case just assumed. In order to pass from the stable equilibrium, through the indifferent to the unstable equilibrium, it is sufficient, in dry air, that the vertical decrease should be greater than 1.6° in three hundred feet, or greater than one degree in one hundred and eighty-three feet. Moreover, it is important to notice, that, according to this theoretical explanation, the condition of indifferent equilibrium is passed before the surface-air is, as Franklin (1753) and Belt (1859) have said, specifically lighter than that above it. This would require a temperature difference of at least 5.6° F. in three hundred feet. It is sufficient that the surface-air shall be potentially lighter, though absolutely (before any motion takes place) heavier, than the higher layers, as Reye first showed (1864); or, in other words, stable equilibrium is lost, and indifferent equilibrium reached, when the surface-air is just enough warmer than any layer above it to make up for the change of temperatures produced in equalizing their densities. Any further excess of surface-warmth brings about theoretic unstable equilibrium. On the other hand, whirlwinds of decided activity will not be formed until the difference of temperature is much in excess of the narrow limits just given, the strength of the up-current increasing with its excess of warmth. Motion of the atmosphere caused by small differences of temperature would be very gentle, and would be perceived only in the 'boiling' of the air, often seen in summer-time over the brow of a hill.

It must be, then, the sun's heat, as was supposed, that destroys the normal stable equilibrium of our atmosphere; and to a disturbance of this kind we can refer more or less directly all storms, and, indeed, all winds that blow about the earth. Without the heat that is constantly showered down on us, we should soon gravitate into a lifeless condition of stable equilibrium, chemical, organic, and physical, and there remain in endless death. But the sun allows no such inactivity on its attendant planets: it keeps them alive and at work.

(To be continued.)

THE FRENCH ECLIPSE EXPEDITION.

P. J. Janssen, the leader of the French expedition which visited Caroline Island to observe the solar eclipse of May 6, has made a report to the French academy of sciences, which is published in full in the *Bulletin hebdomadaire de l'Association scientifique*, no. 181. It contains, first, an interesting account of the voyage to Caroline Island, and a brief description of the island, with the difficulties encountered in landing the instruments; then follows a statement of the instrumental outfit and the plan of observations. The search for intra-mercurial planets was assigned to Messrs. Palisa and Trouvelot. The former used an equatorial of 0.16 m. aperture, having a short focus and large field: the latter was provided with an equatorial of the same size, which had a finder of 0.08 m. aperture, thus giving the observer two telescopes. The finder had a field of 4°.5, and was used in examining the region in the vicinity of the sun, while the larger instrument was intended to give the position of any strange object that might be noted by means of its position-circles. In order to avoid the necessity of reading the circles, an attachment was made to both right ascension and declination circles, by which fine marks could be made upon the circles and verniers by the observer's assistants, and the corresponding readings determined at leisure. The finder was also furnished with a reticule containing cross-threads, and a position-circle for use in noting the appearance of the corona, to the drawing of which Mr. Trouvelot gave a portion of the time of the total phase.

The search for intra-mercurial planets was also conducted by the aid of photographic apparatus, which Mr. Janssen thus describes: —

"At my order, Mr. Gautier had prepared an equatorial mounting with an hour-axis two metres long, carrying a strong and large platform, upon which were fastened the following photographic apparatus: a large camera having a lens of eight inches (0.21 m.), made by Darlot, giving a field of 20° to 25° (plate of 0.40 m. by 0.50 m.), and designed for photographing the corona and the region about the sun with reference to the stars there found; a second camera, with a Darlot lens of six inches (0.16 m.), giving a field of 26° to 35° (plate of 0.30 m. by 0.40 m.), for the same purpose; and a very fine apparatus by Steinheil, for studying the corona. A second mounting carried several cameras with lenses of four inches (0.10 m.), giving a great amount of light, and designed to determine by very sensitive plates what are the limits of the corona, — an apparatus of great light-power, the exposure lasting during the whole of totality."

For spectrum analysis the following apparatus was employed: "a [reflecting] telescope of 0.50 m. aperture, having a very short focus (1.60 m.), and supplied with a direct-vision spectroscope of ten prisms; the slit of the spectroscope could be placed at different position-angles, and rapidly opened or closed, at the pleasure of the observer. An excellent finder, supplied with a reticule, was placed near the spectroscope, and distant from it by such an amount, that, when one eye had fixed upon some point of the corona in the finder, the other could obtain the spectroscopic analysis of this point." There was also attached to this telescope a biquartz polariscope by Prazmowski, and a spectroscope for showing Respighi's rings. A spare mirror of 0.40 m. diameter was carried as a reserve, but was not brought into use, as, by great care, the first was kept uninjured, in spite of the frequent rains and the moisture of the climate.

Mr. Janssen gives the following condensed report of his own observations, drawn up immediately after the observations, in accordance with the plan by which all the observers of the party were governed: —

"My observations were of two classes, — optical and photographic. The optical observations were principally designed to determine whether the coronal spectrum consists of a continuous spectrum as a background with bright lines, or if the Fraunhofer lines exist there generally (an investigation made especially with regard to the question of extra-solar cosmic substances). In 1871 I had announced, that, besides the hydrogen lines, I had established in the spectrum of the corona the presence of the *D* line and of several others.

"In the present eclipse I proposed especially to solve this question. By means of the optical arrangements above described, I have been able to determine that the basis of the coronal spectrum is composed of the complete Fraunhofer spectrum. The principal lines of the solar spectrum, especially *D*, *b*, *E*, etc., were detected so surely that there can be no possible doubt of this fact. I recognized, perhaps, a hundred lines.

"I recognized this composition of the spectrum, particularly in the lower or most brilliant portions of the corona, but not to an equal degree at the same distance from the moon's limb. The details of this will be given and discussed at a future time.

"I studied also the rings of Respighi. The rings did not appear uniform about the moon's limb, but presented peculiarities of structure which will be especially discussed in their relation to the question of the Fraunhofer lines.

"I studied also polarization, but devoted to it only a few moments, using the excellent biquartz polariscope of Prazmowski. The polarization was very well defined, and possessed characteristics already recognized.

"Before the observations, I made a preliminary examination of the corona with the naked eye, and with an excellent telescope by Prazmowski. This examination was for the purpose of guiding me in the subsequent observations.

"All these studies — study of the shape, spectrum analysis, Respighi's rings, polarization — were combined with the view of solving the question of extra-solar cosmic substances. We think that the discovery of the complete Fraunhofer spectrum in that of the corona considerably advances this question.

"*Photography.* — Two great instruments, containing eight cameras, had been prepared for studying the question of intra-mercurial planets, and that of the shape and extension of the corona. With regard to heavenly bodies in the vicinity of the sun, these photographs will require a minute examination; but, with respect to the corona, it can be said that the great power of several of the lenses used [that of eight inches (0.21 m.) and that of six inches (0.16 m.)], and also the length of exposure, permitted us to prove that the corona has an extension very much greater than that shown by optical examination, either with the naked eye or in my telescope.

"Several of our large photographs of the corona have great distinctness. They show important details of structure which ought to be discussed. The shape of the corona was absolutely fixed during the whole duration of totality."

The reports of Messrs. Tacchini, Palisa, and Trouvelot are not given, but are alluded to in the discussion of the results of the observations, which next follows. Mr. Janssen regards it quite improbable that any intra-mercurial planets exist, on account of the negative testimony given by Mr. Palisa, combined with that of Professor Holden of the American party. Mr. Trouvelot's conclusion is less decisive, but the observer wished to re-examine the region of the sky before coming to a final conclusion.[1] The author adds, "When we consider that the bodies discovered by Professor Watson in 1878 can be identified, within the limits of error to which the method employed by that astronomer is liable, with two stars in Cancer,[2] we arrive at the conclusion that it is to-day extremely improbable that there exists one or more planetary bodies of any importance between Mercury and the sun. Our photographs, although not yet completely examined, seem to lead to the same conclusion."

The duration of totality was found by Mr. Trouvelot to be $5^m 24^s.1$, by Mr. Tacchini to be $5^m 23^s$.

On the subject of the corona, Mr. Janssen thus writes: —

"*The corona.* — Mr. Tacchini's report shows that this skilful astronomer made remarkable observations at Caroline Island, especially with regard to the analogy between the composition of the spectrum of certain parts of the corona and the spectrum of comets. It was part of my plan to examine this correspondence, as is shown by a note drawn up by me long before the eclipse, and which I read to my colleagues when we compared our respective reports. It is a matter which ought to be verified with the greatest care in future eclipses. However, I leave to Mr. Tacchini the task of developing his observations.

"It will be seen from my report, that the principal object of my observations was to decide one point of the composition of the spectrum of the corona which

[1] Mr. Trouvelot observed, near the close of totality, a star which he describes as 'bright, and of a pronounced red color;' but, by some misunderstanding, its position was not recorded by the special attachments to the circles above described. Its position, therefore, cannot be determined, nor the question of its identification be positively settled. The observer announces (*Comptes rendus*, Sept. 17) that he has re-examined the region, and finds no star of the corresponding magnitude and color in the vicinity of the approximate position which he was able to assign to it. "Although," he adds, "the absence of a red star as bright as that which I observed in the eclipse seems quite naturally to lead to the conclusion that the body in question is no other than an intra-mercurial planet, yet as the most necessary elements, such as the position and a disk or a sensible phase, are wanting in my observation, I think I ought to suspend, for the present, my conclusions upon the probable nature of the body."

[2] First pointed out by Dr. C. H. F. Peters (*Astron. nachr.*, nos. 2253 and 2254).

has always seemed to me very important; viz., whether the light of the corona contains an important proportion of solar light. The result surpassed my expectation in this matter. The Fraunhofer spectrum, so complete as I witnessed it at Caroline Island, proves, that, without denying that a certain part is due to diffraction, there exists in the corona, and especially in certain parts of the corona, an enormous quantity of reflected light; and as we know, besides, that the coronal atmosphere is very thin, it must be that in these regions cosmic matter exists in the condition of solid corpuscles, in order to explain this abundance of reflected solar light.

"The more we advance, the more we perceive the complex nature of the regions in the immediate vicinity of the sun; and it is only by persistent and very varied observations, and an exhaustive discussion of these observations, that we can arrive at an exact knowledge of these regions. The great eclipse of 1883 has allowed us to take a step forward.

"*Photography of the corona.* — The result of the studies of the photographs will be given later; for they require a thorough examination, since they record many most interesting phenomena. I will simply say at present, that these photographs show a corona more extended than that given by telescopic examination, and that the phenomenon appeared well defined and steady during the duration of totality.

"*Luminous intensity of the corona.* — I had prepared a photometric measure, by photography, of the luminous intensity of the corona. This experiment showed that at Caroline Island the illumination given by the corona was greater than that of the full moon. The exact numbers will be given later. It should be noted, that this is the first time that an exact measure of the luminous intensity of this phenomenon has been made."

The remainder of the report gives an account of the return journey of the members of the expedition. They visited the volcano of Kilauea on the island of Hawaii, and passed a night in the crater on the edge of the lava lake. Mr. Janssen made some experiments, which, he states, "show some curious coincidences between these volcanic phenomena and those of the solar surface. I was able, also, to obtain the spectrum of the flames which issue from the lava, and to establish in them the presence of sodium, hydrogen, and the carburetted compounds." W. U.

THE HIMALAYAS.[1]

MY predecessor, Sir Richard Temple, selected for the subject of his address to this section last year, 'The central plateau of Asia.' Following him in a measure over some of the same ground, I have selected the mountain region south of the Central Asian highlands, viz., the Himalayas, and more particularly the western portion of that range, as the subject of this paper. I propose considering this mountain chain with reference to its physical features, past and present, and consequently with reference to its geological history, so far as that relates to later tertiary times; i.e., the period immediately preceding the present distribution of seas, land, rivers, and lakes. It is not, however, my intention to enter very deeply into the purely geological branch of the subject.

The Himalayas, the highest mountains in the world, comprise, strictly speaking, only the snowy range seen from the plains of India, bordering upon the course of the Ganges; but we might, I think, use the term in an extended sense, so as to include that which we may call the north-western Himalaya, north of the Punjab, and also the eastern Himalaya, bordering on Assam. The orography of this mountain mass has been recently ably handled by Messrs. Medlicott and Blanford;[1] and I follow them in all their main divisions and nomenclature, which are based upon a thorough understanding of the rocks of the country. Some line must be selected where the term 'Himalaya' must cease to be used, and this cannot be better defined than by the valley of the Indus from Attock to Bunji. On this line we find the great bending-round of all the ranges. To the mountains north of the Indus, on its east and west course, the name 'Himalaya' should certainly never be applied. For this north-west, trans-Indus part of the Asian chain we have the well-known name 'Mustagh,' so far as the head of the Gilgit valley; the 'Hindu Kush' being an excellent term now in common use for its extension to the Afghan country.

The observations made by many of the assistants of the Indian geological survey, more especially by Stoliczka, and more recently by Lydekker, in the Himalayas, combined with those made by myself in the same region, have, when considered in conjunction with the ascertained strike of the granitoid or gneissic rocks, led me to separate the great Central Asian chain into the following five principal divisions, with some minor subdivisions: —

1. The main or Central Asian axis, Kuenlun.
2. Trans-Himalaya.
3. Himalaya.
4. Outer or lower Himalaya.
5. Sub-Himalaya.

In our present ignorance as to the composition of the chain eastward from the Sutlej, we cannot attempt to lay down there any axis-lines of original elevation; but the separation of the line of highest peaks into one range, and the water-parting into another, is an acceptable solution of the physical features, as at present known, of this part of the chain. I think, however, that when this ground is examined, it will resolve itself into a series of parallel ridges, more or less close, and oblique to the line of greatest altitude as defined by the line of high peaks, crossing diagonally even the main drainage-line of the Sanspu; just as we see the Ladak axis crossing the Indus near Hanlé, or the Pir Panjal that of the Jhelum. Sir Henry Strachey's conception of the general structure was the soundest and most scientific first propounded.

[1] Abstract of an address by Lieut.-Col. H. H. GODWIN-AUSTEN, F.R.S., F.G.S., F.R.G.S., etc., president of the section of geography of the British association.

[1] A manual of the geology of India, 1879, p. 9.

He considered it to be made up of a series of parallel ranges running in an oblique line to the general direction of the whole mass, the great peaks being on terminal butt-ends of the successive parallel ranges; the watershed following the lowest parts of the ridges, and the drainage crossing the highest, in deep gorges directly transverse to the main lines of elevation.

We can, in a measure, exemplify the structure of the Himalaya by that of the bones of the right hand, with fingers much elongated and stretched wide apart, of which the wrist and back may represent the broader belt of granitic rocks of the eastern area; the thumb and fingers, the more or less continuous ridges of the north-west, some less prolonged than others to the north-west, such as the Chor axis, which may be represented by the thumb, terminating on the southern margin near the Sutlej. The left hand placed opposite will represent the same features to the west of the Indus. We will even carry this simile farther, and, as a rough illustration, suppose the intervals or long basins between the fingers to be filled with sedimentary deposits, and the fingers then to be brought closer together, producing a crushing and crumpling of the strata. At the same time, an elevation or depression, first of one or more of the fingers, then of another or of the whole hand, has taken place, and you are presented with very much what has gone on, upon a grand scale, over this vast area. As these changes of level have not taken place along the whole range from east to west in an equal extent, but upon certain transverse or diagonal lines, undulations more or less great have been the result; and some formations have attained a higher position in some places than in others, producing, very early in the history of these mountains, a transverse system of drainage-lines, leading through the long axial ridges.

The last efforts of these rising, sinking, and lateral crushing, and, as I believe, very slowly acting forces, are to be seen at the southern face of these mountains, in the tertiary strata that make up the sub-Himalayan axis (Sivalik), — a topographical feature which is most striking by reason of its persistence and uniformity for some 1,600 miles. From Assam on the east, to the Punjab on the west, bending round and extending to Scinde, this fringing line of parallel ridges is found at the base of the Himalayas; sometimes higher, sometimes wider, often forming elliptical valleys. Only in one part of the belt, east of the Teesta, are they absent altogether for a distance of fifty miles. These formations are of vast thickness, and, in the Punjab, cover an area of 13,000 square miles. The whole of this material has been derived from the adjacent Himalayas, and has travelled down valleys that have been excavated in pre-tertiary times. This points to a slow subsidence of the whole southern side of the mountain mass, deposition generally keeping pace with it, broken off by recurring long intervals of re-elevation.

The next most interesting feature connected with the former distribution of land and sea is that these sub-Himalayan formations are fresh-water, or torrential, showing that since nummulitic or eocene times the sea has never washed the base of the Himalayas. In fact, there is no evidence of this from the gorge where the Ganges leaves the mountains up to the base of the Garo Hills. I believe that from Assam to Scinde there once existed a great river, receiving its tributaries from the Himalayas, partly a land of lakes and marshes, the home of that wonderful mammalian and reptilian fauna which Cautley and Falconer were the first to bring to light. The southern boundary of this long alluvial plain was formed by the present peninsula of India, and probably of the extension of the Garo and Khasi Hills westward to the Rajmahal Hills. Depression has been considerable in the neighborhood of Calcutta, nearly five hundred feet. At three hundred and eighty feet, beds of peat were passed through in boring; and the lowest beds contained fresh-water shells. The beds, also, were of such a gravelly nature as to indicate the neighborhood of hills, now buried beneath the Ganges alluvium. This is precisely the appearance of the country above Calcutta, on approaching the present valley of the Brahmaputra. The western termination of the Garo Hills sinks into these later alluvial deposits; and along the southern face of the range, up to Sylhet, the waters of the marshes during the rainy season wash the nummulitic rocks like an inland sea, and point to the very recent depression of all this area. The isolated granite hilltops jutting up out of the marshy country from Dhoobri to Gwalpara, and on to Tezpur, all testify to the same continuous depression here. It is exactly north of this that we find the Sivalik formations, absent at the base of the Himalayas.

This gradual depression of the delta of the Ganges, the relative higher level of the water parting and shifting of the Punjab rivers westward, appear to be only the last phase of that post-pliocene disturbance which broke up the Assam sub-Himalayan lacustrine system draining into the Arabian Sea. Zoölogical evidence, which I cannot here find space to quote, is also in favor of this former connection of the now separated waters of the Ganges and Indus basins, and the hill-tracts of the Garo and Khasi Hills with peninsular India.

Within the mountains in the old rock basins — and these are analogous to the valleys of the Alps — are pliocene and post-pliocene beds of great thickness, but of fresh-water origin; the remnants of which are to be seen in Kashmir and Scardo at intervals, along the valley of the Indus, and that large, now elevated, accumulation at the head of the Sutlej River in Hundes, — all in the more sheltered portions of the valley basins, untouched by the denuding action during the glacial period. The extent and displacement of the upper pliocene beds in north Italy and here are very similar. Often abutting horizontally against the mountains, they are in other places found tilted at considerable angles on the margin of their original extension. When we examine their contents, we find that the fauna of that time, in Asia as well as Europe, was more African in character, and included the hippopotamus, crocodiles, and tortoises; of which, the common crocodile, the gavial or long-snouted species, and an Emys, have survived the many geological changes, and still inhabit the rivers and low grounds of India to-day. The fresh-water shells are the same now as then. Many species of antelope lived in the neighboring plains and uplands. The elephant was there in the zenith of its existence, for no less than thirteen species have been found fossil in northern India.

If we now turn to Europe to compare formations of similar age, Lombardy and the valley of the Po, with the southern side of the Alps, present to us somewhat similar physical features. A large area of about the size of the north-west Punjab, once a part of the miocene sea, is occupied by a remnant of rocks of that age, considerably elevated and tilted, but not to such an extent as those of the Himalayas. Near Turin these dip towards the mountains; and a very short examination shows the undoubted glacial character of some of the beds; and, as the whole formation is marine, their large sharply angular material, much of which is jurassic limestone, was probably transported from the adjacent mountains by the agency of ice in a narrow sea.[1] After the great crushing and alteration of the previous outlines of the whole country, another sea filled the basin of the Po, and pliocene deposits were laid down in a sinking area extending to the base of the mountains all round the new bay or gulf. Re-elevation again set in, and with it, or soon after it, the advent of another and the last glacial period.

Before the last great elevation of the alpine chain, the whole line of seacoast, therefore, ran even high up the long deep valleys of Maggiore, Como, Garda, etc. Then came the gradual but uneven elevation of the whole area, including the miocene hills south of the Po; and lacustrine and estuary conditions prevailed over much of the plain country. The lapse of time was probably enormous; and, as the land rose and the sea retired, the climate gradually became cooler, and ushered in the glacial period. With the change and the increased volume of the mountain torrents, the destruction of the upraised marine pliocene beds commenced, and finally culminated in the extreme extension of the glaciers, even into the plains. The denudation of this formation has been enormous along the base of the Alps, and only mere remnants are to be found. Their preservation is due to their being in position where the great denuding force, the ice, has been unable to touch them: in other instances the early deposition of moraine matter upon them has acted liked a shield, and prevented their entire destruction.

The scattered remnants of the pliocene formation south of the Alps show well how soon a great formation may be completely destroyed by denuding forces.

[1] No trace has been observed of this glacial period in the miocene of India. The most lofty portions of the chain had not then attained a greater elevation, probably, than 14,000 to 18,000 feet, and the outer axis-lines far less. However, in the tertiary beds (middle eocene?) of the Indus valley, below Leh, such conditions are indicated by Lydekker (*Memoirs of geological survey of India*, vol. xxii. p. 104, which I have received since this address was sent to press).

It is an established fact, that the great valleys of the Alps and Himalaya existed much in their present form during miocene times; and they may owe their excavation partly to the glacial action of that period, when these mountain slopes rose from the plain or margin of the ancient sea, far in front of the present line of slope, and were far higher than now.

It is not improbable, that, during the earlier extension of the glaciers into the Maggiore basin, the sea still had access to it. This would have greatly aided in the removal of the marine deposits, and then the deeper erosion of its bed near the Borromean Islands, so well put forward by Sir Andrew Ramsay. When we see the gigantic scouring which glaciers have effected in the hardest rocks on the sides and bottoms of valleys, when we know for certain the enormous thickness they reached in the Alps, I do not doubt for a moment their capability of deepening a rock basin very considerably, or their power to move forward over and against slopes so low as 2° to 3°.[1]

Passing from the glacial action displayed in the outer Alps to that in the Himalaya, we find ample evidence of a period of great extension of such conditions, first in the erratics of the Attock plain and the Potwar, lying fifty to sixty miles from the gorge of the Indus at Torbela. We have again the fact that in Baltistan, in the Indus valley, glaciers have twice descended far beyond their present limits, first down to Scardo itself, and then to some thirty miles below their present limits; while the glaciers of Nanga Purbet, towering above the Indus some 22,000 feet, must have descended into the bed of that river.

In fact, examples of the former extension of glaciers are wide-spread along the chain of the Himalayas from west to east. True moraines and moraine-mounds, at 16,000 feet on the north side of the Baralasa Pass, attest the presence of glaciers on the elevated plain of Rukshu, where now the snow-line is over 20,000 feet. Drew gives much valuable information regarding their former size. On the east, in Sikkim, Sir Joseph Hooker has described moraines of great height (700 feet) and extent. Still farther south and east, in the Naga Hills, a short period of greater cold is indicated by the moraine detritus under the loftiest portion of the Burrail range, in latitude 25° 30′.

Whatever may have been the length of the glacial period in the Alps, — and it was very considerable, — in the Himalayas it cannot have been so long and so general, although to a certain extent contemporaneous.

In the Alps, glaciation meets the eye on every side; and the mountains, up to a distinct level, owe their form and outline to its great and universal extension. In the Himalayas it is difficult to trace polished surfaces or striae markings, even in the neighborhood of the largest glaciers that are now advancing in

[1] There appears to be too great an advocacy, on the one hand, of ice-action having done all the work of denudation; while, on the other, some writers consider this to have been extremely limited. It is the combination of the two forces, I think, that effects so much, and in so different a manner and degree.

full activity. Although of such great length, these Himalayan glaciers could never have reached the enormous thickness which the earlier alpine glaciers attained.

Two periods of glacial extension are clearly defined, separated by a milder interval of climate. During the earlier glacial period the Indus valley was filled with those extensive lacustrine and fluviatile deposits, mixed with large angular *débris*, such as we see at Scardo, which may be coeval with the extreme extension of the alpine erratics, so far as the miocene hills south of Turin.

The second period followed after a long interval of denudation of the same beds, and would correspond with the last extension of the great moraines of Ivrea, Maggiore, Como, etc., followed by a final retreat to nearly present smaller dimensions. Nowhere on the south of the Himalaya do we find valleys presenting any features similar to those of the southern Alps, particularly on the Italian lakes, which are, I believe, the result, in the first place, of marine denudation, succeeded by that of depression, and finally powerful ice-action.

This attempt to bring before you some of the great changes in the geography of Europe and Asia must now be brought to an end. I am only sorry it is not in more able hands than mine to treat it in the manner it deserves, and in better and more eloquent language; but it is a talent given to but few men (sometimes to a Lyell or a Darwin) to explain clearly and in an interesting form the great and gradual changes the surface of the earth has passed through. The study of those changes must create in our minds humble admiration of the great Creator's sublime work, and it is in such a spirit that I now submit for your consideration the subject of this address.

FRENCH GEOGRAPHICAL EXPLORATIONS.[1]

SINCE the last re-union of our societies, we have seen the complete success of the French expedition to observe the transit of Venus. This phenomenon, important for astronomy, which requires a unity of measurement of the celestial spaces, should also be of interest to geography, for the unity sought is the correct distance of the sun from the earth. We already know the distance of the moon from the earth, about ninety-six thousand leagues, of which I can easily form an idea, as it is the distance I have traversed by land and sea since 1854, the time that I commenced my isthmus travels. "The French expedition sent to foreign parts to observe the transit of Venus has obtained a great and well-earned success, of which they are justly entitled to be proud." So says one of the most eminent French *savants*, Mr. Dumas, who has largely contributed to that success.

It now remains, and it is not the least difficult part of the task, to compare the results obtained, in order to submit to a delicate analysis the infinitesimal differences, which correspond to errors of hundreds of kilometres, in the distance sought. *Savants* have, it is true, more than a century to make use of the observations of 1882; for the phenomenon will not take place again till the year 2004.

At the extreme east of Europe we find in process of execution a work whereby modern science shall again assert her superiority by a success which the ancients gave up. Through the initiative of Gen. Türr, the Isthmus of Corinth is at this moment being cut, which will shorten by about two hundred and fifty kilometres, on an average, the voyage between the eastern and western parts of the north of the Mediterranean. In the course of the present year, the two plains at the side of the Gulf of Aegina and the Bay of Corinth will be cut away, and workmen will attack the solid mass of forty-seven metres, which it is desired to cut away to eight metres below the level of the sea. It is, *in minimo*, the cut of the Isthmus of Panama, the length of which is seventy-three kilometres instead of six kilometres; that is, double the distance between the garden of the Tuilleries and the Arc de Triomphe in the Étoile at Paris.

Some distance north of Corinth, there is unfolding another episode of the struggle between these two rival powers, the earth and man. There the work has begun which will transform a marshy lake into fertile plains. In a few years, broad Lake Copaïs will suffer the fate of Lake Fucino, Lake Fessara, Lake de Harlem, and the marsh of Pinsk.

There is still a fourth isthmus to cut. The king of Siam has authorized a survey for a maritime canal on his territory, between the Indian Ocean and the seas of China and Cochin China. The object is to escape the dangerous Strait of Malacca, and gain six hundred leagues from Europe to the extreme east.

In Arabia, Mr. Charles Huber, who two years ago successfully accomplished a mission for the minister of public instruction, has resumed the journey he made so fortunately; but he wishes to proceed farther than at that time he was able. At present he is at Palmyra, copying rare inscriptions; and, this completed, he will set out for Hall, for the Nedjed, and perhaps farther if circumstances favor his energy and firm will. The Arabian peninsula is one of the fields of study where French science has a long standing and very honorable record. We can but hope that Mr. Huber may show himself worthy of his predecessors.

In the extreme east, Cochin China and Tonquin have been most recently explored by the French, and I should like to recount the discoveries of Dr. Néis and Lieut. Saptans at the sources of the Donnaï. The former is at present *en route* for the region which he has already visited. Ethnography and anthropology, which are his special objects of study, will no doubt acquire new information, full and exact, from Dr. Néis's present journey. The study of the ancient civilizations and of epigraphy engages the attention of Capt. Aymonier, who has just finished a fruitful exploration at Cambodia. The parcels recently sent to the museum of the Trocadero testify to the importance of the results gathered by Mr. Aymonier, who is one of the most distinguished, perhaps the most distinguished, representatives of Indo-Chinese

[1] Address by FERDINAND DE LESSEPS before the geographical congress at Douai. Translated from *Cosmos-les-mondes*, vi. 91, 121.

students. Tonquin is known to us only by its delta, which has been an object for fine work by French hydrographic engineers. Beyond, to the right and left of the Red River, surveyed first by Mr. Dupuis, and afterward by Mr. de Kergaradec, we know nothing, or almost nothing, with certainty. Last year, in the face of dangers to which his companion Mr. Courtin succumbed, Mr. Villeroy-d'Augis made an examination which has given us the first rough sketch of the course of the Black River. The mineral resources of Tonquin, on the coast at least, have been ascertained by Mr. Fuchs in a recent voyage; and this distinguished engineer seized the opportunity to gather the first materials of the geological constitution of that part of Anam, as well as the rest of Indo-China. The events which are taking place at Tonquin we cannot examine; but they will lead, doubtless, to a state of things which will render journeys practicable. Mr. Harmand, who was conspicuous at the beginning of his career for his important explorations, will doubtless lend his co-operation to the French explorers who are about to set out for these parts of Asia.

If we turn our eyes toward Africa, we see several Frenchmen engaged in the contest which will definitely free this continent to science in opening it to civilization. For all Algeria the time of exploration, properly so called, is past. The country surveyed by geodesians is open to military topographers, who will give us a representation of it as beautiful and as correct as the map of France. At the instigation of our colleague, Col. Perrier, chief of the geographical service of the army, the surveys are being followed up, and the publication of the work will soon begin, to be continued without interruption.

For the extreme south of Orange, geography had only a series of isolated guide-books, with a few descriptions carefully made, but limited. Wars have drawn to this territory a troop of surveyors, whose campaigns have resulted in a survey, based on a triangulation, of all the country between Mecheria, the terminus of the Orange railroad, and the great oasis of Figuig. I certainly do not err in asserting, that the officers who have accomplished this difficult and dangerous work, Capt. de Castries and Lieuts. Brosselad and Delcroix, deserve well of geography.

In France the events in Tunis have been watched with much interest. Geography will gather the first fruits from these events. Here, again, we were reduced to information confined to the surroundings of Tunis, and certain points of the regency, and very estimable itineraries, but whose loose threads circumscribe vast regions left blank on the charts or timorously sketched. Following our exploring column, skilful surveyors have continued to fill up these gaps. Their records have been completed, and arranged methodically by officers attached to the geographical service of the army. If I am correctly informed, this service now possesses the materials for a large map, on which Tunis will appear in a decidedly new light, with the arrangement of its valleys, the character and projection of its prominence, and the precise position of its centres of population.

The minister of public instruction, on his part, has organized an expedition for the scientific exploration of Tunis. Already, from an archeological standpoint, important discoveries have been made on this ground, where exist the relics of several great civilizations. The learned work of Mr. Charles Tissot, the correspondent of the institute, formerly ambassador to London, will be, as far as concerns the Roman epoch, a fine and substantial introduction to the investigations undertaken. Our protectorate will revive the Tunis of the past, while it creates a Tunis of the future. Here is the opportunity to mention the scheme in regard to the interior African sea, rendered practicable by the perseverance, disinterestedness, and knowledge of Commander Roudaire. Other surveys, executed during this campaign by the engineers whom Capt. Henry leads, fill up the gaps in the previous works, complete the information regarding the banks of the Senegal or its tributaries, and prepare the route towards Bammakoo for the next expedition. This time a larger party must be sent out than on preceding expeditions, and they ought to advance farther. After having, while the road was making, removed, without striking a blow, the chief of Moorgoola, who was hostile to us, and after taking by assault the village of Daba, where advance was opposed, the column finally arrived at Bammakoo, Feb. 1; and, on the 7th, Col. Borgnis-Desbordes laid the first stone of the fort. From this first journey, under the direction of Capt. Bonnier, the surveyors, who included some experienced officers (Capt. Vallière, for instance), have brought back very complete results, extending over the ground between Kita and Bammakoo, and in the surrounding countries, Fooladoogo, Gangara, and Bélédoogoo. They have also contributed largely to the geography of a country lately only touched by a few explorers.

I do not know that you will agree with me; but I see, in these three expeditions of Col. Borgnis-Desbordes, a very interesting moral side. Let us imagine a handful of men setting out from Calais, to reach, in a certain time, the neighborhood of Vienna or Budapest: let that be the distance. You know the difficulties that were encountered. After a long journey in barges on the Senegal, it was necessary, under a burning sky, to make weary marches across districts covered with high grass or with thorny plants, and across calcined plains. They must scale steep acclivities, pass through innumerable swamps, slimy and malarious. They must venture through narrow paths on the sides of cliffs into defiles, — veritable Thermopylae, where a few might stop an army. After the departure, fever attacked the column, and each day claimed its victim. Nevertheless their courage did not fail. At times they were compelled to fight, and to the ravages of fever was added the fire of an enemy who could not be disregarded. Sometimes they stopped; but then they were obliged to work without relaxation in building a fort, for the season was advancing. Three times in succession our soldiers, under such circumstances, have penetrated to the heart of the western Soodan, led by a man hardened by bravery. He was commissioned to push to the Niger the line of stations which should establish our claims. He advanced straight to his object: the difficulties of detail discouraged him no more than the unforeseen disconcerted him, or than danger frightened him. Thus supported by officers worthy of their leader, and by soldiers full of devotion, he has accomplished his whole task. The little phalanx re-embarked on the Senegal, ragged, worn out, emaciated, and reduced more than a third; but they had nobly and simply performed a grand deed.

Before leaving the Senegal, I would not forget to mention the efforts of Dr. Bayol to contribute to the geographical knowledge of these countries. You may already see, on the map of Africa, very carefully prepared by Capt. Lannoix for the geographical service of the army, the line of travel which, in his preceding journey, Dr. Bayol followed between Timbo and Medina, in a country still unknown. At present he has just traversed more than three hundred and sixty kilometres in a country, also left blank, or nearly so, on the maps. Lieut. Quiquandon, his companion, gives us a survey of the line of march, which, retreating from the Niger, will join the line of march of the Austrian traveller, Lenz, on his return from Timbuctoo. This is an important paper for geography. Mr. Bayol has arranged so that, up to Ségala, the states through which he has passed have accepted the protectorate of France. Besides the treaties to this effect, he brings back collections which will contribute largely to the geological and zoölogical description of this zone of the African continent.

If, now, we turn farther south, as it were symmetrically with the Senegal and the Niger, we shall come to the Ogowé and the Kongo. Here, too, we find a man firmly resolved to secure for France a country worthy of her on the banks of the Kongo. Here Mr. de Brazza (for you all have recognized to whom I refer) is at work. As I speak to you now, he must be *en route* for the great river, the inhabitants of whose banks will, without doubt, gladly welcome back an explorer who was always full of justice and humanity toward them. It is said that difficulties exist between Mr. de Brazza and Mr. Stanley. The situation has, I think, been much exaggerated. Let us not forget that the origin of the enterprise to which Mr. Stanley devotes his energy is due to his Majesty the king of Belgium, and was formed for the purpose of sparing the travellers of all nations a part of the dangers of their enterprises. The generous founder of the International African association will certainly do all in his power to establish kindly relations between two of the most illustrious pioneers of civilization and of science. Besides, Mr. de Brazza would not falsify by his acts the words which he uttered at the last banquet of the Société de géographie, when he received from the hands of his fellow-explorers the French colors: "There, where I shall be commissioned," he said, "to carry the colors you present to me, they will be a sign of peace, of liberty, of science, and of commerce; they will be kind and compassionate with the weak and courteous, but firm with the strong." Let us, then, be patient. Let us not expect, that, under the present circumstances in equatorial Africa, evolution and progress can be very rapid. Let us also not forget that we owe all respect to the claims of our friends the Portuguese to certain regions bordering the Kongo.

I would not neglect to invoke your sympathies for the calm courage with which, in western Africa, on the route of the great lakes, Mr. Bloyet accomplished the mission placed upon him by the French committee of the International association. The travellers of several nations could tell us what protection they have received, what support, what counsels, they have obtained, from Mr. Bloyet. It is his courage which assists in the noble task of making the French name loved and respected by the natives of these hostilely inclined countries. Still nearer the lakes are our Catholic missionaries, some of whom have already given to geography useful data of the countries in which they are engaged. The same is being done, also, by French evangelical missionaries farther south, in the region of the Lessooto. One of them, Mr. Kurger, is busily at work, perfecting a map of the country. We hear little from Mr. Victor Giraud, who is proceeding in the direction of the great Lake Banguelo, south of which Livingstone died. Our best wishes accompany the young explorer, whose character, knowledge, and equipment warrant us in expecting much of him.

Before leaving Africa, I wish to mention one who has already proved himself a distinguished traveller. I refer to Mr. Georges Rexoil. He is engaged at the south in the large peninsula of the Comalis, which he has explored at the north with so great success. If he succeeds in penetrating into this unknown and formidable region, he will certainly garner a new scientific harvest not less rich than the preceding.

Allow me to approach America, and briefly speak to you of the cutting of the American isthmus between Colon and Panama. Two years have been spent in preparing the field of battle. The entire line is occupied by our workmen and machines. The director, Mr. Dingler, engineer-in-chief, who has just set to work our corps, has returned to Paris to report both his plans and his preparations to inaugurate the canal in 1888. In the course of this year, till July of the year following, he will each month remove from the cut a million cubic metres of *débris*, and from that date two million cubic metres a month, making twenty-four million a year. The enterprise will be finished during the following four years. I intend to visit this magnificent work early in 1884, and I hope that delegates from our geographical societies will accompany me. I must not leave Central America without respectfully referring to the successful perseverance with which one of the most devoted missionaries sent out by the minister of public instruction, Mr. Désiré Charnay, has explored the ruins of Yucatan. His researches and discoveries, together with his inferences, certainly throw unexpected light on the former obscurity of the American civilizations.

The feeling of sadness which we all experienced, on learning the terrible ending of the expedition of Dr. Crevaux, is still with us. Since then, only vague rumors have reached Europe in regard to this tragedy in the heart of South America. Mr. Thouar, a young French traveller, is now facing dangers of every description, in his attempt to discover the remains of our unfortunate countrymen. Gathering information, and supported by good will on all sides, he is making slow but regular advance. We can only hope that he will attain his object; while we do not ignore the dangers to which he so generously exposes himself in trying to penetrate, accompanied only by an interpreter, a country inhabited by Indians who overthrew the mission of Dr. Crevaux. Our warmest hopes for success go with him in his noble undertaking.

At the extreme south of America, at Tierra del Fuego, a French mission, established a year ago, has been commissioned, in accordance with the international programme, to make meteorological and magnetic observations. We look forward to the next return of the guard-ships, whose work, accomplished under the direction of Mr. Martial, commander of the Romanche, will form a valuable contribution to the physical geography of these parts.

Finally, after a successful expedition to the northern latitudes, in the polar seas, which, since the voyage of the Recherche, have scarcely seen the French flag, one of our countrymen, Mr. Charles Rabot, is at present continuing in Russian Lapland the investigations which he began in Sweden. The region which he includes still offers a vast field for geographical and geological study.

Such, my dear colleagues, are the chief means by which the advance of French geography, in its most active and most persistent form is disclosed. I might still speak to you at length, but we must not deserve the reproach of weaving for ourselves crowns; and, in the noble titles I have just recalled to you, we should see rather the obligations they place upon us than the satisfaction which they bring to our proper national pride.

LETTERS TO THE EDITOR.

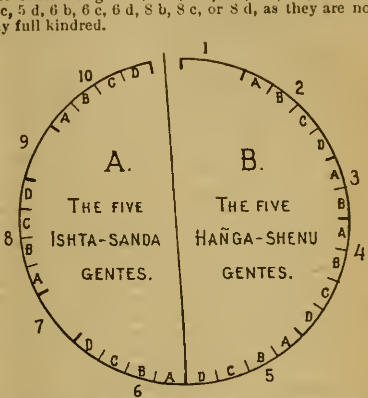
Marriage laws of the Omahas and cognate tribes.

THE Dakotas or Sioux still have mother-right in some of their tribes, and I cannot say how far the following statements apply to them; but the Omahas, Ponkas, Kansas, Osages, and others have father-right, and are governed by the principles here given, with one exception, — the Kansas have recently disregarded their laws, and have begun to marry in the gens.

The Omaha tribe is divided into ten gentes or clans, each gens having its special place in the tribal circle. In the figure the numerals denote the gentes, and the letters the sub-gentes.

Suppose that I belong to 1, the Elk gens, which is also my father's gens: I cannot marry any female of that gens. If my mother belongs to 2, a buffalo gens, I cannot marry any woman of that gens.

Suppose that my father's mother belonged to 3 a, my mother's mother to 4 a, my father's father's mother to 5 a, my mother's father's mother to 6 a, my father's mother's mother to 7, and my mother's mother's mother to 8 a: I cannot marry any women of 3 a, 4 a, 5 a, 6 a, 7, or 8 a, if I know of their relationship to me; but I can marry any women of the other sub-gentes, 3 b, 3 c, 3 d, 4 b, 4 c, 4 d, 5 b, 5 c, 5 d, 6 b, 6 c, 6 d, 8 b, 8 c, or 8 d, as they are not my full kindred.



I can also marry any women of 9 or 10, if they are not forbidden to me for other reasons; that is, if they are not my affinities, such as the wives (*real* or *possible*) of those whom I call my fathers, mother's brothers, grandfathers, sons, sister's sons, or grandsons.

Principles considered. — 1. Marriage in the father's gens forbidden. 2. Marriage in the mother's gens forbidden. 3. The regulation of the sub-gens. 4. Potential or possible marriages must always be kept in mind, and kinship terms are based upon them.

J. OWEN DORSEY.

Washington, D.C.

Francis Galton's proposed 'Family registers.'

Mr. Francis Galton is now planning to push his inquiries into the laws of heredity upon a more extensive and systematic scale than ever before. The success of his early work, 'Hereditary genius,' led him to observations in a wider field, which extended over several years, and were collected in his very valuable book, 'Inquiries into the human faculty,' which appeared last spring. His new proposal involves the collection of a large number of family biological histories, to extend over three or four generations, and to be obtained by circulating an exhaustive schedule of printed questions. The writer has just received a copy of the latter, together with a prospectus of the general plan, which Mr. Galton will call 'Family registers.' The revised schedules will shortly be ready for distribution. In the mean time an abstract of the prospectus and schedule may be given.

Mr. Galton foresees the difficulties which he will encounter; and, appreciating that the obtaining of accurate family histories of health and disease among laymen is almost out of the question, his prospectus appeals principally to the medical profession. Among doctors, all inherited disease is a disease, and not necessarily an hereditary disgrace, as most of the laity are apt to regard it. In this class, also, the scientific interest attached to inherited imperfections of physique or mind often overbears every other feeling. At all events, although the *anonymous* will be strictly maintained, Mr. Galton seems to expect that few non-professional persons will be ready even to put upon paper the rather searching register of replies.

The narrowest scope of inquiry, to be of any value, must embrace three generations; but the results will be far more reliable when they cover four. The latter would relate to at least thirty-six persons, which Mr. Galton reckons as follows: "On the side of the contributor there are his two parents, four grand-parents, an average of three uncles and aunts on each of the two sides, three brothers or sisters, and himself: this makes sixteen persons. There is another set of sixteen for the relatives of his wife in the same degrees. Lastly, I allow an average of four children." A single family register of this size, therefore, at least involves the filling-out of nearly thirty-six of the schedules, which will be no light task, even with the most favorable opportunities of obtaining information. The persons whom Mr. Galton anticipates will assist him the most are young physicians, married and with children. In case the grand-parents are living, their field of information will naturally be very wide. Partly as an inducement to men of this class to undertake such a task, partly as a pecuniary return for the time which it must necessarily occupy, a series of prizes will be offered, amounting, altogether, to £500, including, probably, ten prizes of £25 each, and others not to exceed £50 nor fall short of £5. The returns are to be sent with mottoes, but no signature; the name and address to be enclosed in a separate envelope bearing the motto. The merit of the returns will be estimated by the clearness and exhaustiveness of statement, the number of generations treated of, and the appendix (see beyond).

The returns asked for are in abstract as follows: 1. A separate and full biological history of each member of the family in the direct line of ascent; 2. A very brief statement of the main biological facts in the lives of members of the collateral lines of ascent, that is, of the uncles and aunts, great-uncles and great-aunts, etc.; 3. A full description of the main sources of information for 1 and 2; 4. An appendix which will include an analysis of the medical history of the family, showing the peculiarities which have, and have not, been transmitted, and their identical or changed form. All communications to be addressed to Francis Galton, 42 Rutland Gate, London (S. W.), England.

Mr. Galton has reduced the collection of statistics to a fine art, having arranged this schedule with the greatest ingenuity. The near and remote relationships are indicated by simple symbols; and, by means of horizontal and transverse columns, the required facts can be condensed into an astonishingly small space. Each schedule is intended to cover six periods in the life of the person described, from childhood to late in life, and at each of these periods to give a statement of, *A*, conditions of life; *B*, personal description; *C*, medical life-history. Under *A* are such topics as town or country residence, and sanitary influences generally. Under *B* are descriptions of feature and physique, of habits of work and muscular force and quickness, keenness of sight and dexterity, artistic and allied capacities, peculiarities of character and temperament. Under *C* are diseases, accidents, malformations, age at death, etc. Other facts solicited are, order of birth, age at marriage, number and sex of children. All this is upon one side of a double sheet, and relates to one person in the direct line of ascent. Upon the reverse of the sheet, similar inquiries are made in the collateral lines, or among the brothers and sisters of the person described.

Mr. Galton believes that the interest in each family register will increase rapidly as the investigation goes on, and family histories will result of far more accuracy than could be collected in any less methodical system. The scheme is so much more comprehensive than any thing which has preceded it, that it certainly promises us a much deeper insight into the laws of heredity than we have at present. The moral value of this, and, in fact, of much of the life-work of this author, lies in the dissemination of the stern truth, which is as old as the Mosaic law, that the character of the next generation depends, perhaps, less than we are apt to think upon the education and training we prepare for them, and more upon the life-conduct of the present and the preceding generations.

HENRY F. OSBORN.

MAUDSLEY'S BODY AND WILL.

Body and will: being an essay concerning will in its metaphysical, physiological, and pathological aspects. By HENRY MAUDSLEY, M.D. London, *Kegan Paul, Trench, & Co.*, 1883. 8+333 p. 8°.

CONSIDERED with respect to its announced purpose, this book is one of the most unfortunate and disappointing that we have ever seen bearing the name of an able man on the title-page. The purpose, as set forth on the titlepage and in the preface, seems indeed a noble one. Of will, in its pathological aspect at least, Dr. Maudsley has, one would suppose, the best possible right to speak. And we all have so much to learn about all its aspects, that we come to the book, even after previous experience of the author's eccentricities, with hope of getting some real instruction. That the freedom of the will is to be discussed, we learn without fear: for, old as the topic is, an ingenious man may have something new to say about it; and a straightforward statement of the doctrine of determinism, made from the physiological point of view, may well be useful and instructive, even if it should fail to be new. But, with much more interest than he feels in the promised wrangle over the freedom of the will, the student of psychology looks forward to what is promised in the preface, where Dr. Maudsley tells us that he has long been engaged in dealing with "concrete minds, that must be observed, studied, and managed;" that he has been trying to find out "why individuals feel, think, and do as they do, how they may be actuated to feel, think, and do differently, and in what way best to deal with them so as to do one's duty to one's self and them." In consequence, he says, "I have no choice but to leave the barren heights of speculation for the plains on which men live and move and have their being." He desires, then, "to bring home to mental philosophers the necessity of taking serious account of a class of facts and thoughts which, though they are not philosophy, may claim not to be ignored by philosophy." All this means, if it means any thing, that we may expect from Dr. Maudsley some results of his experience with the laws of human will, some concrete psychology, —such, for instance, as, in case of certain phenomena of sensation and memory, Mr. Galton has given us, in the book that we lately reviewed on 'Human faculty.' Mr. Galton's work has been confined mainly to the lower phenomena of mind. How great the gain, if we can get scientific research to give us correspondingly fruitful results about the higher phenomena of mind! We hope, of course, for nothing final, or as yet very exact, in this field: but Dr. Maudsley will surely offer us something; and his announcement is just such as a sober observer of a special class of facts might be expected to make, in case he had found out something well worth telling. As for the author's denunciation of speculation, we need not be haters of philosophy to overlook or pardon that. The most enthusiastic student of general philosophy ought to admit freely the vast importance to him, also, of just such concrete study of mind as Dr. Maudsley announces; and if Dr. Maudsley has found the heights of speculation barren, then surely he will keep off them, and will tell us what he has to tell so much the better. We reserve, then, our own right to study general philosophy if we find it fruitful; and we just now follow him eagerly to the green pastures of concrete psychology, where he is to give us the result of special study.

We are doomed to bitter disappointment. The book consists of three parts. The first, on 'Will in its metaphysical aspects,' fills ninety-eight pages, and contains a restatement of the bare commonplaces of modern thought on the relation of mind and organism, a like restatement of the oldest and most commonplace of the deterministic arguments, a barren criticism of the oldest and most commonplace arguments for free will, and finally, scattered throughout this discussion in all sorts of wearisome digressions, a string of purely speculative reflections, so confused, so full of contradiction, so ill expressed, that they would be unworthy to pass as the thesis of a fairly instructed student of philosophy in his second year's work.

The second part of the book (pp. 99–232, with four pages of notes) opens far more promisingly, with a good chapter on the 'Physiological basis of will.' But thereafter, at once the discussion sinks back into its native confusion. We are to learn about the 'physiological, sociological, and evolutional relations' of the will; and we have a series of the commonplaces of recent discussion, together with another mass of confused speculations, as full as before of digressions. Mr. Spencer, who is not named, is yet several times referred to very severely as a dangerous speculator; but the most obscure expressions of Mr. Spencer's worst moments are bright sunlight to the gloom of these long and tedious sentences, and his speculations are surely as likely to be good as his rival's.

The third part, at last, on 'Will in its pathological relations,' leads us into the light once more. Here, at least, we have a few concrete instances brought together, and generalizations made from facts, and plainly stated. But how little we learn! The space left is short; and the author's lucid interval ends with the beginning of the last chapter, which he entitles 'What will be the end thereof?' and which he devotes to speculations on the way in which human life will degenerate before its final cessation on this planet.

And so, of the whole, only about one hundred pages, or less than one-third of the book, may be considered as having any real relation to the implied promise of the preface. The rest is simply the 'barren speculation' which we were to avoid, or else it is repetition in obscure language of what has many times been said in clear language.

But we must illustrate, for we are aware that a man of Dr. Maudsley's reputation might be expected to do better than we have here represented him as doing. First, then, as to the 'barren speculation.' Surely, if a man desires to let questions alone, he can very easily do so. Yet Dr. Maudsley goes out of his way, in the first part, to write a chapter on the 'Authority of consciousness.' He goes out of his way, we say; for, in so far as concerns his problem of the freedom of the will, the authority of consciousness might have been very briefly and specially treated. But, once having determined to take up the question generally, Dr. Maudsley runs on in this wise. Self-consciousness, he first tells us, is no more immediate knowledge than is the knowledge of external objects through the senses; since the latter knowledge consists of states of consciousness, as well as does the former. This, of course, is Kant's famous 'Refutation of idealism' in a nutshell. But now, both of these kinds of knowledge being knowledge of facts that are in consciousness, we ask what the truth of this consciousness is, or how we shall test its truth. We learn something about this matter farther on, on p. 41, where we find that "there is no rule to distinguish between true and false but the common judgment of mankind," that (p. 42) "the truth of one age is the fable of the next," and that "the common mind of the race in me" — "common sense, which is more sensible than any individual in all cases (save in the exceptional case of a pre-eminently gifted person of genius)" — is the warrant to which we appeal for the truth of all our beliefs. This would look very much as if, in case one is not a pre-eminently gifted person of genius, one must be unable to know whether either he himself or the external world exists, unless he first discover that 'the common judgment of mankind' agrees with him that both do exist. This is a curious reversal of the familiar fashion of reasoning; since the 'mankind' to whom one is to appeal, surely belongs to the external world, to whose existence its 'common judgment' is to testify. Yet we must be doing Dr. Maudsley wrong. One must not take every statement so exactly. His real theory is expressed on p. 45. Here it is: "Every thing which we know is a synthesis of object and subject. . . . Neither *matter in itself* nor *mind in itself* are words that have any meaning. . . . The hypothesis of an external world is a good working hypothesis within all human experience: but to ask whether the external world exists apart from all human experience is about as sensible a question as to ask whether the shadow belongs to the sun or to the man's body; for what an extraordinarily perverse and futile ingenuity it is to attempt to think any thing outside human consciousness. . . . *To say there is an absolute* [the italics are ours], *and to call it the unknowable*, *is it a whit more philosophical than* it would be for a bluebottle-fly to call its extra-relational the unbuzzable?" P. 46 goes on to say, "A separation of subject and object cannot ever be the starting-point of a philosophy that is not a self-foolery." P. 47 adds, that what Berkeley called an idea "is a synthesis, the *ego* and *non-ego* necessary correlate." All this is perfectly clear by itself, much clearer than the text in which it is embedded; and the sense of it is, of course, pure phenomenism, such as Schopenhauer expressed in his '*kein objekt ohne subjekt.*' Matter is for consciousness, and consciousness is of objects. Spencer's unknowable is nonsense, — a product of perverse ingenuity, worthy of bluebottle-flies. One must not attempt to think of any thing outside of human consciousness; and so we have a doctrine.

No, not at all. Dr. Maudsley does not mean this. P. 51 is not far from p. 47; and yet, on p. 51, the author assures us that "the external world as it is in itself may not be in the least like what we conceive it through our modes of perception and forms of thought." On pp. 52 and 53, Dr. Maudsley outdoes this contradiction by bringing the two contradictories face to face on the same open page, and affirming them both at once with childlike simplicity. "I don't want to think the *thing in itself*. . . . If it is out of me, it does not exist for me, cannot possibly be more than a nonsensical word in any expression of me; and for me to think it out of me, as it is in itself, would be annihilation of myself." But all this, says Dr. Maudsley, teaches him that there *is* a great deal outside of his perception, 'a real world external to me,' of which, however, he can say nothing. So Spencer's rejected unknowable returns: the mind is necessarily obliged to think what it cannot possibly think, to believe in what it perceives to be nonsense, and to assert in one sentence that 'self and the world cannot be thought apart,' and, in the next sentence, that the real external world is so far beyond self that self is wholly unable to make any assertion, save that it exists.

Now, this is not a collection of statements found in various authors, and brought together by Dr. Maudsley for the sake of illustrating the 'barrenness' of the subject. On the contrary, these are his own views. He himself chooses to write a chapter on this topic. He is bringing home to the philosophers something that they need to know. He is dealing with "doctrines arrived at by the positive methods of observation and induction." If not, what does the preface mean? and what has the innocent reader done, that he should be trifled with in this intolerable way? But if in reality Dr. Maudsley is expounding doctrines arrived at by the methods of observation and induction, these doctrines ought not to change nature with every new paragraph. These statements are deliberate and repeated, they are made with much show of earnestness; and yet they are a series of contradictions, and leave the reader feeling as if some one had been trying to make a fool of him. As for this doctrine, that it is "perverse and futile to think of any thing outside of human consciousness" (p. 45), how does Dr. Maudsley venture thus solemnly to propound it and enlarge upon it, when elsewhere, and not far off, he repeatedly insists upon the view that human consciousness is inexplicable, save on the basis of an *unconscious* mental life, which can *never be exhaustively known* at all? Is the relation of author and reader one that involves no responsibilities?

Were not this confusion of statement typical, we should not insist upon it. But throughout the book one finds, if not always such flat contradictions, still a certain slipperiness and uncertainty about nearly every general doctrine that the author chooses to express, on all but the most concrete matters of fact. If he says a thing, you know not when or how soon he will withdraw it, wholly, or bit by bit. He thinks, for instance, that the belief in the vanity of all things, or pessimism, is a 'malady of self-consciousness,' a sign of mental decay; but he adds, that the 'central truth of all religions' is a conviction of the utter vanity of all things, and himself seems in great measure a pessimist. Pure Christianity teaches the noblest virtues, — those, for instance, of self-sacrifice; but the only test of virtue is the experience and common sense of mankind; and these teach us that pure Christianity, put in practice without stint, would render society impossible, since society depends upon conflicts and selfishness even now. The noblest virtues are therefore those that are rejected when the only test of virtue is applied. And so we are led on.

The same tendency appears in the very style of the book. When the author has a definite opinion, he likes to conceal it from you under manifold cloaks of language. He dislikes Spencer's doctrine, that organic evolution is 'progressive adaptation to the environment.' This, he says, is too vague and one-sided a statement. His own statement avoids all vagueness by saying that (p. 137) "an organism and its medium, when they have reached a certain fitness of one to the other and hit upon the happy concurrence of conditions, combine, so to speak, to make a new start, the initial step of a more complex organism;" that is, the organism evolves by evolution, and the evolution is caused by just those conditions that bring it to pass. Our author expands this thought, which he intends as an important complement to the doctrine of natural selection, over quite a number of pages. But that, in the famous words of the Duchess in Alice's Adventures, is not half so bad as our author can do if he tries. Religion he defines (on p. 208) as 'the deep fusing feeling of human solidarity.' Certain beliefs common among men are described (p. 198) as "the imaginative interpretations of an instinct springing into consciousness from the upward striving impulse which, immanent in man as part and crown of organic nature, ever throbs in his heart as the inspiration of hope." Thus our author knows of an instinct that springs from an impulse, which impulse is immanent in a crown, and at the same time strives upwards, and throbs in a heart as an inspiration. All this means, not mere carelessness of style, but a more serious error, else we should not have mentioned it here. It means haziness of thought: it means that our author can write many words in succession without knowing, in any adequate way, what they mean.

Our author's fashion of discussing things of which he is ignorant receives a crowning illustration in his last chapter; and, remote as the topic is from the main subject, we must mention this illustration here, because such matters are important to any student who is seeking a trustworthy guide. In this last chapter Dr. Maudsley has much to say of certain modern tendencies that he considers unhealthy. Of these, one is the excessive display of grief for the dead, which he thinks is growing among us. "Nobody of the least note dies but we are told with clamor of grief . . . that the most amiable . . . the best of men has been taken from us." But nobody, says Dr. Maudsley, is worth all this. "Contrast this modern incontinence of emotion with the calm, chaste, and manly simplicity of Homer; as we observe it, for example, in his description of the death of Achillès." Then follows a page of blank verse, which, of course, is offered to us as somebody's translation of the cited passage from Homer. Now, Dr. Maudsley was not obliged to say any thing about Homer, much less to quote him. He has gone out of his way to tell us, with an air of easily carried learning, what 'we see' in Homer. When a man thus pretends to quote the father of song, whose poems are at hand in all sorts of translations in any library, and to quote him especially for the sake of illustrating a certain important point, a reader supposes, of course, that the quotation will at least be a fairly accurate expression of something that Homer said. But, in fact, nothing resembling the passage quoted is to be found anywhere in Homer. These verses are not even so much as a remote imitation of any thing Homeric that bears upon Achilles. We ourselves are unable to identify them, but their tone is distinctly very modern; and we have little doubt that their author is now alive, or has very recently died.[1] But this is not all. To complete the blunder, Dr. Maudsley, in

[1] A classical friend, to whom we submitted Dr. Maudsley's quotation after we had written the above, assures us that the passage nearest to this one in ancient poetry is the death of Achilles as described in Quintus Smyrnaeus III., and that Quintus's description itself differs in so many important points from that of Dr. Maudsley's Homer as to make the latter not even a fair imitation of any ancient model.

this reference to Homer, has unwittingly chosen the worst possible illustration for his purpose, quite apart from his supposed quotation: for Homer does indeed tell us, in one passage (in the last book of the Odyssey), about the death of Achilles; but that passage informs us of a seventeen-days mourning of gods and men over the hero, with funeral ceremonies of extraordinary splendor, that would have done the dead man's heart good if he could only have been there to see. Nobody doubts Homer's simplicity, but Dr. Maudsley wholly misapprehends what it means. How he could have been so deceived in his quotation, we cannot guess; but such gratuitous blunders show us what to expect of a man that can make them.

If we have little space left to refer to our author's discussion of matters that he is eminently competent to discuss, that is not our fault. On the pathology of the will we receive instruction in the brief space before spoken of. Of heredity of mental disease we here find some illustrations, but we learn nothing new about the obscure subject of the actual laws that govern heredity. As to mental disease and its phenomena, Dr. Maudsley insists with considerable emphasis upon his view that the will, and in particular the most developed activity of the will, as seen in the moral consciousness of the civilized man, is the least stable, because the highest and latest element of man's mind, and must therefore show the signs of decay and disease soonest. This, he assures us, is actually the case. He illustrates his position by means of a good many instances of certain forms of mental disease. The view is not absolutely novel, and Dr. Maudsley has described most of the facts before. But all this is well worth telling, and would have made a useful essay if the rest of the book had reached the fire instead of the printer. As it is, this part of the book is the only one from which a student of such psychology as Dr. Maudsley so well describes in his preface can learn any thing of importance that is in any sense novel.

Our task in reading and reviewing has been no pleasant one. With Dr. Maudsley we hope for a psychology of 'concrete minds,' that may teach us "why individuals feel, think, and do as they do, how they may be actuated to think, feel, and do differently, and in what way best to deal with them so as to do one's duty to one's self and them" We see in the humblest experimental researches conscientiously conducted, in every observation of the mental pathologist, in every advance in nervous physiology, in every new discovery in animal psychology, and, let us freely add, in every fruitful philosophic research into the deeper problems of thought, in all these things, not only aids, but necessary conditions of the approach to the great end thus defined. But we also see in vague rambling disquisitions *de omnibus rebus*, such as nearly fill this book; in efforts at philosophy by a man who is confessedly and very manifestly unable to understand philosophic terms, who ignores the history of thought, and who insists upon writing pages of contradictory statements, — in all this we see, not advance, but serious injury. And when not only the book is such as it is, but also the author is a man whose position and previous services command respect, and who is therefore able to call the attention of busy students to whatever he may choose to publish upon the subject, — then we say that such conduct is a serious breach of the privileges of authorship, and we wish to raise a decided protest against it. For the rest we have no quarrel with the author's determinism, nor with his materialistic basis for mental science, so long as he confines both the doctrines to their only proper sphere; that is, employs them as regulative principles in discussing and explaining the facts of experience. We quarrel only with his confused and purposeless fashion of discussion.

NOTES AND NEWS.

— THE report of the committee of the Geodetic association was presented at a general meeting of the conference, Oct. 23, at Rome, and was adopted after an animated debate. The report favors the universal adoption of the Greenwich meridian, and also recommends, as the point of departure of the universal hour and cosmopolitan dates, the mean noon of Greenwich. The conference hopes, that, if the whole world agrees to the unification of longitudes and hours by accepting the Greenwich meridian, England will advance the unification of weights and measures by joining the metrical convention of 1875. The government of Italy will be requested to officially communicate the foregoing action of the conference to all nations.

— In the October number of the *Harvard university bulletin*, further instalments are given of the geographical index to the maps in *Petermann's mittheilungen*, by Mr. Bliss, and of Mr. Winsor's 'Bibliography of Ptolemy's geography,' containing important notes on early American cartography. Mr. Winsor also commences an account, of which six pages are printed in the present number, of the Kohl collection of early maps in the Department of state at Washington, prefacing it with a brief account of Dr. Kohl's labors.

In the official portion of the bulletin, we find the following appointments gazetted: Arthur Searle as assistant professor of astronomy; Robert H. Harrison, Harold Whiting, Charles E. Faxon, and Edward Burgess, instructors in anatomy, physics, botany, and entomology, severally; O. W. Huntington, assistant in chemistry, G. T. Hartshorn in organic chemistry, and G. W. Perkins in biology; and Dr. C. S. Minot, lecturer in embryology. The establishment of ten fellowships in the Lawrence scientific school, with an annual income of five hundred dollars each, is recommended by the corporation.

— The subjects to be presented at the Society of arts of the Massachusetts institute of technology the coming season will embrace a wide range of scientific and practical topics, arrangements having already been made as follows: —

Oct. 11, Professor Edward S. Morse of Salem spoke on Japanese pottery; Oct. 25, Professor William H. Brewer of New Haven read a paper on the evolution and breeds of domestic animals, as illustrated in swine; Nov. 8, Mr. Thomas Gaffield of Boston will read a paper on glass and glass-making.

At the subsequent meetings, the arrangements for which have not yet been definitely made, Dr. Charles S. Minot of the Harvard medical school will probably speak on some biological subject; Capt. D. A. Lyle, U.S.A., on the rise, progress, and methods of the U. S. life-saving service; Mr. Chauncey Smith of Boston, on the influence of inventions; Mr. R. B. Forbes, on the rigging of ships; and Major C. W. Raymond of the U.S. engineers will speak on Boston harbor. Various mechanical contrivances of interest will also be exhibited.

— A very valuable work on German meteorological bibliography has been prepared by Dr. Hellman. It contains a bibliography proper, limited to German authors, and also historical notices upon meteorological observations, and the progress of the science in that country.

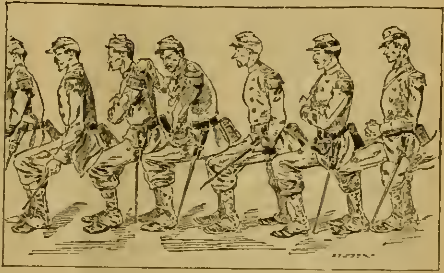
— A free course of popular lectures upon zoölogy, specially intended for teachers and students, will be given by the Cincinnati society of natural history on Friday evenings, commencing to-day. The following is the programme: Oct. 19, Introduction, The study of zoölogy, by Prof. J. Mickleborough; Oct. 26, The human skeleton as compared with that of other animals, by Prof. J. Mickleborough; Nov. 2, The trochilidae, or humming-birds, by Charles Dury; Nov. 9, Fish fauna of Cincinnati, by Dr. D. S. Young; Nov. 16, Comparative anatomy of the mollusca, by Prof. A. G. Wetherby; Nov. 23, The mollusca from an evolutionary stand-point, by Prof. A. G. Wetherby; Nov. 30, Some curious insects, by Charles Dury; Dec. 7, Practical manipulation of the microscope, by Dr. J. H. Hunt.

When this is completed, a second course of equal length will be given on geology and mineralogy, the special topics of which will be announced later.

— Active movements are making to supply, as far as possible, the losses sustained by the Indiana state university in its recent fire. When the first meeting of the board of trustees was held, about a week after the fire, Monroe county was prepared to guarantee fifty thousand dollars; and this, with over twenty-seven thousand dollars' insurance, gave the officials great confidence. No definite action, however, was taken, until a recent meeting of the trustees at Indianapolis, when it was decided to purchase a larger tract of land, just east of the city of Bloomington, much more favorably located than before, and to erect at once two fire-proof buildings, one of which can be used for the present for the literary department, and the other for the scientific department, museum, and library. Later, another building will be added, to which the literary department will be transferred, when the scientific department will occupy one of those now to be built, and the other will be given wholly to the museum and library.

For the present the university will occupy the old building, which was saved. It is reported that the trustees have in view the purchase of some valuable collections and a good library.

— A correspondent of *La Nature* gives a sketch, which we reproduce, of a group of French soldiers, as they appeared when resting on their marches in Algeria, when they were obliged to stop on marshy land, and had nothing upon which to rest. The soldiers seated themselves each on the knees of the one behind, and were arranged in a circle, so that there was no end man. The correspondent vouches for having often seen the operation. *La Nature* recommends the collegians to try the experiment in equilibrium when they return from their vacations, — advice which it would hardly do to transmit to Americans.



— Trouvelot has made an examination of the sky near the place of the sun at the May eclipse, for the purpose of rediscovering, if possible, the red star which he saw at that time, and suspected to be an intra-mercurial planet.

In the re-examination, he used a telescope of the same aperture and power as at the eclipse. He found again, without trouble, his two 'white stars,' and identified them as forty-one Arietis and ε Arietis. As to 'the brilliant star of a pronounced red,' he says he could not find it, and that it is certain that no star of that magnitude and color now exists near the position assigned, nor even within a distance much greater than it is permissible to attribute to the probable error.

At the same time, seeing he failed to obtain a determination of its position, or to notice any disk or phase, he considers it only right to reserve any conclusion as to the probable nature of the object (*Comptes rendus*, Sept. 17). Astronomers generally will be disposed to believe, with those who observed the eclipse at the same station with M. Trouvelot, that his limits of probable error were, under the peculiar circumstances, some of which are mentioned in his original report, much larger than he seems disposed to admit, and quite extensive enough to include the star α Arietis, which was not far from the place he assigns, and in magnitude and color corresponds well with his description.

— The department of entomology, of the New-York state museum of natural history, issues a circular (no. 1) giving directions for 'arresting the chinch-bug invasion' of northern New York, with good figures of the insect enlarged and of natural size.

— Wood sections and vegetable tissue was the subject discussed by Mr. J. F. Whiteaves at the meeting of the Ottawa microscopical society, Oct. 16. Mr. Whiteaves was elected president, and Dr. R. J. Wicksteed secretary, for the ensuing year.

— Among the prizes given to American exhibiters at the International fisheries exhibition just closed, at London, gold medals were awarded to G. Brown Goode, for work on ichthyology; D. S. Jordan, for work on ichthyology; Alexander Agassiz, for work on ichthyology; J. E. Hilgard, for optical densimeter; Capt. C. Sigsbee, U.S.N., for deep-sea sounding apparatus; W. L. Bailee, U.S.N., for deep-sea thermometer c silver medals to G. Brown Goode, for publications relating to the fisheries; Marshall McDonald, for universal hatching-jar; Lieut. Z. L. Tanner, U S.N., for deep-sea sounding apparatus; W. G. Farlow, for collection of marine algae; J. H. Emerton, for model of squid and octopus; T. H. Bean, for works on ichthyology; Marshall McDonald, for map showing shad fisheries: and diplomas to J. E. Hilgard, for salinometer; Capt. C. Sigsbee, U.S.N., for parallel ruler.

The United States receives 48 gold medals, 18 of which go to the fish-commission, mostly on collective exhibits, 47 silver medals, 29 bronze medals, 24 diplomas, and 7 special prizes. Other gold medals are to the national museum, for collective exhibit of fishes; signal-service, for most complete collection of apparatus for weather prediction; and lighthouse board.

— The French government has just issued a geological map of Algeria in five sheets, scale of 1:800,000, with two explanatory memoirs. This work is only preliminary; and appropriations have been made to organize a geological survey, which will make a careful and detailed geological map, first on the scale of 1:400,000, and then on a larger one, say 1:80,000, or even 1:40,000. The directors are A. Pomel, J. Pouyanne, and J. Tissot.

— Col. A. Parnell, R.A., states (*Journ. sc.*, September), that, as recorded by official returns, the number of persons killed by thunderbolts in Russia (not including Poland and Finland), in the five years from 1870 to 1874, was 2,270, of whom no less than 2,161 were dwellers in the country; and that during this period, in the same area, 4,192 fires were occasioned by thunderbolts, 4,090 of them being in the country.

— The speeches of Sir Lyon Playfair and Sir Charles Dilke, during the recent debate in the House of commons on the vaccination question, have been published by Messrs. Jarrold & Sons in pamphlet form, under the title of 'Facts about vaccination.' It is hoped that this little publication may prove a useful antidote to the present mischievous and ignorant agitation against Jenner's great discovery. The Clothworkers' company, one of the old London guilds, has devoted a fund at its disposal for the encouragement of research to offering a prize of a thousand pounds for the discovery of a method of procuring lymph that would obviate the present objections.

— At a recent meeting of the Société d'encouragement pour l'industrie nationale, M. G. Meyer of Paris submitted specimens of paper specially manufactured to resist fire. It was stated by him that the papers and documents shown had been for four hours in a retort in a pottery furnace; and it is further affirmed, that those present were unable to distinguish, either by appearance or texture, the papers so treated from others which had not undergone the ordeal of fire. "From experiments made with a specimen of wall-paper sent us," says a writer in *Iron*, "we are enabled to say, that, although the appearance of the paper does change, the fire-resisting properties claimed for it are undoubted: the paper certainly does not ignite." The paper can be made of a quality suitable for deeds and other important documents, or of a quality suitable for wall-paper, theatrical decorations, or, in fact, for any purpose for which paper is used. Mr. Meyer has also invented an incombustible ink and incombustible colors. Artists using those colors may preserve their works to a certain extent. The invention would appear to be of the greatest value to theatrical managers. By using thick cardboard of Mr. Meyer's material, together with his paints, they are able to render their scenery uninflammable. At the same time, for documents of importance, — deeds, wills, and agreements, — the invention should come into universal use.

— The catalogue of the Miller manual labor school was issued recently, bearing date of June, 1883. It is a neat pamphlet of some thirty pages, printed by the boys of the school. The school is situated in Albemarle county, Va., and was founded by the late Samuel Miller of Campbell county, who left property to the value of more than one million of dollars, to be expended in the erection of buildings, and the endowment of a school in which the students are to be instructed in the branches of a 'good, plain, sound, English education,' in ancient and modern languages, and in the useful arts. The school is now in operation, and a considerable number of students are in attendance, who are not only taught, but are fed and clothed, at the expense of the fund, which yields an income of sixty or seventy thousand dollars a year. Every student works in the shop, in the printing-office, on the farm, or in the garden. The workshop is built from the plans of Mr. M. P. Higgins of Worcester, and a class of twenty-five boys is making good progress. The farm comprises eight hundred and fifty acres, of which a hundred and twenty are fine, rich bottom-lands in the valley of Mechum's River. The farm last year yielded an income of four thousand dollars. Boys are received at from nine to fourteen years of age, and are kept until eighteen.

— The White Mountain club of Portland held their autumn meeting, Oct. 17. The president (Rev. Dr. Thomas Hill) narrated his labors in identifying a mountain seen from Portland, and hitherto taken for the Imp. He finds it is a part of Carter range: the true Imp is scarcely visible. Still another 'Imp' is seen from Copp's house, near the Glen and Gorham road, where it is pointed out by stage-drivers, etc., as the south-west side of the true Imp. Cline's map correctly locates this as another peak.

— The collections of plants made by the late President Chadbourne, comprising thirty-four distinct lots, and containing among them some of interest and value, are offered for sale by his executor, A. Schenck, 30 Union Square, New York.

— Herr Hugo Zöller, who visited the Isthmus of Panama and the South-American states as correspondent of the *Cologne gazette*, has published his experiences in two books, the first called 'Der Panamakanal,' in which he contradicts the too favorable reports spread in the European papers as to Mr. Lesseps' work on the canal, and says his company has too little capital to accomplish the undertaking. He gives a map of the district, and fully expects to see the water-way a fact, and not an idea, within ten years, but not through Mr. Lesseps' means. The second book concerns Brazil, and is called 'Die deutschen im brazilianischen urwald.'

— T. W. Blakiston contributes to the *Japan gazette* of Sept. 8 an account of a voyage across the North Pacific, in the ship Undaunted, from Yedo to Victoria, V.I., between May 20 and June 21, 1883. Temperatures, winds, etc., were carefully noted, and the author came to the conclusion that the Kuro siwo at that season disappears between latitudes 37° and 39°, and west from east longitude 154°. Eastward from this point nothing was seen of warm water referable to that current.

— In a paper recently read before the Geographical society of the Pacific, some remarkable statements were made in regard to the Mahlemuts of Norton Sound, Alaska. Among other things, if correctly reported, the author stated that 'their customs and part of their language resemble the Chinese greatly.' The Mahlemuts are an ordinary small tribe of western Eskimo, who have been studied by a number of ethnologists, and in no respect differ from the other Eskimo tribes of the region. Such wild statements, especially when made before a scientific society, are almost invariably reproduced in European journals, and for that reason should be noticed and corrected.

— J. G. Swan, who has been investigating the Queen Charlotte Islands, returned to Victoria, Sept. 27. He discovered a fine deep-water fish, which is new to the food-supply of the coast, and is said to occur in large numbers. He also reports finding a good harbor hitherto unknown.

— The volume of Washington astronomical and meteorological observations for 1879 has just been received at the naval observatory from the government printing-office, and will be distributed to correspondents immediately.

— A third edition, enlarged and improved, of Paetel's useful catalogue of mollusks, is announced. Though by no means available for text-book purposes, and with the usual allowance of errors, this publication cannot fail to be useful to all who have a large collection of shells to arrange, if it were only to furnish a workable foundation.

— The Iowa academy of sciences met at Ames on Sept. 27. Prof. C. E. Bessey of Ames read papers on the hybridization of Spirogyra majuscula and S. protecta; the effect of frost on leaf-cells, and on certain insect-catching glands on a grass. The glands referred to in the last paper are located on the blossom stems of Sporobolis, and secrete a viscous fluid, in which insects are entrapped. Their utility in these plants seems difficult to understand. In reply to a question by Professor Stalker, whether they could protect the blossoms from injurious insects, Professor Osborn said he thought they might possibly give protection from Cecidomyiae. Professor Herrick of Grinnell described a water-still for obtaining a constant supply of distilled water in laboratories, and offered some observations on the Grinnell tornado, tending to show that at that point the tornado formed a loop in its course. Prof. H. Osborn of Ames offered some additions to the list of Iowa insects, in Lepidoptera, Coleoptera, Hemiptera, and Neuroptera; notes on Mallophaga, taken in Iowa; and a paper on an epidemic disease attacking Caloptenus differentialis. This last is a disease similar in nature to that caused by Entomophthora muscae in the common house-fly, and very fatal to these locusts. It is caused by a species apparently new, and shortly to be described by Professor Bessey in the *American naturalist*.

— The third and fourth parts of volume xiv. of the *Archiv für anthropologie* contain three original papers, as follows: on Hypertrichosis, by Dr. Ranke; on the eyes of the Fuegians, by Dr. Seggel; and on copper in ancient times, by Dr. Reyer. Reviews of the anthropological literature in Russia are prepared by Dr. Stieda; in Scandinavian literature, by Miss Julia Mestorf; in American literature, by Dr. Emil Schmidt. The last named covers twenty-three closely printed quarto pages, and embraces about every paper of importance published in our country during the last year, relating to anthropology. The bibliography occupies 161 pages, and many of the titles are accompanied by a brief note stating the purpose of the publication. It is a thorough piece of work, and is distributed as follows: archeology and priscan history (*urgeschichte*), by J. H. Müller, 41 pages; anatomy, by Dr. Pausch, 6 pages; ethnology and travels, by Dr. Albrecht Penck, 90 pages; zoölogy in relation to anthropology, by Dr. George Boehm, 23 pages.

Students in all branches of science know how difficult it is to find the thing they are seeking. Between those piled up and stowed in great collections and those hid away in private museums, much time is wasted. Now, the anthropologists of Germany long ago felt the necessity of publishing the catalogues of the specimens in their great museums; and already have appeared five of these in former numbers of the *Archiv*. The current number devotes 36 pages to the Senckenberg museums in Frankfort-a.-M., with tables of measurements and descriptions; and 25 pages to the anthropological collection in the Grossherzoglichen naturalien-cabinets im alten schlosse, in Darmstadt, also with measurements and descriptions. Comparisons, of course, are always odious; but it cannot fail to strike our American anthropologists that the especial merit of the German system, that is, co-operation, is wanting with us. It may also be mentioned that none of the foreign anthropological societies seem to know any thing about the work in progress at the surgeon-general's office at Washington.

— There have been issued by the government, under the direction of Gen. W. B. Hazen, chief signal-officer, the meteorological and physical observations on the east coast of British America, by Orray Taft Sherman, as no. 11 of the 'professional papers.' Nos. 8 and 12 consist of papers on the 'Motions of fluids and solids' and 'Popular essays on the movements of the atmosphere,' by Prof. W. Ferrel; the first edited, with notes, by Mr. Frank Waldo. No. 9 contains charts and tables showing the geographical distribution of rainfall in the United States.

— The new British patent law will go into effect Jan. 1, 1884. The patent fee is reduced to about a hundred dollars for all fees, including agents' ordinary charges. Provisional protection is extended to nine months. Annual taxes are substituted for the stamp-duties now charged, although no change has been made in the total amount. The new provisions apply to applications now in the office. No change has been made in regard to examinations. The patent is issued to any applicant who chooses to pay the fees, and without formal examination. A system of comparison of the patent claim with the claim for which provisional protection has been granted, is, however, established, — a commendable innovation, and one which might well be supplemented by the system of complete examination practised in the United States. The duration of the patent is to be fourteen years in all cases, irrespective of the expiration of earlier foreign patents on the same device. The publication in Great Britain of the foreign specification of the invention does not, under the new law, invalidate the British patent. The new law will evidently greatly favor the inventor, and the change will be likely to prove to be very greatly to the advantage of that country as well.

SCIENCE.

FRIDAY, NOVEMBER 9, 1883.

THE LICK TRUST.

It will be remembered that a certain portion of the large estate of Mr. Lick was to be devoted to the uses of science. A specific sum of seven hundred thousand dollars was to be expended in the purchase of the most powerful telescope attainable, and in the construction of an observatory on Mount Hamilton; and the unexpended balance of this sum was to constitute a permanent fund for the maintenance of the observatory. Many specific bequests were made for other purposes not scientific; and after all these specific sums had been paid, it was provided that the sum remaining over should be divided between the Society of pioneers of California and the California academy of sciences. Science is interested, also, in this last bequest. It will be remembered that many changes of trustees, and also of the form of the gift, were made in the early years of the trust; and that vexatious suits were entered by supposed heirs of Mr. Lick, which were successively decided by the courts. At present a definite construction of the deed of trust has been made by the supreme court of California, from which there is naturally no appeal; and the trustees are acting under this construction.

During the period of years over which the preliminary litigation extended, a great shrinkage in the values of real estate took place in California, as well as elsewhere in the United States. At the end of these litigations, the trustees found themselves in control of much valuable property, which could be sold only at a great loss. If it had been sold at that time, there would have been no money left to divide between the pioneers and the academy; and not only this, but some of the specific bequests would have remained unfulfilled: it was therefore the policy of the trustees to manage the estate carefully, and to sell only to advantage. In this way only, would the residuary legatees receive any considerable sum. The estate has certainly been well managed: for from Dec. 1, 1876, to Oct. 1, 1883, the aggregate net profits have been $453,458, or over $66,000 per year. There was no surplus to divide in 1876; while, at the present time, some $192,000 remains over, free of all specific bequests. It therefore would appear that the trustees have deserved well of science for their careful administration of the trust.

Their policy has clearly been wise, when looked at without prejudice: but it has not been acceptable to the residuary legatees, since they have not yet received any immediate benefit; nor can they, under the decision of the court, until the whole estate is settled, and all specific bequests are fulfilled.

This is no doubt annoying to the academy of sciences, which has so many useful purposes which could be served by an increased income. It is specially annoying to the pioneers, who all came to California in 1849–50, and who, therefore, are all men in middle life. When the French countess heard of the Montgolfiers' balloon ascension, she exclaimed that these men would certainly invent the art of never dying; but she added pensively, 'It will be when I am dead.' This is the very natural attitude of the pioneers; and it is this that has led to a recent savage attack on the trustees, reports of which have appeared in the San Francisco and other papers. These attacks have been directed against the whole action of the trustees, without discrimination. It is, however, clear, that the actions of the trustees must be considered in two ways. Most of their official acts have been done under specific directions of the courts of law. These acts are much complained of by the residuary legatees: but it is obvious that such complaints are idle; for, if the trustees had not obeyed the orders of the courts, they would have been long since expelled from their responsible positions. The remaining acts complained of have been done in pursuance of the general policy just outlined. It seems equally clear that these complaints, though natural, are unjust. The residuary legatees have now $192,000 to divide. It is not long since they had nothing. Science is certainly grateful to the trustees, since their economical policy has already saved a large sum which will eventually go to making the California academy of sciences more powerful and useful than it now is.

With regard to the other beqnest in which science is interested, — namely, the Lick observatory, — there is every reason to be extremely grateful to the trustees for their wise administration of the trust.

Their economy has certainly been remarkable. They have expended on the observatory to Oct. 1, 1883, $154,527.98; and they have remaining $545,472.02. This $155,000 has done the following things:. the top of a bleak mountain four thousand feet above the sea, and twenty-seven miles from a town, has been levelled off so as to give a sufficient area for the buildings (forty thousand tons of rock have been removed for this purpose alone); brick enough to complete the whole of the buildings has been made on the side of the mountain, and delivered at the top, at a total cost less than the price of hauling the same amount from the nearest town; a handsome and well-built main building is now nearly finished (the large dome alone remains; a small dome, containing a very perfect twelve-inch equatorial by Clark, has been in use since November, 1881); a four-inch transit instrument, in a convenient house, is in complete working-order; a photoheliograph in a permanent house has been in use since December, 1882; the house for the meridian circle is begun; the meridian circle is half paid for, and a payment has been made on the large telescope. This is the work which is to be seen on the mountain-top proper. Just below this are the houses for the workmen, shops, stables, etc., all in good condition, and a very complete system of water-supply in full working-order.

It will appear to any competent person that this work has been done thoroughly, and that it has been done economically. At the same rate of expenditure, at least $300,000 will remain as a permanent fund for the support of the observatory.

It therefore appears that the trustees have deserved well of science in their administration of their trust, not only in regard to the California academy of sciences, but also in relation to the Lick observatory; and it should be the desire of all interested in the administration of this trust to strengthen the hands of the trustees in the continuance of their wise policy.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1] — II.

The further growth of the desert-whirl may be briefly described. The air standing quietly on a flat, dry surface allows the lower strata to be quickly warmed to a high temperature. If the air were in motion, no part of it would remain long enough close to the ground to be greatly warmed; if the surface were not flat, the lower air would flow up the slopes as soon as it was a little heated, and not wait to acquire a high temperature; if the surface were wet, much of the sun's heat would be occupied in evaporating the water (as will be explained below), and would so be lost to the lower air: it is therefore only in calm weather, on a desert plain, that the sun can succeed in warming the lower air to excess, and so produce a very unstable equilibrium, and a strong updraught when the upsetting begins. The longer the delay before the overturning, the more heat-energy is accumulated, and the more violent the motion when it begins. The lower air rises at some point against the oppression of the upper layers. The surrounding warm air flows in from all sides toward this central point, and follows the leader. Soon the motion becomes general and lively, dust and sand are blown along toward the centre, lifted and carried aloft with the ascending air in its rapidly rising current, and then the whirling column becomes visible. When thus established, the increased velocity and the rotary motion of the air near the centre are constant characteristics of the upsetting. Thirty

[1] Continued from No. 39.

or forty feet to one side, the wind may not be strong enough to brush along the sand, and a few hundred feet away it may not be perceptible; but at the centre it makes a distinct rushing or roaring sound, and carries light objects upwards, sometimes to a height of several thousand feet. This increase of velocity of the surface indraught toward the point of its upward escape is a general feature of the motion of a mass of free particles along a path of varying width: the narrower the path, the faster the motion. The same increase is seen in the growing velocity of a stream running out of a lake, so beautifully shown where the Rhone those of the tornado, as will be shown farther on.

The second characteristic feature of the wind's motion gives name to the storm. A whirl must necessarily be formed when the air moves inwards from all sides towards a centre, for the indraughts will surely fail to follow precisely radial lines. Their aim will be a little inexact; and, as they pass to one side or the other of the centre, a turning must begin in a direction determined by the strongest current. This, once begun, is maintained by the centrifugal force that arises from it; and the size of the central whirl will then depend on the bal-

Fig. 3. (Taken from *Amer. journ. sc.*, 1851.)

flows from Lake Geneva, or, more simply and prosaically, in the running of water from a tub by the escape-pipe. In the case of a desert-whirl, the central wind is held by friction with the surface sands much below the velocity it might attain; for it must be remembered that these whirls are supplied by a comparatively thin layer of superheated air next to the ground, often not more than four or five feet thick. The restraint of friction on such a layer will be very considerable, and its motion can seldom reach a disastrous strength. It is probable that in the desert sand-storms, which are described as overwhelming caravans, there is a much thicker mass of air in activity, and the conditions of motion approach ance between the centripetal and centrifugal forces. In ascending at the centre, the wind follows an upward spiral course, like the thread of a screw of steep pitch, with a diameter of five to twenty feet. The direction of turning is indifferently one way or the other, according to the side on which the indraught happens to pass the centre. The height to which the whirling column rises will be determined by its mixture with the adjoining air, and consequent cooling until its temperature is that of indifferent equilibrium; and at this elevation the current will turn and spread laterally to make room for that which follows. Such a whirl will continue as long as its cause lasts; that is, as long as it is supplied with warm air at the base.

Manifestly it must stop in the afternoon, as the sun's heat decreases; and it can never occur at night, for then the surface-air is, as a rule, cooler than that above, and the atmospheric equilibrium is correspondingly stable. Further, the whirl will remain at one place, unless, as is often the case, it is carried along by a general motion of the upper air.

There is a very strong point of evidence, if any is needed, in favor of the view that heat applied to the lower layers of the air will produce a whirlwind. This is the fact of their pro-

FIG. 4. (Taken from *Abhandl. gesellsch. wiss. Gött.*)

duction over fires. Much interest was excited in this question in connection with the artificial causing of rain, some forty years ago, in this country; and observations were carefully made of the whirls formed over burning woods and canebrakes, showing them to be very similar in form and action to those naturally arising on dry plains (fig. 3). Similar whirls have been seen over volcanoes (fig. 4); and on a calm day the smoke ascending from a factory chimney may be seen to have a slow rotary motion. Heat is therefore an amply sufficient cause of such disturbances. No other excitement is needed, and electricity has no essential part to play. In recognizing this, we see the chief difference between the older and newer theories of storms.

Sand-whirls are common in all desert or dry regions, where they often have the name of spirits or devils, from the fantastic and apparently evil way in which they flit across the burning sands. They have neither clouds nor rain. When well and frequently developed, they may grow to dangerous strength, and lift much dust and sand into the upper air, where it is blown long distances before falling. In this way they serve as important geologic agents. Vessels west of the Sahara, or east of China, are thus often powdered over with fine dust slowly settling down after a long flight from its desert source.

The smaller water-spouts, doubtless, belong near here in our scheme of classification; but as they are usually aided by vapor-force, and approach the character of tornadoes, their consideration is best deferred till later.

Finally, before going on to the larger storms, one point of much importance must be emphasized. The change from the stable equilibrium of night and early morning to the unstable of noon is effected entirely by the sun's heat, which warms the lower air, and causes it to expand. In expanding, it lifts all the upper air that rests on it; and this is no small piece of work, for the air that is lifted weighs about a ton over every square foot. When a point of escape is found, the heavy upper air sinks again, as the expanded air is drained off (upwards) at the centre. It is this gravitative force of the sinking air-mass that causes the dust-whirlwind, in re-arranging the disturbed equilibrium of the atmosphere; but gravity would have no chance to show its strength, if the air had not been lifted by force from the sun. The winds of a dust-storm, therefore, depend on gravitative force brought into play by the sun's heat. All storms and all winds have more or less closely this relation to solar energy and terrestrial gravity.

(To be continued.)

THE INTERNATIONAL FISHERIES EXHIBITION.—FOURTH PAPER.

ON the 1st of October, at noon, the number of visitors to the exhibition passed the much desired limit of two millions; and, although the rainy season had set in, the daily average of attendance was still increasing. The financial success of the enterprise was more than certain two months ago; and the receipts of each day since have been swelling the surplus fund, the disposal of which is now a fruitful subject of discussion in England. Although the organization is a private one, the character of the men in control of it, and the recognition granted by the Queen and the Prince of Wales, render it certain that the profits will be devoted to some public enterprise. In the midst of multifarious minor propositions, two plans are receiving serious support. One of these is that first brought forward by Professor Ray Lankester, in his address upon 'The (possible) scientific results of the exhibition,' and relates to the establishment of a laboratory of marine zoölogy in Great Britain, for the joint advantage of fisheries and science. Professor Lankester's original memorial was signed by sixteen leading men of science, and has since had the indorsement of the British association. The rival scheme relates to the establishment of an orphanage for fishermen's children; and this, as may be imagined, is much more popular among the people and their newspaper exponents. One influential trade-journal expresses itself in energetic fashion in a paragraph which I cannot refrain from quoting, since it shows how little the opinion of a large class of Englishmen has been acted upon by the leaven of scientific thought. Speaking of the meeting of the British association, the editorial proceeds: —

"The conductors of the daily prints, always very amiable to the promoters of these useless gatherings, fool the *savants* to the top of their bent by reporting the 'papers' and discussions at an absurd length, thus making the credulous 'scientists' believe that the public takes a lively interest in their proceedings. . . . It is [the president's] grim task to write an 'address' usually so wildly mystifying as to drive his hearers and readers to the verge of idiocy. By common consent, this year's presidential address was not only more bewildering than any previously delivered, but absolutely incomprehensible; and it is charitably hoped that the Southport meeting is the beginning of the end. But these dreamy gentlemen are sufficiently wide awake to their own interests. . . . This they are, of course, entitled to do; and, if they can squeeze any money out of the public or out of the government, to aid them in the pursuit of their 'fads,' we shall have nothing to say. When, however, they go to the length of proposing to get a portion of the fisheries exhibition surplus into their hands for the purpose of establishing 'a marine zoölogical station on the English coast,' we take leave to denounce such a proceeding as both audacious and preposterous," etc.

In the mean time the executive committee makes no promises, except in the proposition to expend the sum necessary to bring over a Cape-Ann schooner, with a selected crew of fishermen, to demonstrate the American methods of fishing with purse seine, deep-sea trawl-lines, and dories, on those parts of the British coasts in which their use may be practicable. If any precedent is required for devoting a part of the proceeds to scientific ends, they have only to look to the Edinburgh exhibition of 1882, the surplus of which to the amount of nearly eight thousand dollars has been given to establish a marine laboratory near Edinburgh, under the direction of Mr. John Murray of the Challenger, and others. It is to be hoped that the demands of science will be remembered. Charities of all descriptions flourish luxuriantly in England, but the workers in science seem to feel that their needs are often seriously neglected.

The amount of the surplus is variously estimated at from forty thousand to a hundred and fifty thousand dollars. The management is not satisfied with the present success, however, and has leased the grounds for three years more from the commissioners of the exhibition of 1851, who, it will be remembered, bought with the surplus of that great enterprise those tracts of land now so valuable, on which all the museums and schools of science and art in South Kensington are now placed. Three great international exhibitions, similar in plan to the fisheries exhibition, are to follow, year by year; and by the end of 1886 the buildings will have more than paid for themselves, and a substantial sum will have accumulated, to be used, perhaps, in continuing the exhibition and museum movement which England has found to be so valuable to its intellectual and industrial welfare. The character of these exhibitions has not yet been determined upon. That of 1884 would doubtless have been devoted to horticulture, floriculture, and forestry, had not Scotland pre-occupied the field with a similar undertaking, and already secured the patronage of royalty. Edinburgh will therefore have its 'international exhibition of objects relating to practical and scientific forestry and forest products' next year; and London will follow in 1885 with a forestry exhibition, which cannot fail to be of world-wide importance. The London fisheries exhibition of 1883 gained much through the experiences of similar exhibitions in Norwich in 1881, and Edinburgh in 1882. The subject of the London exhibition of 1884 is not announced, but it is very possible that it will have to do with food-products. Another programme, hinted at by the Prince of Wales in his speech at the close of the exhibition, provides for a hygienic exhibition in 1884, one of the progress of invention in 1885, and in 1886 an exhibition of colonial products.

The literature of the exhibition is one of its most important features. Almost every subject connected with marine zoölogy and the technology of fishing has been discussed in at

AMERICAN SECTION OF THE INTERNATIONAL FISHERIES EXHIBITION IN LONDON.

least one special essay. The papers published by several foreign governments have been of great importance, particularly the treatises by Grimm, upon the fishes and fisheries of Russia, and by Apostolides, upon those of Greece. Those issued officially by the exhibition have been numerous, and, if the truth must be told, by no means of equal merit. None, however, are without value; and several, especially those by Huxley, Levi, Hubrecht, Lankester, and Day, are important contributions to science.

The official catalogue, edited by Mr. A. J. R. Trendell of the South Kensington museum, well known in America as the secretary of the British commission to our exhibition in 1876 at Philadelphia, is in itself a contribution to knowledge, and a model for the guidance of future exhibition administrations. Each section is introduced by an essay by some recognized authority, and signed. Much serious work has been done by the English periodicals in recording the teachings of the exhibition. *Nature*, under the head of 'Zoölogy at the fisheries exhibition,' has had a review of the vertebrates by Professor Giglioli, and of the invertebrates by Professor Ray Lankester; also a paper on the present state of fish-culture as illustrated at the exhibition, by Mr. Earll. The birds have been considered by Mr. Howard Saunders in the *Ibis*, and by Mr. J. E. Harting in the *Zoölogist*. Mr. Gwynn Jeffreys described the molluscan collections in the *Annals and magazine of natural history*. Mr. Dunell, Mr. W. B. Tegetmeier, Mr. Senior, and others have reviewed the technological features in the *Field*, and Mr. Fell Woods, the oyster-collections in *Land and water;* while *Engineering* has had an elaborate series of illustrated papers upon the vessels and scientific instruments, devoting several numbers to describing the U. S. steamer Albatross and its equipment, and to American devices for the exploration of the depths of the sea.

An official review, elaborately illustrated, of the exhibition and its teachings, is being prepared for the British government by Hon. Spencer Walpole, governor of the Isle of Man, well known as the colleague of Huxley and Buckland in the various fishery commissions from time to time instituted by Parliament.

Nearly every European government has sent hither specialists to report upon special subjects. Among the most eminent of these men of science have been Dr. Steindachner of Vienna, Dr. Sauvage of Paris, Dr. Möbius of Kiel, Professor Benecke of Königsberg, Professor Hubrecht and Dr. Van Beinmelen of Utrecht, Professor Giglioli of Florence, Dr. von Grimm of St. Petersburg, Dr. Malmgren of Finland, Professor Torell of Stockholm, Dr. Buch of Christiania, Mr. E. P. Ramsay of Sydney, Capt. Comerma of the Spanish navy, and Col. Sola of Madrid. The reports yet to be published will perhaps swell the literature of the exhibition to double its present bulk, and will be of interest to investigators in every department.

The exhibition was formally closed on the 31st of October by the Prince of Wales, who in his speech upon this occasion made certain very fitting allusions to the work of his father, Prince Albert, in the promotion of international exhibitions. G. BROWN GOODE.

A FOUR-DAYS' CRUISE OF THE ALBATROSS.[1]

WE left Wood's Holl at 4.10 P.M., Sept. 29, for an offshore dredging-trip. The weather was clear and pleasant, with light southerly winds and smooth sea.

At 9.02 A.M. the following day, we sounded in 1,342 fathoms, — bottom, globigerina ooze; latitude 39° 29′ north, longitude 70° 58′ 40″ west, — and at 9.38 put over the beam-trawl, veering to 1,900 fathoms of rope. It was up again at 1.03 P.M., the net containing a large number of specimens. [Station 2,095.]

The trawl was cast again at 2.44 P.M., in 1,451 fathoms, latitude 39° 22′ 20″ north, longitude 70° 52′ 20″ west. The bottom specimen brought up in the Sigsbee cup was the same as that of the former cast: but the trawl contained a granite stone weighing a hundred and seventy pounds, several small stones, small pieces of cinder, and lumps of hard clay; there were also several small specimens of what appeared to be oxidized iron. The haul was very successful, being particularly rich in foraminifera. [Station 2,096.]

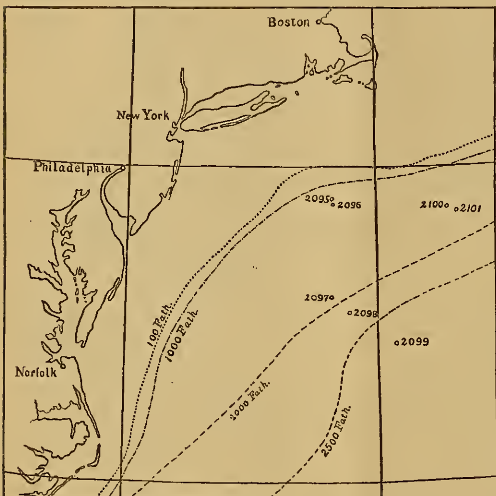
As soon as the trawl was up, a set of serial temperatures and specific gravities was taken to 1,000 fathoms. A temperature of 66° was found at 25 fathoms, 65½° at 60 fathoms, and 57½° at 40 fathoms. These strata of cold and warm water are the rule rather than the exception, in this locality; but, thinking that possibly the observation at 40 fathoms had been read incorrectly, it was verified, using another instrument, which registered 55½°.

At 8.22 P.M. we started ahead south ¾ west

[1] Report to Prof. S. F. BAIRD, U. S. commissioner of fish and fisheries, by Lieut.-Commander Z. L. TANNER, U. S. N., commanding U. S. fish-commission steamer, Albatross, kindly placed at our service by Professor Baird. Some of the appendices are abbreviated to save repetition.

(magnetic), running on that course till 5.30 A.M., Oct. 1, when we sounded in 1,917 fathoms, — latitude 37° 56′ 20″ north, longitude 70° 57′ 30″ west; bottom, globigerina ooze, — and at 6.18 put the beam-trawl over, veering to 2,600 fathoms. It was on the bottom at 8.04; and at 9.04 we began heaving in, landing it on the deck at 10.42 A.M., having made a successful haul. [Station 2,097.]

At 2.08 P.M. the beam-trawl was lowered again in 2,221 fathoms, latitude 37° 40′ 30″ north, longitude 70° 37′ 30″ west. It was down, with 3,000 fathoms of rope out, at 4.03



P.M., dragged till 5.14 P.M., and was landed, after a successful haul, at 7.24 P.M. [Station 2,098.]

At 7.34 P.M. started ahead south-south-east (magnetic), ran till 3.26 A.M., and lay to until daylight (about 5.30 A.M.), when we sounded in 2,949 fathoms, — bottom, globigerina ooze; latitude 37° 12′ 20″ north, longitude 69° 39′ west, — near the centre of the Gulf Stream. The sinker, sixty-four pounds weight, was thirty-four minutes in reaching the bottom; and the specimen-cup came up in thirty-six minutes. The thermometer registered at some intermediate depth not far from the surface, having capsized in some way in its descent. [Station 2,099.] The net of the beam-trawl was examined with great care, and every foreign substance removed, so that there should be no doubt as to whether specimens found were taken during the haul, or were in the net when it went down.

At 7.14 A.M. the trawl was put over, reaching the bottom at 10.13½, having veered 4,100 fathoms of rope. At 0.54 P.M. began heaving up, and at 3.18 P.M. it was landed on deck. It was a successful haul in every respect.

The moderate breeze of the morning increased to a strong wind with heavy swell before the trawl was up, making it doubtful whether we should succeed in landing it. A set of serial temperatures and specific gravities was attempted after finishing the haul; but the strong current, high wind, rugged sea, and threatening weather forced us to give it up after having veered 300 fathoms of rope. The method adopted to regulate the drift was at least original. The current of the stream was so strong that the trawl would not take the bottom; and, to effect this object, an officer was stationed on the forecastle with a dredging quadrant, constantly observing the angle of the dredge-rope, the engines being moved with sufficient speed to maintain it within certain prescribed limits.

At 4.30 P.M., moderate gale from south-west; hove to under fore storm-staysail, head to the southward, drifting rapidly with the stream about north-east by east. At midnight it was blowing a moderate gale with heavy sea, barometer 29.76, the air exceedingly sultry, and incessant flashes of lightning in every direction. At 1.40 A.M., 3d inst., started ahead, course north, and ran under moderate speed till 11.05 A.M., when, wind and sea having moderated, we sounded in 1,628 fathoms, globigerina ooze, — latitude 39° 22′ north, longitude 68° 34′ 30″ west, — and at 12.13 P.M. put the beam-trawl over, veering to 2,300 fathoms. There was still a fresh breeze from north-west, with heavy swell and very strong stream. The trawl was down at 1.59, dragged till 3.08, and was landed at 4.25 P.M. There were some interesting specimens, but most of the things were washed out of the net on the way up. [Station 2,100.]

At 4.31 P.M. we sounded in 1,686 fathoms, globigerina ooze, — latitude 39° 18′ 30″ north, longitude 68° 24′ west, — and at 5.15 P.M. put the trawl over, veering to 2,650 fathoms. It was on the bottom at 7.10, began heaving up at 8.15, and landed it on deck at 9.39 P.M. The heavy swell and strong stream combined washed a large proportion of the specimens from the net, but several new or rare species were secured. [Station 2,101.]

A course was laid to the northward as soon as the haul was finished, and the speed registered so as to strike the 100-fathom line in longitude 67° 50′ west, at daylight, when we proposed setting a trawl-line for tile-fish. We were on the ground at the proper time; but the weather was so boisterous that it was not considered prudent to lower a boat. It was too rough even for dredging; and, as our coal-supply was nearly exhausted, we started for port.

We encountered strong head-winds during the day, finally anchoring in Tarpaulin Cove at 10.40 P.M., where we remained till 6 A.M. on the 5th, when we got underway, and arrived at Wood's Holl at 6.40, making fast to our moorings.

List of fishes obtained.

BY ENSIGN R. H. MINER, U.S.N.

Station 2,095. — Bathysaurus Agassizii, Stomias ferox, Macrurus asper, Coryphaenoides carapinus, Halosaurus macrochir, Haloporphyrus viola, Cyclothone lusca, and one new species.

Station 2,096. — Eurypharynx, Haloporphyrus viola, Macrurus asper, Synaphobranchus pinnatus, Halosaurus macrochir, Coryphaenoides carapinus.

Station 2,097. — Berycid (new species), Macrurus asper, Cyclothone lusca, Scopelus.

Station 2,098. — Macrurus asper.

Station 2,099. — Cyclothone lusca, Scopelus, Berycid (new species), two new species.

Station 2,100. — Cyclothone lusca, Scopelus, Forcipichthys.

Station 2,101. — Berycid (new species), Eurypharynx, Cyclothone lusca, Argyropelecus Olfersii, Sternoptyx diaphana, Scopelus, two new species.

Register of invertebrates captured.

BY J. E. BENEDICT.

The results obtained were good, notwithstanding the sea was quite rough much of the time. The surface-nets were in use when practicable, and a number of fine specimens were taken in them. As heretofore, schools of squid were seen in the water, illuminated by the arc-light. One of the crew captured

three of them with the squid-jig. Several land birds were seen far out at sea. A pair of kingfishers (Ceryle alcyon) flew about near station 2,096. A pair of fish-hawks (Pandion haliaetus) acted as if they were at home near station 2,099, 250 miles from land. A golden-winged woodpecker (Colaptes auratus) and a song-sparrow (Melospiza melodia) came on board to rest, at station 2,100.

The principal invertebrates taken were as follows:—

Station 2,095. — The sounding-cup brought up ooze containing foraminifera from a depth of 1,342 fathoms. The beam-trawl was put over with wings attached. Among its invertebrates were twenty-five holothurians (Benthodites), many large zoroasters, several cup-corals (Flabellum), a shrimp nine inches long with very large eggs, three specimens of a crab (? Galacantha). Some of the holothurians were placed in picric acid before putting them into weak alcohol. A portion of the eggs were taken from the large shrimp, and preserved in Müller's fluid for the study of the embryos, which were plainly visible within.

Station 2,096.— Again the sounding-cup brought up ooze with foraminifera, this time from a depth of 1,451 fathoms. Strange to say, a large stone, weighing upward of a hundred and seventy pounds, was brought up with sponges and worm-tubes attached. This would, I think, preclude the possibility of its being below the surface of the foraminiferous ooze, which came up in quantity sufficient to yield two quarts of clean foraminifera. The principal ingredients found in the stone were quartz, hornblende, and iron. Eighteen holothurians (Benthodites), many specimens of a small ophiuran, a few large shrimp, and some small shells, made up the bulk of the material.

Station 2,097. — Bottom, ooze, with foraminifera from a depth of 1,917 fathoms. One amphipod three inches and a half long, shrimp, Epizoanthus on hermit-crabs (species unknown), Urticina concors Verr. on Sympagurus pictus Smith, Ophioglypha convexa Lym. and Ophiomusium armigerum Lym. in small numbers, a starfish remarkable for its large madreporic plate and ambulacral feet, small ascidians coated with foraminifera.

Station 2,098.— Depth, 2,221 fathoms. Epizoanthus, Urticina concors Verr on Sympagurus pictus Smith, Ophioglypha convexa Lym. and Ophiomusium armigerum Lym., also a few shells.

Station 2,099. — This haul was remarkable from the fact that the sounding was in water 2,949 fathoms. This is perhaps the deepest water ever successfully invaded by a large trawl: certainly it is the deepest we have record of with any trawl. The trawl went down more than three miles at the end of upwards of four miles and a half of wire rope without capsizing, and that in the middle of the Gulf Stream, while the water was quite rough. That there might be no question as to the specimens brought up, the captain had the net thoroughly cleaned before it was put over the side. The amount of material brought up was not large. The only specimens from the bottom were a species of Boltenia, and many fragments of a Bryozoon we had not seen before. A fine large schizopod, with several species of shrimp and small crustacea, were taken in good condition. These, with a cephalopod and the fish, made it one of the best hauls.

Station 2,100, with a depth of 1,628 fathoms, and 2,101 with a depth of 1,686 fathoms, brought us only shrimp and fish.

THE ZOÖLOGICAL STATION OF HOLLAND.[1]

For some years past, zoölogical science has been pursuing a course abounding in brilliant discoveries. The examination, however minute, of animals preserved in collections, no longer satisfies the naturalist: he must study the living animal. Zoölogy has become experimental. On all sides, maritime stations are being established. Numerous works on anatomy and embryology have cleared up the philosophical theory of the transformation of animals by showing that the metamorphoses, which, less than half a century ago, were almost unknown, are very common among marine animals.

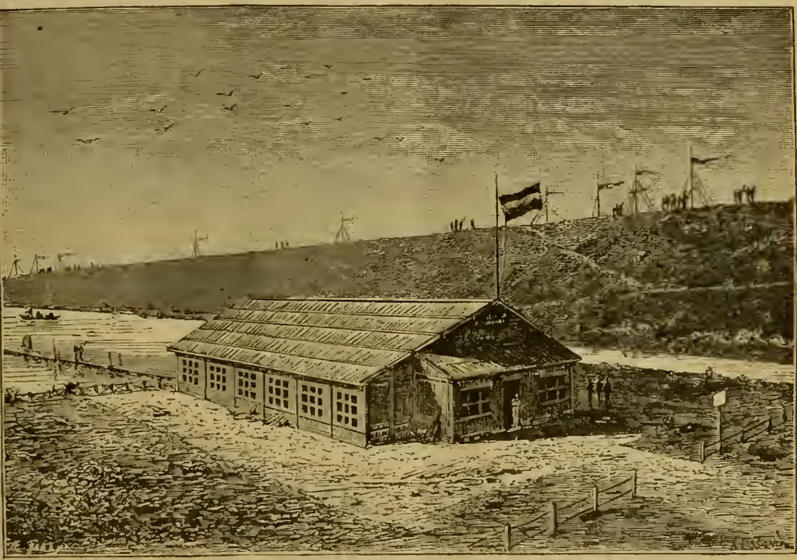
Holland, which has produced so many great anatomists and such patient naturalists, seemed to be tardy in following the example of neighboring nations, when, on the 4th of December, 1875, at the instiga-

[1] Translated from *La Nature* of Sept. 8.

tion of Professor Hoffman, its president, the Zoölogical society of the Netherlands voted to erect a zoölogical station on the shore of the North Sea. A committee, composed of Messrs. Hoffman, Hubrecht, and Hoek, decided on the erection of a station which could be easily transferred from one point to another on the Netherland coast. With its sandy shores and gradual slope, Holland has, it is true, a comparatively poor zoölogical fauna. The committee thought, therefore, and rightly, that a movable station would be more serviceable, as it would permit successive exploration of various parts of the shore.

The appeal made by the Netherland society to the generosity of the state, to scientific societies and private individuals, met with a response; and the sum of ten thousand francs was soon obtained. Work was immediately begun. The choice for the first season fell upon the city of Helder, situated at the northern extremity of the province of North Holland, at a point where an arm of the sea, called Helsdeur, separates the mainland and the island of Texel. The material, loaded in a wagon drawn by cattle, reached its destination, July 8, 1876. Three days after, the station was in readiness, and studies were begun.

As throughout the coasts of the Netherlands, the bottom of the sea is, at Helder, chiefly composed of shifting sand; and one can scarcely, under such circumstances, expect to meet with those fixed animal forms which constitute the wealth of rocky bottoms. Few species can resist the sand which covers and smothers them. But while the downs extend west of the city of Helder, at the north there rises a spur of granite and basalt, in the irregularities of which numerous animals find shelter: it is the only point on the coasts of Holland where seaweeds are found. The minister of the marine having consented to place twice a week a steam-launch at the disposal of the commission, the little dredges invented by Wyville Thompson and the apparatus of Lacaze-Duthiers were employed, and a hundred and thirty species obtained.



THE DUTCH ZOÖLOGICAL STATION.

The second year the station was established at Flessingue; and the coast of Zealand proved not less rich in animal forms than the slope of Nieuvediep and the bank of Helder. In the years following, the station was at Bergen-op-Zoom.

During these latter seasons, the commission has not wholly devoted itself to the examination of animals which live on the coasts of Holland. Researches at the station have since aimed to furnish oyster-cultivators with information as complete as possible, on the anatomy, the embryology, the enemies, and diseases, in a word, on the biology, of the oyster. The eastern Scheldt has to-day become an important centre for oyster-culture; so much so, that the two stations, Kruiningen in Zealand, and Bergen-op-

Zoom in North Brabant, exported in 1881 about two million oysters, valued at some three million francs.

In order that the building may be easily taken to pieces and put in position, it is made entirely of wood; and the parts are arranged with such care that its removal from one place to another requires only three days besides the transit.

The station was at Bergen-op-Zoom when we visited it, and we were received by Professor Hubrecht with the cordiality and kindness characteristic of the *savants* of Holland. It is composed of a principal building about eight metres long and five broad. One façade has four windows; the other, three. The walls are three metres high; the ridge of the roof, four and a half. The framing of the roof is of wood, covered with a double layer of rush-matting. Opposite each window there is a stationary table: tables are also arranged in the centre of the room. In the laboratory are a closet for the instruments, another for the reagents and bottles, and also a small library, containing periodicals and the principal works on marine faunas. Each investigator can, in addition, send for books which he needs, either from the library of the zoölogical society, or from one of the universities of Holland. A desk, foot-rests, and some folding iron chairs complete the furnishings. The work-room, properly so called, is entered through a room in which are the aquaria, the collecting-apparatus, and the smaller dredges. The cumbersome instruments are placed in a room connected with one of the side-façades. Another room, opposite the entrance, leads into the private office of the director of the station. A fence of galvanized zinc wire runs around the building, and, while it wards off the thoughtless, encloses a space which may be used either for experiments in the open air, or for the dissection of animals of large size.

The construction of the house, as it stands to-day, has cost fifty-five hundred francs. An additional sum of six thousand francs was expended in the purchase of furnishings, aquaria, collecting-apparatus, reagents, thermometers, lenses, etc.

The management of the station is regulated in a very simple manner. The members of the zoölogical society nominate each year a committee, which publishes at the end of the year a report of the work, and gives an account of the funds expended.

Although the resources of the zoölogical commission are very limited, nevertheless the members have undertaken important work. During the season at Helder, Mr. Hubrecht was engaged upon fishes; Mr. Hoek studied the crustaceans; Mr. Horst, annelids; while Messrs. Van Harem, Noman, and Sluiter studied the other invertebrates. Mr. Hoek undertook, at Bergen-op-Zoom, his interesting researches on the embryology of the edible oyster. H. E. Sauvage.

LETTERS TO THE EDITOR.

The formation of tornadoes.

In the discussion of Mr. Hoy's paper before the American association for the advancement of science, at the recent meeting at Minneapolis, I notice a number of statements which seem to me erroneous. Professor Rowland, for instance, asserts that "the rotation of the tornado is a necessary consequence of the earth's rotation." Now, if this be true, why are not tornadoes more frequent? Why is it necessary to have brisk, southerly winds, with high temperature and low barometric pressure? Why do they not happen on clear days as well as on cloudy ones? Again: if the earth's rotation determines the direction of the gyratory motion of tornadoes, why does it not govern the motion of the little whirlwinds occurring in dry weather? Every observer knows that these revolve, sometimes in one direction, and sometimes in the other, but perhaps, in a majority of cases, in the same direction as tornadoes.

It is well known that tornadoes in our latitude occur on days when there is a strong breeze from a southerly direction. Now, the air on such days, in spring and early summer, is heavily charged with moisture; to which fact is due the oppressiveness of the heat. As the heat of the day increases, local showers are formed, which move, not with the surface-wind, but in a higher current from a westerly direction. There is usually a divergence of about ninety degrees in the angle formed by a line indicating the direction of the track of the tornado, and another marking the direction of the preceding surface-wind.

Now, the mingling of these currents, or even the passage of one beneath the other, must, on account of their unequal temperatures, condense more or less of the moisture of the warmer current. This condensation is nearly always noticed. A cloud, often of intense blackness, accumulates just under the southern edge of the storm-cloud, and is usually prolonged horizontally to the northward along its base. If the cloud is near enough, so you can see beneath it, the parts farther in the rear will be seen to move rapidly in an easterly direction, just as the air-current moves which bears them. How can it be otherwise than that a gyratory motion shall result from such conditions? People frequently say, in describing a tornado, that "two dark clouds rushed together from opposite directions, and produced the tornado." This statement, if we are expected to construe it literally, seems somewhat absurd, since a cloud is always a passive element, moving only as the air moves in which it floats. That fragments of clouds and often quite large masses move toward each other is true; but tornadoes are not produced because of this, but on account of the *mutual resistance of two currents of air.* If two liquids or gases are brought together from different directions, a whirling motion is produced, as may be seen where two small streams of water flow together, or where a rock or fallen tree interrupts the direct movement of the water. This is but a necessary result of the combination of properties inherent in such a medium.

A volume of air, under pressure, escapes in the direction of least resistance: and, as there is a considerable pressure of the air where the two currents meet, an escape-current must form somewhere; and it forms, in accordance with the above law, in the direction of minimum resistance, obliquely upward to the east or north-east. As soon as this escape-current is developed, its position is at once located by a slender stem of vapor rapidly ascending obliquely; though, if the observer is at some distance, it seems to be suspended from the cloud above it, and even at times to descend toward the earth. Some of the downward movements of this 'funnel' are apparent only, the constantly ascending vapors sometimes condensing near to the ground, and at other times high in air. The tunnel-cloud is often absorbed into the cloud above, almost as soon as formed, the conditions necessary to its full development not existing.

In his excellent article on tornadoes, in the current number of the *Kansas City review of science*, Mr. John D. Parker speaks of the four characteristic motions of these meteors. These motions might be classified as horizontal and vertical. The horizontal motions are the linear, caused by the forward motion of the air-current governing the direction of the storm-cloud; second, the gyratory motion, caused, as above stated, by the mutual resistance of air-currents moving in different directions; third, the swaying motion, due partly to the varying pressure on different sides of the tunnel, and partly to the vertical or bounding motion of the tunnel. This latter motion would not have a very marked effect in producing the 'dentated edges' of the storm's path, if the tunnel-cloud were vertical instead of slanting. What causes the bounding motion it is difficult to say, but it certainly resembles electrical attraction and repulsion. This bounding movement was very marked in the tornado of April 18, 1869, which passed near this locality; but occurring, as it did, in the daytime, I could not distinguish the illumination of the lower part of the tunnel, which may sometimes be seen when these storms occur after dark, and which some think is due to electricity.

It is interesting to produce in miniature the horizontal motions of the tornado by the following simple experiment. When there is a good fire, let a small quantity of light, flaky ashes, or other light material, be sprinkled over the whole top of the cooking-stove. The heat forms quite a strong current, ascending mainly from the central parts toward the pipe. Cool currents flow in from all sides. Now, with the hand or a fan, produce local or opposing currents over the heated surface, and at once little tornadoes are developed, whirling the ashes several inches in the air. I have often produced them on both sides of the stove at the same time; those on the left moving as tornadoes in our latitude, and those on the right in the opposite direction. Now, are not the causes of the gyratory motion of the little whirlwinds on the stove, tiny as they are, the same in kind as those which produced the storms which devastated Marshfield, Grinnell, or Camanche? If this be answered in the affirmative, the rotation of the earth plays no direct part in causing the gyratory movement of this class of storms. Of course, the rotation of the earth causes the higher currents of air to move toward the north-east, instead of due north, as they pass from the equatorial to the arctic zone, and these currents determine the general linear movement of storms in our latitude; but this makes it proper to consider the gyratory motion an indirect result rather than a direct consequence.

S. A. MAXWELL.

Morrison, Ill., Oct. 9, 1883.

The chinch-bug in New York.

Why should Mr. Lintner conclude that the chinch-bug was brought to St. Lawrence county, N.Y., in a freight-car from the west? Harris corrects the erroneous idea that it is confined to the states south of 40° of latitude by demonstrating its occurrence in Illinois and Wisconsin, while Fitch's record of finding it in northern New York would justify us in assuming that it has always existed there, especially when we know that its range is much farther north. Packard found it on the top of the White Mountains; and it is to-day the most serious enemy that threatens the vast wheat-fields of Dakota. It seems to me more rational to consider this injurious manifestation in New York a result of undue increase of a species always there than to call it an invasion. Though we rarely hear of its injury in the Atlantic states, yet it is commonly met with where collecting is done near or in the ground, and in dry years is by far the most common Heteropter in grain and grass fields and dunes. This I know from personal experience, and have found it as far north as Boscawen, N.H.

Should it prove less susceptible to heavy and continued rains in New York than elsewhere, the fact will be remarkable. Such rains affect it most, however, in spring and early summer. My own interpretation of the interesting facts recorded by Mr. Lintner would be, that the species multiplied exceedingly during the very dry seasons of 1880 and 1881, and that the wet season, which it has so far braved (as it often does for a while in the west), will nevertheless tell on the hibernating bugs. In this view there is cause for encouragement rather than alarm. A careful survey would undoubtedly show, as Mr. Lintner suggests, that it exists in many places in the state where it has not yet been detected.

C. V. RILEY.

Washington, D.C., Oct. 24, 1883.

Unusual reversal of lines in the summit of a solar prominence.

On Oct. 17, between 3.45 and 4.30, local time (about 8.45 and 9.30 Greenwich time), a rather unusual phenomenon was observed at Princeton, in a prominence connected with the large and active group of spots which at that time was just passing off from the sun's disk.

The prominence had the very common form of a number of overlapping arches, with a sort of cap above them, or of a cloud connected by several curved stems to the chromosphere below. Its elevation was about 2′, and its extent along the sun's circumference a little less.

The peculiar features were the extreme brilliance of the cloud-cap at the summit of the prominence, and the perfect delineation of the form of this cloud in certain spectrum-lines, which ordinarily are reversed only at the base of the chromosphere; while, at the same time, certain other lines, which not unfrequently are reversed at considerable elevations, showed its form only very faintly, or not at all.

When I first came upon the prominence, in running around the sun's limb with the spectroscope, the brightness of the cloud-cap, as seen through the *C* line, was simply dazzling. I do not remember ever to have seen a prominence, or any part of one, quite so brilliant. At the same time, the line λ 6676.9 (which is in the same field of view with *C*, and is No. 2 of my catalogue of chromosphere-lines, — a line attributed to iron) also showed the top of the cloud quite as well and as brightly as is usual in *C* under ordinary circumstances. The chromosphere, also, was faintly visible in the same line; but the stems and lower portion of the cloud could not be seen at all in it. On turning to line λ 7055 (No. 1 of the catalogue), I was surprised and gratified to find the same appearances conspicuous in this line also. A careful search failed to show any other lines reversed below *C*.

Running up the spectrum from *C* to *D*, I could not find any lines showing the *top* of the prominence, though a considerable number were reversed in the chromosphere at its base. D_3, of course, showed the cloud-cap magnificently, but D_1 and D_2 only very faintly, though *distinctly* enough.

Between *D* and *b* the same remarks apply as between *C* and *D*. The corona-line, λ5315.9, was reversed at the base of the prominence a little more brightly than in adjacent parts of the chromosphere, but not at all in the cloud-cap. The magnesium members of the b group showed the cloud faintly in the same way as the sodium-lines; but in b_3 the form was a little more conspicuous.

Between b and F, *two* lines (λ 5017.6 and 4923.1, both attributed to iron) showed the cloud-cap as beautifully as either of the two below C. Numerous other lines were reversed in the chromosphere, but none of them showed the upper parts of the prominence. F appeared much the same as D_3.

Between F and G, *five* lines were noted as showing the cap. The most refrangible of them was Lorenzoni's f (λ 4471.2): the other four I did not identify at the moment, being in haste to reach the violet portion of the spectrum, and intending to examine them later, — an intention I was not able to carry out, on account of the intervention of clouds.

The lines $H\gamma$ (λ 4340) and h were, of course, conspicuous, each showing the whole of the prominence. I expected that H and K would do the same, but was disappointed. They both exhibited the cloud-cap finely, but I could not make out in them either the stems of the prominence, or the spikes and knots of the chromosphere; and yet both the lines were well reversed, not only in the chromosphere, but also on the face of the sun itself, over all the faculous region surrounding the spots. The ultra-violet line above K, first observed here a few weeks ago, was not visible.

There was no considerable motion-displacement exhibited by any of the lines, — something rather singular in so brilliant a prominence, — nor did its shape change much during the forty-five minutes of observation.

It is perhaps possible that this cloud was indentical with a remarkably brilliant facular *bridge*, which was observed two days before, spanning the largest of the spots which composed the group: still this is by no means certain. The instrument employed was the nine and one-half inch equatorial, with the Clark spectroscope carrying a Rutherfurd grating, of about 17,000 lines to the inch; first-order spectrum.

C. A. YOUNG.

Princeton, N.J., Oct. 22, 1883.

Sternal processes in Gallinae.

Having several times been asked the function of the long processes of the sternum as found in the Gallinae, I would make the following suggestions: —

If the sternum be examined *in situ*, the outer processes will be seen to extend far back, and well up the sides of the body, while the inner pair extend over the abdomen. The notches between the processes are closed by very tense, fibrous membranes. By this means a large area is afforded for the insertion of muscles with a minimum of bone. This must contribute slightly to diminish the weight of the posterior end of the body. Passing now to the muscles, we find that the great pectoral arises from the entire posterior border of the sternum, while the subclavius fills up the angle between the keel and body of the bone.

So much for the anatomy. What are the physiological results, and why could they not be attained in other ways? The results are an increased amount of pectoral muscle, and an increase in the length of the fibres, as compared with many other birds. Both of these are very desirable results for heavy birds of short, rapid flight, — the first, because with the increase in muscle comes a corresponding increase of force in the stroke of the wing; the second, because, by virtue of the long fibres, rapidity of contraction and a long stroke of the wing are secured. The rapidity is gained by all parts of the fibres contracting at once, whence the longer the fibre, the more quickly will a given amount of motion result. Both the first and the second are also aided by the fact that the first part of a muscular contraction is more powerful than the last part.

There is but one other way in which the same results, so far as the insertion of the muscles goes, could be attained; that is, by their origin from the ribs which lie under the sternum, as in the mammals, instead of from the overlapping sternum. To this, however, there is an all-powerful objection. If a man be watched while violently using his arms, it will be noticed that the upper part of the chest is held stationary. The pectoral muscles must have a firm point to pull from, in order to move the arms. As a result, respiration in the upper part of the chest is impeded, or, better, respiration is impeded by the diminished amount of tidal air. This principle is illustrated in the long, slow stroke, about twenty to the minute, of men trained to row great distances. The breathing is done, while the pectoral muscles are relaxed, at the normal rates. The same, only in a much greater degree, would hold good for birds. Were the muscles inserted into the ribs, respiration would be interrupted several times each second during flight: hence it is evident that the muscles could not be inserted into the ribs.

But again: why should the Gallinae require rapid powerful motions of the wings? Why should they not have long wings, and a comparatively slow stroke? This is forbidden by their habits. Long wings would be very cumbersome when the bird was on the ground, and absolutely worthless in much of the brush through which a grouse will fly with wonderful rapidity.

Therefore we may say that the processes are developed to give, with the greatest economy of material, a large area for the insertion of the pectoral muscles in such way as not to interfere with respiration, and that such area is required for the flight of the bird.

J. AMORY JEFFRIES.

A bifurcate tentacle in Ilyanassa obsoleta.

Some years ago, when collecting for my marine aquarium, in Raritan Bay, at Keyport, N.J., I obtained an Ilyanassa obsoleta of such a strange form, that I made a pencil-sketch and notes of it at the time. The left tentacle was bifurcated at the shoulder, or place where the normal tentacle abruptly narrows. The two sub-tentacles thus caused, seemed to be equally sensitive, as each was capable of separate and independent movement. Several instances have been long known to me of bifurcation of the caudal spine of Limulus; but the additional prong in every instance was functionless, and, in fact, an inconvenience. I have also seen malformed antennae in microscopic insects. As I have not heard of a similar instance in the mollusca, it seemed to me that the case should go on record.

SAMUEL LOCKWOOD.

Freehold, N.J.

The mechanism of direction.

Shortly after reading Professor Newcomb's paper in SCIENCE for Oct. 26, 1883, I had the pleasure of meeting him, and of discussing some matters of mutual interest in regard to subjective states of consciousness. It seems to me that the professor does not give sufficient weight to habit, and to unconscious cerebral action. In the strict sense of the word, one is not always *conscious* of the way he is going; for although he may avoid obstacles of any kind, yet he may pass some distance beyond his abiding-place by reason of mental pre-occupation. There are two lines of cerebral action going on at once, — one, the active mental study which engrosses him; the other, the unconscious action that keeps him out of danger from passing vehicles, or from other causes incident to city life. The limitation of direction which Professor Newcomb regards as exceptional, I consider as general: i.e., I believe that there are vastly more men who have no definite idea of lines as a standard of reference, than there are those who refer every thing in direction to such co-ordinates; just as there are many who never have any definite idea of the cardinal points of the compass, either as real or ideal points, and who never arrive at any clear conception of the bearings of familiar buildings, or the direction of streets, though they may live in the same city for years. The domination or tyranny of a fixed idea is explanatory of the difficulty which Professor Newcomb experiences. His ideal or subjective west was the domination of a fixed idea indelibly imprinted upon the super-sensitive cerebral cortex of youth, not necessarily associated with ideal or absolute direction, or with any system of horizontal lines, but an isolated conception, formed out of the perception of different positions, which in early youth could hardly be correlated with any abstruse reasoning. This idea of west, once ingrafted upon a developing brain, became a fixed factor, so dominant as to tyrannize over the understanding, and so persistent as to require some moments of study to dispel the illusion. This becomes evident from an analysis of his third division. The tyranny of the early idea has usurped control over the will, and, indeed, over the whole cerebral outcome. Even though the internal evidence corresponds with the external bearings to show that his preconceived west is really *not* west, but some other point, yet so strong is the power of this subjective idea, that by no process of argument can he rid himself of it. This is not uncommon, but by no means of frequent occurrence. But it is not a normal harmony of relation between the various reciprocal functions of the brain. It is likened to a habit formed in youth, so strong as to be ineradicable in manhood, and has been studied with much care by psychologists. Again: one may be mistaken as to direction, or become confused in tracing his route through the intricacies of his hotel, without associating such perversions with any states of subjective consciousness, so far as these states may involve the consideration or differentiation of the 'co-ordinates.' A man who is ignorant of the cardinal points of the compass, and who never can tell in which direction he is facing, loses his way because he has lost his bearings: the road was known by reason of the association of other facts, — a certain house just here, or a lamp just there, — and not because his horizontal lines have led him astray. In view of what we have learned of unconscious cerebral action, of habit, of the association of ideas, of the tyranny of a fixed idea, and of subjective states of consciousness leading on to abnormal objective conditions, it seems to me that Professor Newcomb's case is not an isolated one, and that what he has written of himself has already been written of and discussed.

HORATIO R. BIGELOW, M.D.

Washington, D.C.

Colorado climate.

For the benefit of other sufferers, please allow me to correct what is likely to lead to an erroneous impression, on reading Dr. Fisk's article on 'Climate in the cure of consumption,' as published in SCIENCE of Oct. 5. Dr. Fisk, in his very able article, like most of those who have written of the fitness of the climate of Colorado for consumptives, speaks as though Denver City were Colorado, and *vice versa*.

Now, this unintentionally misleading impression is calculated to do serious harm. During the late spring, and in summer and autumn, Denver and neighboring localities may be quite as pleasant and beneficial to the consumptive as localities south of the 'divide' that separates the waters of the Platte from those of the Arkansas.

But, during the cool and cold months, the Arkansas valley furnishes a very much better climate than can be found anywhere north of this divide in Colorado. It is scarcely necessary to state that the Arkansas valley furnishes all the necessary comforts of civilization, including convenient railroad transportation. As a rule, with rare exceptions, the consumptive should not sojourn in towns or cities, but rather in rural districts. But, should the consumptive prefer town or city life, Pueblo, Cañon City, and other places in the Arkansas valley, afford ample accommodation.

Having long been a sufferer myself, and having sought health in many portions of North America, I speak of the before referred to localities from observation and experience, and without prejudice or pecuniary interest.

Q. C. SMITH, M.D.

Austin, Tex., Oct. 18, 1883.

[Dr. Fisk's article was written with especial reference to Denver, as the necessary data exist for that place, furnished by the records of the signal-service station: these do not exist for localities in the Arkansas valley. — EDITOR.]

A BIOGRAPHICAL HISTORY OF ASTRONOMY.

Heroes of science — astronomers. By E. T. C. MORTON, B.A., scholar of St. John's college, Cambridge. London, *Society for promoting Christian knowledge*, [1882.] 341 p. 16°.

FROM the title, 'Heroes of science — astronomers,' one might expect to find in this little book an account of the lives and a eulogium of the characters of the greatest astronomers, with some general indication of the nature of their discoveries. This expectation would be partially corrected by the opening paragraphs of the preface: —

"The primary object of this little book is, as its name implies, to give some account of the lives of the chief astronomers. But it is impossible to leave in the mind of the general reader any clear notion of their characters, without giving some account of their work. A good deal of space is therefore taken up with explanations of their discoveries; but, as this is only of secondary importance, the explanations are given in a popular manner, and no mathematics is introduced, except in ten pages (172–182), where a knowledge of the first book of Euclid and of the elements of algebra is assumed.

"The book may possibly be useful as an introduction to the study of astronomy, and, in this aspect of it, it is hoped that it may be helpful in two respects: First, by putting before the student the personal difficulties which the first investigators of the law of the stars met with, and the struggles they passed through to overcome them, whereby a human interest is given to the study of their work; and secondly, by clearly indicating the nature of the problems to be solved by the science."

In point of fact, however, the book does much more than this: it presents a clear, connected, readable account of the chief steps in the progress of astronomy from the earliest times to the present day; and while the lives of the astronomers, judiciously inserted and as a rule well told, greatly heighten the interest of the story of the science, the reader always feels that they are only the accidents of the book, while the unfolding of the successive triumphs of astronomy, and the exposition of its laws, objects, and methods, is its constant purpose.

Interesting and readable as the book is almost throughout, we nevertheless think the author mistaken in regarding it as well adapted to serve as an *introduction* to astronomy for non-mathematical readers. It is true that only very elementary mathematics is explicitly introduced; but few readers who are not either equipped with the habits of thought bred by mathematical study, or possessed of some familiarity with the outlines of astronomy, can follow intelligently and with interest the discussion of complicated motions. To young people who have gone through an elementary course in astronomy, on the other hand, the book before us will be most instructive and stimulating. The subject is vivified, not only by the presentation of the lives, so full of inspiration, of the great founders of the science, but also by a far clearer view of its progressive development than an ordinary text-book can afford. And the impression is not weakened by the introduction of insignificant details, or of merely statistical information. Not that details are avoided when they are necessary to the exposition or illustration of a great law, or of an important phenomenon: on the contrary, one is surprised at the number and diversity of the points which are explained, and in general clearly and satisfactorily explained. The author has not refrained from giving simple expositions of mechanical and physical laws when they are essential to the clear understanding of astronomical doctrines. By explaining the laws of motion, for example, and insisting on their fundamental importance, he puts the reader in a position to understand the great problem of physical astronomy, and to appreciate its solution. In connection with spectrum analysis, a little space devoted to the analogy between sound and light makes the subject clear to the average reader. And many other instances might be mentioned.

As the character of the book does not make it incumbent upon the author to present any thing like a complete survey of even the most prominent astronomical facts, he is able to give a much fuller exposition of the central points in the theory of astronomy than one would expect to find in so limited a space, and to give intelligible accounts of many things having a direct connection with these central principles, which are usually passed over with a bare mention in small works on astronomy. Thus, more than eighty pages are devoted to Newton, only a small portion of which is biographical, a whole chapter of fifty pages being specifically devoted to the Principia. And pretty full accounts are given, for example, of Herschel's theory of stellar distribution, of the nebular hypothesis, of Laplace's proof of the stability of the solar system and Lagrange's previous attempts in that direction, and of the recent researches of Mr. G. H. Darwin.

It would be quite possible to point out minor defects in the book. There is occasionally (but very seldom) an attempt to explain what cannot be satisfactorily explained in a popular manner; once in a while the demonstrations, which are usually in excellent and attractive form, are made pedantically stiff; there are a few inaccuracies, chiefly of expression; and there are possibly a few cases of Sunday-school moralizing from insufficient premises. The only instance we have noticed of unfairness in the historical portion is in the passage relating to the Mohammedan astronomers. Scant justice is done them; and the author permits himself to combine silliness with injustice in saying that 'it illustrates the slavish stupidity of the race,' that a discovery made by an Arab astronomer in the tenth century was afterwards forgotten by them! A grave defect, but one which can easily be remedied in a new edition, lies in the lack of an index, — an omission which seriously impairs the value of this very interesting and useful work. In conclusion, lest we should leave the impression that the book can be read with advantage only by students, we would say that the chapters which combine in the highest degree biographical with scientific interest, — those on Copernicus, Tycho Brahe, Kepler, and Galileo, — and many other parts of the book, may be read with great pleasure and profit by a very wide circle of readers.

PROCTOR'S GREAT PYRAMID.

The Great Pyramid: observatory, tomb, and temple. By R. A. Proctor London, *Chatto & Windus*, 1883. 323 p., illustr. 8°.

This last work of Mr. Proctor's fertile and ingenious mind is of uncommon and enduring interest. To begin with, it concerns the most uncommon and the most enduring work of man, — the Pyramid of Cheops, whose mighty form has for nigh five thousand years remained the least changed and the least comprehensible of all man's great deeds. Then it comes happily into a discussion which is by far the most curious that has recently vexed the minds of learned men. There are plenty of paradoxical folk on the lower confines of science, — circle-squarers, Symms'-hole hunters, and the like; but men of learning, especially astronomers and mathematicians, are a hard-headed lot. The crack-brained do not often find their way up to their upper heights, for evident reasons. But it is a set of these really learned people that has given us the sect of the pyramid worshippers, — the most extraordinary cult of a century, that, of all the Great Pyramid has ever seen, has been the most fertile in religious whims.

Active proselyting not yet having begun, perhaps for want of needed martyrs, the general public has as yet heard little of the pyramidalists or their faith. This is surprising; for their faith has more miracles 'to the acre' than Mormonism, and these miracles are as solid and ponderable as the pyramid itself. They are before our eyes: hundreds of pages of mathematics are needed to express them, and they have all the cheap look of certainty which the public associates with algebraic formulae. The following is in brief the history of pyramidalism, the only mathematical *ism* of the nineteenth century. Many years ago a Mr. John Taylor, pondering on the matter of the Great Pyramid, — which, by the way, he had not seen, and never saw, — came to the extraordinary conclusion that the architects of the structure recorded in its proportions, and in the arrangement of its chambers and passages, certain religious and astronomical truths, which they intended should, after thousands of years of secrecy, be divulged in our day. Mr. Taylor, being otherwise unknown to fame, though clearly entitled by this tour of imagination to rank high among speculators, found no able advocates of his notion, until his book came in the way of Professor Piazzi Smyth, astronomer royal of Scotland, one of the most distinguished astronomers of our time. Captivated with this daring hypothesis, Professor Smyth visited the Great Pyramid, spent many months in a careful and costly survey of the structure, and, in his successive writings on the subject, has not only re-affirmed the conclusions of Taylor, but immensely extended the range of his conclusions. Briefly stated, his position is this: some three thousand years or more before our era, a Semitic prince, probably Melchizedek, that vast shadow of the time, inspired by God, went to Egypt, gained an intellectual mastery over King Cheops, and forced him to build this pyramid, which was designed to "keep a certain message secret and inviolable for four thousand years, . . . and in the next thousand years it was to enunciate this message to all men; . . . and that part of the pyramid's usefulness is now beginning."

This 'message' is thus summed up by Mr. Proctor: —

"The Great Pyramid was erected, it would seem, under the instructions of a certain Semitic king, probably no other than Melchizedek. By supernatural means, the architects were instructed to place the pyramid in latitude 30° north; to select for its figure that of a square pyramid, carefully oriented; to employ for their unit of length the sacred cubit, corresponding to the twenty-millionth part of the earth's axis; and to make the side of the square base equal to just so many of these sacred cubits as there are days and parts of a day in a year. They were further, by supernatural help, enabled to square the circle, and symbolized their victory over this problem by making the pyramid's height bear to the perimeter of the base the ratio which the radius of a circle bears to the circumference. Moreover, the great processional period, in which the earth's axis gyrates like that of some mighty top around the perpendicular to the ecliptic, was communicated to the builders with a degree of accuracy far exceeding that of the best modern determinations; and they were instructed to symbolize that relation in the dimensions of the pyramid's base. A value of the sun's distance more accurate by far than modern astronomers have obtained (even since the last transit of Venus) was imparted to them, and they embodied that dimension in the height of the pyramid. Other results which modern science has achieved, but which by merely human means the architects of the pyramid could not have obtained, were also supernaturally communicated to them; so that the true mean density of the earth, her true shape, the configuration of land and water, the mean temperature of the earth's surface, and so forth, were either symbolized in the Great Pyramid's position, or in the shape and dimensions of its exterior and interior. In the pyramid, also, were preserved the true, because supernaturally communicated, standards of length, area, capacity, weight, density, heat, time, and money. The pyramid also indicated, by certain features of its interior structure, that when it was built the holy influences of the Pleiades were exerted from a most effective position, — the meridian through the points where the ecliptic and equator intersect. And as the pyramid thus significantly refers to the past, so also it indicates the future history of the earth, especially in showing when and where the millennium is to begin. Lastly, the apex or crowning stone of the pyramid was no other than the antitype of that stone of stumbling and rock of offence, rejected by builders who knew not its true use, until it was finally placed as the chief stone of the corner. Whence, naturally, 'Whosoever shall fall upon it' — that is, upon the pyramid religion — 'shall be broken; but on whomsoever it shall fall, it will grind him to powder.'"

It would require all the space of this number of Science to print in full array the evidence on which these conclusions are rested. At every step the able astronomer royal of Scotland has fortified his conclusions by careful measurements of the Great Pyramid. His method of working is as follows: having found that the unit of measurement is a certain length, about an inch, which he terms the 'pyramid inch,' he seeks, in the various measurements of the structure, for correspondences in number of these units with natural and historic units, the distance of the sun, the radius of the earth, etc. Finding a correspondence, or *a close approximation to a correspondence*, he assumes that this ratio was intended by the builders to be a statement of this truth. At first sight, the number and accuracy of these correspondences is simply astounding: they look like insuperable facts. Moreover, the measurement of the sun's distance, and perhaps some other ratios from the Great Pyramid, may turn out in the end to be closer to the truth from the pyramid revelation than they are to our present measurements.

After a sagacious review of the principal coincidences, and an effort to show their generally unintended nature, Mr. Proctor proceeds to develop his own view, which is, in effect, that the pyramids were built for astrological observatories, designed for the casting of the horoscopes of the successive kings. He shows clearly, and we believe was the first to show, that early astronomy was astrological in its aims, and that the pyramid, when it had been carried up to half of its height, would afford the best possible structure for astronomical work of that time. His ingenious, and we must say convincing, argument requires us to assume a much more advanced state of astronomical and geodetic science in those days than many would be willing to admit. Still, the old Semitic civilization is a vast unexplored realm: it is a vain fancy that we yet know what it contained. It is easier to give to it any thing in the way of learning than to accept the monstrous scheme of bungling prophecy that the pyramidalists offer in its stead.

The student of science may have something beyond the entertainment that all readers will find in this book, and the literature of which it will form an important part. He may find in the controversy a suggestion of certain dangers that await all work of a theoretic kind. All the work of extending our conceptions of natural phenomena, all the work of true science, must be carried on by the method of coincidences. A fact, or series of facts, is compared with other facts or series, and, from their observed identities, relations are inferred. The use of this method, under rigorous scrutiny, has given us our modern science, and must give us all that is truly scientific in the time to come. The incident of the Great Pyramid inquiry may well lead us to notice certain dangers in this method. A large part of the facts with which the naturalist has to deal has for him the danger that the Pyramid of Cheops has for the mathematician. Between the thing in hand and other things, there is a practically infinite number of relations. If he sets out on his inquiry with a mind to find resemblances of a certain kind, this liberal nature is sure to gratify him. Nothing but the most rigorous correction of the reasons for an opinion by the reasons against it will keep him safely on his way.

The more fixed the opinion that guides the student in his work, the surer he is to find in the infinite that any object offers the facts to support his views. This is the great danger that lies in the way of many who are seeking to advance the development hypothesis in biology. Having become possessed with the conviction that certain things are to be found, they will see them as Smyth sees revelation in the stones at Ghizeh.

There are some faults to be found with the *making* of this book. More than one-third of it consists of separate essays on the origin of the week, — Saturn, and the sabbath of the Jews; astronomy and Jewish festivals; the history of Sunday; and astrology, — all very interesting in their way, but they are not represented in the title. There is no proper table of contents, and no index. The British seem determined to leave this work of opening their modern literature to students, altogether in the hands of the Index society.

The book is written in the admirable didactic English of which the author is a master.

MINOR BOOK NOTICES.

Man before metals. By N. Joly. New York, 1883. (International science series, no. 45.) 8+365 p., illustr. 8°.

The author of this attractive volume, unlike many European writers on archeology, gives but little space to the subject of North-American antiquities; and, of the one hundred and forty-eight illustrations, not one represents a characteristic stone implement of this country. The little that our author finds to say under the comprehensive title of 'Prehistoric man in America' is included in twelve pages, constituting chapter vii., and is mainly a review of Squier and Davis's Ancient monuments of the Mississippi valley, with brief reference to certain discoveries recorded so long ago as the publication of Gliddon and Nott's Types of mankind. Mr. Joly might readily have done far better. No mention is made of the vast amount of material gathered within the last decade, that bears so strongly upon the vexed question of man's antiquity on this continent. The scores of publications of the Smithsonian institution, the invaluable reports of the Peabody museum, and the transactions of our learned societies generally, have been quite overlooked; and a vain attempt has been made, in lieu thereof, to bolster up the claim of antiquity of America's earliest people by reference to the mounds of the Ohio valley, many of which have recently lost their claim to a pre-Indian origin, and others, doubtless, will yet be shown to have been erected by the ancestors of our modern redskin. As a *résumé* of European archeology, it is valuable, but not otherwise. To the American students of the science it will prove disappointing.

Hydraulic tables for the calculation of the discharge through sewers, pipes, and conduits; based on Kutter's formula. By P. J. FLYNN. New York, *D. Van Nostrand*, 1883. (Van Nostrand's science series, no. 67.) 135 p. 24°.

KUTTER'S formula for determining the velocity of flow of water is one of the class which has the general form $v = c\sqrt{rs}$, where r is the ratio of the cross-section a to the wetted perimeter, and s is the sine of the slope; but the coefficient c is of such a complex form, that the application of the formula to definite problems in water-supply and sewerage is somewhat tedious. This collection of tables is designed to facilitate the work, and gives values of r, $c\sqrt{r}$, and $ac\sqrt{r}$, for circular and egg-shaped sections, and of s and $\sqrt{s}$ for different slopes. The coefficient of roughness or friction used is .015, and a number of examples make clear the use of the tables. Engineers who have such work in their practice will find these tables convenient.

Chemical problems, with brief statements of the principles involved. By JAMES C. FOYE. New York, *Van Nostrand*, 1883. (Van Nostrand science series, no. 69.) 6+141 p. 24°.

THE value of chemical problems as a practical illustration of the rules of stochiometry is recognized by every teacher of chemistry. A thorough knowledge of chemical arithmetic is constantly required in the laboratory, and it can only be gained by actual practice in the solution of problems. The convenience of having a collection of examples at hand will therefore be appreciated by teachers; and this book will doubtless supply a deficiency to those who prefer the problems arranged independently of the text-book. A great variety of examples are presented, with very full illustrations of the relations which exist between the factors and products of chemical reactions, beside calculations of atomic and molecular weights, specific and latent heat, specific gravity and vapor density. Examples are also introduced on the metric system of weights and measures, thermometric scales, and the laws of Mariotte and Charles.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Origin of the lines A and B in the spectrum. — M. Egoroff, by experiments at the physical laboratory of the University of St. Petersburg, has shown that the lines of the solar spectrum known as *A* and *B* are due to the oxygen of our atmosphere. He employed a tube twenty metres in length, closed with glass plates, in which tube the gas under investigation could be condensed under pressures of fifteen atmospheres or less, proper care being taken to dry it thoroughly. The telluric character of these lines has been generally admitted, but has of late been called in question by Mr Abney, who suggested that they might be due to cosmical hydrocarbon gas of some kind, diffused through space in accordance with Siemens's theory. M. Egoroff sets this question at rest, having determined by direct experiment that none of several different hydrocarbons tried gives any such bands, while oxygen unmistakably does give them. — (*Comptes rendus*, Aug. 27.) C. A. Y. [327

On the assumption of a solar electric potential. — Werner Siemens discusses the hypothesis proposed by his brother (Sir W. Siemens), that the sun has a high electric potential, due to the friction of the dissociated matter which, according to his theory, is continually flowing in at the sun's polar regions to replace that which, after combustion, is thrown off at the sun's equator. The paper is an important one, but too long to be fairly summarized within our limits. A considerable portion of it is devoted to an endeavor to obviate one of the most serious objections to Siemens's theory of the solar heat; namely, the objection based on the resistance to planetary motions which would result from a cosmical interstellar medium of the necessary density. Werner Siemens argues that the particles of matter passing off from the sun's equator would continue to revolve around the sun as they receded from it, and at any distance would have the same velocity as a planet at that distance, and so would offer no resistance. The paper is, however, mainly occupied with the planetary consequences of solar electrification. — (*Phil. mag.*, Sept.) C. A. Y. [328

MATHEMATICS.

Development of real functions. — The exact title of this paper, by M. J. P. Gram, is 'The development of real functions in series, by the method of least squares.' M. Gram's paper is an exceedingly interesting one, but unfortunately one which cannot be more than briefly referred to in this place, as a suitable notice of it would require the reproduction of a great deal of algebraical work. The principal problem which M. Gram proposes to solve is stated as follows: let there be given a series of arguments, x, and two corresponding series of quantities, o_x and v_x. These last quantities are all real, and, further, the v_x are all positive. Then in a series which contains known functions of x, — viz., $y_x = a_1 X_1 + a_2 X_2 + \ldots + a_n X_n$, — the coefficients are to be so determined that $\Sigma_x v_x (o_x - y_x)^2$ shall be a minimum. In the first part of the paper, the author gives applications of his process to Fourier's series, spherical harmonics, and cylindrical functions. The second part refers almost entirely to the convergence of certain series; but without quoting much that is obtained in the first section, and defining many symbols, it would be impossible to give here a suitable or intelligible notice of this second section. — (*Journ. reine ang. math.*, xciv. 94.) T. C. [329

ENGINEERING.

Economical pumping-engines. — Mr. C. T. Porter reports the duty of the Gaskill engines at Saratoga as 106,000,000 pounds, raised one foot high, per 100 pounds of hand-picked coal. The Corliss engines at Pettaconsett, Providence, R.I., gave a duty of 113,-271,000; and the Pawtucket engines have an average, for the year 1882, of 113,500,000. The slip of valves is reduced to one-half of one per cent. — (*Mech.*, July 21.) R. H. T. [330

Consolidation of bulky materials. — A steam-hammer has recently been applied to the consolidation of bulky materials in steel moulds. The materials are usually organic, often fibrous, and one blow generally does the work. Four blocks per minute are made; 3,000 pounds of sawdust are compacted into blocks each hour. Bran is thus made denser than flour, and can be preserved indefinitely. Stone is made from earth or sand, and weighing 160 pounds per cubic foot. The following are results so obtained: —

	Cubic feet per ton.		Weight per cubic foot.	
	Unpressed.	Pressed.	Unpressed.	Pressed.
Bran	172	34	13	65
Meal	64	37	35	65
Sawdust . . .	448	34	5	65
Tanbark . . .	140	35	16	64
Cotton (baled) .	93	40	–	56
Hay " .	160	34	14	65
Bitum. coal-dust.	44	28	50	80

— (*Industr. world*, June.) R. H. T. [331

Economy of steam-boilers. — William Kent reports, to the American society of mechanical engineers, the results of a series of tests of fuels in various ways, and under various forms of boilers. He gives the following as relative values of fuels determined by burning under the Babcock & Wilcox boilers: —

Welsh bitum.	109.6.
Scotch bitum.	109.5.
Cambria, Penn., semi-bitum. . . .	91.2.
Pittsburgh, Penn., bitum.	99.5.
Ohio bitum.	84.9.
Vancouver's Island	85.7.

The paper is long and unusually complete. — (*Ibid.*) R. H. T. [332

METALLURGY.

Bessemerizing copper mattes. — Pierre Manhès claims to have overcome all the difficulties in Bessemerizing copper matte, and to have charge of an establishment which is, at the present time, successfully making copper on a commercial scale. He melts the ore in a suitable cupola furnace, casting the matte produced into a Manhès converter, when, under the action of a high-pressure blast, it is rapidly transformed into 98 % to 99 % black copper. The Manhès works consist of three cupolas of twenty-five to thirty tons' capacity per day; two small cupolas for remelting the matte in case of need; three Manhès converters, treating a ton and a half of matte at each operation, and each converter makes twenty-two to twenty-four operations per day; and the necessary blowing-engines. Manhès claims that cost of labor is reduced to a minimum, because operations last only a few minutes, and large quantities of metal are handled. The cost of fuel is low; because no fuel is needed to bring the matte forward to black copper, except that used for the blowing-engine. The saving in cost over the Welsh or Swansea process, according to local conditions, is from 50 % to 75 %. — (*Eng. min. journ.*, June 30.) R. H. R. [333

AGRICULTURE.

Seed-testing. — Comparisons between the germinating and vegetating powers of seeds, made at the New-York agricultural experiment-station, show that the two are by no means identical. Many seeds which were capable of putting forth a radicle failed to vegetate sufficiently to form cotyledons, under the favorable conditions of a testing-apparatus. In eleven tests, with four species of seeds, from ten to forty-six per cent of the seeds germinated, but failed to vegetate. — (*N. Y. agric. exp. stat. bull.*, lxii.) H. P. A. [334

Sulphuric acid as a fertilizer. — The use of sulphuric acid has been proposed as a means of rendering the constituents of the soil soluble. Experiments by Farsky on summer rye, grown in boxes, showed no advantage from the use of sulphuric acid or of acid sodium sulphate. When the soil was kept dry, a slight decrease in the production of grain was noticed as the result of the manuring. The soil was a clay soil, and the sulphuric acid was sprinkled upon it in the concentrated form until it was distinctly moist. A hundred grams of acid were used to thirty-five hundred grams of soil. — (*Biedermann's centr.-blatt.*, xii. 447.) H. P. A. [335

GEOLOGY.

Lithology.

Determination of the felspars in rocks. — Professor J. Szabó's method of determining the felspars in rocks was published at Budapesth in 1876; but he has recently placed it before the English reading public in a paper read at Montreal last year. His method consists chiefly in determining the coloration of the flame by the felspars, and their fusibility. This method, with the addition of Boricky's micro-chemical process, is further used by Szabó for the determination of other silicates. For the details of the process, reference is to be had to the original papers. — (*Proc. Amer. assoc. adv. sc.*, 1882.) M. E. W. [336

Laterite from Huranbee, Pegu, India. — This is described by Dr. R. Romanis as an aqueous rock of a bright red color, friable, and full of cavities. It is stated to be composed of 31.44% of quartz sand, 13.27% of soluble silica, 36.28% of ferric oxide, 9.72% of alumina, and 8.83% of water. When the sand is examined under the microscope, it is seen to be water-worn. Laterite is much used in building and road-making on account of its hardening when exposed to the air. — (*Trans. Edinb. geol. soc.*, iv. 164.) M. E. W. [337

MINERALOGY.

Minerals from Amelia county, Va. — In a vein of granite which for the past few years has been worked for mica, a few rare and interesting minerals have been found, and are described by William F. Fontaine. Columbite occurs in crystals of large size, and rather rarely a manganese variety of a chestnut-brown color is found. This latter has a tendency to assume a fibrous structure. Orthite is found abundantly in long, bladed crystals. The most interesting mineral found at the locality is microlite, occurring both in crystalline masses of large size, and in distinct crystals: the latter are octahedrons, modified by small cubic, dodecahedron, and tetragonal-trisoctahedron faces. Analysis has shown that the mineral is essentially a calcium tantalate. Monazete, another rare and interesting mineral, is found abundantly at the locality, sometimes in masses weighing several pounds. Analyses have shown that this has the composition of a normal phosphate of the cerium metals, while the thorium, which is most always present, and abundantly in the monazete from Amelia, is due to an admixture of a silicate of thorium. Helvite, a rare silicate of manganese, beryllium, and iron, containing sulphur, is found sparingly associated with spessartite (manganese garnet). — (*Amer. journ. sc.*, May, 1883.) S. L. P. [338

METEOROLOGY.

Thunder-storms.—A special investigation of thunder-storms has been made in Bavaria and Würtemburg since 1879. In 1882, in Bavaria there were 252 stations, which number, distributed uniformly, would give a mean distance between stations of about ten miles. To each of these stations, cards were sent, having questions calling for the time of beginning and ending of thunder, hail, or rain; also, the direction from which the storm came, and the direction and force of the wind.

These investigations show: 1°. That the thunder-storm, while not an accompaniment of a cyclone, still appears with smaller secondary depressions, or spurs of great depressions, which are so flat that they do not produce any strong wind. Of special force is the thunder-storm in the ridge of high pressure dividing two great depression-regions from each other. 2°. That the line upon which simultaneous electric discharges take place encloses a space which has, in most cases, great length but little width, and which stands at right angles to the line of progress of the storm. Such simultaneous discharges have been observed over a region 300 km. (186 miles) broad and about 40 km. (25 miles) deep. 3°. That special regions for thunder-storms are marshy low grounds between the Mediterranean or other smaller bodies of water, and the Alps; also the western declivity of the Bohemian forest. 4°. That in cases where the origin of the storm can be well determined, within the region of observation, it is found that electric discharges take their beginning along a long line simultaneously; and it is conjectured, that the disturbance of the electric equilibrium, by the first discharge, propagates its influence from cloud to cloud, and causes simultaneous outbursts in different places. 5°. Heat-lightning is due to the presence of a storm at a great distance. In one instance it was traced to a storm 270 km. (167 miles) distant. 6°. Arranging the storms according to their frequency at each hour of the day, we find the hours from midnight to eight A. M. of little activity, a very rapid rise from eight A. M. to four P. M., and nearly as rapid a fall to midnight.

The above results show the importance of a detailed observance of these meteors. It is hardly probable that we can learn particulars of these so-called local storms, by observing them at stations a hundred or more miles apart. The various state weather-services have an excellent opportunity for undertaking such observations. It may be possible to learn the movements of these storms over large areas, and thus to give warning of their approach three or even four hours in advance. — (*Zeitschr. met.*, June.) H. A. H. [339

GEOGRAPHY.

Bureau of commercial science. — The Ministry of commerce in France has just instituted a new bureau, which is to be directed by M. Renard, formerly librarian of the Ministry of marine. This bureau is intended to bring together the publications, letters, travels, and information bearing on commerce, industry in foreign countries, navigation, etc., which come to the authorities in various ways, and selections and translations of documents from foreign sources and collections. Those considered of importance will be printed for the public use. — (*Soc. de géogr. Paris*, June.) W. H. D. [340

Notes on population. — The late census of Monaco shows the principality to contain 9,108 inhabitants, of which more than one-third are French. —— Born Parisians are always in a minority in that city, numbering, according to the latest figures, about thirty-two per cent of the population. The city contains 164,038 foreigners, of which, in round numbers, 45,000 are Belgians, 31,200 Germans, 21,600 Italians, 21,000 Swiss, 10,800 English, 9,250 Dutch, and about 5,000 each, Americans, Russians, and Austrians. Twenty per cent of the total increase of the population of Paris during the years 1876–81 is due to the increase of resident foreigners. —— The stagnation of the population of France is exciting much attention, and even apprehension. It is sufficiently evinced by its proportional ratio to the Anglo-Germanic population of Europe. This in 1700 was three to three, or fifty per cent; that is to say, France equalled in population the whole of the group referred to. In 1881, however, her ratio was as three to seventeen; or, if the Anglo-Germans of the United States be counted in, it was only three to thirty, or about ten per cent. —— The population native to the Marquesas Islands in 1855 was about 12,000: at present it has diminished to 5,700. —— The population of Tunis, it seems, has been greatly exaggerated. Instead of five or even two and a half million, as has been accepted for some years, the late investigations of M. Perpetue show that the total figure, probably, should not exceed 1,400,000, of which about 36,000 are foreigners. — (*Bull. soc. géogr. Mars.*, June.) W. H. D. [341

(*North America.*)

Fisheries of British Columbia. — Foreign vessels have been officially warned from taking or curing fish within three miles of the coast of the province. The value of the catch for 1882 was $1,842,675, and of vessels, nets, etc., $229,600. Twenty canneries and other land-stations are assessed at $402,000. They employed, in 1882, 5,215 hands and 79 vessels; and the increase in value, over 1881, of the product, was over thirty per cent. More than twelve million cans of salmon and nearly six hundred thousand pounds of herring were put up during the season. — W. H. D. [342

Salmon-fisheries in the north-west. — The output of canned salmon on the Columbia River, at the close of the season, was 629,438 cases, and the disbursements to the fishermen employed were $1,550,000. In 1882, 541,300 cases were put up on the Columbia. About 17,500 cases had been put up on the Fraser River to Aug. 1; but, for the complete returns, details for this and the Alaskan region are not yet received. The total pack on all rivers on the north-west coast of America, in 1882, was 941,187 cases, each containing the equivalent of forty-eight pounds of canned fish, or at least double that amount of fresh fish, equal to about five million individual salmon of ten pounds each. — W. H. D. [343

(*South America.*)

Notes. — C. de Amezaga, in the Bulletin of the Italian geographical society, gives a general description of the Galapagos, with a map, from investigations by Wolf and Icaza, and an historical account of them, and the endeavors to colonize them. It appears that there is actually a small settlement on Chatham Island of recent date. Older ones on Floriana all came to an unfortunate termination. —— The Instituto Argentino meditates an expedition to southern Patagonia, to be directed by Capt. Carlo Moyano, who lately crossed the Patagonian desert from Santa Cruz to Port Deseado. —— The death of Bartolomeo Lucioli is reported on the 9th of June, while on his way from Lisbon to Para. The deceased, who was about fifty years of age, had been a civil and military officer in the Peruvian service, but was afterward more distinguished as an explorer of the Ucayali and upper Amazons, and as the collector of a precious ethnological exhibit now in the Ethnological museum at Rome, relating to the inhabitants of this region. —— The commission for determining the boundary between Venezuela and Brazil, in the vicinity of the Orinoco, has returned to Rio Janeiro. They bring valuable geographical material, but have suffered severely from fever and other evils attendant on such explorations in South America. —— Lovisato, one of Bove's companions, has read a paper before the Italian geographical society on his geological researches in Patagonia and Tierra del Fuego, describing the glaciers of the latter region, and suggesting reasons for the supposition that the antarctic region is occupied by land rather than sea. —— Some notes on New Grenada, made in 1617–30 by Hubert Verdonck, a Belgian Jesuit, appear in the Anvers Bulletin. They contain a few ethnological and historical details of interest; but even at that time the aborigines had totally disappeared from the vicinity of Carthagena and Panama. —— A letter from the French meteorological station at Orange Harbor, in the *Revue géographique* for July, while containing no information of importance, is accompanied by two characteristic illustrations of Fuegian people, and one of their dogs. — W. H. D. [344

BOTANY.

Sylloge fungorum. — The second volume by Prof. P. A. Saccardo, of more than eight hundred pages, includes all the remaining species of Pyrenomycetes not treated in the first volume, together with an index of all the genera and species of the order. There are also several pages of addenda to both volumes, including the species published up to a very recent date. In fulness and general arrangement, the present volume has the same merits as its predecessor. Vol. iii. is announced to appear in 1884, and will include the Sphaeropsoideae, Melanconieae, and Hyphomycetes. — W. G. F. [345

Illustrations of British fungi. — This comprehensive and finely executed work by M. C. Cooke has now reached the end of the second volume, including eighteen parts and an index. The two volumes already issued include figures of all the leucosporic species of Agaricus known to occur in Britain, except twenty-six little-known species, three hundred and seventy-eight species with varieties being represented — a considerably larger number than is included in the works of Sowerby, Bulliard, or Krombholz. The work will be continued, and contain plates of the remaining sections of Agaricus. — W. G. F. [346

Ascospores in the genus Saccharomyces. — In the reports of the Carlsberg laboratory, Hansen gives a *résumé* of his researches on the formation of ascospores in the different forms of Saccharomyces. While in general he agrees with Rees's views, he denies the possibility of distinguishing species of Saccharomyces by the ascospores; and, in fact, he is hardly inclined to admit the specific value of the different forms described by Rees. Hansen's experiments were made with cultures of single spores obtained by a process of dilution, which he describes in detail; and the purity of the cultures was recognized by the formation, on the walls of the culture-flasks, of a single spot formed from the growth of one spore. He also adopted, with good results, Koch's method of gelatine culture. While the ascospores of the different so-called species of Saccharomyces cannot be distinguished by their shape, Hansen found that there was a difference in the time of their germination when exposed to different temperatures; and he gives a series of curves to represent the results of his experiments with regard to the temperature in six different forms. The curves all have a similar form; but the maxima and minima vary with the different species, the minimum being between ½° C. and 3° C., and the maximum about 37½° C. There follows a discussion of what Pasteur calls Torulae, which resemble species of Saccharomyces, but are separated from that genus by Hansen, because he found that they did not produce ascospores. The paper concludes with an account of diseases of beer caused by certain alcoholic ferments. — W. G. F. [347

ZOÖLOGY.

Worms.

Homology of the nemertean proboscis and the chorda dorsalis. — In an article on the ancestral form of the chordata, Hubrecht defends the following speculative thesis: "According to my opinion, the proboscis of the nemerteans, which arises as an invaginable structure (entirely derived, both phylo- and onto-genetically, from the epiblast), and which passes through a part of the cerebral ganglion, is homologous with the rudimentary organ, which is found in the whole series of vertebrates without exception, — the hypophysis cerebri. The proboscidean sheath is comparable in situation (and development?) with the chorda dorsalis of vertebrates." Without adding new facts, but merely basing his arguments on what is already known, the author defends his hypothesis with great ingenuity. His chief argument is, that the proboscis and the hypophysis are both anterior ectodermal invaginations, and are homologous. His use of terms is misleading. By 'proboscis' he designates apparently both the free portion of the proboscis and its sheath; by 'proboscidean sheath,' on the contrary, the posterior portion of the proboscis, which has no sheath, and is not free. At least, his descriptions became intelligible to the reporter only on that assumption. The posterior unfree part of the proboscis he considers the homologue of the notochord. The vertebrates are not connected with the annelids; but, on the contrary, the two lateral nerves of lower worms have united *dorsally* to make the central nervous system of vertebrates, *ventrally* to form the ganglionic chain of annelids and their derivatives. In the second half of his paper, the author endeavors to strengthen his position by comparisons between other organs in nemerteans and vertebrates. [It is possible that Hubrecht's hypothesis will be verified; but the objections to it come to mind so immediately, and in such throngs, that it is difficult to believe the hypothesis well founded. Some of the most serious objections are ably presented by Whitman in an article accidentally published in the same number (p. 376), and arguing in favor of the annelidan affinities of vertebrates.] — (*Quart. journ. micr. sc.*, xxiii. 349.) C. S. M. [348

Embryology of Planaria polychroa. — Metschnikoff has studied the development of fresh-water planarians, and reached conclusions that are, in part, very startling. Pl. polychroa lays its egg-capsules in late spring and early summer. Each capsule contains from four to six eggs, and thousands of the so-called 'yolk-cells.' The egg has no membrane. The yolk-cells immediately around each ovum break down, their membranes disappear; but their nuclei remain for a long time distinguishable, although they finally disappear in the embryo, into the composition of which these disintegrated cells enter. The ovum segments, but the cleavage-cells do not cohere, there being no vitelline membrane: on the contrary, each embeds itself in the mass derived from the yolk-cells. In some manner, which is left in complete obscurity by the author's descriptions, the cells from the ovum gradually spread themselves, and form first the pharynx, and then an epidermal layer of thin cells, which encloses the whole of the disintegrated yolk-mass, together with cells from the ovum, embedded in it. In the centre of this mixed parenchym appears a cavity which communicates with the lumen of the pharynx. This last seizes and swallows the surrounding yolk-cells, each intact. The cells scattered through the body form the mesoderm (mesenchym), which arranges itself so as to form the partitions of the body, dividing the disintegrated yolk-mass into separate accumulations, which, combining with the yolk-cells swallowed, gradually assume the form of the intestine with its coeca. No entoderm exists, unless two cells at the base of the proboscis are a remnant of it. During these changes the nervous system appears, and the sheath around the proboscis is developed. Metschnikoff advances the opinion, that the yolk-cells swallowed, though not derived from the ovum, and being foreign bodies, nevertheless become the cells of the apparent entoderm of the adult. He further believes that the nervous system is derived from the mesoderm. If Metschnikoff is correct in maintaining, that, *first*, there are no epithelial germ-layers; *second*, the cleavage-cells are mixed with and embedded in a foreign substance; *third*, foreign cells form the entoderm, there being no embryonic entoderm; *fourth*, the nervous system is derived from the mesoderm, — then it is obvious that the general conclusions which we are wont to consider to have been well established by embryological research are erroneous, although they rest upon a vast body of evidence. One would suppose that no attempt to set this evidence aside would be made, except after the most unquestionable determination of new facts. Now, Metschnikoff's researches leave every one of the processes involved in his novel views in absolute darkness; for he has not, for the most part, observed them at all. His surprising deductions are based upon a failure to ascertain what are the actual processes, and seem to the reporter invalid. The value of the real observations is, of course, unaffected by the speculative portions of the essay. — (*Zeitsch. wiss. zool.*, xxxviii. 331.) C. S. M. [349

Insects.

Epidermal glands of caterpillars and Malachius. — The following are the principal results obtained by Stan. Klemensiewicz. 1°. The eighth and ninth segments of the larvae of Liparis, Leucoma, Orgyia, and Porthesia auriflua, have each a little protuberance on the median dorsal line, with the opening of a gland at the summit. The secretion is clear and odorless. The skin is invaginated at the top of the papilla to form a pendent sack, at the base of which are inserted two muscles running obliquely backwards; and there also open two glands by a common duct. The external surface of the glands is smooth, but in their interior each gland-cell forms a separate bulging mass: the appearance thus presented is singular. The lumen of the duct is very small; its thick walls are formed by two large cells, much like those of the gland proper. In Leucoma salicis there are quite similar glands on the fourth and fifth segments. 2°. The exsertile horns of Papilio Machaon, larva, are described. They are really developments of the tegument: the epidermal cells of their walls are large, and contain numerous rod-haped bodies; but the cells at the base of the horns are much smaller, and glandular (their secretion being probably discharged through pores of the adjacent cuticula). It may be assumed, that the odorous secretion accumulates in the invaginated horns, and is freed by their exsertion. 3°. The caterpillar of Harpyia vinula has a gland in the first segment, opening ventrally. The gland is flask-shaped, the neck acting as duct, and opening into a large transverse fissure; the body of the flask is the gland proper, and is lined by polygonal epithelial cells, with irregularly shaped nuclei; the epithelium rests upon a thin tunica propria. 4°. A similar organ to the last mentioned was described in Vanessa larvae, by Rogenhofer (*Verh. zool.-bot. ges. Wien*, xii. 1227): it is an invagination of the skin on the ventral side of the first segment; its cuticula is thin, and forms numerous little cups, under each of which is a thin epithelial cell. 5°. The orange-colored fleshy warts on the sides of the thorax and abdomen of Malachius are also glandular. The epidermis presents no special features in the warts, except that it bears scattered unicellular glands of the form typical for insects; they are flask-shaped, with a coiled cuticular duct in their interior, the duct being continuous with a pore-canal through the general cuticula of the wart. In the lower and larger end of each cell, lies the round nucleus. — (*Verh. zool.-bot. ges. Wien*, xxxii. 459.) C. S. M. [350

ANTHROPOLOGY.

Prehistoric copper. — Professor J. D. Butler confidently asserts that the Wisconsin state historical society's collection contains more American aboriginal copper implements than he has been able to hear of in all other cabinets whatever. One axe weighs four pounds twelve ounces and a quarter, and is the heaviest article of wrought copper as yet brought to light. Fourteen new implements have lately been added, some of them unique in form, or size, or in the location from which they were derived. More than fifty coppers have come to the cabinet from Washington county alone. This fact is doubtless due to Mr. Perkins's persistent search in that locality. — (*Wisc. hist. coll.*, ix. 97.) J. W. P. [351

Aztalan. — The largest and most elaborate aboriginal monument in Wisconsin is Aztalan, fifty miles east of Madison. It was first discovered by Timothy Johnson in 1836, and described by Nathaniel F. Hyer in the *Milwaukee advertiser*, January, 1837. Mr. Stephen Taylor gave an illustrated account of it in *Silliman's journal* in 1843; and the place was first accurately surveyed and plotted by Dr. Lapham, in 1850, whose description and drawings were published in 1855, in the Smithsonian contributions to knowledge. "This strange monument," says Prof. Butler, "was styled Aztalan by Mr. Hyer, inasmuch as it seemed to him a structure worthy of the Aztecs." Upon this point Mr. Peet says, "The name Aztalan was derived from a tradition, which was said to be common among the Indians, that a people partially civilized built here a city, and a hundred years afterward, becoming dissatisfied, proceeded south to Mexico." There is no reason to suppose that the Aztecs, or any other Mexican people, were in any way connected with it. Much curiosity has been excited with reference to the Aztalan bricks, which are shapeless clods of clay, burnt red and pretty hard. The process of burning is supposed to have been similar to that discovered by Schliemann at Troy. The soil, a sort of loam, had been thrown up into a rampart, the whole coated with clay matted together with bushes and sedge. Over all were heaped prairie-grass and trees, and the pile set on fire. Dr. Yarrow describes a like process pursued in North Carolina grave-mounds. — (*Wisc. hist. coll.*, ix. 99.) J. W. P. [352

EARLY INSTITUTIONS.

History of agricultural prices in England. — M. Jusserand reviews Mr. Thorold Rogers's work upon this subject. He pronounces it one of the great books of our century, and indispensable to the student of economic history. It is full of facts hitherto unknown, or, if known, unclassified, and inaccessible to most students. Mr. Rogers's opinion that the fifteenth century, and the beginning of the sixteenth, was a golden age for the laboring-people of England, is cited as especially notable, inasmuch as a contrary opinion has generally obtained up to this time. — (*Rev. critique*, 18 juin, 1883.) D. W. R. [353

Indirect taxation among the Romans. — M. Dareste sums up all, or nearly all, that is known upon this subject. Very little is known; and very little is likely to be known, unless some more inscriptions, like that discovered not long ago in the ruins of Palmyra, should be found. It was an important find, — a custom-house tariff with regulations regarding the collection of duties. (See *Bull. corresp. hellén.*, mai–juin, 1882.) The inscription has not yet been published. The principal indirect taxes of the Romans were, the custom-house duty (portorium), a tax on successions, upon the manumission of slaves, and the sale of movable goods. They were not very heavy taxes at any time. M. Dareste gives us a very good account of the portorium. The Roman custom-houses were scattered about here and there, wherever merchants were wont to pass or to congregate. A list of localities where there were custom-houses is given. The portorium was a percentage levied upon the value of merchandise. Only merchandise was subject to it. Personal effects of travellers, *instrumenta itineris*, etc., were free of duty. A list of writings upon the subject is given. The principal work cited is that of M. R. Cagnat: *Étude historique sur les impôts indirects chez les Romains.* It was written before the discovery of the Palmyra inscription. — (*Séances trav. acad. inscr.*, Feb.–March, 1883.) D. W. R. [354

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Field-work of the division of the Great Basin. — In consequence of the extension of the work of the survey to the Atlantic states, the director has found it necessary to divert some of its force from investigations already initiated. One of the most important researches thus stopped is that of the quaternary lakes of the Great Basin. The corps was reduced at the beginning of the fiscal year, and instructed to devote the field season to supplementing the material already acquired, so as to prepare it for publication without future visits to the district.

The office at Salt-Lake City was closed on the 30th of June, and field operations were immediately begun. Mr. I. C. Russell, assistant geologist, proceeded to Mono valley, California, and carried to completion his examination of the existing lake and its ancient expansion. He included in his study, also, the six extinct glaciers which anciently debouched in the Mono valley, tracing them to their common source in the great névé of the Sierra Nevada. Incidentally he examined the ice-masses associated with some of the summits of the Sierra, and brought the camera to bear on them. These have been called glaciers by Muir and others, but are said by King to be unworthy of the name; and it may be hoped that these later observations and illustrations will suffice to place the matter beyond controversy.

From the Mono basin he proceeded to the Walker, Carson, Pyramid, Winnemucca, and Black Rock basins, for the purpose of re-investigating certain points connected with the history of the ancient Lake Lahontan, upon which he is preparing a report.

Mr. W. D. Johnson, topographer of the division, spent the summer, under Mr. Russell's direction, in surveys for a general map of the Mono basin, and is now engaged on a series of special maps of ancient glacial moraines.

Ensign J. B. Bernadou, detailed from the navy for the purpose, has acted during the summer as Mr. Russell's assistant.

Mr. G. K. Gilbert, who has general charge of the work, spent a few weeks in the field, visiting localities of special interest in the Lahontan, Bonneville, and Mono basins. He was accompanied in the Lahontan basin by Mr. R. Ellsworth Call, the conchologist, who is engaged in a study of the molluscan faunas of the quaternary lakes of the Great Basin, and took the field for the purpose of familiarizing himself with their geological relations.

The Champlain valley. — Mr. Charles D. Walcott, with Mr. C. Curtice as assistant, has been studying the formations between the archean and Trenton in Saratoga county, N.Y., and along up the Champlain valley on both sides of the lake.

Saratoga village, west of the fault-line along which the springs occur, was found to be built over a massive, gray, magnesian limestone, that carries a strongly marked fauna closely allied to that of the Potsdam sandstone of Wisconsin. The geologic section from the archean to the base of the bird's-eye limestone was found to be of great interest. At Glen Falls, Essex, Ausable Chasm, and Chazy, N.Y., sections were taken, and collections formed.

The sections taken at Highgate Springs, Swanton, St. Alban's, and Georgia, Vt., by Professor Jules Marcou, were critically examined, and large collections of fossils secured. The data obtained show the dip of the Winooski marble series and the slates above, carrying the Olenellus fauna, to be the same. The five hundred feet of magnesian limestone, with its interbedded arenaceous layers, conformably underlie the Olenellus beds. The fauna at the Georgia locality was increased by the addition of eight species not before reported as occurring there.

NOTES AND NEWS.

Mr. H. M. Stanley contributes to the *New-Englander* an interesting, and, on the whole, clearly written study, entitled 'Evolution as bearing on method in teleology.' The essay follows a train of thought somewhat similar to the one stated in a book that appears almost at the same time, and that we reviewed recently; viz., Mr. Hicks's Critique of design arguments. Mr. Stanley is thankful to the doctrine of evolution for having rid teleology of a useless and somewhat dangerous argument, — the argument from mere ignorance; i.e., from our incapacity to explain certain singular or wonderful things save by supposing a powerful being directly working to produce them. This argument, which covers, on the whole, much the same ground as is covered by what Mr. Hicks calls teleology in the narrower sense, is regarded by Mr. Stanley as superseded by the doctrine of evolution. We now see that nature ought to be regarded as a 'practically infinite series of second causes;' so that, if we are now ignorant of the cause of any phenomenon, we still have a right to expect to find for it hereafter a purely natural cause. Every thing has grown; and we have to view nature as a vast and perfect machine, self-supplying, self-regulating, and not needing any workman to stand by to watch the steam-gauge, to put in the material, or to oil the bearings. Yet this view is not atheistic, according to Mr. Stanley; for the supposition of a designing intelligence remains, only this intelligence is 'immanently behind phenomena.' By this being, all things consist. In fact, the more nearly automatic the machine, the more perfect the contriving intelligence. "If an automatic locomotive-machine is a sign of very great intelligence, how much greater intelligence would an automatic universe-machine exhibit? . . . Teleology has been called a 'carpenter theory,' but a teleology which views the universe as a practically infinite automatic machine would forever destroy the force of any such epithet." In other words, as we understand Mr. Stanley, a 'practically infinite' carpenter would be something much better than a carpenter; and teleology gains rather than loses when the doctrine of evolution shows that the carpenter's tinkering of his work, if there is any tinkering, is practically infinitesimal. All this seems to us not at all novel; but, for the most part, it is very well put, and worth saying.

But when we inquire of any of these evolutionary design arguments, not how they defend themselves against the charge of atheism, but how they demonstrate theism, we are disappointed. Mr. Hicks, as we saw in reviewing him, is very definite on this point as to what he attempts, and as to what he does not attempt; but his definiteness only serves to show his weakness. He declares that order, as such, is proof of intelligence, but adds that the proof is solely inductive. Men are orderly because they are intelligent: hence nature, if orderly, must be somehow associated with intelligence. We answered this induction by asking whether all brilliantly colored objects must needs be visited by insects merely because the colors of flowers depend upon *their* relations to the habits of insects. But with Mr. Stanley we hardly have room for so definite a criticism; for, though his argument in favor of theism, in so far as he suggests one at all, seems to be inductive, it seems also most carefully to shun any such definite statement as should make it definitely answerable. The vast machine needs, it would seem, a controlling intelligence, which does not interfere with it, and yet does somehow direct it. The 'practically infinite series of second causes' is not enough by itself, and we must somehow get outside of it to find a designer; and, when we ask how the designer is related to the series of second causes, we get the charmingly innocent answer, that he is 'immanently behind phenomena,' — an expression that seems to us either mere words, or else an excellent Irish bull. Perhaps Mr. Stanley can explain this phrase for us; but meanwhile, as one casts about for an interpretation, one is reminded strongly of Brer Fox, in the wonderful tar-baby story, as he 'lay low' in the bushes, watching his creation the tar-baby while it slowly intrapped Brer Rabbit. Possibly Brer Fox was 'immanently behind' that tar-baby. But our criticism is only of bad arguments and of obscure expressions, not of the view itself that the order of the universe implies an intelligence. The latter we hold as positively as Mr. Hicks or Mr. Stanley, only we insist that the question is not in the least one of inductive science. The 'design' argument in all its accustomed forms is bad, because it is an inductive argument, applied as true empirical science never applies any inductive arguments; viz., to matters wholly beyond the limits of phenomenal existence. The whole question is one of philosophy. Not as a result of induction, but as an implied premise of the inductive, or of some other rational thinking process, must this doctrine of intelligence in nature be established, if at all; and therefore only a critical philosophy, that examines the assumptions lying at the basis of the thinking processes, has any business with the question. Empirical science, as such, has simply once for all 'no need of that hypothesis.'

— A fire broke out last week in the cellar of the building containing the geological collections at Amherst college. Fortunately it was discovered early, and put out by the students before any serious damage was done. It will be recollected that the college lost the fine mineralogical cabinet of Prof. C. M. Shepard last year by fire; and the fear of a repetition of that disaster caused a too hasty removal of many objects from the lower floor, labels and specimens becoming sadly mixed. The wind was very high; and, had the fire gained greater headway, nothing could have saved the museum, or the observatory attached.

— Charles Leslie McKay of the U.S. signal-service, stationed at Nushegak, Alaska, was drowned in Bristol Bay last April, while engaged in collecting fishes for the U.S. national museum. Mr. McKay had done considerable work in ichthyology, his most important publication being a 'Review of the Centrarchidae,' in the Proceedings of the U. S. national museum for 1881.

— At its meeting, Oct. 27, the Philosophical society of Washington listened to a communication by Dr. T. N. Gill on the ichthyological results of the voyage of the Albatross, and to one by Prof. A. Graham Bell on fallacies concerning the deaf. Dr. Gill described two anomalous fishes, one of which required the institution of a new order. Professor Bell's paper was the subject of a lively debate.

— Those who have followed the discussions in Science on the St. David's rocks will be interested in a new phase of the controversy, introduced by a paper before the British association by Prof. J. F. Blake. The rocks below the Cambrian conglomerate have been described by Dr. Hicks as bedded rocks belonging to three distinct periods. The same rocks have been recently asserted by Dr. Geikie to be partly Cambrian, and partly intrusive. Professor Blake contends that they are pre-Cambrian in age, but form a very complete volcanic series, which may well be designated the Dimetian. The basis of the series is the Dimetian granite, serving as the core. This is surrounded by the more acid rocks, as the quartz felsites and the felspar porphyries (the so-called Arvonian); and the more outlying portions consist of very varying materials, chiefly rough ashes or agglomerate breccias, — on the east side finely-bedded 'halleflintas,' and on the north side many basic lava-flows. These are the so-called 'Pebidian.' The arrangement of these rocks shows the characteristic irregularity of volcanic rocks; and, though many portions are bedded, they have no dominant strike over the whole district. The Cambrian series, commencing with the conglomerates, is quite independent, and hangs together as a whole. In no case can a continuous passage be proved from the one series to the other: the junction is in most cases a faulted one; and, at the places where this is not so, the conglomerate lies on different beds of the volcanic series.

—At the meeting of the Boston society of natural history, Nov. 7, Prof. H. W. Haynes spoke of the agricultural implements of the New-England Indians, Prof. W. O. Crosby read a paper on the origin and relations of continents and ocean-basins, and Dr. M. E. Wadsworth gave brief notes on the lithology of the island of Jura, Scotland.

— Mr. George Shoemaker, a very industrious and promising young naturalist connected with the National museum, died in Washington on the 12th of October.

— Herr Jacobson, who has spent four years on the north-west coast of America in making ethnological collections for the Berlin museum, has recently returned, and will sail for Europe.

— Dr. Leonhard Stejneger has arrived in San Francisco, *en route* for Washington. He has spent a year in Bering Island in the study of its fauna, and in collecting remains of the extinct arctic sea-cow.

— The Hydrographic office has published a monograph (no. 4.), by Lieut. Southerland, upon the two August hurricanes. It contains abstracts from the logs of forty vessels which were near the path of one or both of these storms, a chart of the course of each storm, a diagram of the tracks of two barques which were near the path of the second hurricane, and sailing-directions for managing vessels when near similar dangerous cyclones. The projected paths resemble those previously published by the signal-office in the Weather review for August (Science, no. 37), but differ somewhat in detail. The latter were based upon the reports of more vessels than those enumerated by Lieut. Southerland. Some of the ships mentioned are common to the two reports; but doubtless a more accurate representation of the paths of the hurricanes could have been obtained, had all the data been combined in one report.

— Mr. J. B. Fell, C E., gave a paper on the construction and working of alpine railways, at the recent meeting of the British association, which is thus reported in *Nature*. There are three alpine railways in existence at the present time, — the Mont Cenis and St. Gothard railways, which have been made with long summit tunnels, and with ordinary gradients; and the Brenner railway, that has been made with similar gradients, but without a long tunnel. The important question has now arisen, and has been taken into serious consideration by the governments and local authorities interested, as to how far it may be possible to make other trans-alpine railways, some of which are urgently needed, at a cost that would render them financially practicable; and, to accomplish this object, it has been proposed to effect a reduction of one-half or more of the cost, by carrying these railways over the mountain-passes by means of steep gradients and the use of the centre rail system, as it was adopted on the Mont Cenis railway. Upon these improved summit railways the same weight and number of trains could be run that are now running on the Mont Cenis tunnel railway; and, with the protection of avalanche galleries and covered ways, the regularity of the service would be maintained at all seasons of the year. The extra cost of working-expenses caused by working over a higher level than that of a tunnel line would, if capitalized and added to the cost of construction, still leave a clear net saving of more than one-half in the cost of construction, as compared with the cost of a tunnel railway. The result of the experiences of the last twenty-five years seems to point to the conclusion that a method of constructing alpine railways with long, non-paying tunnels, is a thing of the past. The future belongs to the best system that can be devised for overcoming the difficulties of trans-alpine railways rather by adding to the powers of the locomotive-engine, and by other mechanical appliances for reducing the cost of traction on steep inclines, which methods are capable of indefinite improvement, than by burying in gigantic tunnels enormous sums of unproductive capital, that, when once expended, are irrecoverably lost.

— We learn from *Nature* that the electric railway from Portrush to the Giant's Causeway was opened Sept. 28 by Earl Spencer; and among others present, were Sir William Thomson, Sir William Siemens, and Sir Frederick Bramwell. It is over six miles long, and has cost £45,000. The line, after passing through the principal street of Portrush, follows the seaside road, a portion of a footpath six feet broad being reserved for the railway. The gauge is only three feet; and the gradients are very steep, — in places as much as one in thirty-five; and in parts of its course the curves are sharper than might have been desirable had the route which it takes been chosen by the engineers. The force to work it is generated by a waterfall in the river Bush, with an available head of twenty-four feet, the electric current being conveyed by an underground cable to the end of the tramway. The water-power passing through turbine water-wheels, which utilize the whole force of the fall, is said to amount to ninety horse.

— At the meeting of the Engineers' club of Philadelphia, Oct. 20, Mr. John Haug exhibited and described very complete sets of drawings for two vessels designed by him, — the one a tug-boat for the Philadelphia board of health, and the other a barge for the transportation of freight and passenger cars. Mr. J. H. Harden read a paper, prepared for publication as part of the Report of the second geological survey of Pennsylvania, relating to the "Early mining operations in Berks and Chester counties, including the present condition of the Jones mine." Prof. L. M. Haupt presented notes on conventional colors for drawing.

— Before the Biological society of Washington, at its meeting, Nov. 2, the communications were: Dr. George M. Sternberg, U.S.A., Micrococci; Dr. E. M. Schaeffer, Further remarks on manna, with exhibition of specimens; Dr. T. H. Bean, Arrested asymmetry in a flounder, with exhibition of specimens; Professor Lester F. Ward, Mesozoic dicotyledons.

— The autumn meeting of the Society of mechanical engineers, which has just closed in New York, has been unusually well attended, and some important lines of discussion have been drawn out. Considerable interest was shown in the proposed re-appointment of a board to supervise the work with the Watertown testing-machine.

— The Massachusetts agricultural experiment-station at the Agricultural college in Amherst, Mass., was established by an act of the legislature approved on the 12th of May, 1882. Its management is vested in a board of control, consisting of the governor of the state, two members of the state board of agriculture, two members of the board of trustees of the Massachusetts agricultural college, one member of the Massachusetts society for promoting agriculture, and the president of the Massachusetts agricultural college. The present officers of the station are all members of the college faculty, and are Prof. C. A. Goessmann, director and chemist; Prof. M. Miles, superintendent of field and stock experiments; and Prof. S. T. Maynard, superintendent of horticultural experiments, microscopist, and draughtsman. The station proposes to publish monthly bulletins, of which two have already appeared. The first contains an account of the organization of the station, and a general statement of its purposes, and also analyses of ten samples of fodders. The second and third bulletins contain analyses of four samples of fodders and of fifty-six of fertilizers and fertilizing materials.

— An extended review of the results of the German census of 1881 is given by Ch. Grad in the *Revue scientifique*, 1883, 109.

SCIENCE.

FRIDAY, NOVEMBER 16, 1883.

FROM SUPERSTITION TO HUMBUG.

It is related that especially fortunate English commanders in India have encountered a tendency among the ignorant natives to exalt them as more than human beings. It is not strange that a benighted and superstitious populace, astonished by exhibitions of power to it incomprehensible, should, for a time, turn from its own hazy gods to new and visible wonder-workers.

A somewhat similar revolution appears to accompany the progress of physical science. What its friends have to contend with at present is not so much indifference or hostility, though these are not altogether lacking, as a too implicit and childlike confidence in the efficiency of scientific knowledge on the part of those to whom its ways are in the main unknown.

The real conquests of science have been so vast and unexpected, so much like the workings of magic, that people eagerly pay their homage to a power, which, though mysterious enough to engage their credulity, accomplishes every day feats that witches, ghosts, and magicians performed only upon rare occasions. A genuine scientific man will disdain to abuse this confidence; but there are always camp-followers of the scientific army, who will find in it their opportunity. It is curious to see how those, who, a generation or two ago, would have been the believers in witchcraft and all things 'supernatural,' are now turning to be caught in the toils of scientific charlatanry. The wizard of the present day is an electrician. Electricity and magnetism have become literally words to conjure with.

There is a certain progress in this, though not in itself a valuable progress. It is the advance from sheer ignorance to that little knowledge which is proverbially a dangerous thing. It is the advance from pure superstition, in which men did not reason at all, to humbug, in which they reason from false or insufficient premises to wrong conclusions.

It should be said in justice to the scientific charlatan, that he is frequently not dangerous, and is nearly always amusing. He possesses an audacity, a volubility, that, combined with his habit of blundering, make him a far more cheerful person to contemplate than his gloomy predecessor, the sorcerer. Take, for instance, the modern master of that ancient black art of divination by rods. A newspaper report makes a 'professor' of the science of 'magnetic geology,' as he calls it, speak as follows: —

> "You take the ends of the forks, and grasp them tightly in either hand, allowing that portion where the forks join to point upward. . . . When one walks over a mineral substance in the ground, the electricity ascends through the body into the hands and rod, and draws the central or connecting portion of the rod downward. When this occurs, minerals exist beneath the spot where you stand. If the rod begins to move as the person walks along, take particular notice of the spot where you stand when the movement begins. When the rod turns completely over, measure the distance from where it first began to move to the spot where it indicates minerals. This distance will give you the depth at which the mineral can be found."

'Rabdomancy, or divination by rods, is as old as history,' some one recently remarked. The feature of this science peculiar to our age is the pretence of explaining it. That the method is still resorted to quite widely, there can be no doubt. We read in a Vermont paper, that a few months ago the public authorities of Middlebury resorted to the rod when about to sink an artesian well. They then sank a shaft eighty feet at the spot designated, and there struck, not water, but flint. We have lately heard of a man who ascertains by the divining-rod the proper spot for grounding lightning-rods. We have never seen a statement of his theory in his own words; but it appears that he holds the doctrine that atmospheric electricity follows, or is controlled by, the course of underground electric currents. He claims, moreover, to be endowed with a peculiar sensitiveness that enables him, by walking over the ground with the forked stick in his hands, to detect the location of these currents. The last touch is given to this theory by the statement that it is necessary for the gifted manipulator of the rod to wear rubber boots during the operation of divining, in order that he may be insulated from the ground.

In regard to the human body and the remedies for its ills, people have always been superstitious; and so, naturally enough, the number of 'electric' and 'magnetic' nostrums offered to afflicted humanity is very great. Their descriptions, however, are nearly always worth reading. Custom cannot stale the infinite variety of their absurdities. Here is a specimen which came to hand a few days since in the advertising columns of a college paper: —

"Labor, study, and research in America, Europe, and Eastern lands, have resulted in the Magnetic Lung Protector, . . . which, . . . with the continuous stream of magnetism permeating through the afflicted organs, must restore them to a healthy action."

There is a class of people who call themselves magnetic physicians, — people who cure, in a modern way, by the laying-on of hands. They are apparently closely allied to the spiritualistic mediums, and evidently intend to use something more than a figure of speech in calling themselves magnetic. There is, for instance, in or near San Francisco, a certain Dr. H——, who gives people what he calls magnetic baths. He claims to magnetize the water for the baths by dipping his hand in it. He is said to have an extensive practice. We have heard that the notorious Slade, whose feats made such an impression upon Professor Zöllner, claimed to possess a literal magnetic power, enabling him to rotate the plane of polarization of light.

Whatever may be the case with these peculiar people, it appears that others, not especially superstitious, do believe themselves particularly endowed or charged with electricity, because, for instance, they succeed in drawing sparks from their hair or clothing during cold weather. Of course, some people do have drier hair, or drier skins, than others, and do, therefore, as frictional electrical machines, surpass the majority of their fellow-mortals. Moreover, physiologists believe that in living bodies there exist slight electric currents capable of being detected by very sensitive apparatus. But apparently it is not with any intelligent reference to these exceedingly minute currents, or to an electric charge acquired by friction, that a man speaks, when he offers to rub a weak or disabled arm because he is 'strong, and full of electricity, you know.' The fact is, we do not know, and we wish the man would explain.

It would appear that such terms as 'animal magnetism,' and 'personal magnetism,' originating, no doubt, in metaphor, are sometimes taken almost literally. We have met one or two very intelligent people who seemed to have a vague idea that psychological problems might be attacked by means of the laws of electricity and magnetism.

This list of frauds and delusions might be greatly extended. Enough has been said, however, to illustrate some of the kinds of error into which people are led by their ignorance of the results and methods of scientific research. The need of a wider and more intimate knowledge of physics in the education of all classes would, no doubt, be generally acknowledged. It should be observed, however, that the kind of half-knowledge of this subject which is frequently obtained from newspapers, and even from public lectures and popular scientific books, is the very pabulum of such errors and humbugs as we have described. A woman hears a lecture on sympathetic vibrations, fundamental tones, etc., notes the trembling of a church under the music of the organ, and writes to her religious paper an enthusiastic letter explaining the fall of Jericho in a scientific manner, — and all in the interests of revealed religion.

A man reads, or sees in a public hall, that two electrified pith-balls attract or repel each other. He learns that the human body may be charged with electricity. Straightway he begins, upon this basis, to explain the table-tipping feats of spiritualistic mediums, — a gross error, hardly more respectable than the pure superstitition of the veriest believer in ghosts.

To make such errors impossible would require that definite, familiar knowledge of things, in their quantitative relations, which is hardly to be obtained without actual contact. It would require a laboratory training; and it is perhaps impossible to make provision for a very extended training of this sort in any scheme of general education.

The tendency of the times, however, is toward the objective and experimental in teaching; and it is probable that the next few years will see considerable changes in the methods of general instruction in physics.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1] — III.

We may now pass on from the small day-time whirls of dry air to the larger, long-enduring storms that are accompanied by rain; and here will be met two new elements, — the effect of condensing vapor, and the effect of the earth's rotation, — both of great importance. As a sample under this second heading, we may take one of the cyclones of the Bay of Bengal; for the storms there are very characteristic of their class, and have of late years received much careful attention. There is good reason for thinking that these cyclones generally spring up in calms, much as the desert-whirls begin. The seasons and regions of their occurrence both point to that conclusion; for tropical cyclones seem never to begin in well-established wind-currents, but rather in a place of quiet, weak, or variable winds. By India, for example, the cyclones are almost unknown during the prevalence of the steady blowing monsoons, but are not uncommon at those seasons when the monsoons change: that is, at times when the air has no well-established motion, but stands about idly, waiting for a decisive command to move on. During these idle times of stagnation, the lower air may become very warm and moist, and so prepare for a stormy overturning. The calm that precedes a cyclone often makes part of the description of a storm at sea: the air is close and oppressively warm; the water settles down to a glassy surface; and now we may see, what is not always clearly expressed, that this calmness of the water, and oppressive heat of the air, are not antecedent effects of the coming storm, but are actually the conditions that allow and determine the beginning of a storm. The warmer the air and the quieter the water, the longer must have been the preparatory stage; the greater the quantity of solar force collected in the lower atmosphere, the more violent will be the storm when it begins. This warm calm is really the embryo of the cyclone; and, if it lie long enough in a proper latitude, it will grow to well-developed maturity.

It is often stated that tropical oceanic cyclones begin at the meeting of two opposite currents of air rather than at a time of calm. This may be true for some cases, and undoubtedly has a very general application in temperate latitudes; but it seems more probable that in the Bengal cyclones, and most other tropical hurricanes, this stage is a little later than the earliest beginning, and is really the first development of the inblowing winds. A general calm would doubtless be found to precede such opposed currents if observation could trace the antecedent conditions a little farther back than is usually possible. The principal contrasts between the desert-whirls and the Bengal cyclones, at the time of their beginning, may be thus summarized: —

First, The area and uniformity of the surface on which the disturbance is developed is much greater on the ocean than on the desert.

Second, There is a lower temperature, but a much greater amount of heat, surface for surface, in the cyclone's embryo, than in the whirlwind's. The temperature of the air over the ocean seldom exceeds 95°: over the desert sands it may often rise to 140° or 150° close to the ground. But on the desert the stratum of air that is so excessively warmed is very thin; it often fails to reach the height of a man's eye, and so gives the appearance of a mirage: while over the sea, although the lower stratum is not so warm, its thickness is greater, and there is more of it warmed. What it lacks in temperature it more than makes up in quantity.

Third. The presence of water-vapor over the ocean makes a most important contrast between the two cases; and it is on this account that the warm sea-air is cooler than the hot desert-

[1] Continued from No. 40.

air. Water-vapor is not nearly so diathermous as dry air. Much of the heat that would pass down to the sand on the desert is held back by the vapor over the ocean, and some is caught again from the heat radiated upwards by the water, so that a considerable thickness of air is warmed. Of still more importance is the vapor's action as a great storehouse of solar force, required in the process of its evaporation, generally known as 'latent heat.' For all these reasons, the accumulation of energy in the preparation for an oceanic cyclone is vastly greater than in the making ready for a desert-whirl.

(*To be continued.*)

REMARKS UPON THE OSTEOLOGY OF PHALACROCORAX BICRISTATUS

It is a fortunate thing for science, that time allowed many of our Alaskan explorers to bring back in their collections, and to the museums, skeletons of so many of the rarer forms of the vertebrates, particularly the birds of those unfrequented regions. To Dr. T. H. Bean and Mr. H. W. Elliott, both of the Smithsonian institution, we are under lasting obligations for such material, and for making so good use of their advantages. The writer has enjoyed the unusual privilege of examining and studying long series of skeletons of Lobipes hyperboreus, Haematopus niger, rare forms of Rissa, Larus, and Sterna, many of the auks, puffins, and the like, — nearly all from the source that I have mentioned.

It was during the course of my examination of these sub-arctic rarities that my attention was called to several points of interest in a set of skeletons, representing three young and an old one, of a species of cormorant, Phalacrocorax bicristatus, forming part of the collection of the last-named naturalist. Professor Owen, in the second volume of his 'Comparative anatomy and physiology of vertebrates,' on p. 64, speaks of a bony style that is attached to the occiput in the cormorant as one of the cranial peculiarities of the class. This author does not mention its use; and as the writer has not a cormorant before him intact, with all the soft parts, it would be hardly safe to give its exact function in this bird's economy: but as I do not believe we have a figure showing the site of this bonelet, an illustration of the skull of Phalacrocorax is here given, showing, life-size, the right lateral view. This prominent style is seen protruding from the summit of the occiput in my drawing, not as a spinous outgrowth from that point, but rather as a free bone, concave below, separated into two concavities on its superior aspect by a sharp median crest that is developed on its entire length, — a transverse elliptical facet anteriorly, that articulates freely with a corresponding one on the occiput.

At the base of the cranium, we find that the pterygoids are completely overshadowed by the sub-compressed but rather large brain-case above. There are no basi-sphenoidal processes thrown out to meet these bones. The posterior halves of the palatines form a close union all along their median and inner margins, which portions are much spread out horizontally. Beyond, they become narrower; and in the space that we find existing between them we observe a long attenuated vomer, terminating anteriorly in a free, pointed extremity. The cormorants belong to the Dysporomorphae of Professor Huxley's classification; and he and other eminent anatomists have given other cranial characteristics in their descriptions of this well-defined group. The rami of the lower mandible are deeply grooved on the inner aspects of the dentary portion; and these elements, originally free, retain their sutures, distinctly marked, through life, where they join the other interested segments at the posterior moiety. Seventeen vertebrae are found in the cervical region, before we arrive at one that bears a free pair of ribs. Of this

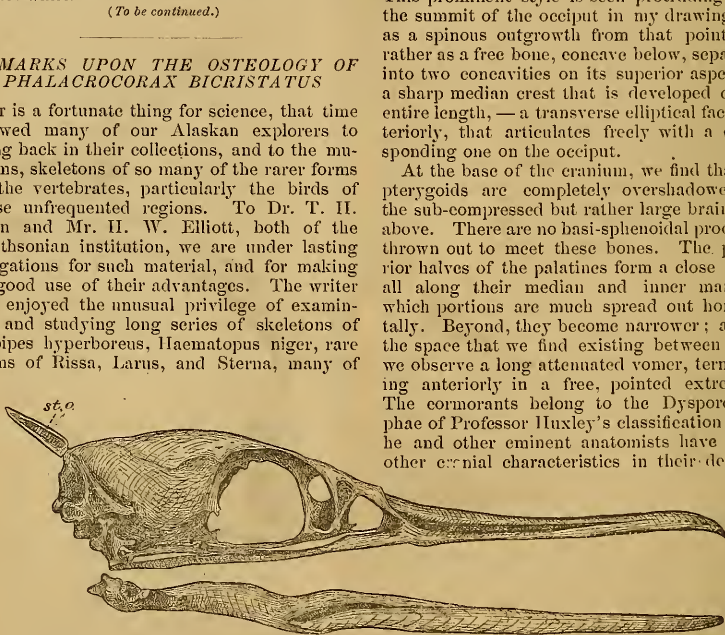

Fig. 1. — Skull of Phalacrocorax bicristatus, life size; right lateral view, showing occipital style, *st. o.*

series, we find the atlas and axis articulating in the usual manner, the former with its cup-like depression with the occipital condyle, the vertebra being perforated at its base. The parial parapophyses beneath the centra of these vertebrae are more or less prominent throughout; but in the eighth, ninth, and tenth, they are developed to an unusual extent, being long, needle-like processes, reaching nearly the entire length of the vertebra. A small pair of rudimentary free ribs are found beneath the transverse processes of the eighteenth vertebra. The next two ensuing ones have their ribs well developed, and bear large uncinate processes; but their lower ends still fail to be connected with the sternum by the intervention of costal ribs. Three more dorsal vertebrae are found before we come to the anchylosed series of the sacrum. These all have true ribs connected with the sternum by costal ribs, and their uncinate processes are strongly produced. A pair of ribs, as well developed in every particular as the series just mentioned, springs from beneath the ilium on either side, joining costal ones below; but the last pair of all, or the second that is produced from the anchylosed vertebrae of the sacrum, is without the uncinate processes, and in the specimen before us the costal rib on the left side is the only one of this pair that meets the sternum in a true facet. On the opposite side it articulates along the posterior border of the haemapophysis beyond it. The neural spines completely coalesce, in the ultimate sacral vertebrae, into a well-pronounced crest, which is surmounted along its entire length with a spreading cap of bone.

There are six free caudal vertebrae, not including the terminal segment or pygostyle, here quite large, pointed above, and possessing a moderately dilated posterior margin, thrown out to support the rectrices of the tail. The two anterior free caudal vertebrae are quite firmly grasped on either side by characteristic spine-like processes thrown backward, and developed on the part of the ilia. A lateral view of the pelvis, which is very long and much compressed from side to side, shows the ischiadic foramen to be an unusually large aperture, while the slender pubic bone fails to close in the other two foramina below, that are found in many other birds. This last-mentioned element of the pelvis slightly expands behind, where it meets the lower margin of the ischium for about a centimetre of its length. It then contracts again in size a little, to be directed downwards, and curved inwards. The body of the sternum is quadrilateral in outline, with two rather shallow excavations on either side of the median line, occupying the entire xiphoidal margin or border.

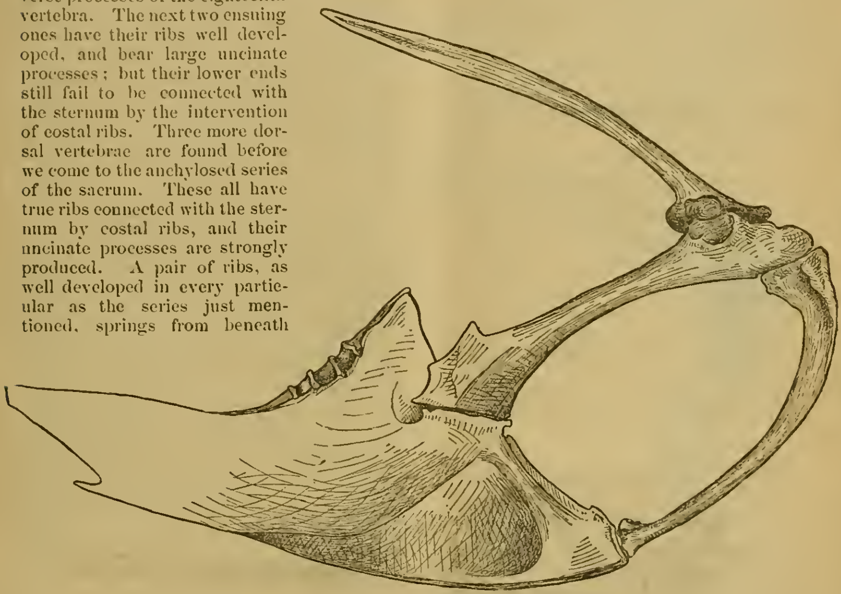

Fig. 2. — Right lateral view of sternum and shoulder-girdle of Phalacrocorax bicristatus, life size.

The keel is very much produced forwards, where, at its lower apex, it has a rough surface of some extent, against which the united clavicles abut. Sufficient material is not at hand for me to say whether anchylosis ever takes place at this point or not: it may do so, because we find in Aluco these bones usually unite at this point; but yet we come across specimens of this owl where the union is no more perfect than it is here. The hypocleidium of the clavicles, and the manubrium of the sternum, are both about equally feebly developed. The upper extremity of each clavicle has a very broad abutment for the head of the corresponding coracoid, to the inside of which expansion these clavicular bones throw backwards a scapular process; but they fail to reach these elements of the shoulder-girdle, as we find them

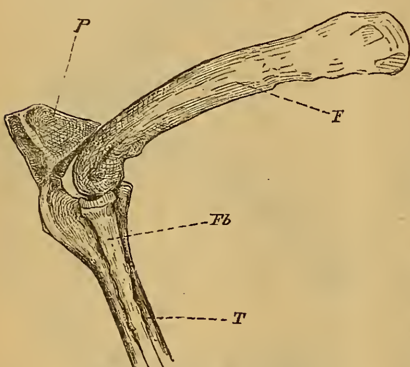

Fig. 3. — Knee-joint of Phalacrocorax bicristatus; right limb, life size. *F*, femur; *Fb*, fibula; *T*, tibia; *P*, patella.

in others of the class. All of the bones of the pectoral extremity, or the arm, are completely non-pneumatic, but otherwise well developed. Faint papillae for the quill-knobs of the secondaries are found along the entire length of the outer aspect of the ulna. The manus is composed of the usual number of bones,— one phalanx for index digit, two for the next, and one for the last.

In the lower extremity we find a femur of $6\frac{1}{2}$ centimetres in length; a tibia of $11\frac{1}{2}$; a metatarsus of 6; and the outer toe with five joints, measuring in all 10.7 centimetres. This limb is likewise non-pneumatic, in so far as its osseous structure is concerned. The fibula is carried unusually far down the side of its companion bone, to within 1.5 centimetres of the lower periphery of the outer tibial condyle.

The greatest interest, so far as the bones of the leg of this cormorant are concerned, centres about the knee-joint. Here we find a condition of affairs which is presented in my drawing. The femur, which is much roughened above for the attachment of muscles, articulates about equally with the leg-bones. In front of this joint is placed a very large and massive patella, of a pyramidal form, articulating with more than half its lower surface with the anterior and lower fifth of the femur, its inferior and anterior margin articulating at the same time with the upper border of the cnemial crest of the tibia. In front, we find that the groove that exists between the pro- and ecto-cnemial ridges of the tibia is produced on the entire anterior face of this patella, and, no doubt, the muscles of the leg are therein inserted, as in many divers. Such examples as this throw some light on such birds as Colymbus and Podiceps, where this bone becomes anchylosed with the tibia in the adult. I have not the skeleton of a loon at hand, to examine the process spoken of by Professor Owen ('Comp. anat. phys. vert.,' ii. 83), and followed by Dr. Coues in his osteology of the same bird ('Mem. Bost. soc. nat. hist.,' i. pt. ii.), as the analogue of the patella. The skeleton I have of Podiceps to examine does not show it; but it is one that has been in my collection for several years, and may have been lost. Penguins have a very large patella, that articulates with the tibia much in the same manner as it does here in Phalacrocorax. Professor Marsh describes a very large, free patella for Hesperornis regalis, and remarks that it bears a general resemblance to that bone in Podiceps ('Odontornithes,' p. 93). In examining this bone in the young of our cormorant, it seems to ossify from one centre. The ossification at the summit of the tarso-metatarsus includes the prominent process at the upper and posterior aspect of that bone.

Many other points of interest are to be found in the skeleton of the adult, as well as of the young of Phalacrocora xbicristatus, which space will not allow me to enter upon here: the leading points, however, I have endeavored to give, and these are always valuable when we wish to have them to compare with kindred forms.

R. W. Shufeldt.

THE ELECTRIC LIGHT ON THE U. S. FISH-COMMISSION STEAMER ALBATROSS. — I.

In pursuit of the hidden treasures of the deep, the work of the Albatross keeps her at sea many days at a time; and the operation of dredging in great depths often carries the day's labor past midnight. To provide for these emergencies, which are frequent, and to afford ample illumination for the naturalists, not only in assorting the contents of the dredge as it is delivered on deck, but to illuminate their microscopes, delicate balances, etc., in the laboratory, the commissioner of fish and fisheries determined to employ the best artificial illumination the country afforded. As the vessel is essentially a steamer, using steam for every labor where it is practicable, the idea of electrical lighting from a dynamo-electric machine, driven by a steam-engine, was readily conceived, and an examination of the different systems was at once entered into. The Edison company for isolated lighting, we found, was prepared to enter into a contract for a complete plant, including the engine and the wiring; and being able to divide the light into eight-candle power lamps, besides giving guaranties, their bid was accepted.

The arc-lamp, though admirable for our deck, where a great quantity of light in a limited space is necessary, can never, from its great brilliancy, be utilized for twelve or fifteen naturalists, each at a special work, in the laboratory. It also occurred to the commissioner, that a lamp which could be lowered into the sea, to attract fishes, would be useful, thus affording another reason for preferring the incandescent light.

Fig. 1 shows the way in which the arc-lights are placed in circuit. And as each arc offers a considerable opposing electromotive force, it is necessary, in order to get light in a number of such lamps placed in series, to use currents of high tension.

Fig. 2 shows the incandescent lamps in multiple arc. The main wires, *a* and *b*, are tapped at pleasure, and the lamps are hung in the short circuits. The carbon threads in the lamps (described beyond) offer so much resistance that the current heats them to incandescence. The electromotive force in the circuit is low, which renders shocks impossible.

The plant on board the Albatross consists of an eight and a half by ten Arminton and Sims engine, an Edison Z dynamo having its field-magnets vertical, a resistance-box in the circuit of the magnetic field, the main and branch wires, lamp-fixtures, safety-catches, and lamps.

The steadiness and uniformity of brightness of the lamps depend largely on the engine driving the dynamo; and the success of the system lies more in the attention paid to the engine, when the plant is correctly installed, than in any thing else. Uniformity of speed is the great object sought; and, to secure this, Mr. Edison has wisely adopted a high-speed engine with a sensitive governor, which is found in the Armington and Sims engine, represented in fig. 3.

The superiority of this engine lies in its well-

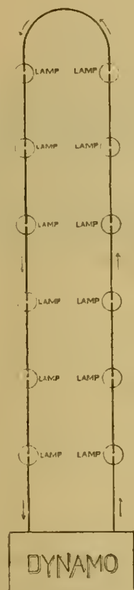

FIG. 1.

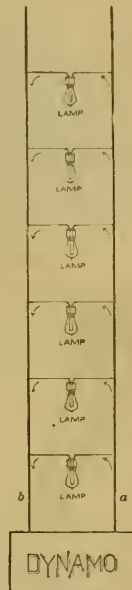

FIG. 2.

balanced working-parts, its relatively large bearing-surfaces, its sensitive automatic governor, and in its simple and well-balanced valve.

To secure high speed without the noise of 'thumping,' great lap has been applied to the exhaust side of the valve, whereby 'cushioning' is effected. This cushioning, or early exhaust closure, also effects a saving by retaining, in the clearance spaces, steam which would otherwise have been exhausted and wasted. To prevent an unequal expansion between the piston-valve and its chest, the castings are so made as to allow live steam to surround that part of the chest which surrounds the working-faces of the valve, as shown in fig. 4, in which S shows the steam space, and E the exhaust space. By this arrangement

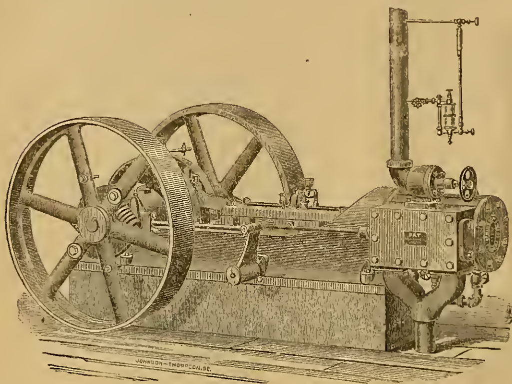

Fig. 3.

the valve-stem is packed against the exhaust instead of the steam pressure. The valve is ground to a sliding-fit, and, so far as I can ascertain, there has not been a particle of wear or leak during the ten months the engine has been in operation.

The governor of the engine, that part which makes it especially valuable for the purpose of electric lighting, is represented in fig. 5.

This automatic device is fixed in the fly-wheel, which is keyed to the shaft. There are two eccentrics, E and F, the one within the other, and both free to move on the axis. There are two weights, with their centres of motion opposite, and fixed in arms of the wheel. These

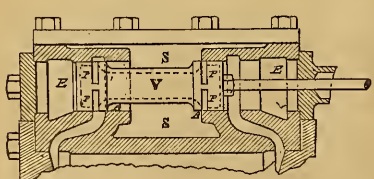

Fig. 4.

weights, W, W, are connected, each to an eccentric, and are connected together by an arm or rod. Springs are provided, to resist the centrifugal force of the weights. The system is so constructed that any centrifugal motion of the weights will throw one eccentric ahead and the other back, thus diminishing the throw of the eccentrics, and effecting a shorter cut-off without altering (within working limits) the lead of the valve. The engine used on board the Albatross has eight inches and a half diameter of cylinder, and ten inches stroke of piston: it runs without noise, three hundred revolutions per minute, requiring no more attention than the oiler can give it in addition to his other duties. When the main engines of the Albatross are in motion, a boiler-pressure of sixty-five pounds is often used, and twenty-six inches of vacuum is scarcely above the average. Lying in port, the boiler-pressure is kept at about twenty-five pounds; and, notwithstanding this great range of pressure, the governor regulates the dynamo to three hundred revolutions per minute, as closely as I can measure it.

In selecting a good engine, Edison has, to my mind, displayed as much genius as in using the Siemens form of armature for his dynamo.

The engines are placed on the starboard side

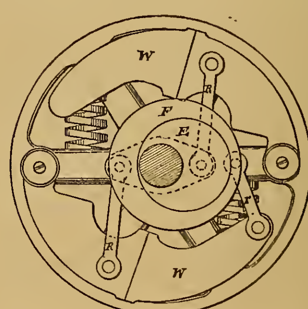

Fig. 5.

of the main engine-room, the engine taking steam from the main boilers, and exhausting into the main condenser.

The dynamo used on board the Albatross is known as the Z dynamo, and is installed for what is called a B circuit. It has its field-

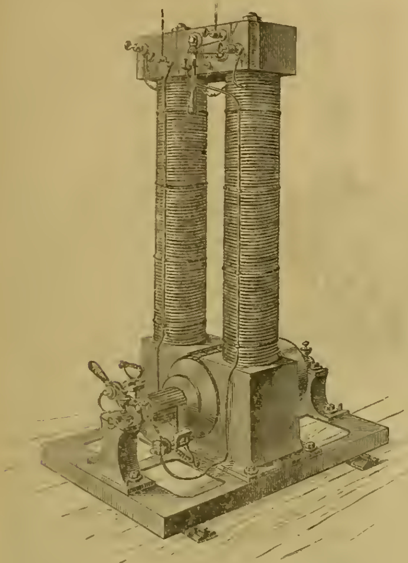

Fig. 6.

magnets vertical (fig. 6), and its armature revolves on a horizontal axis in the magnetic field. The field-magnets are arranged on what is called a 'derivation' from the commutator, placing it in the circuit, as in the Siemens system. In adopting and utilizing known principles and devices, Edison has worked out the details to a state of perfection simply admirable. Wherever the eye rests, it is pleased by correct proportions, sound mechanical ideas, and agreeable outlines.

The armature, on Siemens's principle, is mounted on a wrought-iron shaft. About the shaft, and concentric with it, are circular cylinders of wood, separating copper plates, as shown in fig. 7. Between the plates *a* and *b*, and also between *c* and *d*, there are annular disks of copper, insulated from each other. Between the plates *b* and *c* are similar but very thin annular disks of iron, separated from each other by tissue-paper. This built-up cylinder is then bolted together longitudinally; the bolts passing through the thin iron and copper disks without touching them, but clamping them between the thick plates. Wire bundles or bars are placed equidistant from each other longitudinally, around the cylinder, connecting each a pair of the copper disks, i.e., one at each end; and these bars or bundles generate the current.

Bars of brass or copper, separated by thin sheets of mica, *e,e*, are dovetailed into the projecting end of the cylinder, which forms the commutator. The resistance of the generator is thus small, and allows great subdivision of the current in multiple arc.

To preserve the uniformity of the current, an adjustable resistance-box is placed in the circuit of the field-magnets; and, when a number of lamps are extinguished, additional resistance may be added to the field by a switch on this resistance-box, whereby the internal and external resistances are balanced, preserving not only the uniform brightness of the lamps, but also the economy of the machine. A test-lamp is suspended on the dynamo; and the fireman, who oils the engine, regulates the resistance according to the brightness of this lamp. Automatic regulators have been devised; but as it is necessary to employ a man to run the engine and dynamo, and as the incandescence is more frequently altered by slipping of belts than by the sudden turning-out of a large number of lamps, the same man can attend both:

Fig. 7.

consequently the simple resistance-box answers every purpose on board ship.

(To be continued.)

THE AMERICAN EXPLORATIONS AT ASSOS.

THE excavations in the ruined Greek city of Assos, in the southern part of the Troad in Asia Minor, have been completed; and the members of the expedition have returned to this country. This gave occasion recently to call in Boston a special meeting of the Archaeological institute of America, under whose auspices the work had been carried on, at which Mr. J. T. Clarke, the leader of the expedition, was to give an account of his investigations. Unfortunately, Mr. Clarke was prevented by illness from attending; but this was less to be regretted, because it gave the president of the institute, Prof. C. E. Norton, an opportunity to express, more fully than he could otherwise have done, his sense of the extremely satisfactory manner in which Messrs. Clarke and Bacon had conducted the investigations at Assos.

Too strong terms could not be used to describe the devotion and self-sacrifice, as well as energy, which they had brought to the work, almost to the point of denying themselves the necessaries of life, that the resources of the institute might be diverted as little as possible from the work in hand. They had also labored in a spirit of enthusiasm and intelligence, bringing to bear the methods of modern scientific research, which gave to the results obtained an accuracy and value far beyond that of most of the archeological work of the past. No better archeological work had been done anywhere. He felt sure, that, when the final report upon the explorations at Assos should be published, it would be not merely up to the level of such publications, but would mark an advance in the science, and would take high rank among standard archeological works. This final report would require deliberate preparation: it was desirable that it should be exhaustive, and be published in a fitting style, as a monumental work.

The investigations had been carried out in the most thorough manner; nothing had been left undone which it was desirable to do; and, even had unlimited funds been at the disposal of the expedition, the excavations would not have been carried farther than they had been. The results were mainly architectural. A far more thorough knowledge of the civic buildings of a Greek city than was before possessed had now been obtained. Few marbles had been found (most of them having been previously destroyed), but a large number of terra-cottas were secured. The accession to the body of Greek inscriptions was real, though its importance was not to be exaggerated. In numismatics the expedition had been very successful; a very large number of coins having been found, and the number of types of Assian coins known, largely increased. In all, forty or fifty cases of antiquities would be brought home as the share of the institute. These included the best of the temple sculptures; the Hercules block and the best sphinx; all of the inscriptions, with the exception of the bronze tablet; a large number of terra-cottas; most of the coins, and a considerable number of minor objects, found in the tombs. Among the many architectural fragments, there would be enough to erect a complete order of the temple at the Museum of fine arts. The two thousand dollars which that institution had voted to appropriate for the purchase of a portion of the antiquities belonging to the Turks would fortunately not be called for, as the latter absolutely refused to sell any thing. Hope is, however, entertained, that a gift of these articles may be made by the sultan. It was pleasant to be able to announce that the whole work had been carried on with absolute honesty, and that the Turks had been dealt with in every way as strictly as if they had been Americans.

The final report would embody the results of all this work, published in an authoritative and reliable form. In the mean time a preparatory report would be issued, giving an account of the work done subsequently to the publication of the first volume on Assos. To prepare this report, it would be necessary for Mr. Clarke to go to London in order that he might have access to the British museum, the only place where the necessary materials could be obtained. It was desirable that the institute should retain both Mr. Clarke and Mr. Bacon in its employ until the Assos material had been entirely worked up.

The treasury of the institute was very nearly empty; and it was proposed to hold a general public meeting, at which Mr. Clarke, and other gentlemen interested in the subject, should speak, with a view to awakening such an interest in the community as should enable the institute to raise the sum of money required.

At this meeting, held Oct. 31, Prof. W. W. Goodwin read a report of the first year's work of the American school for classical studies at Athens, founded a year since by the Archaeological institute in connection with several of our colleges, and of which Professor Goodwin was last year the director. As this report affects rather the philological than the archeological student, and will be printed elsewhere, we proceed at once to the main feature of the evening, the address of Mr. J. T. CLARKE, who spoke substantially as follows: —

Assos was a small town, — small even for antiquity, when cities were very far from the enormous dimensions of modern capitals. The number of its inhabitants can never have greatly exceeded twelve or fifteen thousand; but its interest and importance can by no means be judged by that of modern towns of equal size. Athens itself, at the time of its greatest extent and power, is known to have had only ten thousand houses, and twenty-one thousand free citizens; and this figure included the entirely separate harbor-cities of Munychia and the Piraeus. To take a more recent example: the imperial city of Augsburg, at the epoch of its chief historical fame, under Maximilian, had only sixteen thousand inhabitants, — was only about the same size as Assos.

Our work gives as perfect a picture of the life of a quiet provincial Greek capital as the recent brilliant excavations at Olympia display the character of a great place of public festal assemblage. The investigations differ in scope; but I trust that ours has been not inferior as regards thoroughness, and, in some important respects, not as regards the nature of its results.

The first report, which is in your hands, represents three months' excavation. We have now the results of two years of hard work to add to it; and these results have been fully proportionate. The first report was restricted, in the description of buildings examined, to the temple and the Greek bridge. To our knowledge of these structures so many additions have now been made, that our restorations may be said to be as nearly perfect as it will ever be possible to attain. The temple, already better known than any building discovered in a similarly ruinous condition, appears as perfect an example for the history of Doric architecture as many which are standing to the top of the entablature. Other fragments of the reliefs carved upon its epistyle, the importance of which to the history of Greek sculpture is now recognized by all scholars, have been found since the publication of the report, and the entire stone ceiling of the building has been recovered. To this have been added many details, including most interesting and curiously suggestive observations concerniog antique stone cutting and laying.

Our knowledge of the geography of the land has been further enriched by maps, geological as well as topographical. To the story of its archeological recovery many details have been added, while its political history has received most important additions. One of these latter points I may be permitted to mention, because of its striking character. Assos is the first city of Greek civilization mentioned in documental history. The so-called Sallier papyrus, now in the British museum, records, that among the confederates who came to the aid of the Hittites, — those famous men whose empire is the pride of Professor Sayce, — were the 'people of Pedasa.' The inhabitants, then, of our city (Pedasos, Assos), were, in the fourteenth or thirteenth century B.C., of sufficient importance to be enumerated, with the Dardeni of Iluna (i.e., the Dardanians of Ilion or Troy), among those forces which appeared at Cadesh, on the banks of the Orontes, to fight against Ramses III. — the Rhampsinitos of Greek story — in the fifth year of his reign. The importance of this curious notice, in an historical point of view, is hardly to be overrated.

Fig. 1. — City walls of Assos, dating from the fourth century B.C.

The digging of the second and the third years has been almost restricted to the lower town. Much work was done upon the fortifications of Assos, the finest known works of Greek engineering. The oldest inhabitants settled close around the acropolis, building rough walls of enormous blocks, not cut by any metallic tools, upon the levels just at the foot of the volcanic crater, and there did a great deal of terracing, which was cleverly used by the later Greeks. The first outer circuit-wall remaining (I. in fig. 2) was certainly old at the time of the Lydian invasion. Under the favoring influences of the Aeolic colonization, the city greatly increased, and a new wall was necessary. This second masonry (II., fig. 2) may have somewhat antedated the Persian wars. By reason of the troubles brought by the Persian occupation of the land, the city declined; and when, under Lysimachos, its walls were rebuilt, the entire enclosure north of the acropolis was relinquished. The walls partially overthrown by sieges were not considered of sufficient value to be worth repairing, and a connecting-wall was built to the acropolis. This noble mass of masonry of the fourth century B.C. (fig. 1), rising in many places to some sixty feet in height, was joined so accurately that the blade of a pen-knife cannot be introduced between the stones. It was this portion of the wall that gave Col. Leake his well-known opinion that Assos was the finest representative of a Greek city in existence. Under the favorable dominion of the Romans, the commercial city greatly increased, and finally re-occupied the space north of the acropolis; new escarps (III., fig. 2) being built in front of the old walls, and enclosing them entirely. But to enter in any degree into details would lead us too far afield, ranging, as the fortifications do, through a thousand years, down to the time of Constantine; for the masonry in some parts, especially towards the eastern side of the city, closely resembles the ramparts of Constantinople.

The buildings of the agora, or market-place, of Assos, are so interesting and well connected that they are superior to those of all other Greek cities; and, notwithstanding the elaborate works of the many writers who have investigated and described the market-place of Pompeii, we may unhesitatingly assert the agora of Assos to be not only more interesting, but more completely known, than the forum of that city. The enormous stoa, or colonnade, a hundred and ten metres in length, was built, it may be with reason assumed, by the architect of that surrounding the temple of Athena Polias at Pergamon, which has so recently been excavated. It is constructed of the stone of the acropolis, an andesite much resembling granite; and a comparison between the forms given to this material and to the marble mouldings of Pergamon is most instructive. Being ceiled with wood, it needed only one support behind every second column of the front. Next to it, and apparently of the same date, is the bouleuterion, or building in which the archives of the city were kept. It is worthy of note, that most of the inscriptions were found in the slides of earth beneath this part of the agora, evidently having been thrown down during the troubles of the city. The building is exactly parallel in character to the only other bouleuterion known, —that in the Altis at Olympia; or, rather, it is like the inner portion of that structure, there being at Olympia halls on either side of a central structure like the bouleuterion of Assos.

The building which borders the agora on the south is absolutely unique. It is the only instance of a Greek bath known, and the only four-story ancient building ever recovered. Fortunately, we have been able perfectly to restore it. Its arrangement is extremely curious and interesting. It consisted of an enormous hall going through two stories, with twenty-six chambers upon its side. Above this entire structure was a colonnade, the floor of which was upon the level of the agora. In front of the stoa was an enormous basin for the reception of water, covered by stone lintels, and paved, so that it was not visible to the persons on the market-place. From it ran a subterranean conduit to the lower story of the bath-room, and there were arrangements for the water to flow into the thirteen lower cells. The refuse-water was then led into a larger basin beneath the bath-building. There was another reservoir to receive the water from its roof. This connected with the street, and so formed an enormous fountain, giving pure water for the consumption of the people; while the water of the refuse-basin adjoining it was used for the cooling of the theatre.

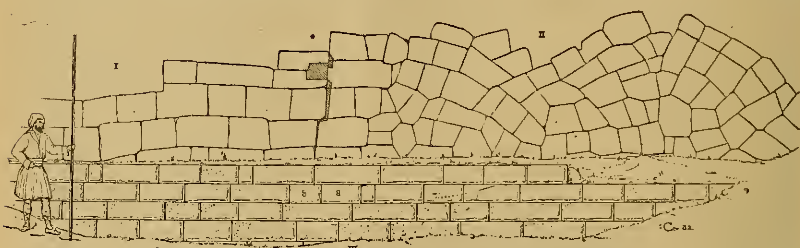

FIG. 2. — Corner of oldest polygonal city wall (I.), with extension in irregular masonry antedating the Persian wars (II.); both reveted, after the age of Lysimachos, with an escarp of squared blocks (III.).

Next to the bath was built, in later times, a small heroön, in which the bodies of the benefactors of the city were deposited, their names being inscribed on the entablature. We opened three sarcophagi, which contained only strigils, small vases, and the bones of the dead.

The changes of plan observable in the agora are peculiarly interesting. In early times there was an inclined plane ascending from a lower street to its level; but, when the heroön was intruded, the passage became so narrow that it had to be turned, and transformed into a stairway. Two fine mosaics of comparatively early date were found just below the retaining-wall. The larger represented Victories carrying votive offerings towards tripods, with a seller of love-gods as centre-piece; the other was bordered with geometrical figures, enclosing couching griffins, — the coat of arms of Assos. At the east of the agora was the bema, the stand-point of the orator in addressing a crowd; the level of the place being there raised above the market, and flagged, while the remainder, like all Greek streets before the Christian era, was unpaved.

Of the other buildings of the lower town, I may say that the theatre is now as well recovered as any theatre in Asia Minor. Because of certain peculiarities of the stage, its recovery is peculiarly valuable to the history of the Greek theatre. The gymnasium, at the west of the town, is equal in preservation and interest to the building of that character at Olympia, — the only one hitherto known. Noticeable, also, is a great atrium, of late date, but showing the preservation of Greek forms far into the Roman period, the arch appearing with purely Hellenic details. In the lower town of Assos there were no less than seven Christian churches. The street of tombs is perhaps the most interesting burial-ground of the ancients as yet thoroughly investigated. It presents monuments of every period. One, notably, cannot be later than the seventh century B.C., and many are as recent as the eleventh or twelfth Christian centuries. In this necropolis is a mausoleum which presents a perfect parallel to the tombs of the kings at Jerusalem. We opened a hundred and twenty-four sarcophagi for the first time, and found many burial-urns. There seems to have been a mixed system of inhumation and cremation, according to the temporary fashion. We also found great numbers of figurini, small vases and glasses, among them some beautiful specimens of thin transparent glass, and several thousand coins. Many other smaller articles of more or less value were found in the tombs; but the inhabitants of Assos, though they must have been wealthy, did not commonly place their best ornaments with the bodies of their dead.

It is my duty, as well as pleasure, to speak of the most creditable part taken by the members of the expedition not present here this evening. Of Mr. Bacon's really extraordinary ability as a draughtsman I have no need to speak. His unremitting labors secured the success of the expedition. The highest praise is due also to Mr. Koldewey, an architect from Hamburg, who worked with us for a year and a half from pure love of science, and was of the greatest possible assistance. My learned friend, Dr. Sterrett, has edited seventy-five or eighty inscriptions found by us, studying them upon the spot. Thanks, too, are due to our photographer, Mr. Haynes, and to Mr. Diller the geologist, who has already made known his work in valuable publications. Other members of the expedition, who were with us on comparatively short visits, worked as well and conscientiously, with results commensurate to the time they spent at Behram.

Archeology, up to within a recent date, hardly deserved the name of science, having been a merely empirical recital of facts, without connection or true historic method. To-day it has conquered a foremost place among the exact sciences of determination; and we trust that the study of the best methods of all previous investigations has enabled the expedition to Assos to be in every respect creditable to the American name. An instance of this special perception and direct search for materials bearing upon our knowledge of the development of various phases of ancient art may perhaps be seen in the fact, that two of the most interesting links that could be desired for Greek architectural history have been found, — a proto-Ionic capital, which stands between the ornamental spirals of Mesopotamia and the perfected Ionic capitals of the erechtheion; and a proto-Doric shaft with a base, which proves with equal certainty the derivation of that column from the tombs of Beni-hassan.

The work of the institute at Assos labors under one signal disadvantage: its results must be long awaited by those high-minded furtherers of science to whose munificence its execution is due. This disadvantage is indeed inseparable from all such undertakings of great extent; but on the other side of the Atlantic, where archeological investigations are carried on in greater part by the various governments, it is much less felt than here, where a large body of private individuals has maintained the work. There, the verdict of a commission of experts is entirely sufficient to the minister of public instruction, who has supplied the funds, and placed the diplomatic influence of the nation at the disposal of the work; and after this is given, a delay of ten or fifteen years in the publication of the results is not looked upon as a drawback. Here, however, the circumstances are different in every respect; and as it has naturally been impossible to give in half an hour any adequate account of the hard work of two long years, it only remains for me to beg for a further extension of credit. The debt shall be paid as soon as it is possible to write the proposed reports; and it will not have escaped your observation, that one object of the present meeting is to so interest you in the work of the institute, and convince you of its value, that the trifling sum required for these publications may be forthcoming.

At the conclusion of Mr. Clarke's address, Prof. W. R. Ware of New York was called upon, as one who had visited Assos for the express purpose of seeing what had been accomplished by the expedition. Professor Ware spoke as follows: —

It was, as you may believe, with special pleasure, that I found myself, in May of this year, passing through the Pillars of Hercules, my face towards the east, with the Troad as my objective point. But it was not until the third week in July, that, like St. Paul leaving Alexandria Troas, we came to Assos. though we were not, like St. Paul, 'minded to go afoot.' Perhaps it would have been better if we had been; for the modern Trojan horse is a small, ill-tempered, not always sure-footed, beast, who requires, indeed, often as much urging and pushing as did his Homeric namesake.

St. Paul probably passed through the valley of the Satnioeis, which flows into the Aegean on the west side of the Troad, a few miles south of Alexandria. But if he had known what was good for himself, in this world, he would have done as we did, and, leaving the plain, have ascended the steep sides of the little mountainous hill which separates the valley from the southern shore. There we found, upon the top, a tolerably level tableland commanding views of most surpassing beauty; to the north and west, Samothrace and Imbros and Lemnos, with Mount Athos just discerned in the western horizon on the other side of the sea; then, to the south, Lesbos, across the strait; and finally, in the gleaming morning sea, the little black hill which marked the volcanic mountain which was the goal of our endeavor.

The mountain of Assos is so steep as it rises out of the sea, that within a distance of half a mile it reaches a height of nearly one thousand feet. The steepest parts of the bridle-paths upon Mount Kearsarge and Mount Washington are not steeper than the road from the sea to the temple on the summit; and the agora, the market-place, which has been described to you, the centre of the city, is five hundred feet above the water.

One finds himself there, as you may now imagine, as on the stage of some classical theatre with all its scenes still standing, — here, the bouleuterion; there, the gymnasium, Mr. Koldewey's stoa, Mr. Clarke's temple and city walls, and, lastly, Mr. Bacon's street of tombs, leading half a mile away, towards his bridge at the river.

But interesting and exciting as is the presence of these monuments of antiquity, one can hardly keep his mind upon these things, for the attractions of the scene before him. To the east, where the long slopes of Mount Ida descend to the sea, the line is taken up by the blue and rose-colored mountains of Asia Minor, stretching along toward Smyrna; toward the south, filling the southern horizon, the island of Mitylene, — the mountain-tops brown in the sunlight, with purple shadows lying in all the valleys, and everywhere encompassing and infolding it all, the wonderful blues and greens of the Mediterranean Sea. Splendid as is the view from the acropolis of Athens, — the most famous in the world, — it seems to me that the view from the heights of Assos surpasses it in loveliness and splendor; and these buildings seem to have been so set, that this unparalleled prospect could be enjoyed to the utmost.

The buildings themselves are constructed of a stone which in its general aspect resembles a fine-grained granite, but in color and hue is more like the darkest and most purple of the Connecticut freestones. Yet the grain is so smooth that the most delicate mouldings can be cut upon it; and one is surprised to find, in passing the hand over the surface, how sharp, clean, and refined are the profiles of the mouldings.

The architectural interest attaching to these remains is unique. And here I cannot do better than to read an extract from a half-finished letter which I found in Mr. Bacon's portfolio, and snatched from oblivion, — a letter dated in December last, and never finished: —

"As the end approaches, my work has assumed a more definite form; and I know pretty well what the results will be. Hitherto I have been working rather blindly, and with but hazy ideas of final results. The street of tombs is such a collection of small, isolated ruins, that any thing like a complete idea of the original disposition was impossible at first. Sobered by the experience of last year, I this year attacked the monuments separately, with a resolute disregard of their relation to each other; excavated the most worthy, and drew them out in plan, elevation, and detail; then located each in a general survey, strung these plans along on a large map; and, lo, order is come out of chaos! Where before seemed nothing but confusion, now appears the hand of man; and the tombs are placed with such a picturesque regard for their purpose and for each other that the appreciative soul is filled with delight. The existing plan is more complete than the Appian Way at Rome, nearly as well preserved as that at Pompeii, and, to my mind, far more interesting than either, for it is pure Greek in every line and detail. Indeed, that may be said of all the work at Assos. There does not seem to be the slightest Roman influence. Of course, it is not always faultless. Work there is of all kinds, good, bad, indifferent, but, good, bad, or indifferent, Greek, not Roman. This absence of Roman feeling in the later work is a very peculiar thing. In Pergamon, Smyrna, and all the cities of Asia Minor, there exists a great deal of Roman work, and most of it pretty bad too. But here the bulk of the people probably never understood a word of Latin. The number of Latin letters upon the inscriptions we have found could almost be counted on your fingers. Whenever the Roman governors had any thing to say, they had to say it in Greek, to be understood. Even on the tomb of the Publius Varius family the dedicatory inscription over the doorway was in Greek.

"This absence of Roman work shows pretty well what a provincial town this must always have remained. Their stonemasons, builders, and architects were born and bred here; and they were a conservative set, with old-time notions about clamps and dowels, and about running down to the ledge for foundations. All this can be read like a book in the buildings we have laid bare. When any thing extra was to be 'run up,' they didn't import a foreigner from Miletus or Ephesus with his new-fangled ideas; not at all: they built it themselves. And this was not owing to lack of money, for the remains show that Assos must have been a wealthy city."

Another point of great interest is this, — almost all the principal publications of Greek work that have been made relate to monumental buildings. We have the temples, volume after volume, exhibiting a complete system of Greek architectural construction and design; but they have left unanswered the questions, how far Greek architecture was confined to sacred buildings, and to what extent the principles and methods which are exemplified in so magnificent a manner in the temples and sacred monuments were carried out in other structures. The long series of secular buildings which have been discovered at Assos offer the best answer that has yet been given to these questions; and the publication of the work, when it comes to be made, will mark an era in the study of the municipal and military architecture of the Greeks. It is a question, moreover, not without practical interest to the working architects of to-day, who are striving to solve for themselves the problem of fitly applying to secular and domestic buildings the same architectural forms, and the same principles of design, which they apply to sacred and monumental structures. This is an ever-recurring problem; and it cannot but be of service to learn how the Greeks, masters of the art, solved it in their own case.

Besides the walls, the buildings, and the tombs, there have been found, as Mr. Clarke has explained, a considerable amount of smaller objects, — vases, glass, pottery, urns, etc.; and of these a considerable portion has been secured as property of the institute. The *firman* by which the excavations were authorized gives us one-third of the objects found, — the most interesting third, perhaps; but it is difficult to speak justly in regard to it. If anybody should maintain that the objects which are to come here are of surpassing interest, and that they will immediately lift our museum to the front rank of such institutions, a decided negative would have to be given to such aspirations. If anybody should assert that the things were not worth the cost of transportation; that they have no general or popular interest; that they belong to a poor period; that they are hardly fit to be seen beside the more beautiful works, which, in the original and in copies, are in our possession, — that, again, could not be for a moment admitted; for the fact remains that the small portion which is secured to us is of surpassing interest to those who take an intelligent interest in such things at all.

The lower drum of a column, the capital, a complete section of the entablature, including the unique sculptured architrave, the frieze, and the cornice, all have been secured, and may soon be placed in position. In addition to that, the best of the sculptures which were discovered are to be brought over; almost all the coins; among the glasses and vases those which, on the whole, were best worth preserving; and most of the inscriptions. But even if the objects secured to us from the discovery were less than they are, it would make little difference in our estimate of the success of the expedition. The real result was intellectual. And the new points which have been proved, the new discoveries which have been made, are such, that, if not a single object were brought here from Asia Minor, we should still have abundant reason to be satisfied with the results achieved. It is impossible that we should obtain any adequate idea of these from the few drawings that have been publicly shown. They are but a fragment of the whole.

How it was possible for these two or three young men, while occupied with the practical direction of from twenty to forty men, to make the surveys and supervise the excavations, and also to prepare the immense mass of drawings which have been executed, it is difficult to understand; and it furnishes abundant proof of the ability and devotion with which the work has been prosecuted. The nature of the results will be seen when the next annual report comes from the printer; but their whole value and importance cannot be estimated until the appearance of that final and monumental work which will, we may hope at no distant day, take rank among the authoritative publications of its kind.

I may add, that the increasing interest in archeological work, and the scientific and precise manner in which it is now conducted, give new encouragement to the prosecution of literary classical study. The competition between the literary and scientific method seems about to end in a reconciliation, in the prosecution of literature on scientific principles, and in allying archeological science as closely as possible with the literature of classical antiquity. Archeology is a common ground on which science, literature, and art meet and join hands, each helping the other. Such a school as that now established at Athens, which you are asked to favor with your approval, is their common home.

On motion of the Rev. Phillips Brooks, the meeting declared, by an enthusiastic vote, that the work of the institute should be generously supported.

THE AMERICAN ORIENTAL SOCIETY.

THE autumn meeting of this society was held in New Haven, Oct. 24 and 25. Letters were read from various members abroad, reporting progress in their work; among others, from Mr. Mills of Hanover, respecting his edition of the Old Persian Gathas (ancient Zoroastrian songs or odes), of which the first volume is printed, though not published.

A paper on the temple to Zeus Labranios in Cyprus was read by Mr. Isaac H. Hall of Philadelphia, one of the pioneers in Cypriote studies, and the chief authority on the Cypriote language in this country. A temple to this deity exists at Mylasa in Caria (described in Fellowes's 'Lycia'). He was, under the name of Zeus Stratios, a local deity of the Mylasians, certainly from the time of Darius to that of Lactantius. The only other temple to him is this one in Cyprus, at Fasuli (or Fasula), near Amathus. The notoriously Lycian-looking architectural and other art remains found in the neighborhood show that this part of Cyprus was settled by Carians from Mylasa or its vicinity. Mr. Hall derived the epithet 'labranios' from a Lydian, Carian, or Lycian word, 'labru' (preserved by Plutarch in the form 'labrus'), meaning 'axe,' the axe being the peculiar symbol of Zeus Stratios of the Mylasians. From this word came the Mylasian name 'Labranda' ('place of the axe'); but the Carian settlers in Cyprus dropped the *d* (which is a sort of locative termination), and called their deity Zeus Labranios; that is, the Zeus Stratios of the Mylasians, and not Zeus Labrandios, which would be the Zeus of the village Labranda. Lycian influence in Cyprus seems confined to this little part of the island.

Mr. Hall also read (supplementing it from his own knowledge of the facts) a short history, from Dr. Van Dyck of Beirut, of his Arabic translation of the Bible, — a version admirable in literary style and in typographical execution (printed at the American press in Beirut). The difficulties in the way of the production of this translation were very great, and the result is highly creditable to American scholarship and energy.

Professor Avery of Bowdoin college gave an analysis of the Khasi language, spoken by a people dwelling in the Nepaul Hills, a representative of the non-

Aryan dialects which preceded the Sanskrit in India. It has no inflections proper, but uses prepositions for the expression of case-relations, and forms tenses very much in the same way as the English. It is noteworthy that this language, though a slightly developed one, has a clear distinction of gender; but the value of gender-distinction as a linguistic differentia is not yet well made out. In common with most of the languages of eastern Asia, the Khasi has a system of tones. The same thing is true of the Siamese, on which Mr. George presented a paper, illustrating the tonic distinctions by a short Siamese reading.

The paper of the most general interest was one on the origin of the Phoenician alphabet, read by Mr. J. P. Peters of New York. For some years past, most students of the subject, accepting for the present the conclusions of the late Vicomte E. de Rougé, have been inclined to derive the Phoenician from the Egyptian. This conclusion is based on the close relations existing between Egypt and Phoenicia in historical times, and on the similarity between certain letters in the two alphabets. But recently the Babylonian-Assyrian alphabet has begun to press its claims to be considered the parent of the Phoenician. It is almost certain that Phoenicia was closely connected with the Tigris-Euphrates valley at a time earlier than the oldest known historical monument. As long ago as 1877, a German scholar, Deecke, came forward as the champion of the Babylonian alphabet; but he committed the anachronism of deriving the old Semitic or Phoenician from the more modern 'cursive' cuneiform. Mr. Peters took the most ancient cuneiform signs, and compared them with the oldest Phoenician, finding in several instances striking resemblances. He urged besides, against the Egyptian origin, the fact that the Phoenician alphabet contains no vowels, while the hieroglyphics have distinct vowel-signs [though this is true of the Babylonian also]; and, further, the fact that the Egyptian had a large number of different signs for the same sound, and would present greater difficulties in the way of deriving an alphabet than the Babylonian, which had fewer homophones. The question is yet far from being settled, one serious obstacle in the way of the Assyriologists being the difficulty of determining the oldest forms of the cuneiform writing; but all such sober investigations as that of Mr. Peters must advance the desired solution. Meantime the Egyptologists, on their part, are bringing forward new material.

The edition of Manu, which was undertaken by the eminent English Sanskritist, Mr. Burnell, has been committed by the publishers, since his death, to Mr. E. W. Hopkins of New-York City, who sent on two papers, — one on the Nandini commentary on Manu, the other on the quotations from Manu in the Mahabharata. The former was a defence of the commentary in question: the latter was a contribution to the criticism of the Manu text. Mr. Hopkins took those passages in the Mahabharata which are introduced by the phrase, 'Thus said Manu,' and, finding that they do not always agree with the existing text of the laws, concluded that both texts rest on an older tradition; that Manu was an ancient sage, with whom tradition connected a number of laws, whence grew the collection called by his name.

Professor Whitney read on the variants of the Sama-Veda, coming to the conclusion (against the position of Benfey and Weber, hitherto generally accepted), that, in most cases in which the Sama text differs from that of the Rig, the latter is entitled to the preference. Professor Bloomfield of Johns Hopkins university, who is engaged in editing the Kauçika-Sutra to the Atharva-Veda, sent an account of the manuscripts of the Sutra in his hands, most of which he had obtained through the kindness of English officials. Mr. Brown made a short report of the recent Oriental congress in Leiden, at which he was present.

The next meeting of the society will be held in Boston, May 7, 1884.

LETTERS TO THE EDITOR.

Geology of Philadelphia.

DR. PERSIFOR FRAZER's explanations of his use of the term 'hydromica slate,' in his Lancaster-county report, as either 'not an equivalent for hydromica schist' or as a 'misprint,' renders it evident that he has changed his opinions since the writing of his report on York and Adams counties. In that volume the term 'hydromica slate' is employed ten times or more to designate 'hydromica schists,' and in several instances the terms are used synonymously. In two instances, localities marked in his printed section as hydromica schist are referred to in the accompanying descriptive text as hydromica slate (v. sections 2 b, 4, and p. 94, 101). As is evident from the context in a number of places, his 'hydromica slate' does not mean 'chlorite slate,' but 'hydromica schist' as it is elsewhere called (v. p. 83, 142, etc.).

There is, however, equal objection to his use of the term 'chlorite slate,' frequently employed in his different reports to distinguish greenish portions in the hydromica series. These are no more slates than are portions of the adjacent hydromicas, which are of identical structure. Nor, indeed, are they true chlorites, having but a low percentage of magnesia. (A recent analysis of some of the greenest of this so-called 'chlorite slate,' made for the writer by Prof. S. P. Sharples, gave only 4.28% of magnesia.)

Hydromica slate, as meaning hydromica schist, is also used several times in the report on Chester county, and the synonymous terms 'talc slate,' 'mica slate,' 'talc-mica slate,' 'talc-mica schist,' 'micaceous talcose slate,' and 'South Valley Hill slates,' are employed more than fifty times in the same report without distinction between slate and schist. Professor Rogers, as is well known, used most frequently the expression 'talc-mica slate.'

That the term 'slate' has been used synonymously with 'schist' in the region of the South Valley Hill, is not only shown by the indiscriminate use of those terms by Rogers, Lesley, and Hall, but is apparent in a remark by Dr. Frazer himself in the Chester-county report, p. 279, where he says: —

> "South of the Valley limestone, which only touches the extreme angle of the township, are hydromicas and mica-schists, dipping about south 35°, east −62°. The southern contact of limestone and *slate* occurs in this corner. . . . The hydromica schists and mica-schists to the south, which enclose this, are principally vertical," etc.

Now, as the only slates which occur at this locality are hydromica slates belonging to the hydromica series of rocks of the South Valley Hill, these must be the slates referred to, even if 'hydromica slates is a contradiction in terms.'

While the undersigned certainly does not intend to be a champion for the term 'slate' instead of 'schist' for these rocks, good reason for the use of that term lies in the slaty character of many of these hydromicas as distinguished from the contorted and schistose character of the micaceous rocks of other regions.

The writer's use of the expression 'hydromica slate' in describing the Edge Hill and Barren Hill rocks (the 'altered primal slates' of Rogers), is thought preferable to the term 'hydromica schist,' since large portions of that formation are slaty rather than schistose. The greater part of the formation is a slaty sandstone or quartz slate, and, where outcropping in Chester county, is so designated by Dr. Frazer. It might naturally be taken for granted that the writer believes, with Dr. Frazer, that the hydromica schists and slates of the South Valley Hill of Chester county are about contemporaneous with this quartz slate or Edge Hill rock.

In order to prevent future misapprehension, it may here be stated, that the writer has been led to the conclusion that the two formations are distinct, and that both Professors Rogers and Frazer have confounded two rock series belonging to different geological horizons, — the one, Cambrian; the other, Silurian. The analogue of the Edge Hill rock is believed to occur in Chester county, on the south side of the hydromicas of the South Valley Hill. The facts leading to this conclusion have been gathered during some extended field-work in Chester county, and will shortly be published. Meanwhile, the remarks upon the primal slates made in the Franklin institute lecture should be understood as referring solely to the Edge Hill rocks proper, and not to the South Valley Hill schists or slates, which are but poorly defined in the vicinity of Philadelphia.

H. CARVILL LEWIS.

The specific distinctness of the American and European brine shrimps.

In Professor Smith's notice of our 'Monograph of phyllopod Crustacea,' he states, that, in the portion relating to the above subject, 'there is certainly confusion,' and quotes two paragraphs relating to the females alone, and finally remarks, "but differences like these in statements of observation betray inexplicable carelessness."

After quoting the two paragraphs relating to the *females alone*, it seems to us a careful critic would have also taken pains to have quoted the longer paragraph relating to the males, which directly follows the first paragraph quoted by our critic. To allow the two paragraphs relating to the females to be so widely separated was an oversight on the part of the author, who, however, thought that he had taken a good deal of pains to show the specific distinctness of the American and European species. Two sets of females from different localities, named by different persons, were examined at different times; and this explains how the two paragraphs became placed too far apart in the author's copy. It would have been better, of course, if the author had added a few words, and dogmatically stated that the two species were undoubtedly distinct. He preferred not to do, or omitted to do, this, but gave in considerable detail, and in as judicial a way as possible, the facts of the case. At first it was 'difficult to find good differential characters' between the females, and those found are but slight ones. The females of any of the species of Artemia, Branchinecta, or Branchipus, do not exhibit good specific characters; but the males do, as the author attempted to show. If the author failed in directness of statement on this subject, or led to any confusion in any one's mind, he sincerely regrets it: on the other hand, he doubts whether there were, in the case, reasons for the charge of 'inexplicable carelessness.'

The paragraph which Professor Smith would have done well to have quoted is the following one: —

"Upon comparing a good many males from Great Salt Lake with several, both stained with carmine and unstained, received from Cagliari, Sardinia, through Prof. J. McLeod of Ghent, the European A. salina is seen to be considerably stouter, the head wider, the eye-stalks longer and larger, and the eyes larger. The frontal button-like processes of the first joint of the claspers are nearly twice as large as in the American species, and a little more pointed, while the claspers themselves are larger and stouter. The legs and sixth endites are of about the same form. The most apparent difference is in the caudal appendages, or cercopods, which in A. salina are several times larger than in A. gracilis, being in the Sardinian specimens nearly three times as long and much larger than in our species. In this respect, the genus shows a close affinity to Branchinecta. However, in a lot of A. salina ♀ from Trieste, the cercopods are very much shorter than in the Sardinian females, and only a little longer than in our American specimens. These appendages do not differ in the two sexes."

A. S. PACKARD, Jun.

Bone fish-hooks.

Recently, while digging in a shell-heap near Narragansett Pier, Rhode Island, I found among broken arrow-points, and fragments of bone, pottery, and shells, a nicely worked bone-hook, and also the shanks of three other apparently similar hooks; while in a neighboring shell-heap two more fragments were found.

The perfect hook measures a little more than one inch in length, and a little less than one inch across from the shank to the point, the latter being nearly as long as the former. The shank is flattened and notched at the end, forming a sort of head, somewhat similar to the fish-hooks of the present day. This hook, although much shorter, resembles a hook from Long Island described and figured by Mr. Charles C. Abbott on p. 208 of his work on Primitive industry. Of this he says, "Objects of this character are exceedingly rare, either as found on the surface, or in shell-heaps. While of so simple a form, bone fish-hooks of this pattern do not appear to be common in any locality in eastern North America."

Figures are here given of the perfect hook, and the fragments of three others which appear to be precisely similar. Margarette W. Brooks.

Nov. 1, 1883.

Supposed glacial phenomena in Boyd county, Ky.

A part of the work devolving upon us who have recently been tracing the southern boundary of the glaciated area in America, has been to follow up the reports of glacial phenomena south of our line.

Boyd county, Ky., having been referred to by a number of authorities as such a locality, I was naturally led to visit it a short time since; and I found, to my satisfaction, that that region was never directly glaciated.

Boyd county is in north-eastern Kentucky, bordering upon West Virginia, and upon the remarkable bend of the Ohio River where it receives the waters of the Big Sandy. Through the attention of Mr. John Campbell of Ironton, O., and Mr. J. H. Means of Ashland, Ky., I was assisted in making a pretty thorough examination of the region. Upon going back about two miles into Kentucky from the Ohio River, opposite Ironton, we find ourselves in a valley two miles wide, running parallel with the Ohio River, and two hundred and twenty feet above it. This valley extends for many miles, reaching the river towards the west at Greenup, and continuing some miles, at least, above Ashland. It is known as Flat Woods. The level is remarkably uniform; and the hills upon either side of it rise about two hundred feet, with numerous lateral openings towards the Ohio. When upon the farther side, and looking northward, one sees the rocky bluffs of the old channel rising so like those facing the river itself, that he can scarcely resist the illusion that he is in the present valley of the stream. The supposed glacial phenomena consist of numerous water-worn pebbles of quartz and quartzite scattered along the whole range of this old valley. Most of the pebbles are small, and perfectly rounded, though some were a foot or more in diameter; and one observed was about two feet and a half through, and only slightly worn. These pebbles are not found upon the hills back from this channel, on the Kentucky side, nor, according to Mr. Campbell, who is a most competent witness, anywhere in Lawrence county, O., back from the river. Plainly enough, they are the result of water-transportation. Whether they were deposited at the very early period when the Ohio flowed at the level of two hundred and twenty feet higher than now, and regularly occupied this old channel, or whether they were brought into place during the existence of the glacial dam which I have supposed at Cincinnati, I will not venture to say; though the latter theory would seem more in accordance with the facts published by Professor White concerning the old channel followed by the Chesapeake and Ohio railroad, extending from the Kanawha River to the mouth of the Guyandotte in West Virginia. The elevation of the Kanawha-Guyandotte channel is nearly the same as that of the one I am describing, and this seems to be a prolongation of that. At any rate, the pebbles can only be indirectly referred to glacial action.

Now that attention is directed to this class of investigations, it would seem to be important for Professor Lewis to give through your columns, or somewhere else, publicity to his investigations of the facts supposed to indicate glacial action in Pennsylvania farther south than the boundary-line indicated by our investigations two years ago.

G. F. Wright.

Oberlin, Nov. 5, 1883.

Elliptic elements of comet Pons-Brooks.

While the orbit by Professor Boss, published in Science, No. 34, represents observation so well that there can be no doubt of the identity of the two comets, still it is of interest to know how closely elements derived from observations of the present comet alone agree with those of the Pons comet.

The arc of anomaly already passed over is only about twelve degrees, — a condition very unfavorable to the precise determination of elements, and inadequate to determine a reliable periodic time.

On account of this, in the solution of the equations, Δe was considered as a known quantity, and finally an assumed value substituted for it.

I find the following corrections to Professor Boss's elliptic elements from the normal places given below: —

$$\begin{aligned}\Delta\pi &= -194.0'' - 78{,}768.\ \Delta e\\ \Delta\Omega &= +\ 19.5'' + 289{,}233.\ \Delta e\\ \Delta i &= -\ 57.5'' + 55{,}256.\ \Delta e\\ \Delta T &= -\ 0.065235 - 108.39\ \Delta e\\ \Delta q &= +\ 0.000716 - 0.04\ \Delta e\end{aligned}$$

Assuming the eccentricity to be 0.954996, which closely approximates to the true value on the hypothesis of identity, we have for Δe, -0.000274.

The resulting corrections to the preliminary elements are, —

$$\begin{aligned}\Delta\pi &= -172.4''\\ \Delta\Omega &= -\ 59.7\\ \Delta i &= -\ 72.6\\ \Delta T &= -\ 0.035537\\ \Delta q &= +\ 0.000727\\ \Delta e &= -\ 0.000274\end{aligned}$$

and the corrected elements are, —

$$\begin{aligned}T &= 1884,\ \text{Jan., } 25.66046\\ \Omega &= 254^\circ\ 07'\ 48''\\ \pi &= 93\ \ 18\ \ 50\\ \omega &= 199\ \ 11\ \ 02\\ i &= 74\ \ 02\ \ 05\\ lg\,q &= 9.889708\\ e &= 0.954996\end{aligned}\quad \left.\right\}\ 1883.0\ (\Omega,\ \pi,\ \omega,\ i)$$

After obtaining the preceding results, the equations were solved for the value of Δe, with the result $\Delta e = -0.000032$; but no use was made of this.

Normal places, 1883.0.

Mean date, Greenwich mean time.	α	δ	No. of observations.
	h. m. s.		
Sept. 8.5 . . .	16 30 38.75	63° 49′ 12.5″	28

The observations enclosed in brackets were not used as exhibiting large systematic or accidental errors.

A few observations were made with ring-micrometers, but it is not possible to determine how many. At Albany the ring was used until Sept. 21, afterwards the filar micrometer.

The following table shows the constant difference for each observer when there are three or more observations given, and includes nothing later than Sept. 26: —

Observatory.	No. of observations.	Δα cos δ.	Δδ.
Albany, B.	8	1″	0″
Albany, E.	4	+ 2	3
Cincinnati	4	0	7
Harvard, Wn.	7	+ 18	2
Kiel	7	− 5	+ 4
Leiden	3	− 3	+ 4
Pulkowa	3	+ 4	0
Strasburg	4	− 1	− 3
Wien	3	− 1	+ 1

These constant errors, though founded on rather slender material, probably represent fairly what is to be expected from modern observations of comets.

Following are the heliocentric co-ordinates: —

$$x = r\,(9.580346)\sin(153^\circ\ 14'\ 15.1'' + v)$$
$$y = r\,(9.996200)\sin(\ 82\ \ 04\ \ 40.0\ + v)$$
$$z = r\,(9.970401)\sin(174\ \ 59\ \ 17.4\ + v)$$

H. V. EGBERT.

Dudley observatory, Albany, N.Y.,
Nov. 6, 1883.

Rapid geological changes in Alaska.

Mr. Dall kindly calls my attention to an error in the note of my remarks, given in SCIENCE of Oct. 19. Hood's Bay is nearly a degree south of the locality of the submerged forest described. Looking at my diary, I find the entry 'Hoona,' which is, I believe, synonymous with 'Bartlett Bay' of some charts. While making my verbal remarks at the academy, I mistook my pencilling of 'Hoona' for 'Hood.' The exact location of the forest is latitude 58° 27′, longitude 135° 40′. I am very much pleased to find from Mr. Dall's letter that my view of the modern changes, drawn from botanical facts chiefly, derives support from some geographical evidence within his reach.

THOMAS MEEHAN.

The mechanism of direction.

I read with interest Professor Newcomb's article on the sense of direction (SCIENCE, Oct. 26). Professor Newcomb says nothing about the behavior of the subjective co-ordinates under a slight change of angle. My experience in this respect I give below, and I have reason to believe the experience to be quite general.

The street A B turns into B C. Walking from A to B, my co-ordinates begin to change when about a hundred yards from B. By the time I get to B, or rather just after B, they have changed by the angle A B C, no matter how large or how small A B C is. The same takes place in going from C to B to A. While close to B on either side, I can by an effort imagine myself under the old co-ordinates; but the new ones are much more natural. In the dark, I think the turn is not seen so far ahead, and the change takes less time. If I go from A to B, with my eyes turned towards A, I have a different experience. I have never tried it by *walking* backwards; but I have observed my sensations while riding on the back platform of a street-car. As the car turns at B towards C, and I am looking towards A, my co-

ordinates begin to change rather suddenly; but there is no sign of a change before B. Shortly after B, I still can conceive myself under the co-ordinates formed on A B, by a mental effort. After about a hundred yards the new co-ordinates have entirely displaced the old.

At the corner of 13th and Spring-Garden streets in Philadelphia I had an experience like that of Professor Newcomb. For a long time I could not approach the place, riding or walking, without my co-ordinates changing by 90°. I cannot account for it. Gradually it wore off, and now no change takes place.

JOSEPH JASTROW.

INTERNATIONAL GEODETIC ASSOCIATION OF EUROPE.

Verhandlungen der vom 11 bis zum 15 September 1882, im Haag vereinigten permanenten commission der europäischen gradmessung. Redigirt von A. HIRSCH und T. VON OPPOLZER zugleich mit dem general bericht für die jahre 1881 und 1882. Berlin, *Reimer*, 1883. 6+155 p., 2 maps. 4°.

THE proceedings of the annual meeting of the committee at The Hague, Sept. 11 to 15, 1882, have just been published. The permanent committee consists of the following members: Lieut.-Gen. Ibañez of Madrid, president; Dr. von Bauernfeind, vice-president; Dr. Hirsch of Neuchâtel, and Dr. von Oppolzer of Vienna, secretaries; Mr. Faye of Paris; and Major-Gen. Baulina of Florence. The delegates, eleven in number, represent most of the countries of Europe. Some invited guests also attended the meeting. The session was opened by the minister of state, Rochusson of Holland, who extended to the members a cordial welcome, which was responded to by President Ibañez.

The last meeting was held at Munich in 1880; but the commission resolved to omit the contemplated meeting for 1881, in order to give its members an opportunity to attend the Geographical congress at Venice: the reports therefore submitted by the several representatives cover the work done, or in active progress, during the two years 1881 and 1882. Secretary Hirsch alludes to the loss sustained by the association since its last conference, in the death of Dr. Carl Bruhns, a member of the commission since 1864; in the death of Gen. de Ricci, one of the veterans of Italian geodesy; of Col. Adan of Belgium, and Professor Stamkart of Holland. The latter had shown that the mean level of the North Sea had not changed during the past hundred and fifty years with respect to the zero of the tide-gauge at Amsterdam. And, last, the association had to mourn the loss of Professor Plantamour of Geneva, whose labors in astronomy and physical geography are so well known, and to whose zeal the recent developments in levels of precision and the progress made in pendulum observations are so largely due.

The Italian commission was increased by Professor Fergola of Naples, by Professor Celoria of Milan, and by Lieut.-Col. de Stefanis of Florence. Austria nominated Capt. von Kalmar and Professor Herr as commissioners; Holland completed its representation by Professor Schols of Delft; and Roumania sent Major Capitancanu. The honorary president and founder of the association, Major-Gen. Dr. Baeyer, who, on account of ill health, was unable to attend, presented a report of the labors of the Geodetic institute of Prussia during 1881–82. He makes mention of the success of the experiments[1] to determine the difference of temperature between the bars of platinum and brass of the Brunner base-apparatus by means of thermo-electricity. The researches for local deflection of the vertical were extended from the Harz to the shores of the Baltic and the North Sea with the result of proving it a region of predominating negative (A.—G.) deflection, varying between 4″ and 7″. A list is presented of seventeen works published by the institute during the interval. Several of these relate to levels of precision; and the pamphlet by Dr. Sadebeck, entitled 'Literature of the practical and theoretical measurement of arcs,' deserves special mention. In a discussion closing the first session, relative to the probable error in the assigned length of the pendulum, it was stated, that, to judge from the accord of the several swings, it might be estimated at about one micron, but that the oscillations of the pendulum support introduced a constant error, seriously influencing the accuracy of the result; the *direct* measure of the motion of the support entering the result being only a fortieth of the correction to pe applied. By this method the accuracy is estimated at .01 mm. The proposition by Cellerier to swing successively on the same stand two pendulums of the same form and construction, but of very unequal weight, promises complete success towards correcting the defect in question; and the experiment is now being carried out. The second session was chiefly occupied with the reading of reports, and with a discussion respecting the value of the prismatic transit instrument. Six of these instruments employed in the Italian survey gave entire satisfaction, especially with regard to perfection of their images. The dis-

[1] Published in *Astronomische nachrichten*, no. 2451.

cussion was continued in the next session with remarks about the greater variability of the error of collimation in the prismatic transit; but its superiority in its low Y's over the common form of the instrument was recognized. In connection with the pendulum of reversion, Hirsch refers to the observations of Mr. C. S. Peirce of the U. S. coast and geodetic survey, at Geneva, Berlin, and Hoboken in America, which prove experimentally the theoretical conclusion of the complete elimination of the resistance of the air by the use of Bessel's pendulum of reversion, — a conclusion indorsed by Ferrero from experiments made in Italy. In the fourth session, Villarceau explains the construction of his new apparatus for the relative measure of the intensity of gravity, and the commission recommends a direct comparison of the new apparatus and of the apparatus of Cellerier at a number of stations. A discussion followed on self-registering tide-gauges and river-gauges; Mr. Diesen stating, that in Holland as many as sixty-four instruments were in operation, or being put to immediate use. Professor Nagel was elected a member of the permanent commission. In the following session the business programme for the seventh general conference of the European association for the measurement of arcs was formulated and adopted: viz., —

1. Reading of the annual report of the permanent commission.

2. Reports of the progress of geodesy by the representatives of the several countries.

3. Reviews of the present state of geodetic operations, subdivided as follows: —

Astronomical longitudes, latitudes, and azimuths (reporter, Backhuyzen); Triangulations (reporter, Ferrero); Base-lines and base-apparatus (reporter, Perrier); Levels of precision (reporter, Hirsch); Tide-gauges (reporter, Ibañez); Gravity apparatus (reporter, von Oppolzer); Refraction (reporter, von Bauernfeind); Geodetic publications (reporter, Baeyer); Arc of the parallel in Europe (reporter, Faye).

The proposition to meet at Rome in October next is adopted, pending the favorable acceptation by the Italian government.

The remaining part of the pamphlet is occupied with reports in detail of the progress made during the years 1881–82 in the countries represented. Their contents may be briefly summarized as follows: —

Baden, Germany. — Levels of precision, and publication of the results of the Rhenish triangulation.

Bavaria, Germany. — Observations of terrestrial refraction, lateral and vertical; spirit-levelling, total development to date 2,578 km.; oscillations of the ground, and pendulum observations at the Bogenhausen observatory.

Denmark. — The fourth volume of the geodetic survey is promised towards the close of 1883.

France. — Connection by new triangulation of the base-lines of Melun and of Perpignan; extension of the Algerian arc of the parallel into Tunis; measures of latitudes and of differences of longitude by telegraph. Volume xii. of the 'Mémorial du dépôt de la guerre' is in press, and a table of logarithms of eight places of decimals is in preparation.

Hesse, Germany. — Levels of precision, mean error per km. equals 2.27 mm., from 32 differences in levels, connected by 14 conditional equations.

Holland. — Connection of lines of spirit-levellings with lines of adjacent countries; total length levelled, 283 km.

Italy. — The reconnaissance for the primary and secondary triangulation completed; geodetic levelling and tidal observations; determination of a latitude, an azimuth, and of several differences of longitude, by telegraph; comparative pendulum observations at Rome.

Austria. — Measure of astronomical latitudes; telegraphic determinations of differences of longitude; pendulum experiments; triangulations and astronomical work in general; occupation of points, and attempts of measures of angles, in the high Alps (among these Ankogl at an elevation of 3,263 m.; station Grossvenediger, of 3,659 m.; and of Grossglockner, of 3,798 m.); extension of triangulations in Bosnia, Herzegovina, and Dalmatia; continuation of levelling operations in Austria proper, and in Hungary; observations of the intensity of gravity in the deep mine of Pribram. The work executed in this country is too extended and diversified to be given here in detail: it is graphically represented in a finely executed map in color-print.

Portugal. — Continuation of the triangulation and of tidal observations.

Prussia. — Revision and completion of principal lines of levels. The following important results are recapitulated: Atlantic higher than the Mediterranean from levels between Swinemunde on the Baltic, and Marseilles, *viâ* Switzerland, 0.664 m.; Swinemunde to the Mediterranean, *viâ* Amsterdam and Ostend, 0.658 m.; and Santander to Alicante, in Spain, 0.662 m. The discussion of the tidal observations at Swinemunde showed no change in the relation of land and water during fifty-four years, and the mean level of the Baltic results with a probable error of ±6.1 mm. The levellings to Constance and to Amsterdam are published, and the mean level of the North Sea is found 9.3 cm. above that of the Baltic. Computation of polar co-ordinates between geodetic and astronomical points. Determination of latitudes and azimuths. Maximum local deflection of the vertical reaches 6″.1 in the meridian, and 12″.7 in azimuth.

Roumania. — Astronomical determinations of positions.

Russia. — Connection of the triangulation of Bulgaria with that of Russia; astronomical determination of differences of longitude, connecting Bulgaria with Pulkowa, and Tiflis with the triangulation of the Caucasus; pendulum observations continued in the Caucasus; extension of the levels of precision (double measures) up to date, 4,123 km., and of single lines 618 km.

Saxony, Germany. — Publication of part i. of the third section of the astronomical and geodetic observations, comprising ten stations; recomputation of the base at Grossenhain.

Switzerland. — Additions to the triangulations to connect astronomically determined positions, and two new base-lines at Weinfelden (length 2.5 km.) and at Bellinzona (length 3.2 km.), both measured with the Spanish apparatus of Ibañez; mean error of measure, $\frac{1}{6000000}$ for the Aarberg base of 1880, $\frac{1}{3000000}$ and $\frac{1}{9000000}$ for the other two bases respectively. The coefficient of expansion of the iron bar of this apparatus had increased during twenty years $\frac{1}{13}$ part. After sixteen years of labor, the operations of levels of precision have been brought to a close.

Spain. — Determination of the length of the triangle side, Mulhacen-Tetica (82827.546 m. ±0.115 m.), of the great quadrilateral connecting Spain with Algeria; adjustment of the triangulation connected with the base of Olite; junction of the Balearic Islands with the mainland, and observation of one side, of 240 km. in length (Desierto to Torrellas), during the night, by means of electric light; tidal and levelling operations; determination of the longitude between Madrid and Badajos; gravity measures at Madrid.

Wurtemberg, Germany. — Connection of lines of spirit-levellings with levels of the Black Forest.

Belgium. — Comparison of results of the adjusted triangulation.

Norway. — Results of the difference of longitude of Christiania and Bergen, and of two base-lines with probable errors of $\frac{1}{1570000}$ and $\frac{1}{1500000}$ of their length; adjustment of a base-connection with a primary line involving fifty-three conditional equations.

In conclusion, Yvon Villarceau presents a paper on observations made at Paris with an isochronic regulator in connection with his new method for relative measures of gravity; the apparatus, however, had not yet been brought to the desired perfection. C. A. S.

TRYON'S CONCHOLOGY.

Structural and systematic conchology (etc.). By GEORGE W. TRYON, Jun. Vol. ii. Philadelphia, *the author*, 1883. 430 p., 69 pl. 8°.

THE second volume of Mr. Tryon's work has appeared with commendable promptness. It contains a discussion of the Cephalopoda, Pteropoda, and the Gastropoda, beginning with the pectinibranchs, as far as and including the nudibranchs. The classification is, of course, the same as that criticised by us in the first volume, and cannot be said to improve on closer acquaintance. Some of the allocations seem particularly inadvisable. For instance: Scissurella, usually regarded as of family rank, is combined without reserve with Pleurotomaria in one family. The Bellerophontidae are retained in full family rank; and yet they are with great probability, as suggested by Meek, only large, symmetrically rolled Emarginulas, which latter are put in a different suborder, with the true Limpets, to which they have no close relation, and divorced from the Haliotidae, which they more nearly resemble.

The order Polyplacophora is defined (p. 103) as having the "shell multivalve, consisting of eight pieces inserted upon the back of the animal, and surrounded by a mantle border;" yet with the Chitonidae are placed, to form this order, a family Neomeniidae, which, to say nothing of other differences, have no shell at all.

The order Pectinibranchiata is defined as having pectiniform branchiae in a cavity above the neck, 'having an external opening upon the side of the neck,' dioecious, and with spiral shells.

The order Scutibranchiata is described as having pectiniform branchiae in a cavity above the neck, *or at the lower edge of the mantle around the foot*, dioecious; shell spiral *or conical*, holostomate.

The portions in italics are intended to cover the Docoglossa, which do not belong with the

Scutibranchs at all, in our opinion. Excluding these, which refer only to the Docoglossa, it will be observed that the only difference (according to the definitions) between the two orders is, that the latter has a holostomate shell. Everybody knows that a large proportion of the pectinibranchs of Tryon are holostomate, that is, have an entire aperture without a canal: for instance, Scalaria, Cyclostoma, Litorina, etc. What, then, becomes of the two orders? As a rule, the definitions are deficient in not giving essential characters, even when the groups defined are perfectly valid, and redundant in giving characters belonging to groups of different rank from the one defined, or of no particular value.

Of small errors we have noted not a few; but it is probable that a book of this kind must be expected to have a certain number, and completeness can hardly be looked for. However, the author has brought together an immense number of genera; and the work, when the index appears, will be very useful to conchologists on this account, though it would have been more so, had each genus been given a date, since, in general, there are no references. The coloration of the plates, also, is better than in the previous volume, and the figures for their kind are fairly good. The work is well bound and on good paper, but suffers from inferior printer's ink, which 'overlays' on nearly every page.

In conclusion we may say, that, for use as a text-book for fresh students, this work would be decidedly inadvisable; but those who have already gained some knowledge of modern classification, and of the anatomy and physiology of mollusks, will find it to a certain extent useful, though by no means to a degree commensurate with the labor which has evidently been spent upon it.

ADAMS'S LECTURE ON EVOLUTION.

Evolution: a summary of evidence. A lecture delivered in Montreal, March, 1883, by Robert C. Adams. New York, *G. P. Putnam's Sons*, 1883. 44 p. 12°.

Mr. Adams has attempted to summarize in a single lecture the various kinds of evidence that have been adduced in favor of the evolution of plants and animals, and the earth itself. The author claims to be nothing further than a compiler, and aims to present 'an abstract of many books' in 'plain language.' As he has not limited himself to any particular class of evidence, nor confined his attention to any single object, or group of objects, it is obvious that any attempt to treat in a single lecture the wide range of subjects embraced under evolution must prove a failure. It is simply a jumble of facts, collected, for the most part, from popular books and essays, with a considerable admixture of error and misconception. A little familiarity with the more recent discussions on the subject of the origin of the vertebrates (for example, those of Dohrn and Lankester) would have led our author to very different views concerning 'the connecting links' between vertebrates and invertebrates, and saved him the trouble of rehearsing exploded ideas respecting Amphioxus and the ascidians. Any respectable text-book in systematic zoölogy would have told Mr. Adams that an ascidian is not a mollusk, that Balanoglossus is not regarded as an 'intermediate form' between mollusks and such 'jointed animals' as crustaceans and insects, and that corals are not protozoa.

The author's reference to intermediate forms and 'connecting links' shows that he has not grasped the ideas now generally received concerning the genealogical relationship of animals. One or two passages will illustrate this point. "If in twenty-one days the chick passes through the forms common to sponges, shell-fish, fish, and reptiles, does it not suggest that its race may have developed through these lower races during vast ages? If in forty weeks a single man now develops through forms common to all the lower races of animals, may not the race of man have slowly arisen through all the ranks of life below him, each great division leaving its record in the unfolding germ of the latest individual? . . . Through the sponges we find the radiates connected with the protozoans, or first forms of life, such as corals and sea-animalcules."

Under the head of 'Unity of substance' we are told that "the germs which produce men, dogs, sheep, or any of the highest class of animals, cannot be discovered to differ by any test of microscope or chemistry. . . . Each individual begins life in the lowest form of matter, and develops through forms common to all the species below it. A man has by turns the forms of the germs of plant, protozoan, mollusk, articulate, and vertebrate — fish, reptile, and mammal."

The lecture abounds in such loose and inaccurate statements as the above, and must therefore be pronounced an unsafe guide to 'the uninitiated,' to whom the lecture is especially addressed.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Rings of Saturn. — Mr. William B. Taylor recalls attention to the announcement made by Otto Struve in 1851, that the observations of two hundred years showed the rings of Saturn to be widening, and the inner edge of the inner bright ring to be approaching the body of the planet. Later observations tend in the same direction; and, though there may have been unintentional exaggeration in Struve's numerical results, there seems little reason to question the general fact.

Accepting the only tenable theory of the rings, — that they are composed of discrete particles, each revolving in its own orbit, — we may, by Kepler's law, compute the period of rotation of any part of the ring. Assuming the period of the inner satellite (Mimas) to be 22 h. 37½ m., the computed period of the outer edge of the ring is 14 h. 30 m.; of the dividing-stripe, 11 h. 20 m.; of the inner edge of the bright ring, 7 h. 12 m.; of the inner edge of the dusky ring, 5 h. 45 m.; and of the ring as a whole (supposed solid), about 10 h. 50 m. The period of the planet is 10 h. 14 m.

With the complex perturbations induced by the exterior satellites, it is evident that no particle of the ring can revolve in a circular orbit; and it follows, that, in a space so crowded with particles as to give a continuous light, there must be much interference. Whether the collisions at intercepting orbits result in heat or in disintegration, they necessarily tend to a degradation of motion, and hence to a shortening mean radius-vector and a diminishing period.

It thus appears that Struve's conclusions, based on observation, have a rational theoretic basis. The rings are falling toward the planet, and will eventually be absorbed. Indeed, on the generally received meteoric theory of their constitution, it is impossible to regard their present condition otherwise than as an evanescent phase of a progressive evolution.

Mr. Taylor points out that the relation between the rotation periods of the planet and the ring, and the relation between the rotation periods of Mars and its satellites, not only fail to impeach the nebular hypothesis, as some have supposed, but even fail to be anomalous.

If the planet had a velocity of rotation equal to that of a satellite revolving at its surface, it could not approach the spherical shape. And, the concrete form having once been assumed, the rate of rotation must necessarily and continuously diminish through the influence of solar tides, until eventually the planetary day and year are identical. — (*Phil. soc. Washington; meeting* Oct. 13, 1883.) [355

ENGINEERING.

Emery's U. S. testing-machine, Watertown arsenal, Mass. — This machine is described from general and detailed drawings furnished by the designer. The machine excels in strength, capacity, durability, accuracy, and sensitiveness. The demand is said to have been: 1°. A machine to test to 800,000 pounds, and so delicate that it would test a single horse-hair. 2°. Attachments enabling it to seize and hold uninjured, while applying such loads, all usual sizes and shapes of specimens. 3°. Safety against injury by shocks of recoil. 4°. Accessibility of samples and straining parts, while in operation, for purposes of measurement and inspection. 5°. Small cost of operation.

The machine was tested, when finished, to 1,000,000 pounds, and under smaller loads, ranging down to a single horse-hair, with success; and was accepted by the U.S. board appointed to test iron, steel, and other metals. The loads are applied by a hydraulic press; and the weighing is done through reducing-pressure cushions and water-columns terminating at a point of connection with weigh-beams without knife-edges and having extraordinary sensitiveness. Mr. Emery is constructing smaller machines, and scales and pressure gauges involving the nicer and more remarkable devices introduced in the large machine, at the works of the Yale & Towne company, at Stamford, Conn. Mr. Emery's inventions are expected to aid effectively in securing a more exact knowledge of the properties of the materials of construction, and of their value in structures. — (*Amer. mach.*, July 21.) R. H. T. [356

Engineering of the great statue of Liberty. — Mr. Ch. Talausier describes the details of engineering involved in the design of Bartholdi's statue of 'Liberty enlightening the world.' The plan was conceived by M. Bartholdi in 1871, while *en voyage* for the United States. On the hundredth anniversary of the declaration of independence, France offered the great statue to the United States. It was accepted, is now nearly completed, and preparations for its erection on Bedloe's Island, in New York harbor, are being made. The statue is of copper. carried and strengthened by an inner skeleton of iron, One arm, carrying the torch, was sent to the Centennial exhibition at Philadelphia in 1876, and has since been on exhibition in New York. The sculptor first made a model 2.11 m. high, which was then copied on a fourfold scale; and the statue was constructed from this model in sections by similarly enlarging each section. For each piece, a 'centre,' or mould, was made of wood, on which the copper could be worked and fitted. The sheet-copper epidermis of the statue is composed of 300 pieces, and weighs 80,000 kilograms (178,000 lbs.). The iron frame weighs 120,000 kilograms (264,000 lbs.). When finally erected, the sheets of copper will be riveted together with copper rivets 5 mm. in diameter (0.2 in.), and spaces 25 mm. (1 in.) apart. The iron skeleton is to be secured to the foundation at four points by 12 foundation-bolts 0.15 m. (6 in.) in diameter, and extending 15 m. (49.7 ft.) into the masonry. The variation of form and dimensions, with varying temperature, is provided against by the elasticity of every part; and corrosive action is to be checked by painting with red lead all points of contact of iron and copper. The height of the statue is 46 m. (150.9 ft.) from base to top of its torch, and 34 m. (111.5 ft.) to the top of the head. The index-finger is 2.45 m. (8.04 ft.) long, the eye is 0.65 m. (2.2 ft.) in diameter, and the nose is 1.12 m. (3.67 ft.) long. A dinner of 26 covers has been given in the trunk of the statue. The total weight will be 200,000 kilograms (440,000 lbs.). The granite pedestal will be 25 m. (82 ft.) high, and the cost of the whole not far from 1,200,000 francs ($240,000 nearly). The maximum pressure of the wind on the surface of the statue is reckoned at 87,000 kilograms (191,400 lbs.). —(*Le génie civil*, Aug. 1.) R. H. T. [357.

METALLURGY.

The basic process at Peine works, Germany — All difficulties at these works are said to have been overcome, and phosphoric pig is being made into Bessemer steel.

Analyses of the steel vary as follows:—

	1	2
Manganese	0.47	0.30
Phosphorus	0.06	0.02
Sulphur	0.06	0.03
Carbon	0.14	0.09

The cinder yields the following analysis:—

Silica	2.45
Ferric oxide	5.74
Ferrous oxide	15.10
Manganous oxide	2.75
Alumina	2.85
Lime	46.82
Magnesia	1.14
Phosphoric acid	22.23
Sulphuric acid	0.38
Sulphur	0.54

The Ilsede pig used in the above works contains 2.5 % to 3.1 % phosphorus. The walls of the converter stand 80 to 95 blows; the bottoms, 16 to 24 blows. — (*Eng. min. journ.*, July 14.) R. H. R. [358

Copper production of the world. — Messrs. Henry Merton & Co. of London have compiled statistics of production of copper in tons, from which the following figures are selected:—

	1879.	1880.	1881.	1882.
Chili	49,318	42,916	37,989	42,909
United States	23,350	25,010	30,882	39,300
Spain and Portugal	12,751	14,559	15,693	15,893
Germany	9,976	11,776	13,718	14,235
Australia	9,500	9,700	10,000	8,950
England	3,462	3,662	3,875	3,875
All other countries	39,299	41,278	45,981	46,451
Totals	147,656	148,901	158,138	171,613

The figures are claimed to have been compiled with great care. — (*Ibid.*, July 14.) R. H. R. [359

AGRICULTURE.

Manuring with potash salts. — In a large number of experiments in which potash salts (sulphate and chloride) were applied in the spring, and within three days of the time of sowing, Farsky found the effect to be a decrease of the crop. It is evident, from the author's statements, that the salts were applied in too large quantity in the immediate neighborhood of the seed. Experiments with the crude Stassfurt salts gave more favorable results in many cases. Potassium chloride gave, in most of the trials, better results than the sulphate, and fall manuring better than spring. The effect in the second year was often better than that in the first. — (*Biedermann's centr.-blatt.*, xii. 459.) H. P. A. [360

Manuring oats. — An extensive series of experiments by Beseler and Märcker gave the following interesting results:—

Manuring with phosphoric acid alone produced no notable increase of the total crop or of the grain. Manuring with nitrogen alone, in the form of nitrate of soda, gave an increase of crop roughly proportional to the amount of nitrogen applied. With a light manuring of nitrogen, addition of phosphoric acid produced a further increase of crop: with a heavy manuring of nitrogen this was not the case.

Manuring with phosphoric acid alone did not increase the percentage of proteine in the grain. Manuring with nitrogen alone increased the proteine, but diminished the fat. Addition of phosphoric acid to the nitrogenous manure restored the fat to its original amount, or even raised it above that point. The quality of the grain was best when the total amount of the crop was greatest. In these experiments the total nitrogen of the crops equalled about fifty-five per cent of the amount applied as manure. — (*Ibid.*, xii. 472.) H. P. A. [361

GEOLOGY.

Synchronism of geological formations. — Professor A. Heilprin called attention to Prof. Huxley's conclusions, that, 1°, formations exhibiting the same faunal facies may belong to two or more very distinct periods of the geological scale as now recognized, and, conversely, formations whose faunal elements are quite distinct may be absolutely contemporaneous; and that, 2°, granting this disparity of age between closely related faunas, all evidence as to the uniformity of physical conditions over the surface of the earth during the same geological period falls to the ground. Prof. Heilprin maintained that it can be readily shown by a logical deduction that the first conclusion is almost certainly erroneous, and that the second derives no confirmation from the supposed facts. If, as is contended, several distinct faunas, or faunas characteristic of distinct geological epochs, may have existed contemporaneously, then evidences of inversion in the order of deposit ought to be common, or, at any rate, they ought to be indicated somewhere; since it can scarcely be conceived that animals everywhere would have observed the same order or direction in their migrations. Why has it so happened that a fauna characteristic of a given period has *invariably* succeeded one which, when the two are in superposition all over the world (as far as we are aware), indicates precedence in creation or origination, and never one that can be shown to be of later birth? Surely these peculiarities cannot be accounted for on the doctrine of a fortuitous migration. Nor can it be claimed, that, through the interaction of the evolutionary forces, a migrating fauna with an early-life facies will in each case, at the point of its arrest, have assumed the character of the later-day fauna which belongs to that position. Therefore it appears inexplicable that a very great period of time could have intervened between the deposition of the fauna of one great geological epoch at one locality, and that of the same or similar fauna at another locality distantly removed from the first. In other words, the migrations — for such must undoubtedly have been the means of the distant propagation of identical or very closely related life-forms (unless we admit the seemingly untenable hypothesis that equivalent life-forms may have been very largely developed from independent and very dissimilar lines of ancestry) — must have been much more rapidly performed than has generally been admitted. What applies to the broader divisions of the geological scale also applies to the minor. Thus the subordinate groups of a formation are almost as definitely marked off in the same order, the world over, as are the formations themselves. After breaks in formations, the appearance of characteristic fossils is largely the same; whereas, on the theory of synchronism of distinct faunas, such a succession would certainly not be constant. The opinion held by the older geologists was therefore probably correct; namely, that formations characterized by the same or very nearly related faunas in widely separated regions belong, in very moderate limits, to approximately the same actual age, and are to all intents and purposes synchronous or contemporaneous. —(*Acad. nat. sc. Philad.; meeting* Oct. 2, 1883.) [362

METEOROLOGY.

Tornado studies. — A study of the tornado of June 7, 1882, in the valley of Säby, has been made by Fineman. It embraces investigations upon the course of this tornado, and the accompanying atmospheric conditions, which are not different from those pointed out by Finley in the case of tornadoes in the United States, and includes a general investigation of the theory of tornadoes, with references to the work of other authors in this field of inquiry. The author refers to the combination of great humidity, high temperature, and absence of wind, as the special condition of tornado formation, and investigates the characteristic phenomena shown in its progress. He further discusses the relation of tornadoes and thunder-storms, and urges increased study in solar radiation and the gyratory motion of fluids, in order to throw light upon this and other meteorological investigations. — (*Sur la Trombe*, June 7.) W. U. [363

Notes. — The annual re-union of the council of the meteorological bureau of France was held in March. The leading discussions related to observations in agricultural meteorology, the securing of reports of thunder-storms and rainfall statistics, and the transmission of telegraphic messages in the interest of the science (*Ann. soc. met.*, March, 1883). —— A valuable contribution to our knowledge of the surface-temperatures of the Atlantic along the coasts of Portugal, Senegambia, and Brazil, has been made by M. Hautreux from the observations taken on the steamers which traverse this region (*Ann. hydr.*, viii. 1883). —— The *Zeitschrift* for August contains a number of climatological articles, discussing observations made at Stuttgart, Frankfort, Lyons, Puebla, Guadalajara, and in southern Brazil. —— The *Annuaire* for May contains a contribution to the study of the climate of central Africa, by M. Angot, from observations, which are rather fragmentary, made at three missionary stations, mostly in 1881. —— Rev. Clement Ley is preparing a work upon the observation of clouds. The international committee, at its meeting in 1882, appointed a committee, consisting of Messrs. de Brito Capello, Clement Ley, and Hildebrandsson, to draw up a scheme of instructions for the observation of cirrus-clouds. —— Dr. Selah Merrill, U. S. consul at Jerusalem, has submitted to the State department a report upon the climate of Palestine, based upon observations covering a period of twenty-two years. An extract is published in the August Weather review of the signal-office. — W. W. [364

GEOGRAPHY.

(*Arctic.*)

Arctic notes. — The Austrian Jan Mayen expedition arrived at Vienna, Aug. 22, and were received with public festivities. No illness had occurred during their stay on the island. The observations taken are satisfactory. Rich collections have been made, and numerous photographs taken. —— The latest news from the English party under Capt. Dawson, at Fort Rae in the North-west Territory, is favorable, and observations were going on with regularity. Spectroscopic observations of the aurora borealis have been very satisfactory, though the phenomena have not been particularly brilliant. —— Satisfactory accounts have also been received of the work done by the Swedish expedition to Spitzbergen, which has returned without loss or accident. —— Reliable information has at last been received from the Schieffelin party, on the Yukon, near its junction with the Tananah River. They have returned to San Francisco all well. Gold had been discovered twelve miles up from its mouth, on a small river falling into the Yukon. The bed-rock was slate, and the gold found was in smooth washed particles in loose gravel. Winter setting in prevented further search, and the season was found to be too short for satisfactory results in placer mining. Mr. Schieffelin warns prospectors against coming rashly into the country, unprovided with supplies and tools, as nothing suitable for prospecting work can be had there. —— Later reports from the Arctic Ocean north from Bering Strait give little improvement in the conditions or catch of the whaling-fleet over previous advices. The whalers were anticipating better luck toward the end of the season. —— A button and coin obtained at Cape Prince of Wales, from the natives, about a year ago, have been forwarded to the Navy department in the idea that they might be relics of

Putnam, who was lost on the ice during the Jeannette search. They were said to have come from the body of a drowned white man. The natives of this region are fond of inventing such stories, especially since the search expeditions, as they suppose they will be paid for them. Navy brass buttons have been an article of trade on this coast for many years. The fact that Putnam had no such buttons on his clothing when lost, settles the case in regard to these particular objects. —— Bove discusses in the bulletin of the Italian geographical society the meteorological observations made on board the Vega during her voyage in Siberian seas. His article is a *résumé* of the work of Hildebrandsson, elsewhere published. —— In the Bulletin of the *Paris société de géographie*, A. Bellot summarizes the history of the Jeannette expedition, and the distribution of the international polar stations. His paper is accompanied by a map. — W. H. D. [365

(*Asia.*)

Population of Japan. — The last census (January, 1883) gives a total population of 36,700,118 souls, nearly equally divided between the sexes, the males being about one per cent in excess. Kioto, the imperial city, contains 709,000, and Tokio, the capital, 1,064,000 inhabitants in round numbers. — (*Bull. soc. géogr. Mars.*, June.) W. H. D. [366

Petroleum in the Caucasus. — According to the British vice-consul at Batum, Mr. Peacock, the oil-region of the Caucasus covers some 1,200 square miles. The most productive locality is the Apcheron peninsula, where the wells far exceed those of Pennsylvania. The total production has risen from 500,000 barrels in 1873, to about 4,000,000 barrels in 1881. The export from Baku has increased at the rate of 1,250,000 barrels in two years. According to the daily papers, a pipe-line is projected from the oil-region to Baku; and the American producer must rely on the quality of his product, rather than on its cheapness, for the future of our export trade. — (*Brit. cons. rep.*, 1882.) W. H. D. [367

BOTANY.

Observations on yeast fungi. — The fifth part of Brefeld's '*Botanische untersuchungen*' forms a volume of over two hundred pages, with thirteen quarto plates, and treats of the development of the Ustilagineae. The author considers principally the germination of different species of Ustilago, Thecaphora, Geminella, and Tilletia; and, besides sowing the spores in water, he sowed them in nutritive fluids, and by this means was able to get more luxuriant growths than other students of this order of fungi. The germination of the different species may be classed under two different types. In the one, a short promycelium is given off by the spore, and the sporidia are borne laterally; while, in the second type, a whorl of cells is borne at the tip of the promycelium. By using nutritive fluids instead of water, Brefeld was able not only to obtain luxuriant growths of sporidia, but also to keep them alive for several months, or even a year. He believes that the sporidia are merely conidia, and in his cultures they produced fresh crops of conidia for an indefinite period. He further considers that the so-called conjugation of the secondary cells of species belonging to the second type, as Tilletia, is not a sexual process at all, but merely a fusion such as exists in other orders of fungi. When cultivated in nutritive fluids, the whorls of secondary cells do not conjugate or fuse, but produce conidia directly; while in water, which is not favorable to further growth, a fusion takes place. He calls the conidia 'hefe,' from their resemblance to the forms of Saccharomycetes; the difference being, that in one case, although the yeast-like form can be made to propagate itself in fluids indefinitely, we know that it came originally from some species of Ustilagineae, whereas, in the other case, illustrated by the beer ferment, we cannot tell of what form it was originally the conidia. He refers to other hefe-forms in the Hymenomycetes and Ascomycetes. In *Exoascus aureus* he states that the polysporic condition of the so-called asci is nothing more than a hefe-like growth of a few round spores within the ascus. In short, he believes that all yeast-like forms are merely conidia, and denies the autonomy of the Saccharomycetes; nor does he believe that they are closely related to the Ascomycetes. — W. G. F. [368

Insect fungi. — Hoffmann figures an interesting branched variety of the rare Torrubia cinerea Tul., on an adult Carabus from Germany, under the name of var. brachiata. The typical form occurs on Carabid larvae. — (*Flora*, Aug. 21.) W. T. [369

ZOÖLOGY.

Mollusks.

Landshells of Gibraltar. — Kobelt reports, that the fauna of the Rock of Gibraltar is very peculiar, many characteristic species of the Mediterranean being wanting. The genus Leucochroa, for instance, is represented neither in Gibraltar nor on the opposite coast of Morocco. Certain species of Cyclostoma and Pomatias are equally absent from both shores. Twenty species of landshells, including three undescribed species and two new varieties, were obtained on the Rock in May, 1881; but it is supposed that this is a more or less incomplete exhibit, the season of the year being not the most favorable. The locality is peculiarly interesting on account of its intermediate position between Spain and Morocco. The sea-fauna of the Bay of Gibraltar is also very rich, and contains many rare or peculiar forms. — (*Journ. conch.*, iv. no. 1.) W. H. D. [370

Absorption of the shell in Auriculidae. — Crosse and Fischer illustrate and describe the peculiar absorption of the inner parts of the upper whorls of the shell in this family, and also in the genus Olivella. These animals appear to have the power of dissolving entirely the internal partitions of the shell, from a point some distance inside the aperture to the very apex. The only exception in the family Auriculidae is the genus Pedipes, in which the partitions were found intact. The absorption is not always complete, nor are the same parts invariably missing. Complete absorption was observed in Melampus, Auricula, Blauneria, Marinula, Tralia, Alexia, Monica, Plecotrema; only partial absorption in Cassidula and Scarabus. The case of Olivella is more remarkable; since the allied groups Oliva, Ancillaria, etc., do not, according to the authors, present this peculiarity at all. — (*Journ. de conchyl.*, xxii. 3.) Tryon, however, observes that in Oliva reticularis he has found the walls absorbed away, so that very little of the substance remained, and considers it probable that all shells with close volutions are in the habit of absorbing them internally. It is certainly the case with many of them. — (*Man. conch. Olivella*, p. 64.) W. H. D. [371

Crustaceans.

Anatomy of the spider-crab, Libinia. — E. A. Andrews gives a very careful description, illustrated with three excellent photolithographic plates, of the anatomy of Libinia emarginata, the common spider-crab of the eastern coast of the United States. The paper, which was originally presented as a graduation thesis for the bachelor's degree in the Sheffield scientific school, describes fully the structure of the body-walls, appendages, and the alimentary, circulatory, nervous, and reproductive systems. The structure throughout agrees very closely with that of Maia squinado of Europe. Mr. Andrews's work will be found a very useful guide for American students, as it is the only description thus far published of the whole anatomy of any American brachyuran. — (*Trans. Conn. acad.*, vi., Aug., 1883.) S. I. S. [372

A new host for Cirolana concharum Harger. — Rev. Samuel Lockwood announced the discovery of this isopod in the interior of the edible crab, Callinectes hastatus Ordway. The crab was an adult female, and the parasites were crowded in the left side of the carapace. Incredible to say, there were twenty-three full-grown specimens, measuring three-fourths of an inch by about a quarter of an inch each. The ovaries and the tissues on the left side were completely honeycombed. How long the animal could have lived, and what its real sufferance of pain was, are questions. But with these predaceous wolves, literally consuming its inwards, it surely would soon succumb. It seemed to Mr. Lockwood that they must, when in the swimming larval state, have entered near the eye-stalks of the crab, which, with a large catch of others, was taken at the close of February in Raritan Bay, New Jersey. From the size of the parasites, it would seem they had been in possession some three months. The determination of the isopods was due to the kindness of Mr. Oscar Harger. The query how so large a number could have entered the same place, and at the same time, he thought was met by the supposition that the crab had found a nest of the larvae, and was feeding on them, when a part of the batch entered the host, as conjectured above. — (*New Jersey st. micr. soc.; meeting* March 19.) [373

Arachnids.

Restoration of limbs in Tarantula. — Rev. Henry C. McCook remarked that a tarantula exhibited to the meeting had been kept in confinement nearly a year, fed during winter on raw beef, and in summer on grasshoppers. In the spring it cast its skin by a laborious process, in the course of which it lost one foot and two entire legs. This summer again, during the latter part of August, the animal moulted. The moult as exhibited is a perfect cast of the large spider, — skin, spines, claws, the most delicate hairs all showing, and their corresponding originals appearing bright and clean. The moulting occurred during Dr. McCook's absence, but was just finished when he returned. When the cast-off skin was removed, it showed, as might be supposed, the dissevered members to be lacking. On looking at the spider itself, however, it was seen that new limbs had appeared, perfect in shape, but somewhat smaller than the corresponding ones on the opposite side of the body. The dissevered foot was also restored. The loss of the opportunity to see the manner in which the legs were restored during moult was greatly regretted, but we have some clew from the careful and interesting studies of Mr. Blackwall. Several spiders whose members had been previously amputated were killed and dissected immediately before moulting. In one of these the leg, which was reproduced, was found to have its tarsal and metatarsal joints folded in the undetached half of the integument of the old tibia. Another like experiment was made with an example of Tegenaria civilis. The reproduced leg was found complete in its organization, although an inch in length, and was curiously folded in the integument of the old coxa, which measured only one-twenty-fourth of an inch in length. Dr. McCook's tarantula had lost both legs close to the coxae; and in the moult the hard skin formed upon the amputated trunks was wholly unbroken, showing that the skin had been cast before the new leg appeared. We risk nothing in inferring, that, as in the case of Blackwall's Tegenaria, the rudimentary legs were folded up within the coxae, and appeared at once after the moulting, rapidly filling out in a manner somewhat analogous to the expansion of the wings in insects after emerging. — (*Acad. nat. sc. Philad.; meeting* Sept. 25.) [374

VERTEBRATES.

Birds.

Anatomy of the Passeres. — Mr. Forbes finds the syrinx, as well as all other points examined, of Orthonyx spinicauda and O. ochreocephala, to be strictly oscinine. The carotid of the first is peculiar in that it accompanies the vagus nerve instead of running in the hypophysial canal. On anatomical grounds, O. ochreocephala is separated from the Australian form as Cletonyx of Reichenbach. Contrary to Prof. Parker, Mr. Forbes finds a perfectly oscinine syrinx in Petrocca. — (*Proc. zoöl. soc. Lond.*, 1882, 544.) J. A. J. [375

Respiratory organs of Apteryx. — Under this title, Prof. Huxley gives a succinct account of the lungs and air-sacs as typically found in birds, and notes that the respiratory organs are separated by an oblique septum from the cardio-abdominal cavity, as in the crocodiles. The lungs of Apteryx are strictly avian, in no wise mammalian, though poorly developed. Prof. Huxley considers them to show a fundamental resemblance to those of crocodiles The introduction of so many new terms is to be regretted. — (*Proc. zoöl. soc. Lond.*, 1882, 560.) J. A. J. [376

ANTHROPOLOGY.

Indian courtship. — Mrs. H. S. Baird recites a bit of her own observation respecting Indian courtship half a century ago in Wisconsin. When a youth falls in love, he places himself a little way from the maiden's wigwam, wearing one blue and one red legging. He then plays in a minor strain an air upon the flute, pib-pi-gwan. If he is permitted to proceed, he knows that there are no objections to his addressing the loved one. If the parents have objections to him, he is informed that he is too noisy, etc. In the latter case he discontinues his serenades: in the former the flute-playing gives place to visits, the father saluting, and saying. 'Come in, friend: there is room for you;' upon which all the family give a sort of hitch up, to make room for one more around the fire. The young man seats himself by the door, and next to the daughter; as the eldest son and daughter always sit nearest the door, on each side of it. The lover then produces a few small pine sticks, one of which he lights at the fire, and hands to the maiden. If she takes it, he is accepted: if she does not, but lets him hold it until it goes out, he is rejected. When the time arrives for them to be united, the parents of the young man bring valuable presents, such as furs, while the parents of the bride bring ornamental work. These are distributed among the friends. The bride is dressed by her sister-in-law. and conducted to her place in the wigwam to await alone the coming of her husband. In other cases, when father-right prevails, she goes to his home. A man can have as many wives as may be required to dress his game and carry it home. — (*Wisc. hist. soc.*, ix. 311.) J. W. P. [377

The mounds of Wisconsin. — If one wishes to keep himself informed upon archeology, he must not neglect the volumes of the state historical societies. The Rev. Stephen D. Peet has done a good service, with reference to the emblematical mounds in Wisconsin, by presenting in a condensed form not only the description of the structures, but also the names of the most important works in which references to them may be found. Mr. Peet is well acquainted with the effigy mounds, and therefore adds many original observations, which are in the main extremely cautious. Attention is directed to the difficulty of determining the shape of the mounds, by reason of deformations due to the plough, the tramping of cattle, the wear of the elements, the avarice of relic-hunters, and the encroachments of the modern architect. Again: many of the animals once common have departed from this region, such as the buffalo, moose, elk, antelope, bear, lynx, and wild turkey. If the mounds represented in shape the badges, weapons, and symbols of the natives, they, also, are unfamiliar.

The author ascribes to all these mounds a religious significance, in which opinion he is not warranted by what is known. His reflections upon the cross-symbol, however, are very just. As to the shapes of these structures, we have the mace, double bow, groups of cones, triangular enclosures, besides every variety of animal supposed to have lived in this region. Mr. Peet dismisses the 'elephant mound' with a modest introduction to its sponsor. — (*Wisc. hist. coll.*, ix. 40.) J. W. P. [378

Chinese not homogeneous. — Mr. E. Colborne Baber, secretary to H. M. legation, Peking, makes the following interesting statement: "The population of China is far from being so homogeneous as is generally supposed. I have often heard English people assert their inability to distinguish one Chinaman from another; but it may surprise you to hear that a Chinaman, on first coming into contact with Europeans, makes precisely the same remark of ourselves. At first they have some difficulty in even distinguishing a woman from a man. In spite of a general persistence of type, there is at least as much variation among the natives of the eighteen provinces as there is among the inhabitants of Europe. A thousand years before Christ the Chinese nation occupied a mere fraction of the territory which they now possess. Even then they were not homogeneous in manners or speech, and they were environed by many non-Chinese indigenous peoples. Since then the Chinese have spread, not by ousting or exterminating their neighbors, but by a process of absorption: in other words, they migrated among them, and intermarried with them: and their superior energy and comparative civilization gradually effaced the national characteristics of the surrounding tribes. The same process is going on in Tibet, in Burma, in the Shan country, in Tonquin, and in the Straits Settlements. The Chinese blood has been mingled with such diverse stocks as the Tatar, Turki, Tibetan, Burmese, Mon-annan, Tai, and Polynesian." The discussion of this paper by Sir Rutherford Alcock, Sir Thomas Wade, Col. Yule, and Mr. Colquhoun, is a valuable contribution to Chinese sociology. — (*Proc. geogr. soc. Lond.*, Aug.) J. W. P. [379

NOTES AND NEWS.

The Maryland oyster commission, which has in view the invention of some plan which should check the depreciation of beds belonging to the state without unduly interfering with trade, met in Baltimore recently. It was suggested that dredging be restricted in various ways, and the available grounds increased by sowing the bottom with dead oyster-shells where none now exist. In 1879 Lieut. Winslow found the average in Tangier Sound to be one oyster to 2.4 square yards. In their recent examination of the oyster area of the state, the commission found that the average of sixty-one beds examined was one living oyster to each 3.7 square yards, showing a rapid and important decrease since 1879. The commission finds, as the result of the examination of forty-six oyster-beds, that there are only 1.35 living oysters to every bushel of dredged shells. While the oysters are growing scarcer, more labor is required to get them, and the amount of dead material which has to be handled is largely increased.

— The Pons comet, now approaching the sun, may be expected to be visible to the naked eye about the first of December; but it is not likely to attain a brightness comparable with that of the conspicuous comets of the last decade, unless it shall have undergone material change since its last reappearance, in 1812. The intensity of its light will be three times greater on Nov. 21 than it was on Oct. 16; and it will increase until about the middle of January, when it may be anticipated that its light will be about equal to that of a star of the third magnitude.

— The announcement of the publication of the Berlin catalogue of zonal stars will have, according to *Nature*, the effect of postponing the publication of the French catalogue, for which a credit of four hundred thousand francs had been asked from the budget commission.

— Dr. B. A. Gould passed through London early in October, *en route* for South America. The printing of the second volume of the Cordoba zones is nearly completed (in London); and Dr. Gould's attention will soon be turned to the publication of another great work undertaken by him at the Argentine national observatory, viz., the Cordoba general catalogue of stars.

— Ensigns H. G. Dresel and A. A. Ackerman, who were detached from the National museum for duty in connection with the recent Greely relief expedition, in spite of unfavorable circumstances, succeeded in collecting some interesting zoölogical and mineralogical specimens. Among them are some of the so-called meteorites of Ovifax.

— Regarding Flamsteed and Morin, Mr. W. T. Lynn writes to the editor of the *Observatory* (August, 1883): "Probably few anecdotes in the history of astronomy are better known to general readers than that related by Flamsteed, respecting the foundation of the Royal observatory being hastened, if not occasioned, by the application of the Sieur de St. Pierre to Charles II. (through the Duchess of Portsmouth) for a reward for discovering a method of finding the longitude at sea, and Flamsteed's own decision on its impracticability until the motions of the moon and the places of the fixed stars had been determined with much greater accuracy than was then possible. But it is not easy to understand the exact meaning of one of Flamsteed's expressions to St. Pierre. He says that he told him, after first proving to him how incompetent a calculator he was, and pointing out, that, independently of this, his method was inapplicable in practice, to go to his own countryman Morin, who would instruct him in a better method than his own, and not to return to the king of England until he had done so. Of course, the general force of this recommendation was, in vulgar English, to bid him go to Jericho. But surely Flamsteed could hardly have been ignorant (though he does not refer to it) that Morin had, in 1634 (forty-one years before the application of St. Pierre to Charles II.), submitted a plan similar in principle to Cardinal Richelieu, and that a committee appointed by the latter came to the same decision as Flamsteed concerning St. Pierre's proposal; that such a method was of no practical use in the existing state of astronomical knowledge. To me, it seems exceedingly likely that St. Pierre was aware of what had taken place with regard to Morin; that, in fact, he had stolen the principle from the latter (who, although he deserves all the contempt that Mädler pours upon him for prostituting astronomy to the purposes of that mass of imposture and delusion which has robbed our science of its more appropriate name of astrology, was a good mathematician for those times), and interpreted Flamsteed's last remark into the imputation that he was in point of fact found out. Flamsteed says that he heard no more of him afterwards; but he certainly did *not* go to Morin, for the best of all reasons, — Morin having died more than eighteen years before, on the 6th of November, 1656."

— In a paper on the germ-theory of disease from a natural history point of view, before the British association, Dr. Carpenter stated that many of the existing genera and species of animals and plants were altogether uncertain; that as fresh knowledge was gained, so it was found necessary to modify our accepted views — this especially holds good with genera which have great power of adapting themselves to various circumstances, and which consequently produce numerous variations. This power of modification, the author stated, was much more marked in the lower than in the higher forms of either kingdom, and was especially found in bacteria. The author then cited the case of the germ producing small-pox, in which he stated the germ had undergone such a modification, that whereas two centuries ago the disease was very severe, and known as 'black-pox,' it now existed only as a mild disease. During the last siege of Paris, however, the conditions were such that the germ reverted to its original form, and produced the same severe disease as two centuries ago. Many facts were brought forward to confirm this view.

— In a paper by Professor Hull before the British association, upon the geological age of the North Atlantic Ocean, the author made use of three leading formations as factors in his inquiry; viz., the archean (or Laurentian), the Silurian (chiefly the lower Silurian), and the carboniferous. He considers that throughout the archean (or Laurentian), the lower Silurian, and the carboniferous epochs, the regions of North America, on the one hand, and of the British Isles and western Europe, were submerged, while a large part of the North Atlantic area existed as dry land, from the waste of which these great formations had been built up; and he urged, that, if such were the case, the doctrine of the permanency of oceans and continents, as tested by the case of the North Atlantic, falls to the ground.

— The meteorological observatory established upon the top of Ben Nevis by the Scottish meteorological society was formally opened on Oct. 17 with interesting ceremonies. A party of ninety, including many ladies, climbed the mountain, in spite of unfavorable weather; and after their return to the base, where a second meteorological station is established, a dinner, with congratulatory speeches, was given. The funds for the establishment of these observatories, £5,000, have been raised by popular subscriptions, the subscribers numbering about two thousand.

— At the meeting of the German society of natural science at Halle, on Oct. 3, a paper was read by Dr. Assman of Magdeburg, on the advisability of establishing a meteorological station on the Brocken Mountain. 'What will become of the spectre?'

— Drs. Schuchardt and Krause, of the Volkmann clinical hospital at Halle, consider that they have placed the connection between scrofula and tuberculosis beyond a doubt. Following up Koch's line of research, they have discovered the peculiar bacilli of tuberculosis to be present in several distinct forms of scrofula.

— Joseph Antoine Ferdinand Plateau, professor of physics at the University of Ghent, died at that place, Sept. 15, at the age of eighty-two years.

— The U. S. hydrographic office has published a 'List of geographical positions for the use of navigators and others,' compiled by Lieut.-Commander F. M. Green. The list is divided into seventeen sections, according to the geographical position of the places, and is confined to points on the shore or on navigable rivers.

— Dr. J. Lawrence Smith died at Louisville, Ky., on Oct. 12, in his sixty-fifth year. He was born near Charleston, S.C., and was educated at the University of Virginia and the Charleston medical college. He afterwards spent some time abroad. His first paper was published while he was in Paris. A large part of his work was in meteorology, his collection of meteorites being especially famous.

— Among the exhibits at the New-Mexico territorial fair, held at Albuquerque, Oct. 1 to 5, was a collection of antiquities from the old pueblo ruins of Arizona, by Mr. Thomas V. Keam. This gentleman has long been engaged in trade in that region, is well known to the Indians and to our national surveying-parties, and has rendered very efficient service, both as an adviser and mediator, in our negotiations with the Navajos. His exhibit was highly spoken of by the Albuquerque press.

— Dr. D. G. Brinton of Philadelphia, who was one of the vice-presidents of the congress of Americanists held in Copenhagen, and the only delegate from the United States, makes a brief report of the proceedings. In 1875 the first meeting was held at Nancy; that of 1877, at Brussels; of 1879, at Luxembourg; of 1881, at Madrid. The meeting of this year was opened in the magnificent hall of the university, in the presence of the king, the royal family, the Princess of Wales, and other dignitaries. Professor Worsall presided, and delivered the address of welcome. The discussions and papers related to paleolithic man in America, Scandinavian discoveries, the history of Columbus, native American literature, ceramics, trephiny, etc. Dr. Brinton reports that the communications were very generally of a high order, though there was enough of Prince Madoc and the pilgrimage of St. Thomas to remind the members of the humble origin of archeology.

— Messrs. Kegan Paul, Trench, & Co., of London, announce Mr. Everard im Thurm's 'Among the Indians of British Guiana,' sketches, chiefly anthropologic, from the interior.

— M. Berthelot has published the results of his researches into the nature of explosives, under the title of 'Sur la force des matières explosives d'après la thermochimie.' One portion of the book appeared as an article in the *Nouvelle revue*.

In presenting his work to the Paris académie des sciences, M. Berthelot explained that he was led to those researches by the events of 1870. The first book is on his theory of the phenomena of explosion, and especially the explosive wave, which he considers throws a new light on the subject. The second book is on the composition of explosives, and the third on their comparative power. The last is very comprehensive, and he gives numerous tables.

— Mr. William J. Fisher, U. S. signal-observer at Kadiak, has found time, in the prosecution of his duties, to collect for the National museum ethnological specimens from the following Alaskan tribes: Ugashagmint, of Ugashag River, Bristol Bay; Tanichnagminte, of Lesnoi Island, near Kodiak Island; Nanuachpachmiute, of Aliaska peninsula, near Iliamna Bay; Keiichwichmiut, at Katmai settlement, Aliaska peninsula; Kiatichmynt, near Maltshatna River, Aliaska peninsula; Tshu-attshigmjnt, around Nuchek, Hinchinbrook Island, Prince William Sound.

The editor of the Smithsonian proceedings holds up this invoice of Mr. Fisher as an example to be followed by all collectors. The excellent features are the native names of the articles, the explanation of their functions, and the location of the tribe from which each comes. There is a very grave objection, however, to the spelling of the names and the identification of the tribes. Mr. Dall and others have located many little bands of Eskimo all along the Alaskan coast. Are these the same, or different ones? If the same, why another mode of spelling; and, what is worse, why is 'mut' spelled '*mint*,' '*miute*;' 'miut,' '*mynt*;' 'mjnt,' '*mjut*,' '*mjute*,' '*mjitt*,' '*mjent*,' *mjunt*,' and '*mut*'? Strenuous efforts are making to bring order out of chaos in the matter of tribes, but nothing will be accomplished if confusion is constantly introduced by observers.

— Prof. T. G. Bonney read a paper before the Geological society of London on Nov. 7, on the geology of the South Devon coast from Tor Cross to Hope Cove.

— The relation of the state to the medical profession was the prevailing topic in the recent inaugural addresses before the schools of the several hospitals of London. Until 1858 the English people had virtually no protection against unqualified practitioners. In that year the act was passed establishing the present system of medical licensing.

A royal commission was appointed in May, 1881, to inquire into the existing provision, and to recommend such additional action as might seem advisable. The proposals of the commission were embodied in a bill which passed the House of Lords during the last session, but was lost in the House of Commons through the 'obstructive tactics of interested parties.' It is believed that the bill which will be presented during the next session will meet with better success. As pointed out by Professor Huxley in his address at the London hospital, 'three grave defects remain to be remedied:' viz., the low standard of examination allowed by some of the licensing bodies; the granting of licenses which do not involve proof of the holder's acquaintance with all three of the great branches of medical practice (namely, medicine, surgery, and midwifery); and the present state of the law, which does not permit the medical council to enforce equality of minimum examination, and the threefold qualification, before admitting a medical practitioner to the register. All of these points are included in the proposed bill.

It is further urged by those interested in the improvement of the profession, that liberal education should be a more general characteristic of its members, and that the student should bring to his medical course a more thorough preparation in physics, chemistry, and biology. Both of these ends will be furthered by the provision recently made in the two great universities for the sciences specified.

Socially the medical profession does not compare favorably with the other professions in England. The fact is curiously illustrated by an extract from a recent book quoted by Mr. W. H. Bennet in his address at St. George's hospital. "This choice of a profession," says the author, "is not an easy matter, when, as a rule, the church, the army, the bar, and the diplomatic service are almost the only professions open to a young fellow." Evidently, as Mr. Bennet observes, "the thought of medicine had never for an instant entered the writer's mind."

— Mr. Henry Brooks has prepared a useful series of specimens of the wood of several of the important timber-trees of the eastern states, for the use of teachers and students of natural history.

Each species is represented by three thin transparent sections of wood framed together, and cut in the direction of the layers of annual growth, at right angles with the grain, so as to show a cross-section of the trunk. The specimens mounted between thin sheets of mica permit a satisfactory examination of the position and size of the different ducts, cells, medullary rays, etc., besides showing admirably the color and general character of different woods. Architects and builders, therefore, as well as teachers, will find Mr. Brooks's contribution to a knowledge of our trees of considerable practical value. Complete sets, representing seventeen species, or single sheets, can be obtained by addressing Mr. Henry Brooks, 35 Bedford Street, Boston.

SCIENCE.

FRIDAY, NOVEMBER 23, 1883.

THE NOVEMBER MEETING OF THE NATIONAL ACADEMY OF SCIENCES.

For the first time in nineteen years, and the second time in its history, the National academy held its mid-year meeting in New Haven, Nov. 13–16. Thirty-three of the ninety-three members were in attendance, and during its four days' session twenty papers were presented.

The meeting was conspicuous for the discussion which most of the papers called forth, and for the general participation of the members in these discussions. It was interesting, also, for the report of the committee on the solar eclipse of last May, which included the detailed reports of the expedition to Caroline Island by the principal participants, Professors Holden and Hastings. It will further be remembered by the members from other cities for the marked hospitalities they received at the hands of their confreres of New Haven, and for its many social pleasures, culminating in the brilliant public reception given them by the president, Professor Marsh, at his residence. The new buildings recently finished, or in process of erection, for the furtherance of scientific research and instruction in Yale college, were also examined with interest, together with the treasures of the Peabody museum, where the finely mounted collections of Professors Verrill and E. S. Dana, and the fossil vertebrates of Professor Marsh, called forth much admiration.

The generous discussion to which the papers gave rise was provoked at the very start by the paper of Dr. Graham Bell upon the formation of a deaf variety of the human race, which had a broad, practical interest, and which consumed the entire morning session of the first day. Mr. Bell claimed, that, from purely philanthropic motives, we were pursuing a method in the education of 'deaf-mutes' distinctly tending to such a result, supporting his assertions by statistics drawn from the published reports of the different institutions in this country devoted to the care of these unfortunates. They are separated in childhood from association with hearing-children, and taught what is practically a foreign language, — a practice which isolates them from the rest of the community throughout their lives, and encourages their intermarriage. Such marriages were increasing at an alarming ratio, and with calamitous results. As a remedy for this danger, Dr. Bell would have the children educated in the public schools, thus bringing them into contact with hearing-children in their play, and in instruction wherever they would not be placed at a disadvantage, as in drawing and blackboard exercises. He would also entirely discard the sign-language, and cultivate the use of the vocal organs, and the reading of the lips.

The report on the solar eclipse covered a variety of topics, and will fill some hundred and fifty printed pages. In presenting it, Prof. E. S. Holden merely touched upon the principal points, and gave the leading results, in much the same form as they have already been given in this journal. The objects of the expedition were successfully carried out; and Professor Holden regarded his special work — the search for a possible planet interior to Mercury — as proving the non-existence of the small planets reported by Professors Watson and Swift.

Dr. C. S. Hastings read in full the greater portion of his report upon the spectroscopic work, which concluded with a critical review of the generally received theories of the solar atmosphere, and suggested, instead, that the corona was a subjective phenomenon, largely due to the diffraction of light.

The presentation of these reports occupied the entire morning session of Wednesday, and their discussion the greater part of the afternoon session.

In criticising the current use of the word 'light' in physics, Professor Newcomb opened a long and interesting discussion. He urged that photometric measurements were comparatively valueless, because they estimate a part only of the radiant energy of the sun; whereas the quantity which should be determined was the number of ergs received per square centimetre. Professor Langley, however, asserted that it would be impossible to estimate the radiant energy received from the stars with our present appliances: not all the stars combined would produce deflection, even in so sensitive an apparatus as the bolometer.

Another feature of marked interest was Professor Rowland's exhibition of photographs of the solar spectrum, obtained by his new concave gratings, by which he had prepared a map of the spectrum much more detailed than heretofore secured, and free from the defects of scale found in previous photographs.

Professor Asaph Hall communicated the results of his researches upon the mass of Saturn, based upon new measurements of the distances of the outer satellites. He determines the relative mass of the sun to that of Saturn to be as 1 to $\frac{1}{3482}$.

Professor Brewer took the occasion of the academy's meeting in the city of his residence to exhibit samples of his experiments of many years' duration upon the subsidence of particles in liquids. They showed the action of saline and organic matter, of acids and of freezing, upon the precipitation of sediments. Most of the samples had been undisturbed for five or six years, and showed varying degrees of opalescence, resulting from the suspension of matter in the fluid.

We have mentioned only the more important papers, or those which provoked a fuller discussion than usual. The following complete list will show how largely the physical side of science predominated at the meeting. In *astronomy*, besides the reports on the eclipse of May 6, papers were read by A. Hall, on the mass of Saturn; by S. P. Langley, on atmospheric absorption; and by O. T. Sherman (present by invitation), on personality in the measures of the diameter of Venus: in *mathematics*, by S. Newcomb, on the theory of errors of observation, and probable results: in *physics*, by S. Newcomb, on the use of the word 'light;' by W. H. Brewer, on the subsidence of particles in liquids; and by H. A. Rowland, on a new photograph of the solar spectrum: in *meteorology*, by E. Loomis, on the reduction of barometric observations to sea-level: in *geology*, by T. S. Hunt, on the Animikie rocks of Lake Superior; by J. D. Dana, on the stratified drift of the New-Haven region; by B. Silliman, on the mineralogy and lithology of the Bodie mining-district; and by J. S. Newberry, on the ancient glaciation of North America: in *chemistry*, by W. Gibbs, on phospho-vanadates, arsenio-vanadates, and antimonio-vanadates, and on the existence of new acids of phosphorus: in *physiological chemistry*, by R. H. Chittenden (present by invitation), on new primary cleavage forms of albuminous matter: in *paleontology*, by J. Hall, on the Pectenidae and Aviculidae of the Devonian system; and by O. C. Marsh, on the affinities of the dinosaurian reptiles: in *anthropology*, by A. G. Bell, on the formation of a deaf variety of the human race; and by J. W. Powell, on marriage institutions in tribal society.

The report of the committee on glucose, appointed by the president in conformity with a request from the government, was accepted by the academy, and will be transmitted to Congress with the president's report. This will also embody the proceedings of recent meetings of the academy, the report of the committee on alcohol, and that on the eclipse of the sun, together with the thanks of the academy to the secretary of the navy and the officers of the Hartford for their co-operation in the expedition to Caroline Island. It will also include an expression of the approval of the academy of the efforts now making to secure a system of uniform time.

The next stated session of the academy will be held in Washington in April next, and it is probable that the following mid-year session will be held in Cambridge.

THE WEATHER IN SEPTEMBER.

THE weather-review of the U. S. signal-service shows that in September there were two peculiar features, — the low mean temperature, and the deficiency in rainfall. The former was characteristic of all districts east of the Rocky Mountains, though the temperature was above the normal on the Pacific coast. The greatest deficiency in rainfall was in the east Gulf states, but the drought has been severe in various sections. Forest-fires burned over large tracts of land, causing the destruction of much property, especially in New England.

The accompanying chart exhibits the mean pressure, temperature, and wind-directions for the month, and needs no special comment. Nine barometric depressions were observed within the limits of the country, the average course being farther north than is usual. Of these, one was especially severe on the Lakes and in Canada, and one was a well-developed tropical hurricane. The latter was first observed near Martinique, on the 4th: it was very violent in the Caribbean Sea, and caused great destruction in the Bahamas, the loss of life being over fifty. It reached the North Carolina coast on the 11th, and was a destructive gale between Cape Hatteras and Wilmington, but lost its energy on reaching the land, and was wholly dissipated. While the damage from the hurricane was great, good service to commerce was rendered by the frequent warnings issued by the signal-service. The depression which existed on the 21st is worthy of note on account of its unusual track. It moved from Milwaukee, north-west to St. Paul, thence southward over Iowa and Missouri, and was the means of considerably modifying the effect of a cold wave which threatened extensive damage by frost. Five storm-centres are traced on the Atlantic, one of which is a continuation of the second of the August hurricanes described in SCIENCE, No. 37, and which passed over Great Britain. Four vessels only report passing icebergs.

With the approach of fall, frequent frosts are reported, and a frost-chart is a special feature of the review: it gives the limits of the regions in which frosts were experienced in connection with the three leading cold waves of the month. In contrast with this, maximum temperatures of 100° or higher were noted in Arizona, California, Idaho, Kansas, Louisiana, Nevada, Texas, and Utah; the highest being 122°.

The extent of the deficiency in the rainfall is indicated by the following precipitation table: —

Average precipitation for September, 1883.

Districts.	Average for September. Signal-service observations. For several years.	For 1883.	Comparison of September, 1883, with the average for several years.
	Inches.	Inches.	Inches.
New England	3.74	2.50	1.24 deficiency.
Middle Atlantic states .	4.14	4.47	0.33 excess.
South Atlantic states . .	5.94	6.63	0.69 excess.
Florida peninsula . . .	6.76	5.07	1.69 deficiency.
Eastern gulf	4.98	1.05	3.93 deficiency.
Western gulf	4.33	3.17	1.16 deficiency.
Rio Grande valley . . .	4.54	6.31	1.77 excess.
Tennessee	3.48	2.29	1.19 deficiency.
Ohio valley	2.49	1.53	0.96 deficiency.
Lower lakes	3.03	2.82	0.21 deficiency.
Upper lakes	3.98	2.78	1.20 deficiency.
Extreme north-west . .	2.24	1.01	1.23 deficiency.
Upper Mississippi valley,	3.45	1.67	1.78 deficiency.
Missouri valley	2.60	2.60	Normal.
Northern slope	1.26	0.89	0.37 deficiency.
Middle slope	1.59	3.02	1.43 excess.
Northern plateau . . .	0.78	0.06	0.72 deficiency.
Southern plateau . . .	1.22	0.57	0.65 deficiency.
North Pacific coast . . .	2.13	1.18	0.95 deficiency.
Middle Pacific coast . .	0.21	0.48	0.27 excess.
South Pacific coast . . .	0.03	0.04	0.01 excess.

The drought in the southern states is a continuation of that of former months, as is shown by the following table of deficiencies in the districts named: —

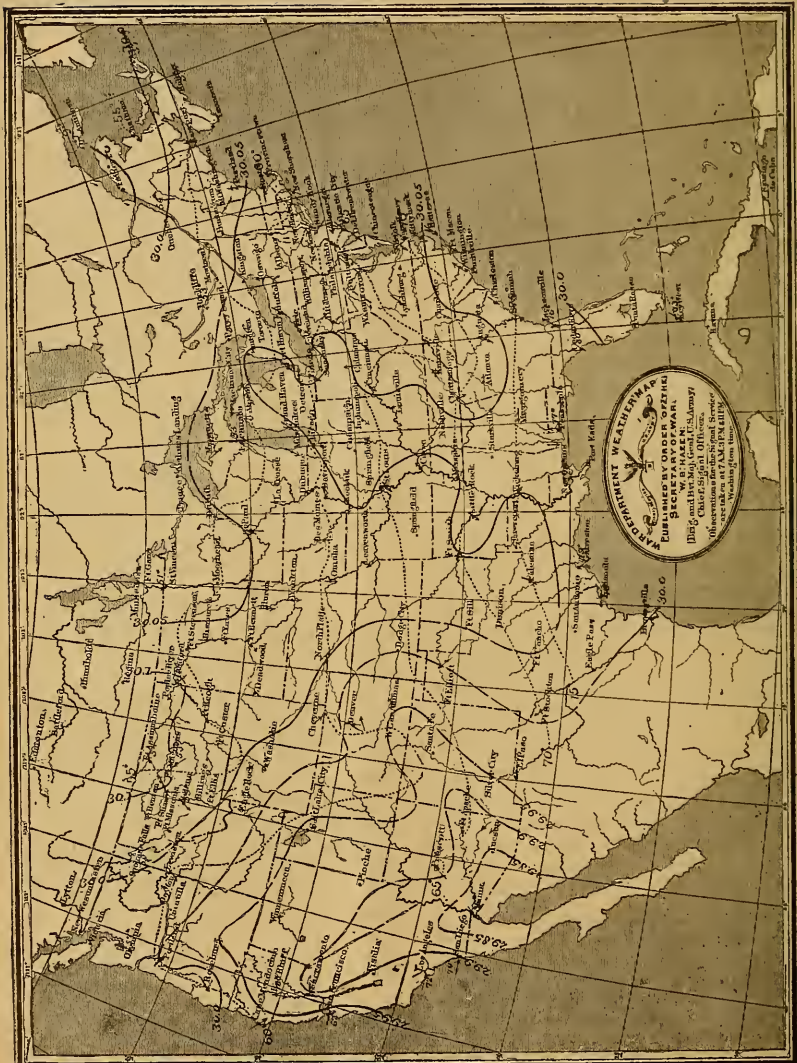
Districts.	July.	August.	September.	Total.
	Inches.	Inches.	Inches.	Inches.
Tennessee . . .	−0.99	−0.41	−1.19	−2.59
South Atlantic . .	−0.73	−0.72	+0.69	−0.76
Eastern gulf . . .	−2.54	−1.94	−3.93	−8.41
Western gulf . .	−1.72	−2.65	−1.16	−5.53

Several instances of great wind-velocity were recorded, the maximum being a hundred and eight miles per hour at Mount Washington on the 9th. At Cape Mendocino, on the Pacific coast, a maximum velocity of ninety-six miles was noted. The singular fact, not unusual, however, in the winter season, is deserving of mention, that the total movement of the air at Delaware Breakwater and Kittyhawk, on the Atlantic coast, is greater than that at the summit of Pike's Peak, the loftiest station in the world.

THE ELECTRIC LIGHT ON THE U. S. FISH-COMMISSION STEAMER ALBATROSS.[1] — II.

As superintendent of the building of the ship, my expectation was, that numerous and intricate problems would present themselves in running the wires about the iron hull, through

[1] Continued from No. 41.



MONTHLY MEAN ISOBARS, ISOTHERMS, AND WIND-DIRECTIONS, SEPTEMBER, 1883. REPRINTED IN REDUCED FORM BY PERMISSION OF THE CHIEF SIGNAL-OFFICER.

iron bulkheads and beams, close to the boilers or hot steam-pipes, and through damp places.

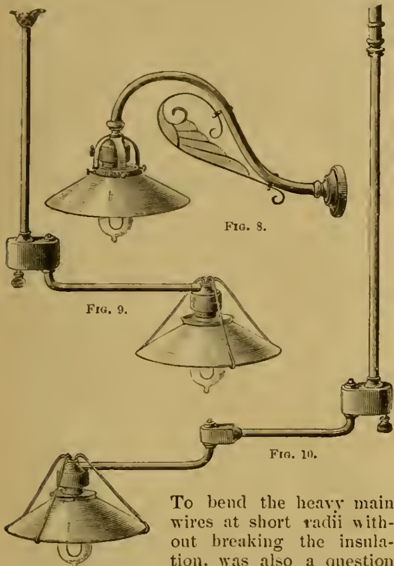


Fig. 8.

Fig. 9.

Fig. 10.

To bend the heavy main wires at short radii without breaking the insulation, was also a question that presented itself. But all these had been apprehended. Where the wires passed damp places, they were incased in rubber tubes, besides their insulation of cotton-cloth and white lead; in all hot places they were incased in lead pipe; where they passed through iron bulk-heads or beams, ferrules of hard rubber or gutta-percha were used; and the mains, instead of being single wires of large size, were composed of a number of smaller wires, which, of course, made them more flexible. Where the wires passed an iron surface, such as a lodger-plate or stringer, they were fitted to a groove in a wooden batten; and, where they passed a wooden surface, they were embedded into a groove cut in the wood; and, when carefully painted over, it is difficult to detect their presence. The main wires, as far as possible, were led behind the wooden lining of the ship. Where the wires were spliced or 'tapped,' their insulation was removed, and the naked metallic surfaces brightened with sand-paper, to insure metallic contact. They were then twisted together tightly, and soldered. The naked place was then covered with insulation-tape, which is common cotton tape saturated with a bituminous insulation compound manufactured by the Edison company, the components of which are kept a profound secret, and which an irreverent young man has named 'gulloot.'

The lamp-fixtures are designed to suspend the shade above, and to cast the unobstructed rays of the light downward. Handsome brass fixtures of three kinds, with porcelain shades, are used on board. Fig. 8 is called a bracket, and figs. 9 and 10 are single and double swing-brackets respectively.

The wires are run through the tubes of these brackets; but in the joints of the swing-brackets the current is transmitted through insulated hinges, to which the wires are fixed by binding-screws, as shown at *a* in fig. 11, by which arrangement the wires are not twisted in swinging the bracket.

The wires are brought to the binding-posts in the lamp-socket, fig. 12, between their binding-posts and brass conductors. One of these brass conductors is soldered to the thin spun brass socket into

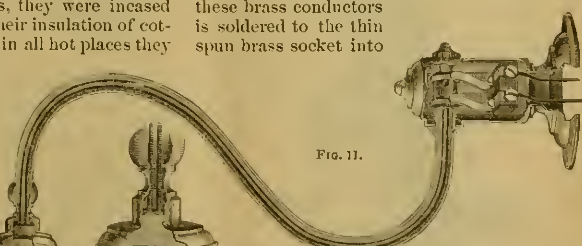

Fig. 11.

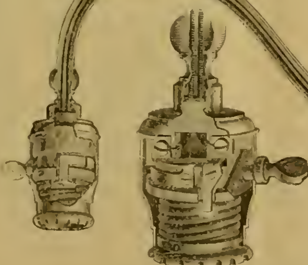

Fig. 12.

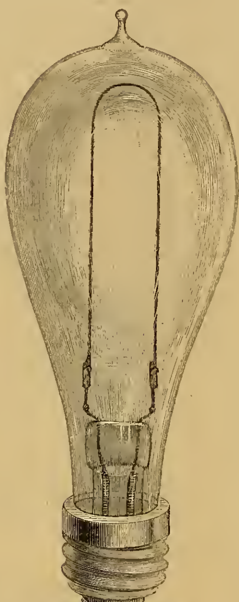
which the lamp is screwed, while the other is connected, through the key, to a brass disk, placed centrally in the bottom of the socket, against which one pole of the lamp presses when screwed in place. The key is mounted on a screw-thread of such pitch that one-fourth of a convolution will give it sufficient axial motion to open and close the circuit. The small number of parts used in these fixtures, their correct proportions, the adaptation of their forms to machine-tool manufacture, and their beauty of design, excite the admiration of the mechanic and the artist.

Fig. 13.



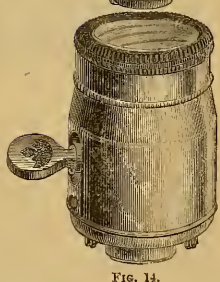


Fig. 14.

The lamps are of thin glass, pear-shaped, containing a thread of bamboo carbon about the thickness of a horse-hair. The small end of the lamp contains glass of sufficient thickness (fig. 13) to make a tight joint on the platinum-wire conductors which carry the current to the carbon. The atmosphere is exhausted from the lamp by Edison's modification of the Sprengel pump, through a tube at the upper end, and the tube is then fused and broken off. Platinum wire is used because its index of expansion is the same as glass, thus preventing any leakage or breakage from unequal expansion from the heat. The bamboo carbon and platinum wire are soldered together by electrically deposited copper. One wire, passing through the glass, is soldered to a small brass disk, which is centred on the bottom of the lamp, while the other wire is soldered to the spun brass screw-thread which surrounds the cylindrical part of the bottom of the lamp; and, when the lamp is screwed into the socket (figs. 14 and 12), the circuit may be completed or broken by the switch or key already described. When the circuit is closed, the carbon thread becomes heated, from its high resistance, to incandescence, and continues to glow, in vacuum, without burning, so long as the current continues to flow. The wires having a larger sectional area and higher conductivity carry the current without perceptibly warming. By varying the length or sectional area of the carbon thread, keeping the electromotive force constant, Edison has varied the candle-power of his lamps.

For example: let the electrical resistance be represented by R, the sectional area of the wire or carbon by S, the length by L, and the constant, dependent on the material of which the conductor is made, by a; then $S\ R = a\ L$, from which simple equation the relative sizes of carbons and wires may be determined, and proportioned to the tension in the circuit. Mr. Edison employs a number of different-sized dynamos, which he designates by letters; but he winds them for but two tensions, i.e., the *A* and *B* circuits. The *A* lamp belongs to the *A* circuit, as its carbon thread is of such resistance that the *B* circuit would heat it to only a cherry red. A *B* lamp, however, in the *A* circuit, would acquire an intense brightness, but its duration would be very limited. Two *B* lamps in series, in the *A* circuit, would, by their augmented resistance, glow at about their normal incandescence.

The average life of a lamp is said to be about 1,000 hours, when kept up to its normal incandescence; but they will last much longer if their brightness is a little suppressed. This may be effected either by throwing in resistance, or by slowing the engine. On board ship, however, about as many lamps are broken by accident as from natural deterioration.

The cost of the lamps is one dollar each; and, at the present rate of consumption from all causes, the annual expenditure will be 56 lamps. The dynamo is run about 2,190 hours per year (about six hours per day), with an average of about $47\frac{1}{2}$ lamps in circuit, so that the annual lamp-hours would be about 104,025 (2190 × 47.5). Thus it appears that our lamps will, at present consumption, last us in the neighborhood of 1,857 ($\frac{104025}{56}$) hours each.

Description of lamps.

Designation of lamps.	Candle-power.	Resistance in ohms.	Current in ampères.	Electromotive force in volts.
A	32	86	1.180	102
A	16	137	0.745	102
A	10	250	0.400	102
B	8	69	0.745	51
B	16	42	1.200	51

In event of a short circuit through a good conductor, between the wires there would be instantly generated heat of such intensity that the wires would melt, and perhaps the armature also. This heat would in all probability set fire to the wood-work along the line of the wire. To prevent this, Edison has devised his cut-out block, or safety-catch, — a neat device for placing a short piece of alloy in the circuit, which, at 400° F., will melt, and open the circuit. When this happens, all the lamps on the branch circuit fed through that cut-out will be immediately extinguished; and, though one is left in darkness at that point, he is rewarded by a consciousness of greater mischief having been prevented. Fig. 15 represents a double pole cut-out block, a front and back view of the cut-out plug, and a binding-screw. Fig. 16 shows a back view of the same cut-out block, and a section through a cut-out plug. The fusible alloy is contained in the plug, and is utilized as a solder to unite the two poles of the plug. The plug is made similar to the bottom of a lamp, and the block-socket is similar to a lamp-socket. The wires are held by the binding-screws, and the current passes through the metal of the block and plug. These cut-outs are placed on each of the main circuits, near the dynamo, and on each branch circuit, and always in convenient positions. The alloy in the plug is the only part destroyed by a short circuit, and it is only a minute's work to substitute a new plug.

(*To be continued.*)

REPORT OF THE GERMAN CHOLERA COMMISSION.[1]

When the commission arrived in Egypt, the cholera epidemic had already begun to decline, so that we could not expect to obtain all the material necessary for carrying out our examinations. Besides, since the termination of an epidemic is the least suitable time for etiological researches, our original plan was to make such preliminary studies as we could in Egypt, and then check our results, as soon as the epidemic had reached Syria, by further investiga-

[1] Report to Minister von Böttleher, secretary of state for the interior. By Dr. Koch. From the *Kölnische zeitung* of Oct. 17.

tions in suitable localities in that country. We were able to carry out the first part of our plan in accordance with our wishes; for the commission found abundant opportunity, during its stay in Alexandria, to collect the material necessary for its preliminary researches. This was mainly due to the active cooperation of the physicians of the Greek hospital, who furnished us working-rooms, permitted us to study the cholera cases in the hospital, and placed the bodies of those who died of the disease at our disposal.

At first the commission had two rooms of the hospital, adjoining each other on the ground-floor, and well lighted. In one room the microscope work was carried on, and in the other the culture experiments. The animals experimented on were at first brought into both rooms. But when their number had been increased, it was thought too dangerous to manipulate the material for infection in the same rooms in which we had to spend nearly the entire day, and they were accordingly removed to another room in the old hospital; and there the experiments on infection were made.

The material for experiment was obtained from twelve cholera patients, and ten bodies of individuals who had died of the disease. The cases of nine of the patients were studied in the Greek hospital, two in the German, and one in the Arabian. The symptoms corresponded in all cases with those of true Asiatic cholera. Specimens of the blood, of the vomited matter, and of the dejections of these patients, were taken, and submitted to examination. It was soon apparent that the blood was free from micro-organisms, that the vomited matters were comparatively poor in them, but that the dejections contained a considerable quantity; and the latter material was therefore mainly used in the infection experiments with animals.

Although the number of bodies used for dissection was small, the material they afforded was of the greatest service in localizing the disease. They represented the most varied nationalities (three Nubians, two German-Austrians, four Greeks, and one Turk), were of different ages (two were children, two over sixty years of age, and the others between twenty and thirty-five years), and the duration of the disease varied in the different cases. The most important fact, however, is that dissection could be begun immediately or in a few hours after death. The changes produced in the organs, and especially in the intestines, by putrefactive decomposition shortly after death, which render microscopical examination difficult, and its results generally entirely deceptive, were thus effectively guarded against. I wish to lay particular stress on this circumstance, because it is hardly probable that such excellent material for microscopic examination as we obtained could be found in other places.

The appearances of the bodies, as well as the symptoms of the sick, left no room for doubt that we had to deal with true cholera, and not, as at first supposed, with diseases resembling cholera, — the so-called 'choleriform' and 'choleroid' diseases.

We were unable to detect any organized infectious matter in the blood, or in the organs which are usually the seat of micro-parasites in other infectious diseases; viz., the lungs, spleen, kidneys, and liver. Occasionally bacteria were found in the lungs; but it was clear from their forms and position that they had nothing to do with the processes of the disease, but had entered the lungs from the vomited matter by aspiration. In the contents of the intestines, just as in the choleraic dejections, there was an extraordinarily large number of micro-organisms of different kinds, no one of which was present in excessive proportion. There were also no special indications which could enable us to draw any conclusions as to their connection with the disease. On the other hand, the examination of the intestine itself gave a very important result. In all cases but one, a specific form of bacteria was found in the walls of the intestine. The exception was in the case of a patient who had died of a *sequela* several weeks after the cholera had subsided. These bacteria were rod-shaped, and therefore belong to the bacilli. In size and shape they most nearly resemble the bacilli of glanders. In cases where the intestine showed the slightest evidence of change, the bacilli had penetrated into the tubular glands of the mucous coat, and had set up a considerable irritation there, as was shown by the distension of the glands, and the accumulation of many-nucleated round cells in their interior. In many cases, too, the bacilli had worked their way beneath the epithelium, and had penetrated between it and the gland membrane. Moreover, they had planted themselves in large quantities over the surface of the villous coat of the intestine, and had penetrated its tissue. In severe cases of the disease, where there was a bloody infiltration of the mucous coat of the intestine, the bacilli were present in great numbers, and had not confined themselves to the invasion of the tubular glands, but had entered the surrounding tissue in the deeper layers of the mucous coat, and sometimes had penetrated to the muscular coat. The villous coat was also thickly covered with them in such cases. The principal seat of all these changes was found to be the lower part of the small intestine. In investigations like the present, the examination ought to be made on perfectly fresh bodies, because putrefactive decomposition can induce similar growths of bacteria in the intestine. From this consideration I was unable last year to attach any value to the discovery of the same bacilli in the same position in the intestines of cholera patients which I had obtained directly from India, because I was afraid of complications with *post-mortem* changes. This former discovery, which was made in the intestines from four bodies of persons who had died of cholera in India, is now confirmed, because there can be no error in the present case due to decomposition in the Egyptian bodies. The inference, too, that the correspondence in the conditions of the intestine in the Indian and Egyptian cholera may be taken as a further indication of the identity of the diseases, is not without weight.

The number of bodies of cholera patients used by the commission for examination, it is true, was small.

Bacilli were found in all the fresh cholera cases, but were wanting in the case where death had occurred after the symptoms of cholera had disappeared, and in others where death had not occurred from cholera, in which examinations were made for the sake of comparison; so that there can be no doubt that these organisms have some connection with that disease. But it is too much to conclude yet that bacilli are the cause of cholera because they are found in the mucous coat of the intestine of cholera patients. The inference might be reversed; and we might say that the disease produces such changes in the mucous coat, that some of the many bacteria present there as parasites are able to penetrate the tissue. A decision of the question, which of the two views is correct, — whether the infection or the bacteria invasion comes first, — can only be settled experimentally by collecting the bacteria from the diseased tissue, breeding them by 'pure culture,' and then reproducing the disease by infection experiments on animals. For this purpose it is necessary, first of all, to have such animals at our disposal as are susceptible to the infectious matter; but in spite of every effort to infect animals with cholera, it has not yet been demonstrated that they can be made to take that disease. Experiments have been tried with rabbits, guinea-pigs, dogs, cats, monkeys, pigs, rats, etc., but always without success. The only statements to the contrary, worthy of notice in this connection, are the accounts of Thiersch's experiment with mice which he fed with the contents of the intestine of a cholera patient, and which were then attacked with diarrhoea, and died. This experiment has been confirmed by reliable experimenters, like Burdon-Sanderson, and has been criticised, and the conclusions drawn from it disputed by others. We considered it necessary to repeat this experiment because it was of the utmost importance for our purpose to discover some species of animal capable of infection with cholera.

Fearing that the requisite number of mice could not be obtained at once in Alexandria, we carried fifty of those animals with us from Berlin, and began the infection experiments with them. We also experimented with monkeys, — because they are the only animals susceptible to certain human diseases, such as small-pox and relapsing fever, — and, besides these, with a few dogs and chickens. But, in spite of all our care, the experiments were failures. The most varied samples of vomited matter, choleraic dejections, and contents of the intestines from bodies of persons dead of cholera, — sometimes fresh, sometimes after standing some time in a cool or warm place, and sometimes in a dried condition, — were fed to these animals; but no symptoms of cholera appeared, and they remained perfectly healthy.

Besides this, 'pure culture' experiments were made with bacilli taken from the contents of the intestine and its walls. The material obtained in this way was fed to the animals, and inoculation was also tried. This latter method, with the products of the 'pure culture,' sometimes produced septic diseases; but no symptoms of cholera appeared.

That the material of the disease is very often contained in the dejections of cholera patients in an active form, is shown in several ways, and particularly by the frequency of the disease among washerwomen who wash clothes soiled with such dejections. A case in point occurred during the present epidemic in the Greek hospital, where a washerwoman who washed for the cholera hospital exclusively was taken with the disease. It is therefore certain, that, of the numerous samples used in our experiments, some at least must have contained the infectious matter. But since our experiments were failures, it must be assumed, either that the animals we used are not susceptible to cholera, or that we had not discovered the right method of producing infection. At any rate, the experiments ought to be repeated and modified; but, with the material now at our command, there is little prospect that they would prove successful.

Our want of success may possibly be explained in still another way, which is this. In a place visited by the cholera it is usual for the disease to cease before all the inhabitants have been attacked; and, although the infectious material is scattered about in great quantity, fewer and fewer persons are affected by it, and the epidemic at last dies out in the midst of individuals capable of taking it. This circumstance can only be explained on the theory that the infectious matter loses its activity, or at least becomes uncertain in its action, towards the end of the epidemic. If, therefore, human beings become less susceptible to the infection of cholera towards the end of the epidemic than at its outbreak, it can hardly be assumed that the animals used for experiment, of whose susceptibility to infection we know nothing, should differ from them in this respect. And for our experiments we could only obtain material which had been collected towards the end of the epidemic, and which must be presumed to have been more or less inactive. It is of course possible, that under suitable conditions, such as the outbreak of a cholera epidemic, the infection of animals with the disease might be successfully accomplished; and such would be the proper time to determine by experiment whether the bacilli I observed in the mucous coat of the intestine constitute the true cause of cholera.

However far the commission may still be from a complete solution of the problems proposed to it, and although its labors have contributed little which may prove of practical value in combating the cholera, yet, considering the unsatisfactory conditions under which the experiments were made, and the short time the commission was able to devote to them, the results thus far obtained should be regarded as encouraging. The experiments fully answer the original purpose of localizing the disease, and, by ascertaining the constant presence of characteristic micro-organisms, have supplied the first condition for the investigation of infectious diseases, and afforded a determinate object for further research.

From the foregoing statements, it is clear that the commission can accomplish no more in Alexandria than has already been done. It might be thought that it could pursue its investigations in some other place in Egypt where the cholera prevails, but there are insuperable objections to such a plan. The cholera has disappeared from all the large cities of the country, and only holds its own in the villages of upper Egypt; and an attempt to carry on our experiments in that part of the country would meet with the strong disapproval of the Egyptian government on account of the disagreeable complications in which the condition of affairs there might involve us. Moreover, I have been assured by responsible persons well acquainted with the Egyptians, that it would be impossible to obtain material for dissection in Egyptian villages; and for these reasons I must renounce all hope of following the course of the cholera up the Nile. The disease also, contrary to all expectation, appears to have gained no foothold in Syria. Since the investigations now in progress will occupy only about two weeks, the work will soon have to be temporarily suspended. The commission, however, entertains a strong desire to prosecute its researches further, and satisfy the object for which it was created. It would be a great disappointment if the results it has already reached should prove fruitless from want of further experiments. The only opportunity which is afforded us at present for continuing our researches is in India, where the cholera is still prevalent in several large cities, particularly in Bombay, and is not expected to subside immediately. It is also probable that we could gain access to some hospital there, and repeat the work which proved so valuable in Alexandria. In case, in your excellency's opinion, it should be deemed advisable to continue the researches of the commission, and extend the field of its labors to India, I am ready to continue in charge of its management.

I must also say a few words about the additional labors which the commission has found time to prosecute in connection with its researches on cholera. Egypt is full of parasitic and contagious diseases, and it was not difficult to obtain suitable material for the examinations we wished to make in order to control the results obtained in studying the cholera, and also to settle some general questions bearing on infectious diseases. For example: I dissected the bodies of two persons who had died of dysentery. In one case, where the patient had died of an acute attack, there were parasites in the mucous coat of the intestine which did not belong to the bacteria group, and were unknown. I also dissected the body of an Arab who had died in the Arabian hospital of malignant disease. The disease in this case was probably taken from sheep, which are imported into Egypt from Syria in great numbers, and die of anthrax *en masse*. I was also afforded an opportunity to observe six cases of bilious typhus in the Greek hospital. This disease closely resembles yellow-fever, with which it is often confounded, and presents much interest to the student. Three of these patients died, and were dissected.

Besides this work, repeated examinations were made of the micro-organisms in the air, and the drinking-water of Alexandria. If time allows, I intend to study the Egyptian ophthalmia.

The labors of the commission, which from their nature were very trying and fatiguing, and for the most part of a disagreeable character, were rendered doubly irksome by the high temperature prevailing in the city. It has been impossible to interrupt the work a single day until now. Nevertheless, the members of the commission are in good health, and have only suffered from some slight complaints, due to a change of climate, which soon disappeared. However, as soon as the condition of the work will allow, I consider it advisable for the commission to rest a few days. I intend, therefore, to go with it to Cairo for a short time, partly for the sake of recreation, and partly in order to visit the principal seat of the cholera in Egypt, and make further observations there.

THE PHYSIOLOGICAL STATION OF PARIS.[1] — I.

We have seen in the last few years all kinds of establishments erected to provide for the new needs of science. Laboratories, although great discoveries have been made in them, have become in certain respects insufficient. In the study of organized bodies, as in that of the physical forces of the earth, one is soon brought to a standstill if he cannot study nature in her own domain.

Special establishments for certain sciences, astronomy for instance, are a necessity; and lately naturalists have perceived the insufficiency of the means placed at their disposal. Maritime stations, gardens for acclimation, experiment stations, agricultural stations, stations for vegetable chemistry or experimental medicine, — all these have responded to the development of certain branches of science.

Physiology, almost the only exception, has been, up to the present time, dependent upon laboratories. These are, in France at least, wretched places, poor and unhealthy, where the investigators are obliged to live in the hope of discovering the properties of the tissues, and the functions of the living organs. There is discovered the action of medicines upon the living organism, of poisons, and the various chemical and physical agents; there, by means of vivisection, or by the use of the proper and delicate instruments, the inner mechanism of the vital functions is analyzed.

This condition of destitution could not continue. It is evident, that with the means at its disposal, within narrow limits, and compelled to operate upon a few lower animals, physiology could not but remain behind the other sciences. In any case, it could not hope to attain its full development: it must abandon, without practical application, the knowledge that it had obtained at the cost of so great efforts.

In the last half-century physiologists have written a large number of works on the nervous and muscular systems. We have learned to distinguish the nerves

[1] By E. J. Marey of the French Institute. Translated from *La Nature*.

of sensibility and those of movement; to determine the courses of the two kinds of nerves in the various parts of the body. We know how excitations, according to their intensity or nature, act on these organs. We have measured the rapidity with which that still mysterious agent, which bears to the muscles the order for motion, travels in the nerves and in the spinal marrow. We have separated the action of the muscles in their elements, — undulatory vibrations which traverse the length of the muscular fibre. Finally, we have studied the nature of contractions, and know how fatigue, heat, cold, and poisons affect these movements.

On the other hand, while considering the mechanical conditions of animal locomotion, we have determined, from a kinematic stand-point, the characters of the various movements of man and animals. We have classified according to their kind the different bony levers of the skeleton, have determined the centres and radii of curvature of the joints, and have estimated the momentum of the opposing forces which represent the power and the resistance in the animal machinery.

It appears now that every thing is ready, and that physiologists have only to apply these studies to the various problems of practical life. They will teach us, doubtless, how best to utilize the muscular work of man and of the domestic animals; they will lay down rules which shall control the physical exercises of the young, the work of the artisan, the drill of the soldier.

Unfortunately it is not so. Limited as they are, physiologists are scarcely able to study the vital functions in man and the more important animals; besides, the usual method, vivisection, which has disclosed so much in regard to the properties of the tissues and the functions of separate organs, cannot discover the regular action of normal life.

The writer of this article has spent long years in his search for methods and an apparatus capable of faithfully interpreting the external signs of the functions of life. The pulsations of the heart or the arteries, the respiratory movements, the contractions of the muscles, record themselves with this apparatus, and obtain, for analysis, curves in which the least details of the movements are represented. The object of other instruments is to trace the course traversed by a man or by an animal, or to express the efforts developed as functions of the time. Recently, instantaneous photography has completed the knowledge of physiological movements, so that to-day we can easily solve most of the problems of the animal mechanism.

But if the methods were perfected, if new apparatus were invented, all the difficulties would not be removed; for it is not in the ordinary physiological laboratories that one can study the motions of a bird on the wing, of a galloping horse, or of a man walking, running, or performing some other muscular exercise. It was to promote these researches on the physiology of man and animals, that the physiological station, of which we will give a description, was erected.

Only the municipal council of Paris could grant land adequate for this kind of experiments. There was a very convenient place on the Avenue des Princes, near the Porte d'Auteuil. With the generosity always shown when science is concerned, the council granted these lands, and even voted a subsidy to cover a part of the expense of experiments. On the other side, Mr. Jules Ferry, the minister of public instruction, pleaded warmly before the chambers in favor of the contemplated establishment. A law, passed in August, 1882, granted the sums for the construction of the necessary buildings. The work was pushed actively forward during the last autumn and winter, and in March experiments were begun at the physiological station.

The practical applications of physiology are infinite; but in this vast number there are certain questions whose solution is near at hand, certain others for which nothing is prepared. The management of the physiological station, although the subsequent needs are foreseen, is, for the present, arranged for the study of the animal mechanism; and the experiments under progress relate to human locomotion.

The problems which present themselves first of all are the following: 1°. To determine the series of motions which are produced in human locomotion of various kinds, — walking, running, leaping; 2°. To search for the external conditions which influence these motions; those, for instance, which increase the rapidity of pace or the length of step, and which thus exercise a favorable or an unfavorable influence upon the locomotion of man; 3°. To measure the energy expended each instant, in the various acts of locomotion, in order to discover the most favorable conditions for the utilization of this energy. Instantaneous photography, and various other appliances of the graphic method, help to solve these problems, which are impossible to direct observation.

Before entering into the details of the experiments, we will describe the general arrangement of the physiological station. Fig 1. shows the land and the building as a whole. A circular and perfectly level course is laid out in a piece of ground used by the city of Paris as a nursery. This course has two concentric tracks: the inner one, four metres wide, is for horses; the outer one, for men. Around these tracks runs a telegraph-line, whose poles are fifty metres apart. Every time a walker passes a post, he causes a telegraphic signal; and this is recorded in one of the rooms of the principal building. We shall refer later to this kind of automatic record, by means of which, for every minute, the rapidity of the walk, the accelerations and diminutions, and even the number of steps, may be known. In the centre of the course is an elevated platform, on which a mechanical drum beats the time for the step. This drum is worked by a special telegraph-line, coming from a room in the large building where the rhythm is maintained by a mechanical interrupter.

From the centre of the course runs an iron track, on which rolls a little carriage forming a photographic studio. From within this apartment a set of instantaneous pictures of the men and horses whose gaits are to be studied, may be taken. These photographs are taken as the walker passes before a black screen. Finally, the dynamographic studies, to measure the energy exerted in the various muscular motions, are possible by means of apparatus which will be described later.

Our readers are already familiar with the history, in detail, of the applications of instantaneous photography to the analysis of the locomotion of man and animals. Many have seen the beautiful pictures obtained by Mr. Muybridge, who has succeeded in photographing a horse running at full speed. For the requirements of the physiological analysis of movements, we have substituted for the complex apparatus of Mr. Muybridge a simple contrivance, giving on the same plate the successive positions of a man or an animal at various instants of his passage before the black screen. We shall refer to these experiments in order to describe certain improvements which make the figures more clear, the time-measurements more exact, and which, by multiplying almost indefinitely the number of images, give a complete analysis of all kinds of movements.

The apparatus employed at the physiological station for the instantaneous photography of movements comprises two distinct parts, — first, the photographic apparatus, with the room on wheels, which holds it; and, secondly, the black screen, on which appear in white the men and animals whose pictures are being taken, as well as the instruments for measuring the distance run, and the time consumed between two successive photographs.

Fig. 2 represents the photographic chamber where the experimenter is. This room is on wheels, and is arranged on an iron track, so that it may approach or move from the screen, according to the objectives which are employed, and the desired size of the photograph. Generally it is convenient to place the photographic apparatus about forty metres from the screen. At this distance, the angle at which the subject to be photographed is presented, changes little during his passage before the black screen. From the outside of this building may be seen the red glass through which the operator can follow the various motions which he is studying. A speaking-trumpet enables him to direct the different movements which ought to be made. The front wall of the building is raised in the figure, in order to show a revolving-disk, provided with a little window, across which the light passes intermittently into the objective. This disk is of large size (1.30 m. in diameter), and its window represents only a hundredth of its circumference: hence, if the disk revolve ten times a second, the duration of the lighting is only one-millionth of a second. The movemement is recorded on the disk by wheel-work, which is wound

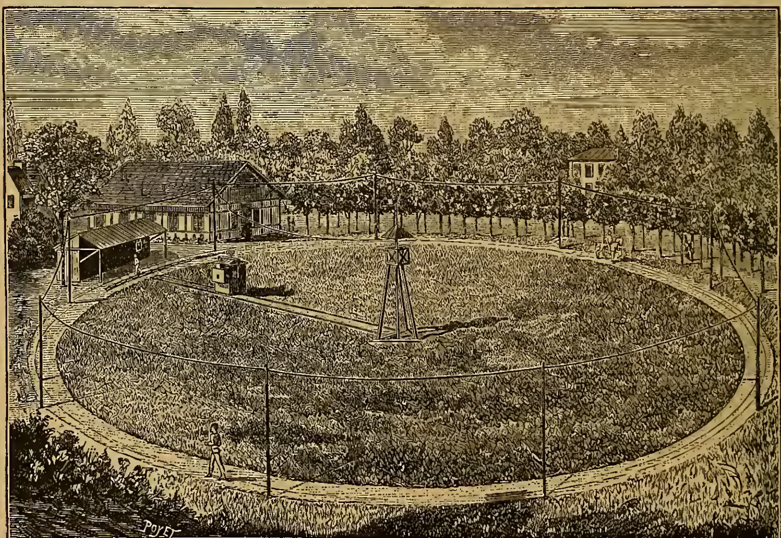

FIG. 1. — PHYSIOLOGICAL STATION AT PARIS.

by a crank, and set in motion by a weight of a hundred and fifty kilograms placed behind the building. A brake checks the disk. A clock-bell, regulated from within, notifies an assistant either to set in motion or to stop the disk.

Fig. 3 shows the interior arrangement of the chamber. The removal of one of the side-walls discloses the photographic apparatus, *A*, placed on a bracket, and directed toward the screen. This instrument receives the long and narrow sensitive plates, which just admit the image of the whole screen. The plates which give the best results for the shortest exposures are those of Van Monckhowen of Ghent, and that of Melazzo of Naples. At *B* is the revolving-disk, which produces the intermittent light; at *D*, a shutter, which is raised vertically at the beginning of the experiment, and falls at the end in order that the light may enter the apparatus only during the time absolutely necessary. *E* is a long slit which unmasks before the objective the field in which the movements to be studied are taking place. The darkness of the chamber permits one to handle at his ease the sensitive plates, and to change them for each experiment.

(To be continued.)

SEPTEMBER REPORTS OF STATE WEATHER-SERVICES.

THESE reports emphasize the general lack of rain, which, without exception, was characteristic of the weather prevailing in every state issuing reports. The low mean temperature is also made a subject of note.

Georgia. — In this state there has been no general rain since April 23, and the crop reports are in consequence unfavorable. Cotton averages sixty-two per cent, and corn seventy-six per cent, of the usual yield. The temperatures ranged between 45°, the minimum in the northern portion, and 95°, the maximum in the southern section. The average rainfall was 1.57 inches.

Indiana. — The temperature averaged 3.5° below the normal for September; and frosts occurred on the 6th, 10th, and 26th, damaging late corn and other vegetation. The prevailing wind was north-east. The rainfall ranged from 0.15 inch to 5.98 inches, averaging 1.99 inches for the state.

Kansas. — At Lawrence the rainfall was smaller and the temperature lower, with one exception, than any other September for sixteen years. Rain fell on seven days, and there was but one thunder-shower. The mean cloudiness was 40.33 per cent, the month being 0.31 per cent clearer than usual.

Missouri. — At St. Louis the rainfall was less than a hundredth of an inch, which has not happened before since Dr. Engelmann began his observations in 1839. The normal rainfall at St. Louis is three inches. Several other stations report no rainfall. Light frosts occurred, but without material damage to the corn-crop, except over limited areas on low ground.

Ohio. — The barometric conditions were normal; but the temperature was about four degrees below the average, and the rainfall showed a deficiency of nearly an inch. The bureau is gradually increasing the number of stations, and makes special efforts to have its observers supplied with standard instruments. In addition to its regular stations, it invites the co-operation of voluntary observers, and will furnish reliable instruments at reduced prices. The rainfall chart published by this service is deserving of being introduced into other similar reports.

Tennessee. — The continued drought has damaged the crops, especially in the eastern portion; but in the middle portion the crops are in fair condition. Frost visited some localities, the temperatures in the state ranging from 32° to 95°. The prevailing wind was north; the average rainfall, 2.06 inches; the average number of clear days, 14.

LETTERS TO THE EDITOR.

Teaching language to brutes.

Is it not quite conceivable that some of the lower animals might be taught to use human language rationally? No doubt the reasons for a first hasty answer in the affirmative would be that the animals seem so intelligent as sometimes even to reason, and that they have, in fact, often had human words put into their mouths, and that they seem sometimes to have a language among themselves. Yet, after all, cannot their intelligence, and even wisdom, and occasional apparent reasoning, be satisfactorily explained, without attributing to them true reasoning, as the result of hundreds or thousands of generations of experience and transmitted memory, by which certain objects or actions become associated with a feeling of pleasure or pain that induces pursuit or avoidance? How few, indeed, are the cases that cannot readily be so explained, where an animal appears at first sight to exercise a reasoning-power! and how extremely simple the effort seems then to be!

True reasoning can always be reduced to the syllogistic form, in effect a statement that what is true of a class is true of something in that class. In order, then, to reason, properly speaking, it is necessary to use a general term (a word or sign with the meaning of a common noun) to indicate the class; and, as we do not know of any evidence that brutes have such words or signs, we have no proof that they can reason. In like manner, the lack of evidence that they can reason goes far towards showing that they have no language that includes such general terms, though it may be true that they sometimes understand words in a singular (not general) sense, and have similar expressions for their own feelings.

The question, then, is whether brutes may not be taught the intelligent use of general words or common nouns, which would enable them to reason. As the step does not seem so very enormous from the undeniable intelligence of some brutes to the lowest form of generalization, it is perhaps worth while to consider how they might possibly be taught to take the step, in hope, that, having once taken it, they might be led farther with still greater ease. Since the idea of plurality appears to lie at the very bottom of the idea of class, number would perhaps be the first and simplest step in generalizing, — number, that is, the regarding things merely as individuals or units. It is a step beyond, to regard things as alike in more complex respects. If that is so, the first effort might be made to teach how to count, and, of course, at the beginning only to count up to two. If that can be accomplished, still further counting can unquestionably be taught, and no doubt by degrees a much greater amount of generalization and reasoning itself. Does it seem impossible that a brute may learn to associate invariably the word 'one' with a single object, and 'two' with a pair of objects, no matter of what kind? At first the two objects should always be two like ones; but by degrees a difference in them might be allowed. The teaching of common names might next be taken up; or it might be begun along with the counting, but without the confusing addition of any plural termination. Even if the mere counting up to two could not be taught successfully to any single individual brute, yet the end might nevertheless be attained, perhaps, in several generations.

The question then comes, With what animal would it be best to begin such experiments, — whether with monkeys, or elephants, or birds, or ants? Of course, articulation is not essential; for a language of signs might be devised suitable to the animal, — a language corresponding to the deaf-and-dumb one of signs, or to one using the Morse alphabet, or something like it. Elephants are very intelligent, but so very long lived that it would take ages to observe the effect of training through many successive generations. Perhaps the convenience of excellent articulation and rapid propagation, both combined with apparently good intelligence, might give the preference, on the whole, to a talking bird, such as the Indian mynah. L. B.

Nov. 9, 1883.

Climate in the cure of consumption.

In your issues of Sept. 28 and Oct. 5, Dr. S. A. Fisk of Denver, Col., compares the climates of the principal health-resorts of the United States with one he happens to represent, i.e., Colorado. At the commencement of his paper the writer states that "he has given the data for Augusta, Ga., as the best substitute for Aiken, S.C., at which place there is no signal-station; and, in doing so, he thinks that he is presenting data which will fairly represent the climatic condition of Aiken." To those familiar with the two places, this is, indeed, a most astounding revelation; and, with your kind permission, I hope to prove, that, although socially very dear to each other, they have climatically but little in common. Augusta is built upon a marshy flat on the Savannah River, which at times overflows its banks, and submerges a portion of the city; while Aiken is located in what is known as the sand-hill region, five hundred and sixty-five feet above sea-level, which is higher than any other town or village within a radius of seventy miles. The soil of the latter place is dry and porous; and to obtain water, wells have to be sunk to a depth of from a hundred to a hundred and twenty feet; and there is no water-course within two miles of the town, and even at that distance there are but brooks or small creeks. The result of this absence of soil-moisture, and of large bodies of water, would of itself tend to diminish the amount of humidity in the atmosphere; but this is still further diminished by the absence of any hill or mountain to interrupt the free circulation of the wind. Augusta, on the contrary, is situated, as before stated, on a plain lying between a range of hills and the river. All this would lead one to expect that the climate of Aiken would be extremely dry; and that this is really the case is proved by carefully conducted observations extending over many years, which show that the average relative humidity, fifty-eight per cent, is lower than that of any other station east of the Rocky Mountains, and eleven degrees less than the figure given by Dr. Fisk as the mean of four years' observation at Augusta. As further proof of the dryness of the atmosphere of Aiken, I would direct attention to the absence of mould on boots and shoes, and to the fact that guns, and even delicate surgical instruments, may be exposed to air for months at a time without rusting. There are many other differences between the climates of Aiken and Augusta; but the above is sufficient to show that Dr. Fisk has indulged in an inference, when, with a little trouble, he could have obtained facts, the meteorological data for Aiken being on file at the office of the chief signal-office, U. S. A., since the establishment of that bureau, and prior to that time at the Smithsonian institution, not to speak of various publications on the climate of Aiken, which have appeared in the different medical journals of the country.

Aiken, S.C., Nov. 5, 1883.

On the possible connection of the Pons-Brooks comet with a meteor-stream.

I desire to call attention to some slight evidence of the existence of a meteor-stream which may possibly stand in some sort of connection with the Pons-Brooks comet. From an examination of all the available material of published meteor-tracks in the interval Dec. 5–8, I find, that after excluding those manifestly emanating from the well-known and active radiants in Andromeda, Gemini, and Taurus, there remain twenty-three meteors observed by Heis on Dec. 8, — about two-thirds of them in 1847, and the rest in 1855, 1857, and 1867, — and ten meteors observed at Vienna, Dec. 7, 1868; all of which indicate a strongly marked radiant in Draco. From these data I have carefully determined the position of this radiant, as follows: —

	R. A.	Decl.	Long.	Lat.
10 meteors on Dec. 7,	198.0°	+72.0°	135.0°	+65.6°
23 meteors on Dec. 8,	190.0	+69.7	137.2	+62.4

and from these I derive the following orbits, to which I add for comparison that of the Pons-Brooks comet.

	Meteors of		Pons-Brooks comet.
	Dec. 7.	Dec. 8.	
T = Perihelion passage.	Dec. 28.	Dec. 23.	1884. Jan. 25.82.
Long. of perihelion .	44.5°	55.1°	93° 21′
Long. of node . . .	256.1	256.3	254 6
Inclination	68.5	72.7	74 3
Log. per. dist. . . .	9.9600	9.9784	9.8894
Eccentricity	–	–	0.9550

The resemblance is thus not sufficient to give any considerable probability to the hypothesis of an intimate relation. On the other hand, the position of the radiant from present data is too uncertain to enable us to pronounce against that hypothesis.

The differences in inclination and longitude of perihelion are not greater than are due to uncertainty in the observed radiant points: the T and the node are, of course, of no significance in the comparison. The descending node of the comet's orbit lies at the distance 0.200 inside the earth's path, and the difference of the perihelion distance of the comet and the meteors is about 0.15. There is nothing in our present knowledge of the dimensions of meteor-streams, or of the nature of their relations to comets, definite enough to render such a breadth as is here implied evidence against a possible connection. On the whole, therefore, it appears desirable that meteor-observers should give close attention to the radiant in question about the date of the earth's passage through the plane of the comet's orbit, Dec. 5 to Dec. 7. Observations this year are likely to prove especially instructive on account of the proximity of the comet, which passes the node only a few weeks later.

Prize-essays on the experimental method in science.

Dr. Maurizio Bufalini, an Italian *savant* who died nearly ten years ago, left provision in his will for the payment of a prize to the person presenting the best essay on the subject of 'the experimental method in science' to the section of medicine and surgery of the Royal institute of higher studies at Florence. The essay must be written in Latin or Italian, and be presented to the chancellor of the section of medicine and surgery on or before the 31st of October, 1884. The prize is five thousand francs.

The institute has declared that all persons are at liberty to compete for this prize; and accordingly the representative of the Italian government, acting under instructions from that government, forwarded to our Department of state a programme giving in detail the subject proposed for the essay, and the conditions to be followed by the competitors, with a request that it be brought to the attention of Americans. The programme has been forwarded to the Bureau of education by the Department of state, and will be published as a bulletin as soon as practicable. In the mean time, such information, relative to the matter, as the Bureau of education possesses, may be obtained by addressing Gen. Eaton, commissioner of education, Washington, D.C.

The model of Architeuthis at the Fisheries exhibition.

In the number of SCIENCE for Nov. 9, you have copied without correction a photograph of part of the London International fisheries exhibition, which shows my model of Architeuthis wrongly put together. For convenience of packing, the tentacular arms were made to take apart in three pieces; but, when the model was set up, the basal and terminal pieces were put together, making the tentacles ten feet too short. The man who had charge of the work, not knowing what to do with the remaining pieces, stuck them in at the sides of the mouth, thinking that he might find in some other box a pair of terminal clubs to put on them. In this way the model was left at the opening of the exhibition, until some visitor happened to notice the mistake, when, I believe, the extra pair of arms was taken out, leaving the tentacles still too short.

J. H. EMERTON.

New Haven, Nov. 11, 1883.

A strange sassafras-leaf.

The observations upon the sassafras-leaves — a report of which appeared in Science, no. 36 — have been continued through the year, with results which do not differ materially from those already given. Three other forms, however, have been found, which are given in the accompanying outline-engravings. Fig. 1 shows a peculiar modification of the three-lobed form, and differs from it in having the main central lobe reduced to a slightly raised emarginate end to the leaf. At first sight it seemed as if the leaf had lost its middle lobe by some foraging animal; but the absence of any roughness in the outline, and other characteristics of the edges, preclude this view. The form shown in fig. 2 helps to confirm the above view. In this we have a three-lobed form, with the lateral lobes unequal, and the central and upper portions of the leaf inverted heart-shaped (obcordate). The mid-rib has stopped short, and divided into two equal parts, which run to the tips of the two diverging lobes. If this failure of the mid-rib to extend had taken place earlier, a leaf might have been produced similar to the one shown in fig. 1.

The most interesting of the three new forms is shown in fig. 3. Here we have a happy combination of the three-lobed and the 'mitten' form. The manner in which this has been accomplished is simple, and is fully shown by the outline given. The middle lobe has become lobed upon one side, — a 'thumb' has formed; and, were the lower portion of the leaf removed, it would leave a 'mitten' of good shape. The whole framework of the leaf has become somewhat distorted: the mid-rib does not take a direct course; and the lower lobes are neither equal, nor at the same distance from the base of the leaf.

It is due the reader to state that these three forms were all found upon the same shrub, — not a large one, — and that only a single specimen of each was discovered. These were all upon the same branch, though scattered among fifty or so of leaves of the three forms before described, and which, from their uniform presence, may be considered normal. How

3.

1.

shall these deviations be viewed? Is the foliage of the sassafras passing through a period in which different forms of leaves are being tried to see which is best adapted to the surroundings? It may be that there is a tendency from the simple towards the more complex; and fig. 3 shows the form which may be finally adopted. This is a subject about which even the philosophic botanists know but little; but, when one finds these deviations from the common form, he cannot help wondering after what end the plant bearing them is striving. BYRON D. HALSTED.

The thickness of the ice in New England in glacial times.

In the issue of SCIENCE for Sept. 28, Professor Wright corrects a reported statement of what he said about the depth of ice over New England, changing 600 feet to 6,000 feet, and giving as proof the well-known fact that Mounts Mansfield and Washington show ice-action to a height *above sea-level* of between five and six thousand feet.

It seems to me that the depth 600 feet must be more nearly correct than 6,000 feet. The ice-sheet over New England must have had a thickness equal to the height of these mountain peaks above the level of the contiguous valleys. From the nature of the case we cannot well prove a greater thickness, though from theoretical considerations we may believe the ice to have been much thicker. 4,370 feet, the approximate difference between the top of Mount Washington and the Crawford House, must cover the greatest differences in elevation between neighboring valleys and mountains. The average thickness of the ice-sheet must have been much less (from this proof), possibly not more than 1,000 feet. This thickness would accord with what is believed to be the thickness of the ice to the north-westward.

The glacial striae and drift-bowlders upon Mount Washington at an elevation of 6,000 feet do not necessarily lead to the supposition that the upper ice-surface had that level in northern New England, and a greater elevation to the north-westward; for local accumulations of snow and consequent ice must have existed about the summits of the White, Green, and Adirondack Mountains, as in Switzerland and in Greenland at the present time, and have constituted the source of much of the ice which spread southward over southern New England and New York.

L. C. WOOSTER.

Eureka, Kan., Nov. 7.

Museum of the Indiana university.

In the account of the burning of the museum building of the Indiana university, given in SCIENCE for July 27, are one or two errors which need correction.

The Owen collection of minerals and fossils was not entirely destroyed. Eight large cases, including the great majority of the typical specimens of David Dale Owen, were saved. The very perfect skeleton of Megalonyx Jeffersoni was also saved.

No specimens belonging to Yale college or to Cornell university were in the museum at the time of the fire. About two thirds of the very large collection made by Professor Gilbert on the Pacific coasts of Mexico and Central America were destroyed; the remaining third having been returned to the U. S. national museum, to which institution it belonged.

A new fire-proof museum building is to be erected at once, and the restoration of the collections lost is rapidly progressing. D. S. JORDAN.

THE FISH-COMMISSION BULLETIN.

Bulletin of the U.S. Fish-Commission, vol. ii., for 1882. [Edited by CHARLES W. SMILEY, A.M.] Washington, *Government*, 1883. 467 p., illustr. 8°.

IN looking over the pages of this book, we find several papers of marked scientific value, written by eminent specialists in biology and fish-culture, — articles which of themselves are sufficient to give this document a prominent place upon the book-shelves of naturalists, and to render it a valuable book of reference, especially to embryologists and fish-culturists.

The articles written by J. A. Ryder deserve prominent notice; for not only do they have an important bearing upon the subject of embryology, but they also show the importance of scientific treatment in hatching and maturing fish-eggs. The two most important papers by this author are, 1°, The absorption of the yelk in the embryo shad; 2°, Microscopic sexual characteristics of the American, Portuguese, and common edible oyster of Europe compared. Several smaller papers by the same author have especial bearing upon the successful hatching and rearing of the food-fishes of the Potomac.

The papers upon the distribution and specific character of fishes, with descriptions of new species, will be of special interest to systematic ichthyologists. A large part of the book is composed of letters of greater or less importance, written to the commissioner, mainly relating to the movements of fish in certain districts. We are of the opinion that a great many of these letters might have been left out entirely, without any serious loss to science. They might at least have been judiciously cut down, and published together as a series of notes; thus giving the important points, and omitting the great preponderance of useless words and sentences which one so frequently finds in these letters. The last article in the book is entitled, "A geographical catalogue of persons who have stated that they are interested in fish-culture," by C. W. Smiley.

Sandwiched between these various papers, we find one, which, in our estimation, is grossly unfit for a scientific publication of such a high standard. The title of this article is 'Life in the sea,' by J. B. Martens. It is a translation from the Dutch; and the author is teacher of natural sciences at the seminary of St. Nikolas, Belgium. From beginning to end, it is an absurd misrepresentation of facts, and deserves the severest condemnation. For instance: we find in the introductory paragraph the statement that "life in the sea shows still greater abundance and variety" than life on the land. We cannot understand why such an article should be translated from a foreign language at considerable expense to the commission. To say the least, it shows a lack of discretion on the part of the editor; for, were articles of a popular nature desirable, it would not be necessary to incur the expense of translating, since hundreds of popular articles, with fewer misrepresentations, and of far more scientific import, could be found in our ordinary newspapers, and published with much more credit to the commission. When, moreover, it is an open secret that there are papers of real scientific value, written by eminent naturalists, kept waiting for an opportunity of appearing in one of the Fish-commission publications by the great mass of material to be issued before them, the folly of burdening the pages of the Bulletin with material of this kind becomes only too evident.

BRIGGS'S STEAM-HEATING.

Steam-heating: an exposition of the American practice in warming buildings by steam. By ROBERT BRIGGS. N.Y., *Van Nostrand*, 1883. (Van Nostrand's science series.) 108 p. 24°.

THIS little volume is one of the latest issues in the 'Science series,' and is one of the most valuable of a collection of monographs which includes an unusual proportion of excellent contributions to science and to engineering literature. The author of the paper, Mr. Robert Briggs, who died just before the publication of this last of his many papers on the science and the arts of engineering, was well known, both at home and abroad, as one of the ablest writers in the profession. This paper was written as his last annual contribution to the proceedings of the Institution of civil engineers of Great Britain, of which great association he had long been a member.

The subject of steam-heating is here treated from a purely practical stand-point, and the paper is full of useful information. An historical introduction is given, in which the introduction of this method of heating dwellings is ascribed to the late Mr. Joseph Nason of Boston, who was a pupil of the celebrated Jacob Perkins. Later, Messrs. Walworth of Boston, Gregg and Morse and Professor Mapes of New York, Greenwood of Cincinnati, and Tasker of Philadelphia, were influential in perfecting the system in the United States.

In heating by steam, welded wrought-iron tubes are employed, united by a system of screw-threads, which have been brought to certain standard forms and dimensions peculiar to the trade. The size of the tubes, and their thickness, are also fixed in accordance with settled standards. Tables are given of these sizes. The forms of the various kinds of couplings and other uniting parts are prescribed by standard practice, and the author gives tables of their principal dimensions.

The steam-boilers in use in steam-heating are usually, in the United States, either the common horizontal tubular boiler, or that form of the so-called sectional boiler known as the 'Babcock & Wilcox.' Both of these boilers are stated to be practically safe from disastrous explosion. Probably one-half of all the boilers in use are of the first type.

The two methods of heating most in vogue are that in which 'live' steam is carried direct from the boiler to the heating-pipe, and that in which 'exhaust-steam' from a steam-engine is employed. Both systems are often in use together. Several methods of application of the former system are practised, all of which have advocates among old practitioners. Loss of heat by conduction and radiation from the heating-pipes, where such disposition of heat is likely to be objectionable, is prevented by the non-conducting coverings, such as hair-felt, porous plaster, etc.

The diffusion of heat in the apartments to be warmed is accomplished by the use of radiators. The communication of heat to the air to be warmed may be done either in the rooms to be warmed by it, or before the air enters the rooms. Direct radiation in the apartment is effected by the use either of series of pipes properly set, or of slabs of wrought or of cast iron, hollow, and strong enough to receive the pressure of steam safely. In many cases the heating-pipes are placed overhead, and this system has been found perfectly satisfactory.

Systematic ventilation is usually combined with steam-heating, and in large buildings the air-currents are produced by the action of blowing-fans. This method of heating and ventilating is often carried out upon a very extensive scale. A large office in New-York City contains 1,923,590 cubic feet of space, occupied by 1,300 people, and is heated by a system in which are used 8 boilers having 173 square feet (16 sq. m.) of grate, and 8,000 square feet (743 sq. m.) of heating-surface. The state lunatic-asylum of Indiana, at Indianapolis, contains about fifty per cent more space.

Steam-heating is now adopted in the United States for all large buildings. An appendix to Mr. Briggs's paper contains tables of the more important data in use in the computation of efficiency, etc. The book is likely to prove very useful to engineers engaged in this department of construction.

NEW-YORK AGRICULTURAL STATION.

First annual report of the board of control of the New-York state experiment-station, for the year 1882. Transmitted to the legislature, March 6, 1883. Albany, *Weed, Parsons, and company, pr.*, 1883. 156 p. 8°.

THE rapid multiplication of agricultural experiment-stations in this country during the last few years has been one of the most encouraging signs of the times to those who have at heart the advancement of agricultural science, and the application of rational and scientific methods to the prosecution of a calling which has contributed, and will in the future contribute, so much to our national welfare. Since the establishment of the first state experiment-station, somewhat more than six years ago, their number has steadily increased, until now there are seven such stations, besides some half-dozen institutions which are experiment-stations in fact, though not in name. Those who are familiar with the gain which has accrued to agriculture through the work of such stations in other countries cannot but be solicitous that the movement in our own land shall be wisely guided, and that every new station shall have a high ideal as regards the kind and quality of its work.

The first report of the New-York state experiment-station is worthy of more than a passing notice, for the reason, if no other, that it seems to enunciate a view of the duties of an experiment-station.

If we correctly apprehend the introductory paragraphs of Dr. Sturtevant's report, he holds that an experiment-station, or at least the station of which he is director, should select chiefly so-called 'practical' subjects for investigation; that is, as we understand it, subjects pertaining to the art rather than to the science of agriculture. This view has evidently been put in practice during 1882. Thus a large amount of work has been done in testing the comparative value of divers varieties of field and garden plants. Fifty-eight varieties of garden-beans have been grown; their times of vegetating, blooming, becoming edible, ripening, the number and weight of seeds produced per plant, etc., noted; and a detailed description of the botanical characters of each variety prepared. Many varieties of other garden-seeds have been compared in a similar manner; and the same is true of several varieties of maize, oats, and barley. Other subjects of a similar character are, the value, as seed, of butt and of tip kernels of maize, of whole potatoes and single eyes variously cut, of level and of ridge culture for potatoes, etc. We would not be understood as implying that all the work of the station is of this character, but it is plain that the tendency has been in this direction. The institution has been in many respects more nearly what is generally understood by an experimental farm than an experiment-station.

That the director of the New-York station should hold a view of the duties of an experiment-station differing from that generally entertained is, of course, no ground for adverse criticism, except in so far as it tends to obscure the signification of the name. Neither can it be claimed that the work done has not been well done, or is not useful; though we venture to think that much of such work must generally be published either too early to allow of its being properly verified, or too late to be of much service. What we object to is the deliberate and avowed adoption, by the largest and most liberally supported of the American stations, of what seems to us a low view of its duties to its constituents and to science, — a view which fosters the demand, on the part of the public, for a species of cheap experiments, easily and rapidly made, and of little permanent value.

An agricultural experiment-station exists for the purpose of investigating the applications of natural science to agriculture. It is primarily a scientific institution, concerning itself with the science and not with the art of agriculture, and, in our opinion, can only attain to the best and most enduring success when it keeps this fact steadily in view, and devotes its energies mainly to the discovery of new truths, and the verification of old hypotheses, in the science of agriculture. That a lower aim will prove more popular need hardly be said; and, since public institutions exist by popular favor, that favor must be secured in some way. Moreover, it is impossible to draw an exact line between experiments which advance the science and those which advance the art. At the same time, fully admitting that the work of an experiment-station ought to be guided by the desires of its constituents to a certain extent, we hold that it is equally its duty to guide and educate public opinion to the point of supporting it in undertaking work of scientific value.

We urge this, not simply because of the

advantages to science, both agricultural and to a less extent general, which would result, but because we believe such a course to be the only one which will lead to enduring popularity, or yield gains to agriculture commensurate with the outlay. We are confident, that, if Dr. Sturtevant will make it his avowed aim to do as much real scientific work as possible, the state will receive a far larger return for its outlay, and that within no long time it will acknowledge such to be the case; while the beneficial effects of such a course, in promoting an appreciation of and respect for true science among the people, would not be its least recommendation.

Agricultural experimentation is attracting increasing attention; and it seems important that a clear idea should be reached by those concerned in it of its proper aims and methods; and this can be attained in no better way than by a free criticism, on the part of all concerned, of methods and ideas which seem to them false or unwise.

HERRICK'S TYPES OF ANIMAL LIFE.

Types of animal life, selected for laboratory use in inland districts. By C. L. HERRICK. Part i., *Arthropoda.* Minneapolis, 1883. 33 p., 7 pl. 8°.

THE author says in the preface, that the notes which this work contains are only a small part of the material collected some years ago for a 'Laboratory assistant for western students, arranged upon quite a different plan.' During the delay in completing the proposed work, the great need of it has been in a measure supplied by recent works; but as these treat chiefly of marine forms, or such as require dissection, he has 'thought best to place at the disposal of students and teachers in summer science classes' his notes on such types as can be studied, while living, under the microscope. The types selected are the larva of Corethra, Canthocamptus, and Gammarus, which are described, without directions to the student, or explanations of methods of work.

A text-book of this kind ought to be clearly written, and accurate, a model for the student: but Mr. Herrick's work is far from this, and no better than we might expect to find the rough notes of the student in a 'summer science class.' The description of the heart of Chironomus, on p. 7, is throughout almost or quite unintelligible, and ends with the statement that 'the last chamber is closed behind, and has the ostia quite a distance beyond.' On p. 25 we have the opening of the green or antennal gland of Gammarus described as 'an auditory or other sensory organ;' and on plate 8, an antennula, or first antenna, figured, for comparison, as the 'second antennae of prawn, with auditory sac and secondary flagellum.' The Copepoda are Mr. Herrick's specialty, and so we naturally turn to the chapter on Canthocamptus for better work: but in the first paragraph we are told that the Copepoda are divided into three sections, — Gnathostoma, having 'the mouth-organs in the form of jaws;' while 'the other sections, Poecilostoma and Siphonostoma, have the mouth-parts more or less modified for piercing or sucking.' The student may search long and unsuccessfully to discover what the 'Poecilostoma' may be. In this chapter, also, we naturally look for some account of the 'heterogenesis' of which Mr. Herrick has written elsewhere, and find the following: —

"The young of Canthocamptus become fully developed sexually before they assume their final form; and it is not unusual to find females bearing egg-sacs which are not only much smaller than the parent, but with considerable differences in the various organs. This sort of heterogenesis is not uncommon among lower crustacea, for the mother may differ much from the young till after they have themselves produced young."

Grammatical, verbal, and typographical errors so abound that it is needless to point them out. The illustrations, engraved by the author himself, are for the most part far from accurate, and very rude.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

ASTRONOMY.

Photographing the solar corona without an eclipse. — Dr. Huggins has continued his experiments on this subject during the past season. He has made use of a fine seven-and-a-quarter-inch speculum by the late Mr. Lassell (loaned for the purpose by Miss Lassell). Three inches and a quarter of the central portion only are employed, the light being received a little obliquely, so as to throw the image to one side, as in the Herschellian telescope, thus avoiding a second reflection. The absorbent screens of potassic permanganate, or blue pot-glass, have been dispensed with, and an emulsion, prepared specially for the purpose by Capt. Abney, and containing only chloride of silver, has been generally used for the sensitive plate. This film is said to be sensitive only to rays between h and H, or at least to be only slightly affected by rays of either higher or lower refrangibility. Between April 2 and Sept. 4, fifty plates have been exposed on fifteen different days; and all of them are said to show a more or less distinct coronal appearance around the sun.

The plates have been put into the hands of Mr. Wesley, the celebrated engraver, who made the magnificent plates of Mr. Ranyard's Eclipse volume; and he has prepared for each day a drawing of what he could make out on all the plates taken on that day. "This was desirable," as Dr. Huggins says, "because, whenever sufficient duration of sunshine permitted, photographs were taken on silver-bromide films as well as on silver-chloride plates: some photographs were taken with the sun screened off by a brass disk (close to the plate), others without it: also photographs were taken with the sun in different portions of the field. As a rule, Mr. Wesley has introduced into his drawings only those coronal features which were common to all the plates taken on that day."

Four drawings were presented, each of them showing incontestibly details belonging to the lower portion of the corona. The paper was presented to the British association. — (*Brit. journ. phot.*, 1883, 575.) C. A. Y. [380

Saturn. — Dr. William Meyer of Geneva gives the results of a large series of measures of Saturn and his rings. The measures agree very well with those taken in 1880. He also determined the position of the belt in the southern hemisphere of the planet. Encke's division was observed several times, and its position seemed to be nearer the exterior edge on the left than it was on the right ansa. On one occasion the ball seemed of a grayish-blue tint, while the ring was glittering white in color. — (*Astr. nachr.*, 2,517.) M. McN. [381

MATHEMATICS.

Equations of equilibrium. — M. Appell remarks that the analogies between the equations of equilibrium of a flexible and inextensible thread, and the equations of motion of a point, have long been noted, but that no one has put these equations of equilibrium into their canonical form, which would permit the application of Jacobi's principles. M. Appell considers first the case of a free thread acted on by forces possessing a potential, and transforms the equations of equilibrium into forms analogous to those giving the motion of a point. He next introduces the notion of generalized co-ordinates, q_1, q_2, q_3, replacing x, y, and z. The transformations made here are quite similar to those given by Jacobi, in his *Vorlesungen über dynamik*. The author finally studies the position of equilibrium of a thread acted upon by the same forces as before, but constrained to lie upon a given surface. — (*Comptes rendus*, March 12.) T. C. [382

Parallel surfaces. — Mr. Craig gives expressions for the ratio between the corresponding elements of area on a given surface and its parallel. The relations between corresponding elements of length, and the relation connecting the measures of curvature on both surfaces, are also derived. The area of the parallel to the ellipsoid is obtained as the sum of the areas of the given ellipsoid, a certain derived ellipsoid, and a sphere whose radius is the modulus of the parallel surface. — (*Journ. für math.*, 1883.) T. C. [383

ENGINEERING.

Simple and compound engines on short routes. — Mr. Boulvin has determined a series of formulas expressing the relations between size of vessel, weights carried, and distances traversed, and the weights of the simple and the compound engine, and finds, that, for short routes, the best form of engine is the single cylinder rather than the compound. He finds that for lines from twenty to sixty miles in length, as those from Dover to Calais and from Ostend to Dover, a gain of a knot an hour may be obtained by the use of the simple engine instead of the compound, in consequence of the saving in weight of machinery. On long routes the economy is on the side of the compound engine, in consequence of the saving in weight of fuel. The later practice of English constructors has been in accordance with this result, and with the principles involved in the work of Mr. Boulvin. He constructs curves showing the equations graphically, and illustrates their use by examples. — (*Ann. trav. publ.*, xli.) R. H. T. [384

Transportation by steamers on the Rhone. — Mr. F. Moreaux has investigated the conditions of transportation by steam on the Rhone and other fast-running and shallow rivers, and has incidentally developed a new formula for the resistance of vessels, which he applies in his study of the best methods of transporting merchandise.

He takes an expression of the form

$$R = K_1 S' + K_2 \times \frac{l}{p} \times S'',$$

in which R is the resistance, K_1 and K_2 are numerical coefficients, S' and S'' are the areas of the middle body and of the tapered ends of the vessel: l and p are the length and the breadth of these ends. The values of the coefficients vary, according to stated conditions, from 0.10 to 0.22 for K_1, and from 0.48 to above 2 for K_2. They can only be used, evidently, in cases in which these conditions are definitely known. Where used as by Mr. Moreaux, however, they give very satisfactory results. The formula is applied to a river-navigation, now conducted largely with steamers about 135 metres long, 7 wide, 1 metre in draught, with 8 square metres area of immersed midship section, 1,100 square metres area of wetted surface, and 900 tons displacement. Their engines are of 1,150-horse power, and their speed is about 4½ metres per second. The current is, in places, nearly 4 metres. Mr. Moreaux concludes that the best system for such river-transportation is that in which is used what he calls the '*Bateau mixte a ancres*,' which is fitted as a towboat, but which is also supplied with anchors of peculiar form and of great holding-power, by which the tug may be held at the head of a rapid, and then, by hauling in a tow-line attached to the tow, bring the latter through into still water. Two such boats sometimes act alternately, the one hauling, while the other is getting a new position ahead. The advantages thus secured are, that the propelling craft is not detained at either end of the line of transportation; that transshipment and the breaking of bulk are avoided; that the rapids are surmounted with comparative ease; that canal-boats are thus transportable from river to canal, and the reverse, making long trips through river and canal, and thus saving expense of repeated handling of merchandise. This system is proposed for use between Arles and Lyons. The author proposes the connection of Arles and Marseilles by a canal, and the continuation of this system through the waterway thus formed. — (*Mém. soc. ing. civ.*, April.) R. H. T. [385

AGRICULTURE.

Hill-culture of potatoes. — Experiments by Wollny having led to the conclusion that hill-culture was superfluous, or even injurious, on light soils, Schleh has made experiments with potatoes which in general have corroborated Wollny's conclusion. — (*Biedermann's centr.-blatt.*, xii. 483.) H. P. A. [386

Proteine of maize-ensilage. — Stutzer finds, that, in the preparation of ensilage from maize, the proteine is largely broken up into products which are not precipitated by copper hydrate, and which are probably of inferior nutritive value. Jordan has made the same observation in experiments at the Pennsylvania state college. — (*Ibid.*, xii. 497.) H. P. A. [387

Nitrification in the soil. — Nitrification is dependent on the presence of oxygen, and Schlösing has shown that a diminution of the amount of oxygen present decreases the rapidity of the change. Such a diminution of the amount of oxygen in the soil is effected by the presence of organic matter, which unites with it, forming carbonic acid, and thus acts, as Déhérain and Maguenne point out, to moderate the rapidity of nitrification, and so to prevent a loss of nitrates in the drainage-water. The same authors explain in this way the greater richness in nitrogen of untilled land, and claim that the presence of organic matter is necessary in order that the soil shall gain nitrogen from natural sources. — (*Ibid.*, xii. 506.) H. P. A. [388

MINERALOGY.

Albite. — Des Cloizeaux gives the results of the optical examination of a large number of specimens of albite. Although this mineral is the most constant of all the felspars in its chemical composition, its variations in optical properties are great, and dependent upon the homogeneity of the material, the number and arrangement of the twin lamellae, and, without doubt, upon the circumstances of temperature and pressure at which the crystals were formed. The following are the properties of the purest and most transparent crystals, which may be regarded as normal: the plane of the optic axes is normal to a surface truncating the acute edge between oP and $\infty \breve{P} \infty$, and making an angle of 101°–102° with the base; the acute bisectrix is always positive, and nearly normal to the edge oP and $\infty \breve{P} \infty$; the axial angle for red in oil is about 80°–85°, ordinary dispersion $\rho < \nu$; the obtuse bisectrix is always negative; the axial angle for red in oil is about 104°–106°, ordinary dispersion $\rho > \nu$; basal sections give for the angle of extinction 2°–4° on either side of the plane of twinning; on the brachypinnacoidal section the angle of extinction is nearly 20°. The results of the examination of thirty-four different varieties of albite are given, many of them accompanied by chemical analyses. — (*Bull. soc. min.*, vi. 89.) S. L. P. [389

METEOROLOGY.

Meteorology in China. — Dr. Doberck of the Hong Kong observatory proposes to study the climatology of the region, to determine the magnetic conditions, and to investigate the magnetic attraction of various mountains and hills in the vicinity. It is probable that he will endeavor to arrange for the receipt of regular reports from neighboring observatories with the object of making weather forecasts. — (*Nature*, Sept. 27.) W. U. [390

Hygrometer studies. — A good hygrometer which can be used in place of the wet- and dry-bulb thermometers, and be equally convenient, but more accurate in cold weather, is one of the needs of practical meteorology. Comparative observations of the psychrometer and the improved hair hygrometer, as manufactured by Höttinger, have been made at Breslau by Dr. Galle since 1880. As a result, he states, that if the saturation-point is determined at intervals of from eight to fourteen days, and the instrument carefully cleaned when necessary, the relative humidity can be obtained with as great accuracy as with the psychrometer, and in winter with greater accuracy. Unfortunately, there still remains in the instrument the liability to unexpected changes in the saturation-point, and in the working of the mechanism; so that a psychrometer must be at hand for the purpose of comparison. — (*Preuss. stat.*, lxxi.; *Ergeb. met. beob. königl. met. inst.*, 1882.) W. U. [391

GEOGRAPHY.

(Asia.)

Investigations in Thibet. — At the suggestion of Gen. Walker, geodesist-in-chief to the survey of India, an interesting exploration is about to be undertaken by one of the pundits attached to the survey. This pundit was a companion of the famous Nain Singh, and succeeded, in the midst of a thousand obstacles in the eastern part of Thibet, in recording and preserving his itineraries, and obtaining many latitude observations. Thanks to his researches, an area three times as extensive as France can be to a certain extent corrected, and mapped with tolerable accuracy. The great Thibetan problem as to the relations of the Dzang-bo River are probably settled by his work, from which it would appear that this belongs to the head waters of the Brahmaputra rather than (as formerly supposed) to the Irawadi River. — (*Bull. soc. géogr. Mars.*, June.) W. H. D. [392

(Africa.)

Sociology of the Kabyles. — M. Sabatier, who has long been a resident of Algeria, and served as a judicial officer among the Kabyles, gives the following details as to their civil and social organization. These people, sharply distinguished from the Arabs, are of the Berber race, and number about three hundred thousand.

The villages are associated in governmental groups of not more than twenty settlements each. Such a group is termed a kabila. The supreme chief, or magistrate, of the kabila, is the amin. There is always another chief called ukil, charged with defending the rights of the minority of the electors. In each kabila the karuba, of forty or fifty male adults, forms an electoral body. The right to vote, or the attainment of individual majority, is decided in a singular manner. A thread is measured off, which, when doubled, shall exactly encircle the neck. This thread, made single, is then passed from the occipital base of the head over the cranium; and, when the other end reaches only to the chin, the development of the head is supposed to be complete, and the individual politically mature. This ordinarily happens about the age of fourteen. Each karuba has a distinct jemmáha, a sort of municipal council, presided over by a tamen. The tamens, all together, form the general council of the kabila, which, with the ukil and amin, forms the administration. The rights of minorities in each karuba are carefully guarded. The minority is called the saf, and may elect a chief, who serves one day to redress grievances, after which he retires to his private station. They have no prisons. The grand council may banish a criminal, destroy his house, burn his clothing, or order him, as a last resort, to be stoned to death. The council directs all municipal matters. If hostilities break out between two villages, and blood is shed, neighboring villages generally intervene by proclaiming anaya. This anaya is an invitation to cease hostilities, which the combatants dare not disregard. Were it disregarded, it would be considered an extreme insult to the safs of the peace-making villages, which all other village safs would be bound in honor to avenge.

The family organization of the Kabyles is unique. There is, in fact, no family, in our sense of the word. Such as there is, is terminable conditionally. A Kabyle who desires a wife says to her father and brother, 'You must sell me this girl.' The price is debated, and an agreement made before witnesses. Fifteen to forty dollars is the usual range. The money paid, he gives a dress to the bride, and all is done. The wife may be sent back without explanation, and the price reclaimed from her family.

If the wife quarrels with her husband, she may call upon a third person to proclaim anaya between them. The husband may then not only reclaim his payment to her family, but set on her head a price, often exorbitant, which any other lover must pay into his hands before he can take her to wife. The woman is then said to be 'retired from circulation.'

Children, if boys, are held in honor, representing one more vote and one more gun; girls must shift as best they may; at least half the Kabyle women live by gathering sweet acorns.

Kabyle law regulates the disposition of property. If a peddler possesses a field which he cannot use on account of the demands of his business upon his time, the law obliges him to plant it with olives. The property in such matters is wonderfully divided up: one man may own the fifth part of a field; another, a fifth of the crop of olives, or a third of the crop of figs; still another, the third branch of the fifth olive-tree, or that branch which points to the east.

In Kabylia the discoverer of a spring of water, even if situated in the field belonging to another person, owns the water from it. This tends to encourage the search for water, the most important element in that arid region. The Kabyles are excellent agriculturalists. If there is a spot of earth in a chasm, a Kabyle will descend by a rope and cultivate it. They are extremely industrious, and work in concert. In the Kabyle country, land suitable for cultivation is worth eighty dollars an acre, while in the Arab districts it does not average four dollars in value per acre, — a difference illustrating the respective characters of the two races. The question of ousting the Kabyles from the land they cultivate, to make room for French colonists, is being discussed in France: so it would seem that the Americans are not the only people capable of robbing the aborigines. — (*Rev. géogr.*, June, 1883.) W. H. D. [393

BOTANY.

Columbines. — Grant Allen (*North-American review*, September) traces several of the steps by which the typical ranunculaceous flower has been modified to form that of Aquilegia and the other more highly specialized genera. The more important are the elongation of the petal, which "is just the petal of the buttercup, with the tiny depression or hollow of the nectary prolonged backward into a tubular spur," as a protection against small, thieving insects; and the reduction in the number of carpels, without a corresponding lessening of the ovules, which insures a more certain fecundation of the latter. The fact that A. canadensis is even more perfectly adapted to pollination by humming-birds than by bees, seems, however, to have escaped him. Though more greatly modified, the hooked spur of European columbines is in no wise more perfectly adapted to the end it is to serve than the straight spur of American species. In his zeal for demonstrating the correlation of highly specialized forms and colors in entomophilous flowers, the writer is also led to ignore such species as the common European Aconitum lycoctonum, which, with the structure of its immediate relatives, has the much less specialized yellow color of those lying lower in the scale.

Dr. Gray (*Bot. gazette*, September) calls attention to the longest columbine (A. longissima), a species from northern Mexico, with spurs four inches or more in length, and clearly adapted to profit by the visits of some long-tongued hawk-moth like Amphonyx antaeus, which occurs in the south-west, and has been found by Mr. Henshaw to have a proboscis certainly five inches and three-quarters long. It should be stated that all of our American columbines that have been studied, whether fertilized by bees, moths, or birds, are strongly protandrous, like the European species. — W. T. [394

Symbiosis. — Dr. Sedgwick gives a well-written synopsis of the results of the more important recent studies concerning the occurrence of chlorophyll in animals, and its significance. These seem to show that the so-called 'animal chlorophyll' has no actual existence, being in every case (possibly excepting Hydra and Spongilla) connected with a vegetable structure living in the tissues of the animal. This association of plant and animal, in the mutual benefits derived, is held to be somewhat different from the so-called parasitism known in lichens; but it is hard to see in what important respect the two cases differ. — (*Pop. sc. monthly*, Oct.) W. T. [395

ZOÖLOGY.

Coelenterates.

The anatomy and histology of Porpita. — A diffused nervous system, made up of a plexus of scattered ganglion-cells connected with each other by nerve-fibres, and similar to that described in the Medusae and Actiniae by the Hertwigs, and in the Hydroids by Jickeli, Lendenfeld, and others, has been described by Chun in Velella. Conn and Beyer have independently discovered the same structures in Porpita; although they express some doubt whether they are really nerve-cells, rather than some form of connective-tissue corpuscle without any nervous function. They incline, however, to the belief that the close resemblance which they bear to cells which have been found in the Medusae and Actiniae justifies us in regarding them as a very primitive nervous system.

The cells in question are, in Porpita, ectodermal; and sections show that they lie actually in the ectoderm-cells, outside the supporting layer and the layer of muscles. They are always found in connection with the muscles, and they are most abundant where the muscular system is most developed. They are bipolar, tripolar, or multipolar; and their processes could be traced to a considerable distance. Their distribution is as follows: they lie wholly in the ectoderm; and their fibres, after running for a considerable distance beneath the outer ectoderm-cells and immediately upon the muscle-layer, finally penetrate this layer, and are lost. The whole of the upper surface of the animal is supplied with them, somewhat sparsely toward the centre, but much more abundantly towards the edge, and especially in the velum. The under surface of the velum has also a rich supply, and the tentacles also contain great numbers; but towards the centre of the lower surface of the disk they gradually disappear, and none could be found upon the nutritive zooids. They are everywhere few in number, as compared with the ectoderm-cells, and they are very irregularly distributed. There is nothing like a central nervous system, and no union of the cells into a nerve-ring could be made out. Conn and Beyer also describe a number of so-called 'sensory organs,' which are placed in pockets, or pouches, around the edge of the velum. Each of these is filled with large and highly modified ectoderm-cells, which the authors regard as sense-cells. They have no connection with the ganglion-cells. — (*Stud. biol. lab. Johns Hopk. univ.*, ii. 433.) W. K. B. [396

Mollusks.

Visual organs of Solen. — Dr. Benjamin Sharp had been led to believe that Solen ensis and S. vagina, the common razor-shells, are possessed of visual organs, by observing that a number of these animals which were exposed in a large basin for sale in Naples retracted their siphons when his hand cast a shadow over them. Repeating the experiment at the zoölogical station, he became convinced that the retraction was due to the shadow, and not to a slight jar which might have been the cause. Upon examining the siphon, he found as many as fifty fine blackish-brown lines or grooves between and at the base of the short tentacular processes of the external edge. When a vertical section of these pigmented grooves is made, the cells of which they are composed are found to be very different from the ordinary epithelial cells of the surrounding tissue. The pigment-cells are from one-third to one-half longer than the latter, and consist of three distinct parts. The upper ninth or tenth part of each cell is perfectly transparent, and is not at all affected by the coloring-matter used in making the preparation; the second part is deeply pigmented and opaque, and forms about one-half the cell; while the remainder consists of a clear mass, which takes a slight tinge when colored. This portion contains a well-defined nucleus filled with granular matter, and is probably the most active part of the cell. These retinal cells, if so they may be called, resemble those of the very primitive eye of Patella. The value to the Solen of an organ which would enable it to detect the shadow of approaching objects as it lies embedded in the sand, with the end of the siphon protruding, must be evident; and the structure of the cells described bear sufficient relation to those of the eyes in Patella, Fissurella, and Haliotis, to make it highly probable that they constitute true primitive visual organs. — (*Acad. nat. sc. Philad.*; *meeting* Nov. 6.) [397

Organization of chitons. — A second part of Dr. Béla Haller's valuable investigations of the chitons of the Adriatic has appeared. It is illustrated with three double plates; and the species which have served his purposes are Chiton siculus and C. laevis. This part is devoted especially to the finer structure of the buccal muscles, of the parts surrounding the mouth and below the radula, and the minute structure of the branchia. He confirms the conclusion of Dall in 1879, — that the separate branchial tufts correspond each to a distinct branchia, instead of to the old cyclobranchiate theory, — and adds very materially to our knowledge in each of the above-mentioned directions. The author wisely refrains from much theorizing, as no group of equal rank exhibits more polymorphism than this, and no general rules can be laid down with confidence from the examination of two species. — (*Mittheil. zool. inst. Wien*, v. heft 1.) W. H. D. [398

Crustaceans.

Trilobites from the Hamilton rocks of Pennsylvania. — Professor Angelo Heilprin has found in a small collection of invertebrate fossils obtained from the Hamilton rocks of the vicinity of Dingman's Ferry, Pike county, Penn., a complete specimen and several tail-pieces of Phacops bufo, and several well-preserved fragments of Homalonotus Dekayi. The determination of these species is of peculiar interest, inasmuch as it had been asserted that no trace of trilobites could be discovered in the rocks of this series. — (*Acad. nat. sc. Philad.; meeting* Oct. 30.) [399

VERTEBRATES.

Origin of fat in cases of acute fat-formation. — The chief part of this paper by Lebedeff is taken up with a discussion of the origin of the fat formed or deposited in the liver in phosphorus-poisoning. The author criticises at length the different theories of the origin of fat, under both physiological and pathological conditions. He does not admit the generally accepted theory of Voit, that the fats of the body form one of the products of the destruction of proteids, and gives some calculations showing the insufficiency of such an hypothesis to account for the amount of fat found in the liver and other organs after poisoning by phosphorus. His own view is, that, under normal conditions, the animal fat is derived directly from that taken into the body as food, while, in pathological cases, — fatty infiltration of the liver, for instance, — the fat originates from that already stored up in the body. The change in the chemical composition of the blood, produced by phosphorus, causes the fat in the subcutaneous connective tissue to pass into the blood, whence it cannot be removed on account of the diminished supply of oxygen, which is one of the results of phosphorus-poisoning, and therefore accumulates in the liver. Lebedeff has shown in a former paper, that when a dog is starved until all fat has disappeared from its tissues, and is then fed on foreign fats — linseed-oil, for example — and some proteids, there is a large accumulation of the strange fat in the body. Similar experiments were again made, with the addition that the animal was afterwards poisoned with phosphorus. Chemical analysis of the fat of the liver in such cases showed that it also, like the subcutaneous fat, contained a large proportion of the foreign fat. This fat could not have resulted from the destruction of proteids of the body, but must have been derived from fat already stored up in the body before poisoning, especially the subcutaneous fat. Lebedeff also made chemical analyses of the fats contained in the milk of the cow, woman, and rabbit, and compared them with the fats of other parts of the body. He finds that the 'fat of milk has no analogue in the body,' and consequently is not derived directly from these fats. He does not believe, however, that this fat results from proteid metamorphosis. The increase in the fat of milk, that takes place after feeding with meats, is owing, he thinks, to the fact that the albuminous material taken serves to emulsify the fats, and thus insures an easier passage from the blood. He comes to the conclusion that the fat of milk is directly influenced by the nature of the fat taken as food, and gives the results of some experiments demonstrating this fact. With regard to the origin of the milk-fat, his statements are not very satisfactory. It is derived directly, in the first place, from the fat of the mammary glands, with which it agrees in composition. This, in turn, is formed, he thinks, from the fats taken as food, or, in the case of starvation, from the fats stored up in the body. — (*Pflüger's archiv*, xxxi. 6.) W. H. H. [400

Mammals.

Vaso-dilators of the lower limb. — In previous papers, Dartre and Morat have shown that the view which was generally held of the distribution of the vaso-motor nerves — that the vaso-constrictors take their course through the sympathetic, the vaso-dilators through the cerebro-spinal nerves — is not true for the cervical sympathetic. They succeeded in demonstrating in it the presence of vaso-dilator nerves for the cheek, lips, etc. In the present paper they give the results of similar investigations upon the lower segments of the sympathetic, and the vaso-motors of the lower limbs. In order to estimate the vaso-motor effects, two methods were used. A manometer, or sphygmoscope, was connected with the femoral artery below the origin of the profunda; and, at the same time, the color-changes in the skin of the toes were noticed. Young dogs with little or no pigment on the feet were used. They first investigated the effect of stimulation of the peripheral end of the divided sciatic. In all cases the manometer showed a rise of arterial pressure, indicating that vaso-constriction had taken place; but, together with this general vaso-constriction of the blood-vessels, it was found, in some cases, that the balls of the toes were congested, showing local vaso-dilatation. If, instead of the sciatic, the abdominal sympathetic was divided at the level of the fourth lumbar ganglion, and the peripheral end stimulated, the same result was reached, — a general constriction of the arteries, together with a local dilatation of the skin of the toes. The latter phenomenon, as in the first experiment, was not constant. When the sympathetic was stimulated still higher, just below the diaphragm, the manometer gave a rise of pressure; but the dilatation of the vessels of the toes was more evident, and occurred in all cases. The interpretation they give to their experiments is, that vaso-dilator as well as vaso-constrictor fibres run in the sympathetic to the lower limbs; the vaso-constrictors predominate: hence the general rise of blood-pressure in the limb. The fact that the vaso-dilator effects are always obtained when the lower part of the thoracic sympathetic is stimulated, while in stimulation of the lumbar sympathetic and the sciatic this phenomenon is very inconstant, means, they think, that the vaso-dilators terminate, in part at least, in the ganglia of the lumbar sympathetic, and exercise their influence on the blood-vessels by means of these ganglia, and not through the hypothetical peripheral ganglia of Goltz. Facts of the same general import have been given before by the authors, with regard to the last cervical and first thoracic ganglia. — (*Arch. de physiol.*, 549, 1883.) W. H. H. [401

Sexual variation of Rhytina. — Drs. Stejneger and Dybowski have given in two different journals a preliminary account of their joint discovery of a remarkable variation, supposed to be sexual, occurring in the skull of the arctic sea-cow. Their conclusions are based upon an examination of five adult male and three adult female skulls. The male skulls have the zygomatic arches both absolutely and relatively wider than the female skulls. The whole central portion of the former, also, is wider than that of the latter. In the female the vertical ramus of the mandible is longer than in the male, and the posterior angles are much nearer together. It appears that these differences have long been recognized by the Eskimo. — (*Proc. U. S. nat. mus.*, v. 79 ; *Proc. zoöl. soc. Lond.*, 1883, 72.) F. W. T. [402

ANTHROPOLOGY.

The death of King M'tesa. — Col. J. A. Grant, once the guest of this renowned king of Uganda, gives credit to the report of his death, published in the daily papers of the 13th of July. Some years ago the king was suffering with a malady which the missionaries believed would terminate fatally unless an operation was performed. The king was dissuaded from this; though the Africans, as a rule, operate upon one another without fear. When Speke and Grant visited him in 1862, he was a minor, the lineal descendant of a line of thirty-five kings, which accounts for the 'blue blood' and vanity which certainly ran in the veins of M'tesa. Col. Grant alludes to the princes of Uganda, whom Stanley saw in chains, as following a custom by no means irksome, to which M'tesa himself had submitted previously to his election. The vigor with which he administered his government, and his courtesies to travellers, have given him a world-wide reputation. He raised his subjects above the ordinary scale of Africans by making them observe while travelling. He fearlessly adopted the Mahometan, and afterwards the Christian religion, by listening to the Mollahs and Christian travellers who entered his country; his previous belief having been in one supreme being and in charms. To M'tesa is greatly due the discovery of the sources of the Nile; for it was he who gave us the route from the Victoria Nyanza to Egypt, and the knowledge that we have of the people, and the flora and fauna, of equatorial Africa. The army and navy of this king is said to have numbered 125,000 soldiers. His government was carried on by daily durbars, where several hundred chiefs of districts assembled with their followers to hear the eloquence of the prime-minister and members of the government. — (*Proc. geogr. soc. Lond.*, Aug.) J. W. P. [403

The tribes of the Cunéné, S. W. Africa. — The earl of Mayo, having spent the best part of a year in Mossamedes and its vicinity, gives us the benefit of his experience. Not much new information is conveyed about Portuguese rule; but a very interesting account is given of a colony of Boers, at Humpata, who, with their wives, children, and cattle, had trekked from Pretoria in the Transvaal, and reached his place after seven years' wandering. The negro tribes encountered were: 1. The Mundombes, holding the region from Mossamedes to Capangombe, at the foot of the Sierra de Chella. They have a language of their own, and belong to the Bantu family. They are large cattle-keepers, and are the native porters who carry travellers' luggage as far as the top of the Sierra de Chella. 2. The Munhanecas and Quipongos, tribes who inhabit the country around Humpata, Huella, and three days eastward. They are of the Bantu stock, cultivate the soil, and are armed with poisoned arrows, assegais, and knobkerries. 3. The Chibiquas, who live on the west slope of the Sierra de Chella, north of the Cunéné River. They belong to the Damara race, intermixed with Ovampos, whose language they speak. They capture the elephant by prodding the hind-feet so as to sever the muscles. The animal, thus brought to a standstill, is despatched with assegais. 4. The North Ovampos, who speak a dialect of the Damara language, and cultivate each an hereditary farm, having no communal farming, as the Hahé and Huilla natives. — (*Proc. geogr. soc. Lond.*, Aug.) J. W. P. [404

The Lolos of central China. — There is one indigenous tribe or people, now completely enveloped by a Chinese population, which has successfully resisted the wave of Chinese encroachment. They are termed 'Lolo' by the Chinese, 'Lo-see' and 'Ngo-see' in their own dialect. They inhabit a mountainous region on the Yangtsze, between 27° and 29° north. They make incursions into Chinese territory for blackmail and ransom, which they call 'rent,' and hold in slavery the Chinese then captured. We have the word of Marco Polo that "they are a tall and very handsome people, though in complexion brown rather than white, and are good soldiers." They never intermarry with the Chinese, even the Chinese female captives being given to the male captives as wives. Mr. Baber, who has closely studied these people, seeks to identify them with the *Colomon* of Marco Polo, and in the course of his argument makes some interesting statements respecting their burial-customs. They possess the art of writing; and Major-Gen. Mesny, of the Imperial Chinese army, some years ago obtained a thick folio manuscript from a tribe near Chenning, in Kuei-chou (25° north, 105° 40′ west). The work is bound in goat-skin with the hair on, and is written in the ordinary Lolo script, with illustrations of a crude and primitive nature, depicting human figures, animals, and plants. Mr. Baber pays a just tribute to Baron v. Richthofen and Col. Yule, in stating his conclusions respecting the Lolos. — (*Proc. geogr. soc. Lond.*, Aug.) J. W. P. [405

Ethnology of Timor. — In a letter addressed to Sir Joseph Hooker, in 1880, Mr. H. O. Forbes wrote from Sumatra, offering, if some assistance could be forwarded him, to attempt an expedition to Timor-laut. The British association granted the needed funds, and the trip was made. This island must not be confounded with Timor, lying to the south-west. A large collection of crania and culture-objects was made, and a vocabulary of several hundred words compiled. Among their customs described are their methods of dressing the hair, the clothing and ornamentation of the body, their agriculture, meals, fishing, armor, marriage, care of children, mourning, inheritance, oaths, government, slavery, physical characteristics, intellectual and moral qualities, pastimes, music, and calendars. Commenting on the paper, Prof. Flower stated, that, of the twelve crania, eight were brachycephalic, and of decidedly Malay type; one was dolichocephalic, prognathous, and with large teeth, indicating Papuan or Melanesian affinities; and the other three were more or less intermediate. Nearly all showed signs of artificial flattening of the occipital region.

Mr. Keane remarked that Mr. Forbes confirmed the prevalent opinion regarding the extremely complex nature of the ethnical relations throughout the whole of Malaysia and Polynesia. In Timor-laut, Papuan, Malayan, and even Polynesian tribes had here become intermingled in diverse proportions; the result being a distinctly mixed race, such as was everywhere in this region often designated by the inconvenient term of 'Alfuro.' Timor-laut, however, seemed to present the peculiarity that the various elements had not here become so completely amalgamated as in most of the neighboring islands. Hence the remarkable phenomenon of frizzly and lank hair, brown and black complexion, very tall and very short stature, dolichocephalous and brachycephalous heads, etc., all still found side by side in the same village community. The resemblance in so many of the crania to those of the brown Polynesian race of Samoa, Tahiti, Hawaii, etc., was very striking; so that Timor-laut must have been one of the last islands occupied by this race in Malaysia during its eastward migration to the remote archipelagoes of the Pacific. — (*Journ. anthrop. inst.*, xiii. 8.) J. W. P. [406

The Mavia tribe of negroes. — Cape Delgado is on the east coast of Africa, about 11° south. Mr. H. O'Neill, H.M. consul, has made a journey inland from this point into the country of the Mavias, or Mahibas, whose existence was first pointed out by Livingstone, and who have baffled the efforts of succeeding travellers to penetrate their country. Mr. Joseph Thomson and Mr. Chauncey Maples both testify to their exclusiveness. A description of one village will serve for all. A circular belt sixty to eighty feet wide was thickly planted with trees and underbrush. At two or three points a narrow path was left for entrance, and guarded by double or triple gates. The gate is a framework of two strong uprights, deeply embedded in the ground, and strengthened by two horizontal bars about five feet apart. Two other movable horizontal bars fit, one end in a hole, the other in a niche in the uprights. A number of smaller uprights have holes burnt through both their ends, by which they are threaded upon the two horizontal bars until the framework is completely closed, when the ends are thrust into the holes and niches, and the whole strengthened by beams placed against it on the inside. The gates are carefully closed at sunset. Forty or fifty huts are built in the space, and goats and poultry take the place of the Irishman's pig in each shanty. This tribe wear immense lip rings or studs, which give to them a hideous profile. They show a great respect for the dead, and carefully tend the graves of any of their chiefs or head men. On some of these are raised mounds of clay, enclosed with a low ridge. This again had a raised framework upon it, roofed in with thatch, and the corner posts ornamented with small streamers of cloth. Mr. O'Neill appends a vocabulary of about a hundred words. — (*Proc. geogr. soc. Lond.*, July.) J. W. P. [407

EARLY INSTITUTIONS.

French and English law. — Some time ago the Institute of France proposed as a subject for competitive writing a comparison of the French and English systems of law in their history and development. An extensive work (5 vols. 8°) was forthwith produced by M. Glasson. It was accepted and 'crowned' by the academy. It is entitled *Histoire du droit et des institutions politiques, civiles, et judiciaires de l'Angleterre, comparés au droit et aux institutions de la France, depuis leur origine jusqu'à nos jours*. The book is being reviewed, and is much praised. The student who finds Reeves' History of the English law obsolete and tiresome will be glad to have a substitute for it. The writer takes up different subjects,—'the king,' 'parliament,' 'property,' etc., — and treats them separately. The sequence of events, and their relationship with one another, are by this method lost sight of to a certain extent. The method has its advantages, however; and a subject so comprehensive could hardly be treated, we should think, in any other way. It is quite impossible to bring history, with its innumerable beginnings and endings, or issues, into one continuous narrative. French history begins with the meeting of the Germans and the Romans. French institutions are, to begin with, partly German, partly Roman. English institutions are, however, almost purely German down to the period of the Norman conquest. It is in England, therefore, that we trace the development of German institutions, rather than in France. The monarchy, for example, was in France framed upon the Roman model; while in England the Teutonic model was adhered to. While we have an absolute monarchy in France, we have a very limited monarchy in England, — a democratic republic, with a monarchical head, so to speak. Feudalism is described as the result of German and Roman influences. It established itself in France, and was taken from France into England. The English were verging towards feudalism, to be sure. There was a good deal of feudalism in England before the conquest. The custom of commendation was not unknown, but it was not associated with the holding of benefices. The holding of *boc-land* under the *trinoda necessitas* resembled the holding of a benefice in later times; but the holders of *boc-land* were not vassals of a lord. Their services were due to the state rather than to the king. The king was not the universal landlord until after the conquest, when the Norman lawyers persisted in describing proprietorship as a tenancy. At the same time a great deal of proprietorship was converted into tenancy. The position of the isolated proprietor was unsafe; and proprietors very generally converted their inheritances into tenures, under the overlordship of the king or some other great lord. M. Glasson describes the various forms of tenure which existed under the feudal system, and the condition of the tenants. A large part of the work is devoted to legal procedure and judicial organization. — (*Edinburgh rev.*, July, 1883.) D. W. R. [408

NOTES AND NEWS.

The death of Dr. John L. LeConte at his home in Philadelphia on Thursday of last week, at the age of fifty-eight, removes one who has long been the leader, *facile princeps*, of American entomologists. With his death, the younger men are completely separated from the former generation of workers in this field, and they will lose a friend and teacher to whom they constantly looked. Dr. LeConte was as highly honored abroad as at home, and has been an active investigator for nearly forty years. His death occurred during the session of the National academy, of which he was a member, but was not known in New Haven until its close. We shall give in a future number an account of his services to science.

— President Arthur, in carrying out an act passed by Congress, has invited the various countries to send representatives to an International conference at Washington, the date of which is not yet fixed, to establish a common prime meridian. The governments of Austria, Norway, and Sweden, have declined; but the latter two approve of the object. Spain is favorable, but has deferred its reply. Belgium is uncertain, but Denmark and Portugal have accepted the invitation conditionally. Switzerland, Venezuela, Mexico, Turkey, Greece, China, Japan, Hawaii, Hayti, Liberia, Holland, Canada, Guatemala, Roumania, Nicaragua, and Honduras have accepted. Replies are expected from Italy, Great Britain, Russia, France, Chili, Brazil, and Germany.

— Mr. Edward Atkinson has prepared a plan for a textile laboratory and museum in Boston. He thinks that a hundred thousand dollars would be ample for the construction of a proper building, and its equipment, which should be an adjunct of the Massachusetts institute of technology. The purpose is to afford special training for young men intending to pursue textile manufacture. The first two years' course of instruction in the institute is suited as a basis for the future special study of textile manufactures; and it is in the next two years of the curriculum that special training should be followed. The first two years would ground the student in modern languages and mathematics, in mechanical drawing, in general geology and chemistry, as well as in the practical work of the physical and chemical laboratories, and will thus prepare him for entering upon the special course of textile industry. The professional studies would include geology, botany, mechanical engineering, building and architecture, mechanics, textile design in all branches, industrial chemistry, history, and political economy.

— Professor Balfour Stewart and Mr. W. L. Carpenter discussed, before the British Association for the advancement of science, the supposed sun-spot inequalities of short period. Putting aside for the time the question of true or nearly apparent periodicity, they exhibited certain results obtained by application of a method of detecting unknown inequalities in a mass of observations. Thirty-six years' observations of sun-spots were divided into three series of twelve years each. Two apparent sun-spot inequalities of about twenty-six days came out very prominently, appearing for each of the twelve years in the same phase, and to very nearly the same extent.

— A design for a new high-level bridge at Newcastle-on-Tyne has been prepared by W. G. Laws, city engineer. It shows a clear span of six hundred feet, and a clear headway above high water of eighty-two feet. The bridge will be of steel, and the cost of superstructure, foundations, and approaches, is estimated at two hundred and fifty thousand pounds.

— Sir J. Whitworth & Co. have lately completed and tested a 9-inch (23 centimetres) gun for the Brazilian government. The peculiar feature of this system is the hexagonal section of the bore of the gun. The material is compressed cast steel, which is superior to other steels in its combined ductility and tenacity, and in its perfect soundness. This gun, on trial, threw a shell of the weight of 300 pounds (136 kilograms) 7,876 yards (over 7,000 metres), and drove a steel shell weighing 400 pounds (181 kilograms) through a wrought-iron plate 18 inches (48 centimetres) in thickness; and its backing broke up a cast-iron plate supporting it, and finally buried itself in the earth. Such results are not attainable, so far as experience has yet indicated, by any other system of ordnance.

— An electric tram-car was recently tried in Paris very successfully. It was driven a distance of thirty miles in about three hours without accident or detention. The current was supplied by Faure accumulators placed under the seats, and driving a Siemens dynamo under the floor at the rate of twelve hundred revolutions per minute. The car-wheels turn sixty times to twelve thousand revolutions of the dynamo. The speed attained was five and a half to nine miles an hour, according to the gradient.

— In a paper before the British association, Professor Boyd Dawkins remarked that the classification of the tertiary rocks, sketched out some fifty years ago, and since then altered in no important degree, is out of harmony with our present knowledge, and the definitions of the series of events which took place in it has been greatly modified by the process of discovery in various parts of the world. The terms 'eocene,' 'miocene,' and 'pliocene' no longer express the idea of percentages of living species of fossil mollusca upon which they were founded; and post-tertiary, quaternary, and recent are founded on the assumed existence of a great break comparable to that separating the secondary from the primary or tertiary periods, which is now known not to exist. The author proposed a classification of the tertiary period in Europe by an appeal to the land mammalia, and since that time his definition has been found to apply equally well to the tertiaries of Asia and the Americas and to the late tertiaries of Australia. He stated that the forms of life in the rocks have changed at a very variable rate, and in direct proportion to their complexity of organization; the lower and simpler having an enormous range, while the higher and more complex have a much narrower range, and are more easily affected by the change in their environment.

—The proposed discussion on the possibility of establishing a universal time by selecting a meridian common to all nations has given rise to many suggestions more or less valuable. One of these, published in the *Journal of the society of arts*, is, that 'the simplest way of expressing this universal time would be by using Roman figures; while the civil time would be expressed by Arabic numerals, followed by a large *H* for the morning hours, and a small one for those of the evening. In fact, the hour would be expressed in a manner similar to that in use among the Russians for designating the old and new style in dates. In the same manner as they say 16/28 June, the railway time-tables would say, Arrival at Paris, XXIII./10 h. 24 m.; departure from Paris, XVI. 40 m./4 h. 04 m.; departure from St. Petersburg, VIII. 10 m./9 H. 26 m.

—At the meeting of the French academy of sciences, held Oct. 3, M. Alphonse Milne-Edwards reported the foundation of a new laboratory of marine zoölogy at Marseilles. It is to be under the direction of Professor Marion, of the Marseilles faculty of sciences.

—The periodicity of drought and floods in the Rhine district, and its connection with sun-spots, aurorae, and the magnetism of the earth, is dealt with in a work by Professor Paul Reis of Maintz, just published by Messrs. Quandt and Handel of Leipzig. The volume is entitled 'Die periodische wiederkehr von wassersnoth und wassermangel.'

— In Austria, as well as in Germany and England, systematic efforts are being made to settle the questions as to the contagiousness and heredity of tuberculosis. A circular has been sent to eight thousand medical men in Austria, requesting them to give particulars of any cases which they consider to have proved the contagiousness of the disease, and also to give the particulars of cases of supposed heredity, and of any cases in which complete cure is believed to have been effected. The determined international effort which is being made to cope with this fell disease must be regarded as one of the results of Koch's discovery of the Bacillus tuberculosis.

— At a recent meeting of the French entomological society, Dr. Laboulbène instanced a case in which dipterous larvae had been vomited by a woman thirty-nine years old, under the care of Dr. E. Pichat of La Rochelle. Specimens of the pupa, and of the fly hatched from them (Curtoneura stabulans Fall.), were exhibited to the society. The woman had been troubled for some days with bronchitis and very fetid breath, and finally, after a severe attack of coughing, vomited twice. Dr. Pichat afterward found in the basin used a hundred to a hundred and fifty of these larvae; and the circumstances as related by him leave no serious doubt of their source, though he was not present during the vomiting, but only called immediately after it.

This larva, according to Laboulbène, is well known, and is ordinarily found in decomposing animal and vegetable matter, in mushrooms, etc., and has also been reared from caterpillars and hymenopterous larvae.

The possibility of the existence of such flies (Muscariae) in the human body was formerly generally accepted, but has lately been denied by Davaine. Experiments have proved, says Dr. Laboulbène, that such larvae, introduced into the stomach of animals by a fistula, have been discharged alive in the excrement, one, two, or even three days later.

— At the meeting of the Engineers' club of Philadelphia, Nov. 3, Mr. Charles H. Haswell presented 'Notes upon roads, streets, and pavements;' Mr. E. A. Geiseler read an illustrated paper upon 'Tides, and Newton's theory of them;' Mr. Allen J. Fuller spoke of the 'Effect of frost upon fire-plug casings,' — a paper which will be noticed next week under the 'summary.' Professor Haupt also exhibited a 'History of the manual arts, or the inventions of human wit,' published by Mr. Herringman, London, 1661. The secretary read the following account from the *Mexican national* of Laredo, Tex., of a bridge construction by Mr. C. A. Merriam: "On the sixth day of September (the anniversary of loss of bridge last year) the Mexican national railroad-bridge was carried away by high water. On Monday the 16th the first pile was driven for the new structure, which was completed on the 23d; and trains are now running regularly. This is pretty quick work, — the erection of a bridge six hundred feet long in seven days."

The secretary narrated his experience on behalf of the club, and read extracts from correspondence, etc., with the custom-house, through the stupendous inscrutability of the management of which the Transactions of the society of engineers of London, and of the Institution of civil engineers of Ireland, are charged with duty; and all the other foreign societies upon the exchange list of the club are admitted free.

— *Scandinavia*, published in Chicago, is the title of a journal devoted to the interests of Scandinavian life, past and present. It is printed in English, and is intended to keep the American public informed as to the movements, both in politics and literature, among the people of Denmark, Sweden, and Norway. The first number is dated November, 1883.

— Lindström has published in the *Bihang* to the Swedish academy's *Handlingar* an annotated index to the generic names applied to the corals of the paleozoic formations. A list, by Dalla Torre, of the generic names given to Hymenoptera during the decade 1869–79, appeared in Katter's *Entomologische nachrichten* of last December.

— The *Humoristické listy* of Prag for Oct. 27 contains an excellent large portrait of the late Mr. Barrande. We shall publish one next week.

— The mathematical magazine conducted under the name of the *Analyst* for the past ten years, by Mr. J. E. Hendricks, will be continued under the editorial charge of Ormond Stone, professor of astronomy, and William M. Thornton, professor of engineering, with the title, *Annals of mathematics, pure and applied.* The numbers will be issued at intervals of two months, beginning Feb. 1, 1884. In scope the journal will embrace the development of new and important theories of mathematics, pure and applied; the solution of useful and interesting problems; the history and bibliography of various branches of mathematics; and critical examinations and reviews of important treatises and text-books on mathematical subjects. The office of publication will be at the University of Virginia.

— Dr. Macgowan recently sent a communication to the *North China herald* on the art of making luminous paint in the celestial empire. The Chinese, says Dr. Macgowan, used powdered mussel-shells instead of oyster-shells. The method seems to be ancient. The emperor, Tai Tsung, who flourished towards the end of the tenth century of the Christian era, received a picture which was luminous by night. The picture represented, by night, a cow lying within a fence; while, by day, the cow appeared as browsing outside of the enclosure. His Majesty asked for an explanation from his ministers, but they were no better informed than he. At length some one informed the emperor that the effect was produced by mixing Southern-Sea pearl-paste with a pigment which at night became luminous, and that the day-picture was made of a powdered reef-stone. In after-ages the picture was attributed to the genii, whilst some denied its existence altogether. Dr. Macgowan shows, by extracts from a Chinese writer of three centuries ago, that the tradition of the art had not died out.

— The meeting of the Philosophical society of Washington, held Nov. 10, was devoted to the consideration of geologic subjects. Mr. Edwin Smith exhibited a seismographic record obtained in Japan, and described the system of observations conducted by Professor Paul. Capt. C. E. Dutton read a paper entitled 'The volcanic problem stated,' and Mr. W. J. McGee made a communication on the 'Drainage system, and the distribution of loess, in eastern Iowa.'

— John T. Short, professor of history at the Ohio State university at Columbus, died Dec. 11, after a long illness. He was especially well known for his researches in the history of Central America. His 'North-Americans, and their early history,' passed through many editions.

— The papers read at the meeting of the Biological society of Washington, Nov. 16, were by Professor Lester F. Ward, Mesozoic dicotyledons; Mr. C. D. Walcott, Fresh-water shells from the lower carboniferous, with exhibition of specimens; Mr. Frederick W. True, Exhibition of a unique specimen of a West-Indian seal, Monachus tropicalis Gray; Dr. C. A. White, Persistence of the domestic instinct in the cat.

— An unpretending but useful little paper has been lately published as Bulletin no. 5 of the Illinois state laboratory of natural history, by N. S. Davis, jun., and Frank L. Rice. This paper contains concise descriptions of seventy-four species and sub-species of North-American batrachians, and fifty-four of reptiles, found east of the Mississippi. Analytical keys to the families and genera are given, but no synonymy. The classification and nomenclature are those of Professor Cope's Check-list, and the descriptions are in great part compiled from writings of the same author. There is, however, evidence of considerable study of specimens; and the collector of reptiles in the region covered will find this catalogue very convenient.

— A boy fourteen years of age was fishing at Tomioka, Nizen, Japan, recently, when his right arm was seized by a large octopus with two of its tentacles. His cries brought succor as he was being dragged into the water, and the tentacles were cut. The lad reached home; but his arm seemed paralyzed, and in five days death ensued, probably from shock.

— H. Schällibaum recommends a mixture of one volume of collodion with three to four volumes of oil of cloves, to secure microscopic sections in place upon the slide. The oil is evaporated over a water-bath, after which the sections may be stained, etc. An advantage is thus offered over Giesbrecht's shellac method. The full directions are given in the *Archiv für mikroskopische anatomie* (xxii. 689).

— Four mummies have been obtained from the Aleutian region for the Berlin museum. They are in a good state of preservation, and are believed to be of great age.

— M. A. Dumont has submitted to the Paris academy of sciences a suggestion for increasing the irrigating waters derived from the Rhone by regulating the discharge from the Lake of Geneva. This project, recommended by the Geneva commission, involves the expenditure of about £180,000, and the creation of a hydraulic force of 7,000-horse power, by which the level of the lake at high water might be reduced by at least 0.60 m., and the minimum discharge of the Rhone at the outlet increased by 80 mc. per second.

— The science of forestry has hitherto been much neglected in England: but the *Athenaeum* states that the proposal to hold an International forestry exhibition in Edinburgh during the summer and autumn of next year has been taken up with much earnestness; and the sum of £3,500 has already been obtained as a guaranty fund, without any direct appeal to the public at large. Besides specimens of forest produce, implements used in forestry, fungi, rustic work, etc., there will be a collection of illustrations of trees, scenery, forest labor, and the like, along with books, maps, and reports bearing on forest history, surveys, and the geographical distribution of trees.

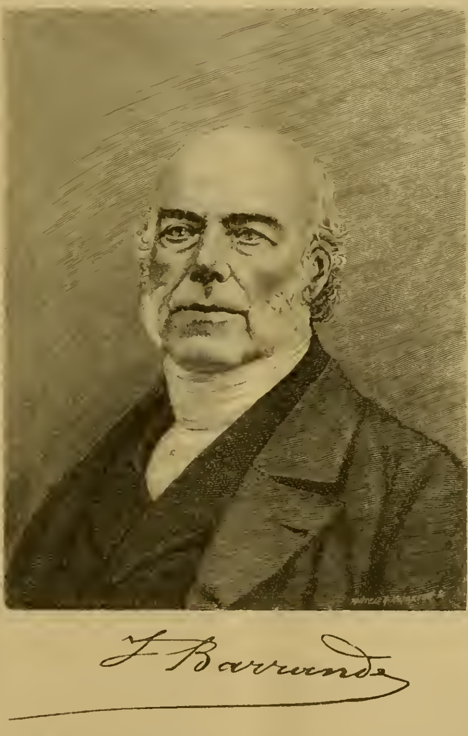
SCIENCE.

FRIDAY, NOVEMBER 30, 1883.

JOACHIM BARRANDE.

I., HIS LIFE.[1]

The death of Joachim Barrande, who for more than half a century has attracted the respectful regards of the world of science, severs the last link between the times of Cuvier and our own. The example of this noble life may be truly said to have borne threefold fruit. He was, after Cuvier, intellectually by far the most dangerous of the opponents of evolution. He was great in his works, and great in the example of a life devoted to research and to the service of his unfortunate sovereign. He belonged to that illustrious body of men who acknowledged Cuvier as their teacher of science; and, in order to understand him, one must recognize this, and also realize that to him loyalty was inseparable from faith and truth. The chivalrous side of his character is best illustrated by the reason which he gave for refusing peremptorily the high honor of an election to the French academy. He said simply that he had no desire for membership in a society with such avowed aims, but which had refused admission to some of his masters in science. — Alcide D'Orbigny, Deshayes, and Edouard Lartet, who had taught him all that he knew. He dedicated himself to science always without personal reservation; but his opinions were never free. He was bound by his loyalty to the memory of his masters in science, and by his faith in the doctrine of the divine right of kings; and both in science and in politics he remained throughout life a consistent opponent of the new theories of evolution and republicanism.



Born in the year 1799, in the town of Saugues, department of Haute Loire, we first hear of him in 1819, when he entered the École polytechnique of Paris, whence he graduated in 1821 among the first in his class, and then passed into the École des ponts et chaussées, graduating in 1824 with high honors.

[1] We are indebted to Professor Jules Marcou, an intimate friend of M. Barrande, for the personal facts in this notice.

During these five years he was assiduous in his attendance on the various courses of lectures given by Cuvier, Brongniart, De Jussieu, Constant Prévost, and Desfontaines, upon zoölogy, geology, and botany, and constantly visited the collections of the Jardin des plantes. After graduation he was appointed engineer at a small town in the basin of the Loire: and there, during one of the visits of Duc D'Angoulême, then the dauphin of France, he was presented to the duke; and any one who has ever had the privilege of Barrande's acquaintance will readily understand the favorable impression his character and attainments made upon his royal highness. Subsequently the young engineer became the most favored candidate of the dauphin for the office of instructor in science to his nephew, the Comte de Chambord, the grandson of Charles X.; and he secured this post for him. The unsolicited appointment to what was considered and sought by learned men as one of the highest honors in the gift of the king, reads like the climax of a fairy-tale; and like that, also, the daring of the young engineer in accepting the appointment had the happiest results for himself and for his royal charge.

The revolution of 1830 put an end to the reign of Charles X., and drove the elder branch of the Bourbon family and their faithful servitor into exile; and it was during the sojourn in England and in Scotland that Barrande perfected himself in the use of the English language. In 1832 they removed to Prague, and carried with them this man who was to make Bohemia classic ground for the geologists of all countries. Barrande found himself here in a new field, where all his previous education and preparation were at fault; but for a true investigator, such as he was, this merely excited the greater interest. He and his pupil began by collecting every thing in the vicinity; and then, little by little, their attention was irresistibly drawn to the fascinatingly rich deposits of Silurian fossils.

Their collections in time became too extensive to be accommodated in the halls devoted to study at the Chateau de Hradschin, and Barrande removed his collections to a house which he had purchased as a residence for himself. With immense labor, and without assistance from books, he built up the first steps of a classification by which he could arrange his collections in natural sequence and in their respective faunas. In 1840 he met with a copy of the 'Silurian system' of Murchison, and became assured of the fact that he was working among similar fossils and in the same geological period. This service was later gratefully and intentionally recognized in the general title of his works, 'Système silurien du centre de la Bohême.'

The royal family changed their residence, going first to Goritz, and then to Frohsdorf; but Barrande, though continuing to serve the Comte de Chambord, having exchanged the post of tutor for that of trusted friend and superintendent of finances, did not live in his household, being permitted to remain with his beloved collections at Prague. His duties, however, called him a part of the year to Paris; and he there leased apartments, first in the rue Mézières, and subsequently in the rue de l'Odéon. There are probably few geologists of reputation who have not, in passing through Paris, made these apartments a visit, and experienced the delight of being received by this stately and warm-hearted gentleman.

Besides the mastery of English, Barrande found it necessary to acquire German, which he spoke and wrote with facility, and also the Czech language, in order to direct and control the workmen employed by him as collectors of fossils. These men varied in number at different times, from six to twenty, and sometimes even to thirty. The practical difficulties which were overcome in this part of the work, and the anecdotes which might be related of the efforts made to deceive him about the localities of fossils, for which he had offered special rewards, would be instructive as well as amusing. We have, however, space only to relate that he acquired among his workmen the reputation of being a generous gentleman, but one of great firmness; and, being obliged also to account for powers beyond their comprehension, they attributed to him a mastery of the black art of divination, and a possible intimacy with the devil himself.

In finishing his work, neither money nor labor was spared: the best illustrators were constantly employed; and one, M. Humbert, became noted, lived constantly with him, and died in his employ after twenty-five years of service.

Barrande found it necessary to be his own publisher. He accordingly organized a French press at Prague; and the typography of his books justify his own assertion, that they could not have been printed with greater technical elegance by any press in Paris. We know from personal inspection that errors are very rare. The quotations, which generally show carelessness, if any part of a book does, excel in this respect; and the desire for correctness has been carried so far, that, instead of tables of 'corrigenda,' he has carefully corrected errors with printed slips pasted upon the pages of the text. All this was done while engaged in administering a fortune of about fifty millions of francs, and arranging many complicated questions of business connected with his position, and relations to the Comte de Chambord, which required much time, and many journeys to different parts of Europe. That this was accomplished successfully is shown by the terms of the will of this last heir of the elder Bourbons, who appointed him his executor. The expenses of the whole work were met by the personal sacrifice of his own income from all sources, but principally by the generous assistance of his royal friend. These presents were always made with the greatest delicacy by the count as his subscriptions to the 'Système silurien de la Bohême:' and Barrande has recognized their essential importance in dedicating each of his volumes to this generous patron, and also by a direct statement that his own labors would have failed but for this assistance. The world of science owes to the Bourbon family its perpetual recognition of this example of friendship and generosity, which has brought out to full fruition the life of one of its representative men.

No government can point to a finer single monument to science than this one, created by an exile in a foreign country; and the sums expended were large, since, as we are assured, the average cost of each of the twenty-two volumes, as estimated by Barrande himself, was not less than twenty thousand francs, making a grand total of nearly ninety thousand dollars for the parts published up to the present time. M. Barrande never married; and his only surviving relatives are a sister, Mme. Vuillet, and a brother somewhat younger, M. Joseph Barrande, a distinguished engineer.

It is impossible adequately to present a life so varied and so full of activity in every direction, at once scientific, and yet so picturesque from political and social stand-points. He had become, before his death, the only survivor of the ancient servitors of the royal house of France; and the cause, and even the surroundings, of his death, completed the beautiful picture of his life of voluntary exile and chivalrous service. He sacrificed himself to his duty as executor, and died from a cold contracted from exposure while engaged in carrying out the last wishes of the man who had been to him pupil, friend, patron, and rightful sovereign. His decease took place Oct. 5, at the Chateau of Frohsdorf, near Vienna, under the same roof, and within a short time after the death of the Comte de Chambord. We who are republicans cannot estimate his motives, nor feel with him as a royalist, but we can respect the rare moral qualities of his devotion; and we feel, also, that it is essential to express our reverence and gratitude to the memory of a really great man for his consideration and kindness to all young students in science who have had occasion to come into personal or professional relations with him.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1] — IV.

The beginning of the upsetting in a tropical cyclone is not fully accounted for by observation. It is not so easily explained as the first

[1] Continued from No. 42.

uprising on the desert, inasmuch as the ocean's calm surface is too smooth to offer any distinct starting-point for the up-draught. There are, however, several plausible ways out of the difficulty. It is possible that localized warmth and expansion where the air is calmest may produce a gentle up-current, which, once begun, will be soon well established. Again: an excess of evaporation will cause a rapid upward diffusion of vapor. It will reach an altitude where it must condense, and form a cloud-layer, and thereby warm the surrounding air both by its latent heat and by catching the warmth of the sun's rays; and, as this will go on at a considerable altitude, it will be especially effective. Finally, if after a time of calm a breeze should opportunely penetrate the district from an adjoining one of higher pressure, an ascending current would surely be started. In some such way a gradual overturning of the unbalanced air must begin, and its further action is now to be traced.

The rising mass expands as it escapes from the pressure of the air that it leaves below, and in expanding it is mechanically cooled. As it cools, some of the vapor with which it is well charged condenses into cloud, and, on accumulating, soon begins to fall as rain. Here we have the entrance of a new and potent cause of disturbance, — the bringing-forth of a great amount of energy in the form of heat from the condensation of the vapor. It is probable that this aid to the up-draught seldom takes the initiative: it waits till some other cause begins the upsetting, and then falls to with a will to help it along.

This effect of condensation is so important that it may well be considered a little more closely. As water evaporates, its molecules are spread widely apart, and take on a very active motion; but in doing so they must be furnished with energy in some form, for they cannot develop out of nothing the energy needed for their increased activity. As a general rule, the desired supply is found in the sun's radiant heat: so, when water evaporates from the sea-surface, it takes to itself nearly all the energy that comes down in the sun's rays, and thereby its molecules are enlivened up to the point of vaporization. It will be readily understood, that, if heat-energy be taken by the water and transformed into vapor-energy, it can no longer make itself felt as heat; and, so far as our senses are concerned, it is lost or hidden, and for this reason is called 'latent heat.' The term is misleading and improper, for it implies that the sun's energy still remains somewhere in the vapor as a kind of heat that we cannot feel; but this is wrong, for as heat it no longer exists. It will be further seen, that, when the vapor is condensed back again into water, all its vapor energy must take some other form: it must abandon the vapor molecules, and allow them to quiet down and approach one another as they resume the liquid condition; and the energy thus thrown out of employment must make itself felt in some other way. We are therefore prepared to find that condensation is attended with the production of just as much heat-energy as was lost in the process of evaporation. This is of capital importance in the understanding of storms.

It has already been seen, that the cause of continued action in a desert-whirl is found in the excessive warmth of the lower strata; in virtue of which the air in the ascending column finds itself warmer, and hence lighter, than the surrounding air, and consequently is impelled to rise as oil rises through water. It was further noted, that the ascending whirl will continue as long as it is supplied with excessively warm air at the base; but, as soon as the bottom air is not more than 1.6° warmer than the air three hundred feet above it, the whirl will die away. In the case of an ascending column of air saturated with vapor, it would also, as in the previous case, expand as it rose to higher levels of less pressure, and, in consequence of this expansion, it would cool. But when saturated air is cooled, some of its vapor must condense; and when vapor condenses, heat is evolved; and the heat thus produced will partly make up for the loss of heat by expansion, and therefore the ascending column of moist air will not be allowed to cool so fast as if it had not been saturated with vapor. Several important consequences now follow. In the first place, a less warming at the base is needed to produce unstable equilibrium in saturated than in dry air. In the latter, the turning-point is reached when there is a difference of 1.6° F. between the temperatures of the surface-air and that three hundred feet above. In the former, if the surface-temperature be 80°, as is common in the Bay of Bengal, a difference of only 0.6° is required. In other words, if a mass of dry air at 80° rise three hundred feet, its temperature falls to 78.4°: if a mass of saturated air at the same temperature (fig. 5) rise through the same distance, it is cooled only to 79.4°; and conse-

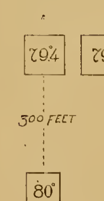


Fig. 5.

quently, for every three hundred feet of ascent it has an advantage over dry air of one degree of warmth (and more at great altitudes), tending to make it lighter than its surroundings, and so intensifying its upward motion. Moreover, a storm which is thus nourished may continue its activity through the night, instead of dying away as the sun declines; for it is supplied with energy continually brought out of the vapor storehouse. Of course, in both cases the sun's heat is the source of the disturbance; but on the desert there is no way of storing up the heat, while at sea a great amount of energy may be stored up before the final upsetting begins, and then the storm-winds arise, and show all this accumulated strength in their blowing.

We have much this kind of action, in a small way, in the formation of a heavy cumulus-cloud on a quiet, hot summer day. The air on the ground is warmed, and contains a good share of moisture; and, as it rises and cools, its vapor begins to be condensed. Some of the vapor-energy is given out as heat, and so the ascending current is re-enforced. If the air be very warm or very moist, or both, the ordinary cumulus-cloud may grow into a thunder-shower; and, being then unable to carry up all its condensed vapor, some of it falls as rain. It should be noted, that, when the lower air is not fully saturated, its temperature must be somewhat reduced to bring it to the point of saturation before any cloud is formed. This decrease is mechanically effected at the rate of 1.6° every three hundred feet, by the expansion of the rising air, — essentially the same rate as that already given for the cooling of a rising column of dry air; and, when enough cooling has been thus effected to reduce the air to its temperature of saturation, some of the vapor will be condensed into liquid cloud-particles, and so become visible. It is for this reason that cumulus-clouds have nearly level bases, and that a group of such clouds stands at about the same altitude. The air-currents rising from the warm ground have to ascend a certain distance, and cool a certain number of degrees, before condensation takes place. Their altitude in feet will be about a hundred and eighty-three times the number of degrees between the temperature of the lower air and its dew-point.

All tropical cyclones are attended by clouds and by excessively heavy rain; and this points very clearly to the important part played by the heat evolved in the condensation of so much vapor. The rapid reproduction of the heat stored up through many previous days of sunshine retards the cooling of the ascending current, excites the winds to active motion, and the storm is thus set going. Espy (1835) was the first to recognize the important part played by the condensing vapor in an ascending current of air, but he greatly exaggerated its effects. The proper measure of its action, and convenient statement of the results in tabular form, are chiefly due to Reye (1864) and Hann (1874).

The ascending current moves outward at a

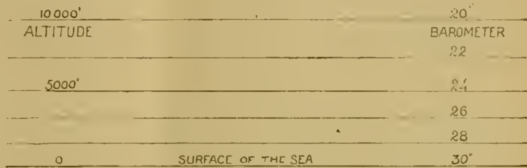

FIG. 6.

height of one or two miles, spreading itself over the surrounding atmosphere. To show its relation to the storm circulation, we may refer to the following figures. Fig. 6 shows the air in a quiescent state, before the storm begins. At such a time, there being no wind, the weight of the air, or the barometric pressure at sea-level, — say, 30 inches, — is uniform throughout the area preparing for cyclonic disturbance. The pressure is uniform, not only at the sea-surface, but also at any given altitude above it (the effect of the upper winds is here omitted as being non-essential to the explanation, as well as unknown); so that the lines in the figure will represent level surfaces of equal pressure of 28, 26, 24 inches, or isobaric planes at altitudes of about 1,600, 3,300, and 5,000 feet. As long as the vertical gravitative pressure is at right angles to these planes, the air is not tempted to move, but will remain at rest till disturbed by some new condition. This new condition will be some form of the disturbing actions already suggested, by which a central region of greatest warmth is determined, in consequence of which there will be an expansion of the atmosphere at that place. The isobaric planes will become convex there, as in fig. 7; for the altitudes at which barometric pressures of 28, 26, 24 inches are found must now be greater than before. As there has been, as yet, no lateral motion, this produces no change in the pressure at sea-level. But a reason for lateral motion has now appeared: the gravitative pressure of the upper air is no longer at right angles to the convex isobaric surfaces, and consequently there will be a tendency for the air to slide down from the centre. In obedience to this impulse, some of the central expanded air moves laterally or radially outward to the marginal region; and now there

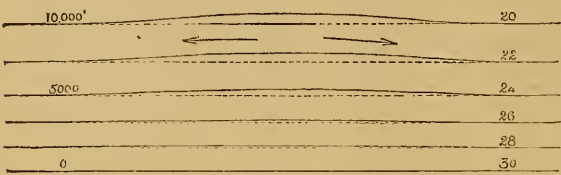

Fig. 7.

is no longer a uniform pressure of 30 inches at sea-level. At the centre, whence the upper air has rolled away, the pressure will be reduced, let us say, to 29 inches: on the surrounding district, over which the air has advanced, the pressure has increased to 30.25 inches. In this new arrangement of pressures there is cause for still further gravitative motion; namely, a rising of the air at the centre, a sinking at the marginal region, and a horizontal motion along the sea-surface, toward the centre of low pressure, in the attempt to restore an equilibrium. But this will not fully overcome the inequality of pressures, or correct the sloping of the isobars; for the existence of an ascending and expanding warm current at the centre requires that the isobaric surfaces there shall be separated by a greater vertical distance than in the normal cooler air of fig. 6. Further, the marginal descending current of air, greatly cooled by radiation in the upper regions, is heavier, volume for volume, than the ascending current, and hence has its isobaric surfaces closer together than usual. A shorter vertical column of it is needed to balance an inch of mercury in the barometer. Fig. 8 shows this final condition, — the diminished pressure and greater separation of the isobaric lines at the warm centre; the increased pressure and the approach of the isobaric lines in the cooler margin. Now, in virtue of the greater distance between the isobars at the centre, the altitude of some surface, say that of 24 inches, will be as great there as over the marginal region, in spite of the inequalities of pressure and inward slope of the isobars at sea-level; and at greater altitudes the isobaric surfaces will become convex, and hence slope outwards, instead of inwards, as below. The two directions of slope will be separated by a level or neutral plane, on which there will be no tendency to motion. Here we have excellent illustration of the convectional motion of the wind in a storm. It ascends at the centre, where it is lightest; it then flows outward, down the barometric gradient; it sinks at the marginal region of higher pressure, and then flows inward, down the reversed gradient, back to the centre again. This may be called the vertical circulation of the storm: and it will be continued as long as the central current is warmed to excess, so as to raise its isobaric surfaces. In the desert-whirlwind we have seen that the supply of warm air depends immediately upon contact with the surface-sands heated by direct sunshine. In the cyclone at sea, the greatest part of the warmth needed is given out by the vapor that condenses at the centre, and falls in the heavy rains, without which a cyclone cannot form. Such a storm may last many days.

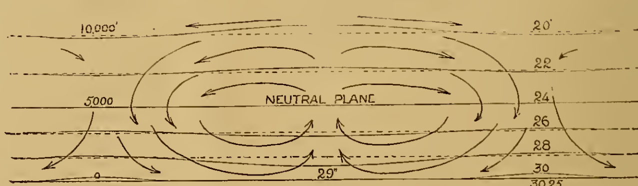

Fig. 8.

The explanations thus far given of the beginning of a cyclone apply strictly only to the hurricanes of tropical latitudes; for in the temperate zones our numerous storms are by no means always dependent on local warmth and calmness of the air. The most that can now be safely said of the origin of such storms is, that they depend on some immediately preceding disturbance, somewhat as one water-wave depends on another; for no one has yet been able to trace one of our storms so far back as to show it quite independent of previous storms, as seems to be the case with the tropical cyclones. In the irregular blowing of the winds of higher latitudes, for which no full explanation can be given, too much air is accumulated in certain districts, which then appear as regions of high pressure. In seeking a better balanced re-arrangement, surface-currents are established with a rotary deflection, as explained below, toward intermediate areas of lower pressure; and an up-draught is formed at their meeting. This becomes a storm-centre. It might be said that friction would soon cause all these local disturbances to cease, and atmospheric pressure would then remain more uniform. So it might, if the air were dry; but the condensation of vapor, by which the cooling of the ascending current is retarded, brings out a new supply of energy every time an up-current is established; and thus the disturbed condition of the atmosphere is maintained. It cannot settle down into a condition of equilibrium as long as the sun shines, and water evaporates. Some maintain that it is unlikely that the storms of the torrid and temperate zones should have different causes, and that as temperate storms certainly do not, as a rule, arise in a warm calm, tropical storms cannot have such an origin. But as already stated, and as will be further shown, the regions and seasons of tropical cyclones point very conclusively to this origin; and, moreover, it is not necessary that similar results should have identical causes. All the peculiarities of a rotary storm can be satisfactorily explained from either starting-point. And the essential contrast between the two cases is, that in one, differences of temperature precede and bring about differences of pressure, and, in the other, differences of pressure precede and bring about differences of temperature; so that, in both cases, the established storm differs in temperature and pressure from the surrounding atmosphere: and, once established, the motions of rotation and translation, yet to be described, are closely alike in the two cases.

(To be continued.)

THE ELECTRIC LIGHT ON THE U. S. FISH-COMMISSION STEAMER ALBATROSS.[1] — III.

To determine the efficiency of the system of incandescent lamps, I measured, by means of a steam-engine indicator, the power required to run the engine and dynamo, the current being switched off. By the same instrument I measured the indicated power required to run 45, 50, and 70 lamps, respectively. By deducting from these experiments, respectively, the power required to run the engine and dynamo, we obtained the power applied to the shaft; and from this quantity we deducted the friction of the load, leaving, as a remainder, the net powers required to revolve the armature in the magnetic field with 45, 50, and 70 lamps in circuit. The lamps used were each of eight-candle power.

Efficiency of the incandescent lamps.

Horse-power required to run the engine and dynamo	5.36
Indicated horse-power required to run 45 incandescent lamps	5.79
Indicated horse-power required to run 50 incandescent lamps	5.85
Indicated horse-power required to run 70 incandescent lamps	6.92
Net horse-power applied to the revolution of the armature in the magnetic field, using 45 incandescent lamps	1.80
Net horse-power applied to the revolution of the armature in the magnetic field, using 50 incandescent lamps	1.85
Net horse-power applied to the revolution of the armature in the magnetic field, using 70 incandescent lamps	2.84
Mean number of incandescent lamps per indicated H.P., using 45 lamps	7.77
Mean number of incandescent lamps per indicated H.P., using 50 lamps	8.50
Mean number of incandescent lamps per indicated H.P., using 70 lamps	10.11
Mean number of incandescent lamps per net H.P., using 45 lamps	25.
Mean number of incandescent lamps per net H.P., using 50 lamps	27.02
Mean number of incandescent lamps per net H.P., using 70 lamps	24.63

The wires being fixed, their resistance may be considered a constant quantity, and the only variation as existing in the engine and dynamo. The distribution of the power, as above recorded, may, if necessary, be verified by electrical measurements on the wires.

To illuminate the machinery on deck, the derrick-gaff, the lead of the cable, the trawl as it comes on deck, and to afford ample light to the naturalists while culling the contents of the trawl as delivered on deck, an arc-light of great power became indispensable. In the then existing state of electric lighting, an additional dynamo appeared to be imperative, as no arc-light had been run from a tension of 51 volts.

The Edison company, however, was willing to experiment, and in a short time produced a

[1] Concluded from No. 42.

lamp of 750-candle power, which we are now using; and we find, in practice, that a no. 18 copper wire will carry the current without heating. The power of this lamp, to be comparable with other arc-lamps, should be multiplied by four, as the commercial candle-power of the arc-lamp is the aggregate of four measurements, the photometers being placed equidistant from each other in the same circumference. The power required to drive these arc-lamps, though more than necessary for others of equal power, is yet quite small.

Efficiency of the arc-lamps.

Indicated horse-power developed by the engine with two arc-lamps in circuit	6.69
Horse-power required to drive the engine and dynamo	3.56
Net horse-power applied to the shaft	3.13
Horse-power absorbed in the friction of the load	0.23
Net horse-power applied to the revolution of the armature in the magnetic field	2.90
Net horse-power applied to the armature for one lamp (half of the last quantity)	1.45

The number of eight-candle power incandescent lamps per indicated horse-power is taken as a mean between the quantities as determined above, i.e., —

$$\left(\frac{25 + 27.02 + 24.63}{3} = \right) 25.55;$$

and this quantity multiplied into the net horse-power required to drive one arc-lamp gives $(25.55 \times 1.45 =)$ 37.04, which is the power in units, of incandescent lamps, to run one arc-lamp of 750-candle power.

Fishermen in nearly all parts of the world use a light in their boats, when fishing at night, to attract fishes into their nets; and it is a common thing for flying-fish to come on board ship at night if a light be advantageously placed to attract them.

Until incandescent lamps were invented, there were no convenient means of sustaining a light beneath the surface of the waters; and there is consequently opened up to us an unexplored field in fishing.

Just what service our submarine lamps will be, we are as yet unable to say: but, with the small lamp which we use from one to ten feet below the surface, amphipods in great numbers, silver-sides, young bluefish, young lobster, squid, and flying-fish, have been induced into the nets, and dolphins have approached it; but whether the dolphins were attracted by the light, or were pursuing the squid, Professor Benedict, the naturalist of the ship, was unable to say. Squid are especially susceptible to the influence of light. I am informed by the very eminent authority of Professor Verrill, of Yale college, that a heavy sea, breaking upon a lee shore when the full moon is casting its rays across the land into the sea, will throw hundreds of squid upon the beach in a single night, — an evidence of their moving in the direction of the light until caught in the spray and hurled upon the shore.

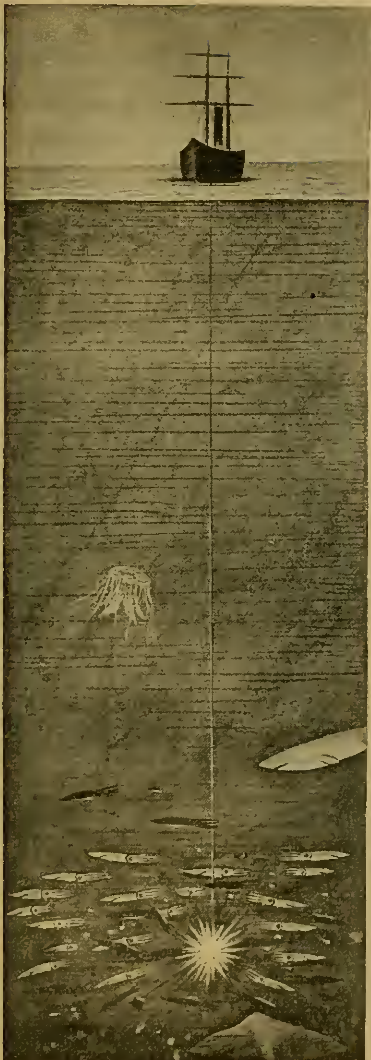
To succeed in producing the light at considerable depths has been by no means easy.

The Edison company first prepared a lantern of two thicknesses of glass, hemispherical in form, with its flat side tightly joined to a bronze disk on which were placed three sixteen-candle-power B lamps in multiple arc. At a moderate depth it burned beautifully; but at about a hundred and fifty feet the packing leaked, and the sea-water, entering, short-circuited, and the lamp was extinguished by the destruction of the cut-out plug. A similar lamp was then tried with improved packing; but its glass walls were crushed by the pressure of the water, and it was extinguished.

The next essay was with a single Edison lamp, its glass vessel being cylindrical in form, with hemispherical end, to give it strength; its thin platinum wires extending through one end without any external attachment. To these delicate wires I succeeded in soldering the copper wires of the cable, but broke (or cut) off one of the platinum wires at the point where it enters the glass, while putting on the insulation. When it is remembered that a hundred fathoms depth of water brings a pressure of over two hundred and fifty pounds per square inch on the lamp, it will be understood that great care was required in every procedure.

Our next attempt was with a single Edison lamp exactly the same as the last. I succeeded in soldering and insulating the joints perfectly; but the pressure of the water upon the insulation cut the delicate platinum wire on the glass before it had reached a hundred feet in depth.

The Edison company then produced a lamp in which the platinum wires were soldered to copper wires in a glass cavity, and filled in with rosin, so that copper wires, about no. 30 in size, projected from the lamp for our attachment. I coiled the copper wires spirally, and soldered their ends to the ends of the heavy wires of the cable, separating them by a small block of pine wood: this gave some freedom of motion, without danger of cutting or breaking the wires. A paper mould was placed round the joint, and filled with warm 'gulloot.' When



FISH-COMMISSION STEAMER ALBATROSS.
A SUBMERGED ELECTRIC LIGHT TO ATTRACT FISH, AND ILLUMINATE THE WATER.

this had cooled, it was wrapped with insulation-tape, and served tightly with twine. This was again covered with gulloot, then tape, and finally with melted gutta-percha; and, when the gutta-percha had cooled, its entire surface was seared over with a hot iron to make sure of filling any cracks or holes it might contain. The lamp was then lowered into the sea, about seven hundred and fifty feet of cable being paid out, without any indication of failure. To ascertain if the lamp was lighted at all times, we substituted a lamp for the cut-out plug in the deep-sea circuit. This brought both lamps in the same circuit, which caused them to glow at about a cherry-red instead of a white light; and had any accident happened to break the lamp in the water, or to cause a leak, our upper lamp would have immediately sprung into incandescent whiteness.

G. W. Baird,
Passed assistant engineer, U.S.N.

CRYSTALS IN THE BARK OF TREES.

In examining the interior of certain insects and myriapods living in and feeding on the wood and liber of decaying trees, the writer has often had his attention attracted by many beautiful and well-defined crystals mingled with the food-contents of the intestinal canal. The crystals appear to be insoluble in the intestinal juices, as they pass through the entire tract unchanged. Recently, in examining a large lamellicorn larva obtained from beneath the bark of a decaying white oak, I again observed an abundance of the same kind of crystals; and shortly after, numerous others were found in a Polydesmus taken from beneath the bark of a hickory log. Feeling sufficient interest in the matter to learn the source of the crystals, I examined a large white oak, dead and decaying, but still standing, with the bark loosely attached. On the inner side of the bark was a thick, yellowish-white, pulverulent layer, — the decayed liber. This readily crumbled to powder; and a small portion, diffused in water and submitted to the microscope, exhibited a multitude of crystals, forming the greater proportion of the powder, and of the kind previously noticed in insects. The crystals appeared perfectly fresh, and not changed by the surrounding decay, but were isolated, sharply defined, and highly lustrous. They measured from about the two-thousandth to the six-hundredth of an inch. Two forms were common, — simple, as represented in fig. 1; and twinned, as in fig. 2. A portion of the powder was submitted to my friend, Prof. F. A. Genth, for analysis, without informing him as to its source. The report was, "It seems to be mostly calcium oxalate, with some carbonate and organic matter." The crystals pertain to the monoclinic system, like the mineral whewellite. In another decayed white oak examined, the pulverulent liber, of darker appearance than in the former, consisted of crystals, cellular *débris*, with no bast-fibres, but with numerous long, dark-brown, many-celled sporidia of a fungus, and a few dead rotifers. Under similar circumstances, the same kind of crystals, equally abundant, were observed in a dead chestnut-tree.

The liber of the fresh or undecayed white oak and chestnut exhibits the calcium-oxalate crystals arranged in close longitudinal rows, as represented in fig. 3, situated among the bast-fibres, and nearly as abundant. The crystals are smaller, approaching the ends of the series; and the spaces occupied by the latter taper at the extremities. Each crystal occupies a separate cuboidal cell, or at least a distinct compartment of a long fusiform space, bounded by the bast-cells. In the rows of crystals of the white oak, from twenty-five to thirty-five were counted, occupying a space of about the fiftieth of an inch in length. In the chestnut liber, from twenty-five to forty-five crystals were counted in different rows. In the liber of the butternut the crystals are compounded in spheroidal clusters, and form rows arranged in the same manner as in the preceding trees.

FIG. 1. — Calcium-oxalate crystal.
FIG. 2. — Twin form of the same. Both from decayed liber of the white oak, magnified 250 diameters.
FIG. 3. — Portion of a series of crystals from fresh liber, magnified 300 diameters.

Without having had any intention of investigating the occurrence of crystals in plants, I have been led to make the present communication on what, to botanists, may be a familiar fact, under the impression that many, like myself, have heretofore been ignorant of it; and this for the reason that sufficient notice of the matter has not been given. Our ordinary manuals, while referring to the occurrence of crystals in plants, and giving a few illustrations of those observed in herbaceous plants, take almost no notice of the beautiful forms in the inner bark of our forest-trees. The 'Micrographic dictionary' mentions the occurrence of raphides in the bark and pith of many woody plants, as the lime and vine, but makes no reference to, nor gives illustrations of, such as occur in oaks, the chestnut, the hickory, etc. No more beautiful example of plant-crystals can be so readily obtained than that exhibited in thin slips of the liber of the oak or chestnut.

Although the occurrence of crystals in vegetable tissues was observed and described by Payen in 1841 (*Comptes rendus de l'académie des sciences*), the first and fullest account of the crystals of the liber of forest and fruit trees was given by Prof. J. W. Bailey, in a communication to the American association of geologists and naturalists, in 1843, afterwards published, with a plate, in the *American journal of science* for 1845, p. 17. Sanio subsequently described the same crystals in the *Monatsberichte* of the Prussian academy of sciences for 1857.

JOSEPH LEIDY.

THE PHYSIOLOGICAL STATION OF PARIS.[1] — II.

THE black screen shown in fig. 4 is a kind of shed, three metres in depth, fifteen long, and four high. This height is necessary in photographing birds on the wing; for, on rising, they immediately leave the dark field. When the walk of a man or an animal is being studied, the opening of the screen is limited by a frame covered with black cloth suspended from its upper part: this regulates the ingress of light under the shed, and makes its cavity darker. In addition, a long strip of velvet two metres and a half broad fills all the lower part of this cavity. Thus the light coming through the bottom of the screen is almost entirely cut off.

In fig. 4 a man dressed entirely in white is walking before the dark screen. The course on which he walks is slightly inclined, in such a way that a visual ray, proceeding from the objective, passes very near the surface of the ground without meeting it anywhere. This is necessary in order that in the picture the feet of the walker may be entirely visible, while the ground is not: otherwise the light reflected from the ground would make an impression on the sensitive plate at the very points where the images of the feet should be produced, and make them obscure. The course is raised about twenty centimetres above the surrounding ground; and along the full length of this relief there runs a plank on which alternate divisions, each a metre and a half long, are painted black and white. The plank thus divided is seen in the photographs, and is useful in measuring the distance run between two successive images, and in estimating the size of the subject, the amplitude of his reactions, and the extent of displacement of each part of his body. In order to know the rapidity of movement, the time consumed in traversing the various spaces must be measured. Now, if the machinery which

[1] Concluded from No. 42.

Fig. 4.

turns the disk always worked with the same speed, and if the number of openings were the same for all experiments, we should only have to determine once for all the interval of time which elapses between two images, and we should immediately have the expression of the rapidity: in short, if the successive illuminations were separated by one-tenth of a second, and if the interval in long measure between the images were five-tenths of a metre, it is evident that in one second five metres would be traversed. But the rapidity of the disk varies with the experiment: it must, then, be controlled. This control can be obtained by means of a chronograph which shall indicate the interval of time between the various turns of the disk during the experiment. But this method would give two kinds of independent indications, — that of the spaces on the photographic plate, and that of the times on a revolving cylinder. It seemed to us better to obtain, also on the plate, the indications of the times elapsing between the successive images. This result was obtained in the following manner. In order to know the frequency of rotation of the disk, we have only to photograph the successive positions of a body moving with a uniform and known velocity. Fig. 4 shows, above the head of the walker, an apparatus which answers this purpose, and which we will call a *photographic chronograph.* It is a black velvet dial, on which bright nails, arranged in a circle, divide the circumference into a certain number of equal parts. A bright needle on the face of this dial is in continual motion, turning at the rate of a revolution a second. It is evident, that, if the disk of the photographic apparatus revolve only once a second, we shall have only one image of the needle on the dial; if the disk make six revolutions a second, we shall have six images, etc. Since the velocity of the disk is uniform, the images on the dial are separated by equal distances. These divisions allow us to easily estimate the fraction of a second corresponding to the interval between the images.

This method will be better comprehended if we consider its application. Fig. 5 represents a runner jumping a bar. The series of photographs commences at the moment when the leaper started on the preliminary spurt, and ends when the leap is finished, and the fall to the ground has partly destroyed the velocity. Let us analyze this figure. We see the subject represented nine times; that is, the disk revolved nine times during the experiment. Each rotation, bringing the opening of the disk in front of the objective, has permitted light to enter for a brief instant, which has sufficed each time to give an image. These successive images were produced at different points on the plate, because the leaper himself occupied different positions before the screen when each of the illuminations took place. The space traversed either on the ground or in the air, between successive images, is easily measured by means of the divisions in the planks

Fig. 5.

seen at the bottom of the picture. We see that the interval is not always the same, and that, if we suppose equal intervals of time to separate successive images, the greatest velocity occurs in the run which preceded the leap, and that there was a diminution of speed while the leaper was in

Fig. 6.

the air: in fact, this diminution is still increased after the fall, the velocity being partly lost the very moment the body touches the ground. In order to know whether the images have been produced at equal intervals of time, and the duration of these intervals, the dial of the chronograph must be consulted. It is then seen that the luminous needle is represented as many times as there have been illuminations, namely, nine times; that the interval between the illuminations was uniform, for the images of the needle whose rotation was uniform form equal angles: in short, the absolute value of the time-intervals between the illuminations is expressed by the angle which the images of the needle on the dial make. This angle is about 36°, which shows that the time-interval between successive illuminations is one-tenth of a second. From these measures of time and space we easily deduce the velocity of the leaper in the various phases of the experiment. This speed was seven metres a second during the preliminary run, five metres during the leap, and fell to three metres and a half after the fall.

When one takes on the same plate a series of photographs representing the successive attitudes of an animal, he naturally tries to multiply these images in order to know the largest number possible of the phases of movement; but when the latter is not rapid, the frequency of the images is soon limited by their superposition, and by the confusion which results. Thus, a man running even at moderate speed can be photographed nine or ten times a second (fig. 6) without confusion of the images. If sometimes one limb is depicted where the other limb has already left an impression, this superposition does not at all affect the images: the white only becomes more intense where the plate has received two impressions, so that the contours of the two members are still easily distinguishable. But when a man walks slowly, as in fig. 7, the images present so many superpositions that confusion results. This inconvenience is remedied by *partial photography*; that is, by suppressing certain parts of the image in order that the rest may be more easily distinguished. As by our method white and bright objects only make an impression on the sensitive plate, it is necessary merely to clothe in black the parts of the body which we wish to exclude from the image. If a man dressed half in white and half in black is walking on the track, and turns toward the photographic apparatus the part clothed in white, the right, for instance, there will appear in the picture only the right half of his body. These images allow us to observe in their successive phases, first, the pivot-like turning of the lower limb around the foot during the time of support; and second, as the foot rises, the turning of the same limb around the hip-joint, while at the same time this joint is moving forward without cessation.

Partial photographs are also serviceable in an analysis of rapid movements, because by this means the number of attitudes represented may be many times

Fig. 7.

increased. Nevertheless, when the image of a limb is moderately large, the partial photographs cannot be too much increased without confusion through superposition. We must therefore diminish the size of the image, if we desire to repeat them at very short intervals. For this purpose the walker is clothed wholly in black, and narrow bands of some bright metal are placed down his arm, thigh, and leg, following precisely the direction of the bones of these parts. This arrangement allows us to easily increase tenfold the number of images received in a given time on the same plate: hence, instead of ten photographs a second, we can obtain one hundred. For this, the rapidity of rotation of the disk is not altered; but, instead of one opening, there are ten, equally distributed on the circumference. One of these openings must have a diameter twice that of the others. The result is a much larger size for one of the images; and this renders the estimation of the time easy, and also furnishes data to compare the movements of the lower and upper limbs. The images obtained under these circumstances are so close, that one is present, as it were, at all the successive changes of place of the limbs and body. Thus, in fig. 8, between two successive touches of the ground by the right foot, there are twenty-one different positions of the lower limb. As the foot meets the ground, the knee is bent perceptibly; then it straightens as the foot, resting on the toes, prepares to leave the ground. After the raising of the foot, the knee bends again, and the leg forms with the thigh a right angle; then it gradually becomes straight, and the sole of the foot, which was at

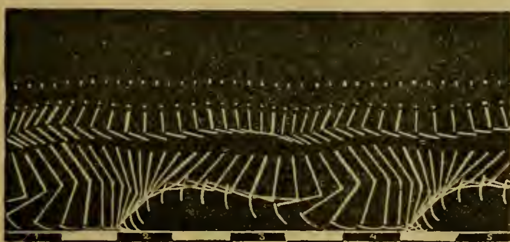

FIG. 8.

first in a vertical plane, is apparently parallel to the ground which it touches for some time before it rises again. The scale at the bottom of the figure shows that the total length of the step was 2.6 metres. The chronograph was not used in this experiment, but we may estimate the number of images at about sixty a second. The movements of bending and extending the fore-arm are obtained in the same manner as those of the leg. The turnings of the head are expressed by the undulatory motion of a bright point placed on a level with the ear. In short, the diminutions and the accelerations of each part are expressed by the crowding or separation of the images. To ascertain the corresponding positions of the arm and leg at a given instant, we take for data every fifth figure, which is larger than the others. These images are formed at the moment of passage before one of the larger openings; and they correspond, therefore, to the same instant of time. This is not the place to analyze in detail the various types of locomotion. The few examples just given sufficiently explain the method, and show its exactness. For a complete study of human locomotion, photographs under the most diverse circumstances must be obtained. The subject must be photographed not only from the side, but also from the front and rear, in order to show the lateral oscillations of the different parts of the body. Finally, after studying the mechanism of the various motions produced in walking or running, the final result — the more or less rapid transportation of the man — must be studied, either as he walks freely, or as he bears or draws a burden.

These researches have a practical interest, even as those having for their object the determination of the product of machines, and the most favorable conditions for this production. Experiments in regard to this are in process; and it is with this object in view that the circular course with telegraphic signals, to note the phases of the walking or running, has been established.

THE FUNDAMENTAL CATALOGUE OF THE BERLINER JAHRBUCH.

A VERY important comparison by Dr. Auwers, of the fundamental catalogue of the *Berliner jahrbuch* with those of the *Nautical almanac*, the *Connaissance des temps*, and the *American ephemeris*, appears as a supplement to the *Jahrbuch* for 1884; and the following abstract of it is given. The year 1883 is the first in which such a comparison is possible.

The *Berliner jahrbuch* contains at present, and will contain for the future, 450 stars whose apparent places are given, and 172 stars for which only mean places are printed; i.e., 622 in all. The places of these stars, both in R. A. and Dec., depend strictly on the system of the Fundamental catalogue of the *Astronomische gesellschaft* (publ. xiv.). They lie between the north pole and — 31°.3 declination.

The *American ephemeris* contains the mean places of 383 stars, for 208 of which ephemerides are given: 44 of these stars lie south of —31°. The *Nautical almanac* has 197 stars (15 south of —32°), and ephemerides are given for all. The *Connaissance des temps* has 310 stars between the north pole and — 70°, and gives an ephemeris for each.

Dr. Auwers's account of the sources from which the star-places of the various almanacs are taken we omit. It shows how various these are. 450 stars have ephemerides in the *Jahrbuch*; 149 stars (mostly southern) which have ephemerides in the three other almanacs are not contained in the *Jahrbuch*.

A table is given in Dr. Auwers's paper, showing the comparison between each star of each almanac and the *Jahrbuch*. From this table the elements by which the catalogue of each almanac can be reduced to the system of the *Jahrbuch* are deduced. A subsequent table gives the two reductions which must be added to each almanac R. A., and the two reductions which must be added to each almanac Dec., in order to reduce to the system of the *Jahrbuch*.

The catalogue of each almanac, after the application of the systematic reductions from this table, is then compared with the Fundamental catalogue. For the *Nautical almanac*, the mean difference in declination is 0″.395; in R. A. (from 134 stars), 0s.0332. Of the 168 stars common to both almanacs, there are 27 whose R. A. differs more than 0s.067, and 8 whose declinations differ by more than 1″. These differences are, in the main, errors of the *Nautical almanac*, and are largely due to the erroneous proper motions adopted in the Greenwich catalogues.

For the *Connaissance des temps*, the table shows large systematic errors. After these have been eliminated, the comparison shows for 229 stars, common to the *Connaissance des temps* and the *Berliner jahrbuch*, a mean difference of 0″.373 in declination, and a mean difference of 0s.0282 (from 162 stars) in R. A. The errors here, again, are largely due to erroneous proper motions.

The correspondence of the reduced positions of the *American ephemeris* with those of the *Jahrbuch* varies according as one or another basis of comparison is chosen. A complete comparison can only be made for those stars for which ephemerides are given, since the newer stars have their positions derived from several sources, not comparable among themselves.

The declinations of the *American ephemeris* and those of the *Jahrbuch* agree excellently for those stars which have been investigated by Boss. The mean difference (162 stars) is 0″.177. The other 111 stars do not agree so well, there being 12 differences between 0″.5 and 1″. The stars north of 64° depend upon Gould's R. A.; and, of the 36 stars common to both almanacs, 15 differ by more than 0s.15. Of the remaining 126 stars whose ephemerides are given, 8 have differences as great as 0s.067. The mean difference for 100 stars between +40° and −20° is 0s.0127. For the 111 stars without ephemerides, there are seven cases where the difference is more than 0s.067.

For the stars south of −32°, the *Nautical almanac* will give the best positions, on account of its data being derived from the most recent catalogues.

A comparison of the system of the *Jahrbuch*, 1861–82, with the new system, and a general table for the reduction of the data of any almanac to the *Berliner jahrbuch* system, concludes this very important paper.

It is to be hoped that in the immediate future all star positions may be reduced to the system of the *Jahrbuch*, and its admirable list of stars will be amply sufficient for observers in the northern hemisphere. For the determination of time and longitude, the stars of the other almanacs will serve a useful purpose, especially as they may easily be made homogeneous with the Berlin list by tables given by Dr. Auwers in this paper.

LETTERS TO THE EDITOR.

English *ch*.

IN SCIENCE, ii. 452, you assert that the English '*ch* (in *chair*) is not a simple consonant, but a compound,' consisting of '*t* followed by *sh*, as is apparent in pronouncing with 'due lingering emphasis' the words, 'even *such* a man, so woe-begone,' etc. Now, the same length and emphasis may be produced by a prolongation or continuous repetition of the vowel-sound of the word 'such,' and, it seems to me, would be so in the case of anybody who was unacquainted with the *tsh* theory. But even if not, the change from a simple *ch* to a compound *tsh* would not be the only instance in the language, where under special circumstances, such as a prolongation or drawl, a sound is liable to an essential change; and it must be peculiarly so where the sound can be properly made only by an instantaneous movement. *Ch* seems to be caused by such a movement, just as a smack of the lips is, which is certainly a decidedly different sound from the one made in the same way, except more gently and slowly, — a *p* made with inward-drawn breath. The relation between the smack and that *p* seems to be the same as the relation between the English *ch* and *t*, and the difference in each case to depend on the mode of contact and of its interruption, not on any combination or succession of sounds.

Again: it appears quite possible to pronounce the word 'chair' perfectly with the teeth kept slightly open by the finger or a pencil, and held, therefore, in such a position that it is impossible to pronounce the word 'share' correctly, showing that *sh* is not properly a part of the *ch*.

Moreover, if *ch* is the same as *tsh*, or the German *tsch*, the Germans would at the outset have no difficulty in pronouncing the English *ch* in a way not noticeably different by its hissing sound from ours.

It has been said, that after pronouncing the word 'check' to a phonograph, on turning the machine backwards, the sounds re-appear as *kesht;* but is that not wholly due to an incorrect, prejudiced pronunciation of the first word, as if written *tshek?* L. B.

Nov. 9, 1883.

[Argument is out of place in reference to what is a matter of mere observation. The suggested experiment by 'lingering emphasis' ought to satisfy any ear as to the reality of the stopped or shut commencement of the sound of *ch* in *chair*, and of its hissing termination. L. B. evidently associates some meaning different from the ordinary one with the terms 'simple' and 'compound.' *Ch* is compound because its shut commencement and its hissing termination are elementary effects, each of which is susceptible of separate utterance. — EDITOR.]

Report of the Assos meeting.

Henry W. Haynes, Esq., calls my attention to an error in the remarks on Assos made by me at the meeting of the Archaeological institute, Oct. 31, and printed by you in your recent report (SCIENCE, no. 41).

For 'to fight against Ramses III. — the Rhampsinitos of Greek story,' read, 'to fight against Ramses II. — the Sesostris of Greek story.'

May I beg you to make this correction public.

JOSEPH THACHER CLARKE.

Boston, Nov. 19, 1883.

Analysis of the wild potato.

In the spring we received from Mr. J. G. Lemmon, Oakland, Cal., some tubers said to be of Solanum tuberosum, var. boreale, and collected in Arizona. Of thirteen tubers planted May 4, nine furnished plants, which bloomed July 12, and in September ripened a crop of tubers no larger than the seed planted, or of the size of small hazel-nuts. The leaves were small, deep grayish-green above, not hairy; the stems, much branched, deep purple at the nodes; the flowers, white and numerous. The tubers were very diffusely spread in the soil.

An analysis of the tubers harvested by the station chemist, Dr. S. M. Babcock, is as below: —

Water	64.44
Ash	1.17
Albuminoid (N. × 6.25)	4.86
Crude fibre	.78
Nitrogen (free extract)	28.62
Fat (ether extract)	.13
	100.00

Musical sand.

In September (no. 31) you published a brief abstract of our preliminary paper on the singing-beach of Manchester, Mass. Since then we have continued our investigations, and collected additional data and material. One of us has just returned from a visit to the singing-beach on the west shore of Lake Champlain, four miles and a half south of Plattsburg, Clinton county, N.Y. This beach is about seven hundred feet long, crescent-shaped, and terminates at the south end in low cliffs of limestone, and at the north end in shelving rocks of the same material. About a hundred feet north of the beach the limestone is quarried for building-purposes.

The acoustic phenomena previously described in connection with Manchester and Eigg are reproduced at Lake Champlain quite perfectly. On the occasion of our visit, however, the sand retained traces of moisture, and the noise, indicated by the syllable *groosh*, was less strong than it would otherwise have been. Two tests, however, showed that the sound made by rubbing the sand with the hand, and pressing it on the strata below, could be heard distinctly at a distance of more than a hundred feet. The tingling sensation in the toes, produced by striking the sand with the feet, was also perceived. We failed, however, to obtain sounds by rubbing the sand between the palms of the hands, — a method which yielded remarkable results at Manchester and at Eigg; but this failure is doubtless due to the imperfect dryness of the sand. Having learned, by experience with samples from the aforesaid localities, that they lose their acoustic properties after repeated friction, we tested this question directly on the beach. We found, that, by rubbing a definite quantity of sand continuously, its power of emitting sounds gradually diminished, and finally ceased.

The sand is unusually fine, and its grains of remarkably uniform size, averaging about 0.2 millimetre in diameter. Even to the naked eye their tendency to a spherical shape is apparent; and, when examined under the microscope, they are found to consist, to the amount of about thirty per cent, of round and polished grains of colorless quartz, usually of spherical, ellipsoidal, and reniform shapes; about the same quantity of angular to subangular grains of the same mineral, colorless, reddish, and yellowish, sometimes enclosing scales of hematite, grains of magnetite, and fluid cavities; a considerable number of fragments of a triclinic felspar, angular to subangular, colorless, and sometimes exhibiting cleavage-planes, and lines of striation; many short fibres and fragments of hornblende, and apparently augite, of a deep green color, often irregularly colored reddish brown by decomposition, and possessing strong dichroism; and a few minute particles of menaccanite and magnetite.

In conclusion, we will be greatly obliged to any reader of Science for information of additional localities of sonorous sand, and especially for samples for microscopical study.

Nov. 19, 1883.

November shower of meteors.

Watch was kept here for the November shower of meteors by myself and a number of students on the mornings of the 13th and 14th, — on the 13th from 2 to 4, on the 14th from 2 to 6. The observers were in a room having southern and eastern exposures, and meteoroids were looked for only in those directions. It was quite cloudy on the 13th, and only one meteoroid was seen; nearly clear on the 14th; and considering the fact that the moon was nearly full, and stars of the fourth magnitude could not be seen without attention, more meteoroids were seen than were expected, nearly all coming from the radiant in Leo. Owing to the fact that their appearance was not frequent enough to maintain constant attention, it is likely that most of those which were near the limits of visibility escaped observation. The maximum seemed to be at about 4.30. At 3.20 a very brilliant one, much exceeding Sirius in brilliancy, was seen.

SOME RECENT STUDIES ON IDEAS OF MOTION.

Studien über die bewegungs vorstellungen. Von Dr. S. Stricker, professor in Wien. Wien, *Braumüller*, 1882. 6+72 p. 8°.

These studies are efforts in experimental psychology, with accompanying speculations, by a physiologist who has already written upon like subjects in his 'Studien über das bewusstsein.' The style is fragmentary, and not always very clear; and there are some confusing efforts to frame a new terminology. Above all, the author's training in general philosophy is very imperfect; and therefore what he says in the latter half of this essay, 'Ueber die quellen unserer vorstellungen von der causalität.' is almost wholly antiquated and insignificant, having been superseded ever since Hume, whom, in fact, our author seems in one respect to have wholly misapprehended. But in his direct observations of mental facts, Professor Stricker attracts one's attention as having given some independent contribution to the discussions about the relation of the muscular sense to our ideas of motion. Even here, it must be remarked, he pays little attention to the fact that others have been at work before him, and seems to think his ideas quite new. Yet what he has done is to observe, and record his observations; and in so far forth he has done what we want done in the psychological field.

Professor Stricker asserts that practice in the use of his muscles, and especially in the training of the muscular sense for mechanical purposes, has rendered him uncommonly well qualified to note the presence of muscular sensations as elements in any complex state of mind. Some of his colleagues have like skill. He has thus been led to pay attention to facts such as, that, when he perceives the movements of another person, or remembers these movements clearly afterwards, or deliberately imagines a movement of a man or even of an animal, he always is aware of a slight feeling of effort in those muscles of his own body that would be concerned in the same or in some analogous movement. The appreciation or conception of a bodily movement is thus accompanied by a more or less well-marked dramatic imitation of the movement. Again: if he perceives or conceives the visible motion of a body in space, he is conscious of a motion, or of a tendency to motion, in the muscles of the eye. These personal observations he finds confirmed by others in proportion to their training in introspection, and in the special observation of the muscular sensations. In watching the motions of many small objects at once in the field of vision, as in case of a snow-storm, the author is not quite so fortunate. "I find difficulty," he says, "in discovering any trace of motions of the eyes; yet, after long exercise, I have now no longer the least doubt that I follow the single flakes with small and quick motions or nascent motions of the eyes" (p. 23). In case, however, of an effort to picture in memory just how a snow-storm looks, the author either finds himself picturing a stationary mass of flakes, or else following in mind the motions of single flakes. In the latter case he discovers that the muscles of the eyes are perceptibly innervated. The result, therefore, notwithstanding the difficulty, is in the end the same.

In the case of the illusions of motion in the 'wheel of life,' the author asserts that the illusion is always accompanied by motions of the eyes, and that it is impossible without such motions.

His conclusion from all this is, that "motion is conceivable only in connection with, and by means of, the muscular sense," — a result that, in this extreme form, probably very few investigators will accept. Certainly Professor Stricker has not proved it; since he has, on the one hand, left very numerous facts wholly unnoticed, and, on the other hand, has adduced facts that are of doubtful force for his purpose. As for the omitted facts, a reviewer of this book in the *Philosophische monatshefte* has challenged Professor Stricker to show what part the muscular sense plays in the perception of the motion of an object seen double in indirect vision, when the eyes are fixed on some chosen point. Thus, if one's gaze is fixed directly in front on some bright point, or on one of the eyes of the observer's own face as seen in a mirror, so that the eyes are surely at rest, then the finger, or a pencil, held up so as to appear double, will yet in both its shadowy images be seen to move when the real finger is moved, or when the pencil is moved by an assistant without the observer's previous knowledge. Yet here, says the reviewer, the double images show that the eye does not follow the motion at all, else they would coalesce. And if the mirror is used, the observer, looking at his own eye in the mirror, can be doubly sure that his eyes are motionless. This objection, however, is not so near at hand as another, mentioned by the same reviewer, — the one that must at once occur to any reader of Professor Stricker's book; viz., the case of the motion of some small object over the skin, say a crawling insect. Here the motion is felt as motion, and not as mere tickling, as soon as the requisite speed and amplitude are attained. What has the muscular sense to do here?

But, obvious as these objections are, they are not final. Professor Stricker might reply, that, according to Lotze's own suggestion, the now well-recognized *localzeichen* themselves may be of the nature of muscular impulses. In the retinal field the tendency to bring any point of attention into the point of sight may exist universally; and the motion of the indirectly seen finger over the resting retinal field may be known by reason of the change in the magnitude and direction of the effort that during the experiment constantly exists, to bring the finger, as the object most attended to, into the point of sight. Something analogous may make possible the perception of the motion of a point on the skin. But these are hypotheses. They are doubtful; and they require of Professor Stricker supplementary investigations, whereof he seems to have had no thought.

There remain, however, the cases of what a late writer in the *Wiener sitzungsberichte* (Fleischl, *Optisch-physiol. notizen*, no. vi., in bd. lxxxvi., i., for 1882) has called *bewegungsnachbilder*, which have long been observed and discussed. These are the subjective appearances of motion in the visual field, after the continued observation of swiftly-moving real objects; as when one has been looking at a waterfall or at a rotating-disk. Helmholtz, indeed, explains all these appearances together as visual vertigo; putting them with the phenomena of apparent motion in dizziness, and regarding them as all alike caused by motions of the eyes, unconsciously continuing after the cessation of the observation of the objective motions. Yet Helmholtz has trouble to apply this explanation, whose validity in its own class of cases is undoubted, to the case where contrary motions appear in the field of vision at the same time; and Hering, in Hermann's 'Handbuch der physiologie' (iii., i., 562), insists for these cases on the rival explanation, "Die scheinbewegung beruht auf einer localen reaction des sehorganes gegen die vorangegangene erregung." Thus we should have true spectra of motion.

One may add, that the recent article by Drs. H. P. Bowditch and G. Stanley Hall in the *Journal of physiology*, vol. iii., p. 297 sqq., leaves no room to doubt that optical illusions of motion of this class do exist, that cannot be explained as resulting from visual vertigo, and that can properly be called *bewegungsnachbilder*, at least until we know more about them.

If, now, the explanation of Helmholtz is not sufficient for all cases, if there are any cases of true *bewegungsnachbilder*, then surely they cannot be brought in any wise under Professor Stricker's extreme theory without a simply appalling mass of hypotheses. Such cases are insisted upon by Fleischl in the note above cited; and he even notes the curiously contradictory character of the spectra of motion, — the presence in them of a motion, without any actual transferrence from place to place that the eye *can* follow. They excite him to the rather petulant outburst with which his note closes; viz., that *empfindungen* are fundamentally illogical, and that the principle of contradiction does not hold good for them, but only for their more developed relatives, the *vorstellungen*. Perhaps, however, our author will insist that it was of *vorstellungen* only that his studies treat, and that with such wicked and illogical *empfindungen* as Fleischl's *bewegungsnachbilder* he has nothing to do. Yet, if his theory is to be complete, he must not be allowed to shrink from its applications. What can he do with the own cousins of these illogical phenomena, namely, the chaotic sensations of the darkened visual field? Here is for some eyes, such as the present reviewer's, little more than motion or change, without any power of distinguishing what it is that moves. So it is with Mr. Galton ('Human faculty,' p. 159). Helmholtz himself describes, in his own case, motions of 'two systems of circular waves advancing towards their centres;' and so, of course, there must be for him, in the darkened field, motions at the same time in contrary directions, that cannot well be explained as the result of muscular efforts. A similar experience is described by Professor LeConte (in his book on 'Sight,' p. 72); and Purkinje's observations, as Helmholtz gives them, are also to this effect. In all these cases, then, we have motions — whether manifold and confused, or definite and regular — which, it would surely seem, cannot be explained as resulting from, or in any way implying, muscular sensations. These cases, then, lie wholly out of Professor Stricker's range.

Yet possibly it may not seem to most readers worth while to spend time in refuting the hasty generalization of our author. But the object here is to suggest both the necessary limitation and the possible scope of this theory of the ideas of motion. Its limited scope seems clear, but its very one-sidedness is instructive if we look a little closer. It is one-sided, for instance, in the inductive methods used. In case of the mental picture of the snow-storm, Professor Stricker found his theory in danger of failing: so he followed the single snow-flakes with the mind's eye; and lo! the theory is verified, and so throughout. The influence of attention upon the result is so plain, that the reader must have noticed the fact in reading our previous summary of the book; and yet this formal error in the reasoning does not make the result wholly erroneous. If one takes note in himself of the facts upon which such stress is laid by our author, one will very readily find that there is at least this in them; viz., every clearly conceived or perceived objective motion tends, just in proportion to the *clearness and definiteness* of perception or of conception, to become associated with a certain kind, degree, and direction, of muscular effort. That muscular efforts are involved in mapping out the visual field; that we follow every point in whose motion we take special interest, and are partially conscious of what we do in following it; and that analogous facts exist for the sense of touch, — are truths now generally recognized. Professor Stricker is interesting as having given us an independent, and, in so far forth, unprejudiced, contribution to the theory. That it has charmed him over-much is itself a fact of interest for the theory: for it shows how much clearer and better Professor Stricker seemed to himself to have conceived motions, when he had brought their conception into immediate connection with the facts of the muscular sense; that is, we see hereby how the muscular sense, used as the *measure of the amount of our activity*, is for that reason the especial means of helping us to build up definite ideas of complex facts. Motions we could know, it would seem, apart from the muscular sense; but we should have no such clear ideas as we have of the differences among motions. Even so it probably is with space. We should know of space if we were motionless; but we should not know of what Mr. Shadworth Hodgson calls figured space, — space mapped out as the mathematician needs to map it out. In fact, the connection of the muscular sense with the simple perception of movement, to form the complex perception of the definite character of the manifold differences between one movement and another, gives us an excellent illustration of that general law of mind according to which as many originally separate mental facts as possible are constantly being brought together, in order that, from their blending, a new and more definite unity may come. Increased complexity of data running side by side with increased simplicity of form, — this is the law of mental progress; and so the motions perceived by the pure sense of touch become definitely comparable with one another, and with the motions of the pure sense of sight, by means of the union of both with the data of the muscular sense, the whole thus forming the basis for higher rational mental processes.

Professor Stricker's facts are also useful as independent illustrations of certain other allied laws that have been elsewhere recognized. For instance: the tendency to join the conception of a motion with an imitation or nascent imitation of this motion has been before illustrated by the phenomena of hypnotism, by the gestures of sensitive and vivacious people, by the facts of so-called 'mind-reading,' and by many similar and very common experiences. Professor Stricker has attended more to these imitative tendencies than most people are accustomed to do, and has verified them subjectively for himself. Mr. Galton's 'histrionic associations' ('Human faculty,' p. 198) belong to the same group of facts.

Another law, however, is indirectly verified by Professor Stricker, as far as his observations go; and it may be well to mention this law here, because, so far as the present writer knows, little attention has been devoted to it by psychologists. It is the law formulated as an aesthetic principle in Lessing's 'Laocoön,' that moving objects, actions, events, can be properly described by the poet in language; while things that have to be spoken of as resting, and, in general, things that are coexistent, cannot successfully be represented by language. Still more generally stated as a practical principle of the rhetorician, the law is, that, to describe vividly, one must seize upon every element in the object that can be spoken of in terms of motion or action, and must either neglect or very briefly indicate whatever elements cannot so be interpreted. This principle explains one use of personifications, whether total or partial. The mountains rise into the sky, or lift their heads; the lake stretches out before one's sight; the tower looms up, or hangs over the spectator, — such are some of the more familiar devices of description. An exception that illustrates the rule is found in the case of very bright colors, whose interest and comparative brilliancy in the mental pictures of even very unimaginative persons may make it possible for the descriptive poet to name them as coexistent, without suggesting motion, particularly if he render them otherwise especially interesting. So in the well-known description, in Keats's 'St. Agnes' eve,' of the light from the stained-glass casement, as it falls on the praying Madeline. Even here, however, the light *falls*. And color-images, however brilliant, are increased in vividness by the addition of the suggestion of motion; as in Shelley's 'Ode to the west wind,' where

> "The leaves dead
> Are driven like ghosts from an enchanter fleeing,
> Yellow, and black, and pale, and hectic red,
> Pestilence stricken multitudes."

Much less effective would be the mention of the most brilliant autumn hues apart from motion.

Lessing gave as basis for this theory the somewhat abstract statement that language, being spoken or read successively, is best fitted to portray the successive. But this is hardly the whole story. The modern generalization that men and animals alike observe moving more easily than quiet objects, in case the motion is not too fast or too slow, seems to come nearer to offering an explanation. But this account is still incomplete; for it will be found that we do not always picture mentally the motion of an object, even when we try to do so. To see a man walk in the mind's eye is not always so easy as to picture a man in some attitude. Professor Stricker notes that his dreams seldom picture to him actual motions. In many dreams we must all have noticed that the rapid transitions that take place are rather known as motions or alterations that have happened, than as changes in process of taking place. The present writer's own image with Shelley's lines above quoted is not so much of dead leaves actually moving, as of the leaves rustling, with the sense or *feeling* that they are driven by the wind. The words descriptive of motion give, rather, the feeling of action connected with the leaves, than a picture of movement itself. So, to say that the mountains *rise* is to direct the mental eye upwards, rather than to introduce any picture of objective motion into the mental landscape. So, then, it seems probable, that, while we notice moving rather than resting things, our mental pictures tend to be representations of resting attitudes, rather than pictures of motion. And the greater vividness which descriptions of motion nevertheless possess would seem to be due to the sense of activity that they introduce into our ideas of the objects; and that this sense is connected with the muscular sensations that we are accustomed to associate with all clearly perceived motions seems both probable in itself, and in some wise confirmed by Professor Stricker's observations. The whole leads us, in fact, to another probable law of mental life; viz., that, since an animal's consciousness is especially useful as a means of directing his actions, the ideas of actions, however they are formed, will naturally be among the most prominent elements of the developed and definite consciousness. We need not make any assertion about the direct source of these ideas. Whether the active muscular sense is a direct consciousness of the outgoing current, or a true sense through the mediation of sensory nerves, the result will not affect either Professor Stricker's argument or our own suggestions.

In conclusion it may be well to say, that, if psychology were already a developed experimental science, such independent and hasty observations and generalizations as our author's would hardly be worth discussion. But as things are, even very imperfectly conducted observations, if they are direct and sincere, must be thankfully accepted. Something of the same sort may possibly hold good of the similarly hasty suggestions that have here been thrown together.

JOSIAH ROYCE.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Algebraical equations. — M. Walecki, in a note presented to the Académie des sciences by M. Hermite, gives a proof of a fundamental theorem in the theory of algebraical equations; viz., that every algebraical equation has a root. The theorem being evident for real coefficients, M. Walecki assumes the coefficients as imaginary, and writes the first member of the equation in the form $P + iQ$, and also makes $F(x) = P^2 + Q^2$. He considers first the case of an equation of odd degree, say p; then it is only necessary to prove that the equation $F(x) = 0$, of degree $2p$, has a root. To do this, he writes $x = y + z$, and distinguishes the odd part in z from the even part in the development of $F(y+z)$, writing thus: $F(x) = \varphi(z^2) + z\psi(z^2)$. The resultant of ϕ and ψ is shown to be a real polynomial of odd degree in y, and vanishing for a real value of y. Two cases present themselves: viz., one of the functions φ or ψ may vanish identically; and this can only be ψ, for the coefficient of the term of highest degree in ϕ is not zero. Then, ϕ being of odd order, $F(x)$ has a real divisor of the second degree. The second case is when ψ is not identically zero, and when ϕ and ψ have a common divisor, $F(x)$ being then decomposed into the product of two factors. The author shows, then, that in either case a divisor of $F(x)$ is obtained of either the first or second degree, and with real coefficients; thus proving the proposition for an equation of odd order. A similar investigation is given for equations of even order. — (*Comptes rendus*, March 19.) T. C. [409

A differential equation. — M. l'abbé Aoust has here given a method for obtaining the formula giving the general integral of the differential equation —

$$x^n \frac{d^n y}{d x^n} + A_1 x^{n-1} \frac{d^{n-1} y}{d x^{n-1}} + \ldots + A_n y = F(x),$$

by aid of a certain multiple definite integral. The quantities $A_1, A_2 \ldots A_n$ are constants. He proposes first to solve the problem of finding a function, φ, in terms of another function, ψ; the two functions being connected by the relation —

$$\psi(x) = \int_0^1 d\,a_n \int_0^1 d\,a_{n-1} \ldots \int_0^1 d\,a_1 \varphi\left(a_n^{\frac{1}{a_n}} \ldots a_1^{\frac{1}{a_1}} x\right).$$

The process for the reduction of this is by substituting successively z_1 for $a_1^{\frac{1}{a_1}} x$, z_2 for $a_2^{\frac{1}{a_2}} z$, etc.; and finally the expression of ϕ in terms of ψ is obtained. The transition from the solution of this problem to the solution of the problem of finding the general integral of the given differential equation is then indicated, and the integral given in the form —

$$y = \Sigma_1^n M_i x^{a^i} + \frac{1}{a_1, a_2 \ldots a_n} \int_0^1 d\,a_n \int d\,a_{n-1} \ldots$$
$$\int_0^1 F(a_n a_{n-1} \ldots a_1 x)\, d\,a_1.$$

The quantities $M_1, M_2 \ldots M_n$ are arbitrary constants, and a_1, etc., roots of a certain algebraical equation. — (*Comptes rendus*, March 19.) T. C. [410

ENGINEERING.

Effect of frost upon fire-plug casings. — Mr. Allen J. Fuller referred to a general impression that the freezing of the earth around fire-hydrants has a tendency to gripe fast to the frost-jacket, and lift it with the expanding or heaving earth, which he denied for the following reasons. 1°. The frozen earth slides on the surface of the frost-jacket, because its expansion is greater than that of iron. 2°. As the expansion of the earth must be in proportion to the intensity of the cold, so will it be greater above than below a given point: therefore the first foot of frozen ground will have a greater upward movement than that which is below it, and the second foot greater than the third, etc. Thus it will be seen that the earth below a given point rises more slowly than that above, and its friction is opposed to the one above. 3°. If this is true of feet, it is true of inches and of portions of an inch: therefore there is a retardation movement throughout. 4°. The upward movement of the ground: the freezing being greatest towards the surface, and such movement involving a more complete fracture of the earth surrounding the frost-jacket, it follows that the friction is less at this point than that below it, and in consequence there is less power to move upward than downward. Of course, the above does not apply to any construction that the frost can get beneath.

Mr. Frederic Graff noted and described the form of wooden casing which had been successfully used in the early practice of the Philadelphia water-department.

In response to the theory advanced in regard to the action of frost in raising the casings of fire-plugs, and to the statement that if the base of a structure extended below the frost-line it would not be lifted, Prof. Haupt remarked, that he thought the theory was in part sustained by the fact observed by some of the district surveyors, and verified by the accurate measurements they were obliged to make, that fences moved bodily to the south and east in consequence of the action of the sun and frost upon the ground on opposite sides of them. He thought, also, that the deductions concerning the immobility of structures resting below the frost-line were not fully sustained by the facts; as in the north-west, where ice forms rapidly, he had heard of numerous instances of piles driven for bridges, and extending some distance below the frost-line, having been raised as much as five to six inches in a single night; and he conceived the action in this case to be similar in kind to that of piles driven entirely through solid ground, the only difference being in the *amount* of the resistance offered by friction and weight of pile. The water, in freezing around the pile, acts upon it as a griper or vice; and the expansion of the various strata or laminae of water, as they become converted into ice, acts as a lever to force up the pile.

Mr. Howard Murphy did not consider the case cited by Prof. Haupt as parallel, as the so-called piles, being driven through water and soft mud, were probably columns resting upon their bases, and depending but little upon the frictional resistance of the material through which they passed. Therefore the expansive force upward of the freezing water would be opposed by little more than the weight of the pile; whereas in a fire-hydrant casing, or other deeply planted post, the presumably well-rammed material around the whole length under ground would offer such proportional frictional resistance as to cause the freezing earth to slide up the post rather than to lift it. If the ice could be supposed to act downwards upon the piles in question, it is hardly likely that it would have forced them farther home. — (*Eng. club Philad.; meeting* Nov. 3.) [411

An enormous steam ferryboat. — The Solano, on the Central Pacific railroad ferry, between San Francisco and Oakland, Cal., was built by the Harlan & Hollingsworth company of Wilmington, Del. The boat is 494 feet long on deck, 406 on the water-line, 116 feet beam, 6½ feet draught, loaded. The tonnage is given as 3,540. The engines are two in number, beam-engines working independently, having cylinders 62½ inches in diameter, and of 11 feet stroke of piston. These engines are each rated at 2,000-horse power. The boilers are 8 in number, of steel, have 19,630 square feet of heating-surface, or about 1,500-horse power according to a usual rating (12 square feet to the horse-power). The wheels are 30 feet in diameter, and are fitted with 24 buckets. There are four lines of rails on the deck; and 48 freight or 24 passenger cars can be carried at once. — (*Mechanics*, July 28.) R. H. T. [412

Surface-condensers for marine engines. — Cadet engineer J. M. Whitham, U.S.N., compares the performance of surface-condensers of marine engines with the results of a formula for required area of surface constructed by him, and deduces a constant for usual application. He obtains the expression, —

$$S = \left\{ \frac{L}{T_1 - t} + \log_e \left(\frac{T_1 - t}{T_2 - t} \right) \right\} \frac{W}{c\,k},$$

in which

S = square feet of condensing-surface,
W = pounds of steam condensed per hour,
L = latent heat of steam of temperature, T,
T_1 = temperature of exhaust-steam,
T_2 = temperature of feed,
t = mean temperature of circulating water,
c = coefficient variable with efficiency of surface,
k = conductivity of the metal (556.8 for brass, 642.5 for copper).

He finds the usual value of c to be 0.148. He finds that this figure may be increased ten per cent where independent circulating pumps are used. The common value of $c\,k$ is taken as 82.2252. An inspection of the table of areas in use indicates that the smallest areas are very nearly as efficient, as a rule, as the greatest. — (*Proc. naval inst.*, ix. 303.) R. H. T. [413

Protection of iron from rust. — As it has been observed that iron embedded in lime-mortar is hindered from rusting, Riegelmann of Hanau uses a paint containing caustic alkaline earth (baryta, strontia, etc.), so that the iron may be protected as it is by lime. The *Neueste erfindung* states that a mixture of ten per cent of burnt magnesia, or even baryta or strontia, mixed cold with ordinary linseed-oil paint, and enough mineral oil to envelop the alkaline earth, will protect iron by its permanent alkaline action, the free acid of the paint being neutralized. — (*Build. news*, Sept. 14.) C. E. G. [414

Asphalt mortar. — A composition of coal-tar, clay, asphalt, resin, litharge, and sand, an artificial asphalt, has been used for some years with perfect success on the Berlin-Stettin railway for wall-copings, water-tables, and similar places requiring a waterproof coating. It is applied cold, like ordinary cement. The space to be covered is thoroughly dried and cleaned, and then primed with hot roofing-varnish, the basis of which is also tar. The mortar is then spread cold with the trowel, to a thickness of three-eighths of an inch. If the area is large, another coat of varnish is given, and rough sand strewn on. The material is tenacious, impregnable to rain or frost: a piece exposed four years to the drainage of a slope thirty-three feet high is perfectly sound, and has required no repairs. — (*Centr.-blatt. bauverw.*) C. E. G. [415

AGRICULTURE.

Relative value of soluble and reverted phosphoric acid. — Experiments by Voelcker gave no result, the differences between the unmanured plots being greater than those between manured and unmanured plots. Wildt, in experiments in five different places, found in one case that the soluble form gave the greatest increase, in three cases no effect could be observed from the phosphoric acid in any form, and in one case the results were contradictory. — (*Biedermann's centr.-blatt.*, xii. 514.) H. P. A. [416

Influence of quality of seed upon the crop. — One of the most important conditions of a successful vegetation experiment is uniformity in the seed used. With this in mind, Hellriegel has investigated the effect of variations in the absolute weight, and in the specific gravity of seeds upon the growth of the resulting plants. He finds, that, of seeds (of barley) having the same specific gravity, the heavier seeds produced at first more vigorous plants than the lighter. As the plants continued to grow in good soil, the differences gradually diminished, until, at the time of harvest, they had entirely disappeared. When the plants grew in poor soil, the effect of differences in the seed was more lasting, and even affected the total weight of the crop. Differences of specific gravity in seeds of the same weight produced no recognizable effect upon the crop. The stage of ripeness of the seeds affected the development of the plants in the same direction as it did the absolute weight of the seeds; the riper seeds being heavier, and producing the most vigorous plants, and the differences being most manifest on a poor soil. Essentially the same results were obtained in experiments with potatoes. The attempt was also made to raise potatoes of greater or of less specific gravity, by selection; the heaviest or lightest being continually selected for seed. The experiment was continued through three seasons, with a negative result. — (*Ibid.*, xii. 530.) H. P. A. [417

MINERALOGY.

Albite. — This mineral usually occurs somewhat impure, owing to the presence of small quantities of potassium and calcium. C. Baerwald claims to have found for the first time a perfectly pure albite from Kasbék, Caucasia, in which no trace of potassium or calcium could be detected, and which yielded, on analysis, SiO_2 (68.75). Al_2O_3 (19.73). Na_2O (12.29) = 100.77; gravity, 2.618. This albite is regarded as of special interest in relation to Tschermak's theory, that the soda-lime felspars are all isomorphous mixtures of a pure soda felspar (albite, $Na_2Al_2Si_6O_{16}$) with a pure lime felspar (anorthite, $CaAl_2Si_2O_8$), giving a continuous series between the two extremities which vary in physical properties. Pure albite not being known, an idea of its properties was arrived at by calculation, and the author regards it of interest to compare the albite from Kasbék with the theoretically pure albite of Tschermak.

	FOUND ON ALBITE FROM KASBÉK.	CALCULATED BY TSCHERMAK.
Gravity	2.618	2.624
Angle of base on brachypinnacoid,	86° 22′,	greater than 86° 29′

When examined with crossed nicols and sodium light, the extinction upon a basal section was found to be 2° 17½′ on either side of the twinning-plane; and, with a section parallel to the brachypinnacoid, the extinction took place at an inclination of 18° 23⅜′. These values vary considerably from those arrived at by Schuster, respectively 4° 30′ and 19°; but the author regards his values as especially correct, being obtained by experiment on pure material, and not by calculation. — (*Zeitschr. kryst.*, viii. 48.) S. L. P. [418

GEOGRAPHY.

(Arctic.)

Population of the Chukchi peninsula. — Dr. Aurel Krause gives a *résumé* of the exploration of this district from the middle of the seventeenth century, and a discussion of the ethnic relations of its people, largely from the observations of himself and brother during their late travels. To this is added a small ethnological map, showing the distribution of the various stocks on either side of Bering Strait; and a valuable vocabulary, chiefly of Chukchi words, but containing also some words of the Asiatic Eskimo, and some recognized as jargon. — (*Deutsche geogr. blätter*, vi. 3.) W. H. D. [419

Hydrography of the Siberian Sea. — Otto Pettersson contributes to the second volume of the 'Scientific results of the Vega expedition' a study of this subject, illustrated by charts of the Kara Sea, and of that part of the Arctic Ocean between Novaia Zemlia and Bering Strait which has been named the Nordenskiöld Sea. An important part of the paper consists in the discussion of the movements of the ice in the Kara Sea, which, the author concludes, depend less on wind and weather than on the varying amount of warm surface-water which enters the Kara basin in different years. This warm water depends largely upon the discharge of the great Siberian rivers, and differs according to the time when the ice in them breaks up in different years. As a complement to this investigation, may be mentioned a paper on Nordenskiöld's explorations, printed by Fr. Schmidt of the St. Petersburg academy of sciences, in which the author endeavors to clear up some doubtful points in the observations made on the Vega voyage, by combining with them the results of explorations by Saunikoff, Hedenström Anjou, and others. — W. H. D. [420

New charts of north-east Siberia. — The Hydrographic office of the navy department has issued a chart of Plover Bay, derived from Russian surveys by Maksitovich, and one of the Anadyr River estuary, founded on the surveys of the Telegraph expedition in 1865, with corrections by Russian officers on the ship Haidemak, in 1875. Following an error of the Russian hydrographic office, the title of 'Port Providence' is given to the whole of Plover Bay, and the latter name to the smaller and included port, in direct reversal of the custom of American and other navigators for the last thirty years. — W. H. D. [421

Graah's investigations of 1829–30 in Greenland. — Apropos of Nordenskiöld's Greenland expedition, a very full account of Graah's voyage, and a deserved tribute to his qualities as an explorer, appears in the last number of the *Deutsche geographische blätter*. This is doubly useful, as the account of the journey originally published has long been out of print, and difficult to obtain. The same number contains a statement and criticism of the hypothesis offered by Nordenskiöld in regard to the interior of Greenland, from the pen of Prof. Börgen, whose views have been sufficiently confirmed by the results of the voyage, so far as yet made public. — W. H. D. [422

(*Africa.*)

The Portuguese in Africa. — In support of the rights claimed by Portugal on the Kongo, and elsewhere in the interior of Africa, a memorandum was issued, some time since, by the geographical society of Lisbon, in which it was claimed for Portuguese explorers that they had revealed to science precise and exclusive information in regard to the orography and hydrology of the Dark Continent. The plea of this memorandum has been traversed by President Wauters, of the Royal Belgian geographical society, in a very lively and interesting article. Without expressing an opinion as to the merits of parties now struggling for supremacy on the Kongo, attention may be called to the manner in which the author shows how the characteristics of the hydrology of the interior of Africa on ancient charts were derived. Two centuries before the Christian era, Eratosthenes, from information obtained on the Ethiopian expedition of Ptolemy Philadelphus, described with tolerable accuracy the chief features of the river-system of Abyssinia, and placed the source of the principal branch of the Nile in a lake situated to the southward of that country. Ptolemy and the Arabian geographers added other lakes and branches, the details of which appear to have been based chiefly on rumor and imagination. In 1444 certain Abyssinian monks visited Rome on an ecclesiastical errand; and, from information derived from them, Brother Mauro corrected the geography of that part of the Nile basin comprised in the Abyssinian watershed, the remainder finding its source on a vast marsh located in the centre of the continent. This appeared on his celebrated Mappe-monde in 1458.

According to the author and Father Brücker, the curious network of lakes and rivers found on the globes of Martin Behaim and medieval geographers, which suggest so curiously the lakes and rivers now known to exist, were all derived from the sources above mentioned. In many cases the names of the lakes and towns can be recognized; and in suppressing synonymes, and replacing Abyssinian rivers (which appear spread over central Africa on such maps) where they belong, the central region of the continent becomes almost a blank. It was reserved for the celebrated De Lisle, in the early part of the last century, to sweep from the charts every thing not due to actual observation, leaving to Livingstone and his successors the occupation of the blank thus made by delineating the physical features recognized in these modern and only authenticated explorations. — (*Bull. soc. Belg. géogr.*, ii. 1883.) W. H. D. [423

BOTANY.

Synonymy of higher cryptogams. — The 'Nomenclator der gefässkryptogamen,' by Carl Salomon, gives the genera and species of the higher cryptogams, together with their synonymes, and the geographical distribution of the species, — a work which is much needed by students in this department of botany. — W. G. F. [424

Ohio fungi. — The third part of the 'Mycological flora of the Miami valley,' by A. P. Morgan, has appeared, and includes the species of Agaricini from Coprinus to Lenzites. The paper is accompanied by colored plates of two new species, — Coprinus squamosus and Hygrophorus Laurae. — (*Journ. Cinc. soc. nat. hist.*) W. G. F. [425

Phycologia Mediterranea. — In this volume of about five hundred large octavo pages, Prof. F. Ardissone of Milan describes the Florideae of the Italian coast, followed by the Bangiaceae and Dictyotaceae, under the heading Incertae sedis. From the context, however, one understands that the writer considers the two last-named orders to be nearly related to the Florideae. The descriptions and synonymy are given in full in Latin, and there are many notes in Italian on the microscopic structure and development. The antheridia of Spyridia are said to be unknown. They have, however, been described and figured in American specimens of S. filamentosa, which also occurs in Italy. — W. G. F. [426

Pollination of Asclepias. — Dr. Taylor speaks of the temporary capture of flies by A. purpurascens, and of the removal of pollinia by them on their escape, and suggests that North-American botanists examine the insects caught on our asclepiads for the peculiar pollen-masses (*Sc. gossip*, Sept.).

Like Apocynum, the milkweeds have long been known to catch insects not adapted to fertilize their flowers; and irritable movements have several times been ascribed to their pollinia or stamens (e.g., Kirby and Spence, 'Entomology,' 7th ed., 167; Willdenow, 'Principles of botany,' 321; Potts, *Proc. Philad. acad.*, 1878, 293). In reality the insects are captured by a purely mechanical action of the fine V-cleft in the saddle of the pollen-mass, which seems especially adapted to hold the tarsal hairs of insects, especially certain Hymenoptera.

The pollinia have been frequently noticed on insects. Bee-keepers often complain that their bees become so weighted with them as to be unable to regain the hive. Potts (*Proc. Philad. acad.*, 1879, 207) mentions one bee which bore the remains of thirty pollinia; and Bennett (*Pop. sc. review*, 1873, 343) speaks of a butterfly which had eight entire masses, and the bases of eleven others, on one of its feet. Curious mistakes have also been made in descriptive entomology through a failure to recognize these bodies when they have been met with on insects. Savigny, in his great work on Egyptian insects ('Hymenoptera,' pl. 11), figures one as an appendage of the maxillary palpus of a Larrid; and his figure is copied by Westwood ('Modern classif.,' ii. 197), who says (p. 201) that 'it may possibly be the effect of disease.' Reakirt (*Proc. ent. soc. Philad.*, ii. 357) described them as natural appendages of the tarsi of a butterfly, giving them the name of eupronychia. If I am not mistaken, a species of Mantispa has also been characterized by the presence of these pollen-masses; but I am unable to refer to the description.

Among the numerous modern accounts of the pollination of the genus, none is more thorough than that given by Delpino, in his 'Fecondazione nelle piante antocarpee,' 1867. — W. T. [427

ZOÖLOGY.

Rare forms of microscopic life. — Dr. A. C. Stokes recently described and exhibited specimens of a new species of Acineta, a stalked, loricate infusorium. At the same time he called attention to an example of the blue Stentor (Stentor ceruleus Ehrenberg) which he thought had not been mentioned heretofore as found in America. He also announced that he had recently collected the beautiful rotifer, Stepanoceros Eichhornii, which, though abundant in Europe, appears not to have been previously found in this country. Specimens of Salpingoeca urceolata were also shown, which in no way differed from marine specimens. All the above forms of minute life were found in Watson's Creek, a small fresh-water stream in Mercer county, N.J. — (*Trenton nat. hist. soc.; November meeting*, 1883.) [428

Mollusks.

Pulmonata of central Asia. — E. von Martens publishes a valuable contribution to our knowledge of central Asiatic Mollusca. The region treated of is between the frontiers of China and the Caspian, for which material has been gathered by Prjevalski, Potanin, and Regel. Besides descriptions of new forms, it contains a review of the fauna, with a tabular exhibit of the distribution of the different species. The central Asiatic Helices are broadly divisible into two groups: the one, characterized by reddish and yellowish tints of coloration, and related to the Fruticicola of Europe, is more northern in its distribution; the other, allied to Xerophila, inhabits the Thian-Shan region, and is distinguished in general by sharper sculpture and a whitish color. Several forms common to the pleistocene and to the boreal region are found here, while several sections of the Helices not found in the pleistocene are also absent from central Asia. The fauna is more nearly related to that of the post-tertiary, or northern American, than to the existing fauna of middle Europe. The fresh-water snails are European, but Unio is conspicuous by its absence. A supplement by Schacko gives anatomical details of several species. — (*Mém. acad. St. Pétersbourg*, (7), xxx. no. 11.) W. H. D. [429

Mediterranean oysters. — The Marquis de Gregorio has undertaken a special study of the Mediterranean oysters, recent and fossil. Two short papers printed at Palermo give some preliminary results; among other things determining the existence in a living state, on branches of red coral, of the true Ostrea cochlear of Poli, believed to have become extinct. We recall, however, the identification of this species some time since, by Dr. Jeffreys and others, from specimens attached to a telegraph-cable which had been recovered from great depths for repairs. — W. H. D. [430

Mollusks at the fisheries exhibition. — Dr. J. Gwyn Jeffreys prints some notes on the Mollusca exhibited. Leaving out oysters, which were well represented from Great Britain, the United States, and France, the collections are not remarkable. British Columbia showed a fine example, in spirit, of Cryptochiton Stelleri. This species, by the way, though rare in European collections, is abundant in proper localities from Santa Barbara, Cal., north and west to the extreme limit of the Aleutian Islands. It is eaten raw by the natives of Alaska. Norway showed a small collection of fine specimens of her mollusks, as did the museum of Gothenberg, Sweden. The most important and interesting collection was that of the Vega, dredged in the Arctic seas from Norway to Bering Strait by Baron Nordenskiöld. Among these was a Pleurotoma (from the description, closely resembling P. circinata Dall, of the Aleutian Islands), which Dr. Jeffreys believes to be larger than any other known species, and to which he has applied the name of P. insignis. — (*Ann. mag. nat. hist.*, Aug., 1883.) W. H. D. [431

Worms.

Notes on worms. — C. Vignier has published a preliminary notice of his researches on the annelid Exogone gemmifera in the *Comptes rendus* (xcvi. 729), and promises a full memoir. —— W. H. Caldwell gives, in the proceedings of the Royal society of London (xxxiv. 371), a preliminary note on the structure and development of Phoronis. —— A third preliminary publication is that on the development of Borlasia vivipara, in the *Bulletin scientifique du département du Nord* (v. 462), by W. Salensky. —— In the journal of the Linnaean society of London (xvii. 78), Dr. T. S Cobbold describes Ligula Mansoni, n. sp. Twelve specimens were found, in a Chinese, lying in the subperitoneal fascia about the iliac fossae, and behind the kidneys; a single one being found lying free in the right pleural cavity. They were twelve to fourteen inches long, and an eighth of an inch broad, and come near Ligula simplicissima. —— H. Griesbach has given a preliminary report of his observations on the connective tissue of cestods, as studied in Solenophorus. His article appeared in the *Biol. centralbl.* (iii. 268). —— J. Poirier found in the intestines of Palonia frontalis, from Java, three new Amphistomidae, for which he establishes two new genera, — Homalogaster and Gastrothylax. Three species are described and figured (*Bull. soc. philom. Paris*, (7), vii. 74). —— J. Chatin reports a few observations on the histological alterations occasioned in man by trichinosis (*Ibid.*, 107). —— The larvae of Gordius occur both in fishes and in many insect-larvae. In opposition to Villot, von Linstow maintains that the insects are the real hosts, and the parasites are present in fishes only accidentally, from their feeding on infested insects. — (*Zool. anz.*, vi. 373.) C. S. M. [432

VERTEBRATES.

Direct irritability of the anterior columns of the spinal cord. — Mendelssohn, in the present paper, states that he has repeated all of the experiments of Fick upon the irritability of the anterior columns, and obtained similar results. In his own experiments, special efforts were made to prevent any escape of current on stimulating. The spinal cord was laid bare in its whole extent, and isolated from the surrounding parts by caoutchouc. The anterior and posterior columns of the cord were stimulated just below the brachial plexus, which had been previously divided; and the movements of the gastrocnemius muscle which resulted were registered upon a myograph. In some cases the anterior portion of the cord was completely separated from the posterior by a section running from the origin of the sciatic to the cervical cord. It was found in all cases that the reaction of the anterior columns was shorter than that of the posterior columns; that is, the time between stimulation of the cord and contraction of the gastrocnemius was less in the first case than in the second, the difference in time varying from 0.01 to 0.025 of a second. Assuming that the contraction resulting from stimulation of the posterior columns is reflex, then that resulting from stimulation of the anterior columns must be direct. — (*Arch. anat. physiol.*, 1883, 281.) W. H. H. [433

Fishes.

Sudden increase of a rare sunfish. — Professor A. C. Apgar recently referred to the results of a fishing-excursion in central New Jersey. He found that the hitherto rare species of sunfish (Mesogonistius chaetodon) was remarkably abundant, and in a short time gathered seventy-five specimens. Where heretofore the common spotted sunfish (Enneacanthus simulans) and the still more abundant 'pumpkin-seeds' (Lepomis gibbosus) have been the characteristic species, these now appear to be largely crowded out by the small banded sunfish, which but a short time ago was only to be found in scanty numbers and in very limited localities. — (*Trenton nat. hist. soc.; November meeting*, 1883.) [434

Birds.

Anatomy of Biziura. — From the dissection of two males of B. lobata, Mr. Forbes finds that this duck forms an exception in that its trachea is simple, and devoid of a bulla, and that a subgular pouch, comparable to that of the bustards, exists. The ambiens tendon perforates the patella, as in Phalacrocorax and the Hesperornis of Marsh. — (*Proc. zoöl. soc. Lond.*, 1882, 455.) J. A. J. [435

Does the Carolina wren mimic? — Dr. C. C. Abbott read a short paper on the habits of the Carolina, or mocking-wren (Thryothorus ludovicianus). He had carefully studied a pair of these birds for a year, seeing the male bird at least three times each week, from September to September. In all that time he had never heard the male bird utter a note not distinctively its own. Prof. Austin C. Apgar remarked that he had been familiar with the song of this wren for years, but had not heard it mimic; yet in all works on ornithology that refer to this species it is called the mocking-wren; and the habit is more or less referred to by Wilson, Audubon, and by Baird, Brewer, and Ridgway, in their 'History of North-American birds.' — (*Trenton nat. hist. soc.; meeting* Sept. 19.) [436

The tongues of Tenuirostres. — In this paper, Gadow describes the modifications of the tongue which adapt it for sucking. The basal portion of the tube is formed by the rolling-up of the tongue, while the tip is formed by the rolling-up of the divided portion. In the Melaphagidae the end is broken up dichotomously into several tubes, and only the external borders of the tubes are lacinated. In the Hectariniinae the end is formed of only two tubes, and the internal edge is lacinated. In the hummers the tongue is double to near the base. Some peculiarities of the serpi- and mylo-hyoid muscles are mentioned. We notice that the author gives the anterior cornua of the hyoid apparatus as obsolete, though he describes the os entoglossum as double. From this we infer that he has forgotten that the ossa entoglossa are the anterior cornua. — (*Proc. zoöl. soc.*, 1883, 62.) J. A. J. [437

Mammals.

Innervation of the movements of the iris. — In the reflex narrowing of the pupil, which takes place when the eye is exposed to light, it has been generally accepted that the afferent fibres concerned in the act follow the same general course as that taken by the rest of the fibres of the optic nerve, passing along the optic tracts to a centre somewhere in the neighborhood of the corpora quadrigemina. Bechterew has shown that this is not the case. Section of the optic tracts in various places, from the chiasma to the corpora geniculata, causes no dilatation of the pupil, and does not interfere with the reflex narrowing of the pupil when exposed to light. Injury of the corpora geniculata and of the corpora quadrigemina, so long as the lesion in the latter case does not extend so deep as to involve the origin of the oculo-motor nerves, gives the same result. Lesions of the gray matter of the lateral and posterior walls of the third ventricle, on the other hand, cause a widening of the pupil, and a loss of the 'direct' light reflex in the eye of the same side. If, however, the eye on the uninjured side is exposed to the light, a narrowing of the pupil of both eyes takes place, appearing to show that the lesion has involved only the afferent fibres, and not the reflex centre. The author's view of the path of the fibres is, that they leave the optic nerve at the chiasma, pass directly into the gray matter of the walls of the third ventricle, and end finally each in the nucleus of the oculo-motor nerve of its own side. The fibres do not cross anywhere in their course, since lesions of either side affect only the corresponding eye; and a sagittal section of the floor of the ventricle or of the chiasma is without effect. The nuclei of the oculo-motor nerves he considers as the true centres for the reflex: and the commissural fibres connecting these nuclei explain the occurrence of the indirect reflex, that is, the narrowing of one pupil when the pupil of the other eye is exposed to light. The dilatation of the pupils which follows painful stimulation of any portion of the periphery of the body cannot be owing to stimulation of fibres running in the sympathetic; since, in the first place, the widening is not maximal, as it is when the sympathetic is directly stimulated. and, in the second place, this reflex is entirely destroyed when a deep section is made behind, or in the posterior part of, the corpora quadrigemina. He explains the action of painful stimuli as an inhibition of the normal light reflex contraction of the pupil. The pathological reflex paralysis of the iris, which occurs in certain diseases, in which the iris does not respond to stimulation of the eye by light or to painful stimuli of the body, is owing, he thinks, to an affection of the gray matter of the third ventricle. — (*Pflüger's archiv*, xxxi. 60.) W. H. H. [438

ANTHROPOLOGY.

Languages and ethnology. — In a recent communication, Gustav Oppert proposes to divide languages, according to the mental propensity towards concreteness or abstractness possessed by the various races, and exhibited in their speech, into concrete and abstract languages. The concrete division is again separated into the heterologous (having special words when persons of different sex address each other), and homologous (males and females use the same words as if addressing their own sex). The abstract division is separated into digeneous and trigeneous. In the former all things are either masculine or feminine: in the latter there are three genders. Each division is again subdivided into three classes, as follows: 1°. Elder and younger relatives have special terms, sex denoted by the words 'male' and 'female,' or by modulation; 2°. Having special terms for elder brother and elder sister, but one in common for younger brother and younger sister; 3°. Having four distinct terms for each variety of kinship. Representing the concrete and abstract by C and A, their classes by α and β, and their groups by 1, 2, and 3, and the monosyllabic, incorporative, euphonic, euphonic inflectional, alliteral, agglutinative, agglutinative inflectional, dissyllabic inflectional, inflectional synthetical, and inflectional analytical, by I., II., III., IV., V., VI., VII., VIII., IX., and X., any

Muskoki strategy. — The following method of Indian stratagem is told for the first time by Mr. H. S. Halbert. When a small party of Muskokis wished to attack a Choctaw village, they would arrange themselves in ambush at convenient intervals to within three hundred yards of the village. The bravest man would now crawl up as near the village as practicable, dig a pit and place himself in it, where he would wait until daybreak. The first Choctaw whom he then saw stirring about near his ambuscade he would shoot down, spring forward, and scalp him in the twinkling of an eye. He would then flee toward the second ambuscader. If he was pursued, which was generally the case, the pursuer received the fire of this ambuscader. The two warriors then fled to the third man in ambush. If the pursuers still followed, they received the fire of this man. The three now ran to the fourth ambushed warrior, where the same scene was enacted; and so on until the place of the last man was reached. — (*Amer. antiq.*, v. 277.) J. W. P. [440

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Paleontology. — Mr. Lester F. Ward, paleobotanist of the survey, is at work preparing a catalogue of fossil plants, with their geological relations, which will probably be published during the coming spring. Fifty-one boxes of Fort Union fossil plants, collected by Mr. Ward near Glendive, Montana, last July, have been received at the office of the survey.

A paleontological report on the paleozoic fossils of the Eureka district of Nevada, by Mr. Charles D. Walcott, is almost ready for the press. The number of paleozoic fossils from this district exceeds four hundred species.

During the month of October a large number of Potsdam fossils from Saratoga, N.Y., and some Trenton fossils from Trenton Falls, N.Y., were added to the collections in the hands of Mr. Walcott, who has charge of the department of paleozoic paleontology.

One of the papers in the fourth annual report of the survey is 'A review of the North-American fossil Ostreidae,' by Dr. C. A. White. It will be illustrated by forty-eight full-page plates of figures, giving figures of all the leading species of fossil forms of oysters, and of the leading varieties of Ostrea virginica, for comparison. For it, also, Professor Angelo Heilprin furnishes a revised catalogue of the tertiary oysters; and Mr. John A. Ryder adds a concise life-history of the common oyster, illustrating its anatomy, and giving the results of his recent experiments in the artificial propagation of oysters.

Chemistry. — A laboratory, to be in charge of Prof. F. W. Clarke, is being organized in connection with the survey. Heretofore the chemical work of the survey has been done at various laboratories scattered through the country, and at the field-laboratories at Denver, Salt Lake City, and San Francisco. A laboratory for physical experiments will probably be established in connection with the chemical division.

West-Virginia forests. — During September and October, Col. George W. Shutt examined the southern and eastern portions of West Virginia with especial reference to the distribution of timber, its economic value, and the facilities of transportation to market *viâ* the streams of the region. He travelled over a thousand miles by wagon, and two hundred on horseback, and expresses the opinion that nearly one-half of the state is covered with a virgin forest, the value of which, if rendered marketable, would amount to billions of dollars.

Geology. — In making an excavation a few weeks ago for a building on Connecticut Avenue, in the north-western section of Washington, D.C., the interesting discovery was made of the remains of a subterranean forest. The fact was mentioned at the meeting of the Biological society of Washington, Nov. 2, by Professor Lester F. Ward; and, from the excellent preservation of the wood, the opinion was expressed that it was simply a collection of drift-wood that had been washed into a ravine in comparatively recent time. Mr. W. J. McGee of the Geological survey, who has been working up the geological structure of the District of Columbia for some time, had also examined the locality in question, and was of the opinion that the deposit was of quaternary or prequaternary age. A few days after the meeting of the Biological society, above mentioned, he, with Professor Ward, Mr. G. K. Gilbert, and Mr. J. B. Marcou, re-examined the buried forest; and Mr. McGee's opinion was confirmed, — the stratum was found to underlie the quaternary gravels of the district. The occurrence is of interest, since the slightly altered wood undoubtedly represents the end of the long interval extending from the cretaceous to the beginning of the quaternary, during which the lignite beds and iron-ore deposits, so common in the region, were formed.

Publications. — The survey has just issued a miscellaneous work, one of a series of statistical papers, which is distinct from the Monographs and Bulletins, but, like them, is for sale at cost price (fifty cents in this case). The title of this work is, 'Mineral resources of the United States,' by Albert Williams, jun., chief of division of mining statistics and technology. In its 813 pages it gives the statistics of our mineral production for the year ending June, 1883, and also a mass of information in relation to the production of coal, petroleum, iron, copper, lead, and zinc. It also treats of building-stones, clays, fertilizers, etc., and gives lists of the useful minerals of the United States, with localities, and concludes with extracts from the new tariff relating to import duties upon chemical products, metals, mineral products, etc. It will therefore be seen that the work is of practical value; and this fact is also indicated by the demand for it, which comes largely from miners and mine-owners, particularly from the west.

Bulletin no. 2 of the survey is also by Albert Williams, jun. Its title is, 'Gold and silver conversion-tables, giving the coining values of Troy ounces of fine metal, and the weights of fine metal represented by given sums of United States money.' It is a pamphlet of eight pages, and is of especial value to assayers and bullion-dealers.

The third annual report is printed, and waiting for a few of the illustrations. The fourth annual report, with the exception of the index, is in type. Both these reports will probably be issued early during the forthcoming year.

Dutton's 'Tertiary history of the Grand Cañon district, with atlas' (volume ii. of the Monographs of the survey) has been distributed to European institutions, and will now be distributed to American institutions.

Volume iii. of the Monographs, 'Geology of the Comstock lode and Washoe district,' with atlas, by George F. Becker, is being delivered to the survey by the government printer, and will soon be ready for distribution.

The Monographs of the survey are not for gratuitous distribution. They can only be distributed through a fair exchange for books needed in the library of the survey. Copies over and above the number needed for such exchange are for sale. The price of volume ii. is $10.12, and of volume iii., $11.

NOTES AND NEWS.

Those who are interested in our leading article this week will be pleased to learn, that, in his will, Barrande bequeathed his collections, library, and undistributed copies of his publications, to the museum at Prague. He further provided for the continuation of his work by a bequest of ten thousand florins to the museum, which, by its acceptance, pledges itself to fulfil his wishes. Drs. Krejči, Frič, Kořiska, Prachenský, and Bellot were appointed by him a commission to see that his designs are carried out; and Drs. Waagen and Novák, well-known paleontologists, designated to execute the work, — the former to complete the 'colonies,' gasteropods, and echinoderms; the latter, the bryozoans and corals.

The museum proposes to establish a Barrande fund for supporting further studies on the Silurian formation of Bohemia; and any gifts that may come from America for that purpose would, we are assured, be deemed particularly valuable. The editor of Science will be pleased to forward to the museum at Prague any contributions that American naturalists may desire to make, and to acknowledge the same in these columns.

— Sir Charles William Siemens died in London, Nov. 20. He was born at Leuthe, in Hanover, in 1823. From 1844 he resided in England. In 1858 he established, with his brother, the firm which has become famous through the telegraph-cables they have made. For ten years (1853-63) Dr. Siemens was engaged on the regenerative gas-furnace, and since that time his methods of manufacturing steel have met with the greatest success.

— Information has been received from Sunda Straits, giving details of the hydrographical and topographical changes due to the great Java earthquake. These seem to be less extensive than heretofore reported by the press. Commander P. F. Harrington, U.S.N., reports the hills and trees in the vicinity of St. Nicholas Point covered with ashes, but otherwise unchanged. The soundings here remain the same. The sea has rushed through the valleys of Thwartway Island, tearing away the vegetation, and leaving the low land bare; and, from a distance, these breaks in the forest give it the appearance of five islands, but there is no change in the shore-line or soundings. The same is true of Anjer, where the base of the lighthouse at Fourth Point, and the buoys of the submarine cable, are the only monuments of that populous town. The plains have been swept by the sea, and show only uprooted palms, and ghastly relics of the inhabitants. Krakatoa volcano appeared active; but on a nearer approach it was found that the appearance resulted from ashes, etc., falling down the precipitous cliffs, and carried off by the wind.

The north-western part of Krakatoa Island has disappeared. The immense mass which is missing seems to have formerly been the choked-up crater; and its material has probably modified the sea-bottom northward from its place. No bottom could be found in the vacant spot with twenty fathoms of line. Prior to the eruption, Verlaten and Lang islands were covered with verdure. Their contour has been but slightly changed, but they are covered with scoria. A small island has formed eastward from Verlaten. The Polish Hat has disappeared, and where it stood is more than twenty fathoms water. A new rock, about twenty feet in height, has risen in eight fathoms, near the southern point of Lang Island. The channel south from Bezee Island has been closed to navigation by reefs and islets not yet surveyed. From the northern end of the island a reef extends in a north-westerly direction, apparently connecting with other islands to the westward.

The whole coast of Java between Second and Fourth points has been swept clean by the sea, but there is no essential change in the shore-line and soundings. Masses of floating pumice are wedged in Lampong Bay, and interrupt communication with Telok Betong. The lighthouse at Java Head remains undisturbed, as does that at Flat Point. Other dangers may be developed on a careful survey, but the main gate of the Straits of Sunda seems unimpeded.

— Mr. W. F. Denning of Bristol, Eng., noting the fact that accounts of large meteors form a frequent subject of correspondence in the columns of scientific journals, but that it is not often the case that the descriptions of these phenomena are sufficiently exact to be valuable for purposes of calculation, suggests, in a letter to the editor of *Nature*, the proper methods of useful observation of these bodies. Rough estimates of the direction and position of flight are of little utility; and the vague statements often made occasion an endless source of difficulty in the satisfactory reduction of results. The observers of large meteors should attend scrupulously to that most essential detail, the direction of flight, and express it by some method of uniformity. In place of the customary vague and variable methods of description of the apparent paths of these bodies, Mr. Denning suggests that observers uniformly give the right ascension and declination of the beginning and end points of the visible paths, — elements which admit of ready determination by projecting the observed flights upon a star-chart or celestial globe, and reading them off. This system would render the after-comparison of observations a work of greater facility and precision. Though the direction of flight is the all-important element to be determined by meteor-observers, some minor points — as the time of appearance, brightness, and approximate duration — should be recorded whenever feasible; also whether the body is accompanied by phosphoric streaks or spark-trains. If this were done more systematically, the observations of fireballs would acquire additional value, and quite possibly might develop some new facts either as to their appearance or origin.

— Mr. Thomas Gaffield read a paper on glass and glass-making, illustrated by specimens, at a meeting of the Society of arts of the Massachusetts institute of technology, Nov. 22.

— At the meeting of the Portland, Me., society of natural history, Nov. 19, the president, Dr. Wood, gave account of the unearthing of bones of some unknown animal from a peat-bed on Ragged Island, Casco Bay, by Capt. Thomas Skolfield in 1835. Eighty-five feet in length of vertebral bones were taken out and thrown away. The head and tail were not uncovered, and the animal was estimated to be a hundred and ten feet long. No ribs were found, and no marks of rib attachment appeared on any of the vertebrae, which were hard and smooth. Only four bones were saved: two were given to the Portland society, but were burned in 1854; the other two have been lost sight of, but were said to have been taken to the Philadelphia academy in 1836 or 1837, by a Mr. Coolidge. Of the two given to the society, the large one was unquestionably a vertebra: its length was from fourteen to sixteen inches; its diameter, nine or ten inches on the articular faces, and eight midway. The other bone was limpet-shaped, four or five inches in diameter and height. The shape and size of these bones are well remembered by members of the society, and Capt. Skolfield; and the story of the last is well vouched by many others.

Two unsuccessful attempts have been made by the society to unearth more bones. Another trial will be made next season.

— On the retirement of Mr. R. Hering from the presidency of the Engineers' club of Philadelphia, at the close of its fifth year, he gave a summary of recent progress (*Proc. eng. club Philad.*, iii.). The work of the late U. S. board appointed to test iron, steel, and other metals, was referred to; and it was stated that there was at least some possibility that its work may be in time resumed. The chief of ordnance recommends that an appropriation of ten thousand dollars be made by Congress for the purpose, as urged by the convention of the societies of civil, mechanical, and mining engineers. The differentiation of the profession into the several branches, — civil, mechanical, mining, — and the subdivision of these into specialties, were considered as marking the tendency of recent change. Inventions are coming forward with increasing number and rapidity, but it is becoming each day more evident that they are all the products of growth and of gradual development. No new thing comes into use at once fully perfected. Of accomplished work, the East-river bridge, with its span of 1,595 feet, suspended 135 feet above the water; our Kinzua viaduct at Bradford, 2,052 feet long, spanning a valley 302 feet below it; the Henderson bridge over the Ohio, of 525 feet span; and the great bridge to be built over the Firth of Forth, — are among the most marvellous. The great canals in progress, or proposed, — that in Florida, opening the Kickpochee Lake; the interoceanic canal through the Isthmus of Panama; the great Sirhund canal in India, 500 miles long; the Corinth canal in Greece; and the Manchester ship-canal, — are evidences that the days of canals are but just commencing. The United States boast to-day 116,000 miles of railroad, and are building over 30 miles per day, and earning $550 per mile. Locomotives for the Pennsylvania railroad are built weighing over 60 tons, and make 90 miles in 80 minutes. Electricity is a competitor, which, however, is not likely at once to displace steam on the rail. Heat and steam supplied from a central station, as at New York, where the New-York steam company are preparing to work 16,000-horse power of Babcock & Wilcox boilers, 2,000-horse power of which are constantly at work, is a promising illustration of advance. Electricity similarly distributed, — as by the Edison company and the Brush company, — and the telephone, are the latest of these achievements of the profession. Sanitary engineering, although the most essential of all, seems to be the last to come in, and is but now beginning to take its place.

— Since the article in this number on crystals in the bark of forest-trees was in page, the writer has seen a recent work, Anatomie der Baumrinden, Berlin, 1882, Dr. Joseph Moeller, in which the subject is fully treated and richly illustrated.

— Microscopists will regret to learn of the death of Mr. Robert B. Tolles at Boston, on the 17th, at the age of sixty-one. No one has done more than he to raise the standard of excellence of American objectives for the microscope; and his ingenuity in devising special methods to overcome particular difficulties is known to all who have tested his powers. He has been in feeble health for several years, but continued to work with astonishing vigor and pertinacity.

SCIENCE.

FRIDAY, DECEMBER 7, 1883.

JOACHIM BARRANDE.

II., HIS SCIENTIFIC WORK.

The influence of Barrande upon science in this country and throughout Europe has been of the first importance; and he has done much for the reputation of many of our investigators by his careful attention to their works, and his respectful quotations. He recognized the work especially of Dr. E. Emmons, and gave him the credit of being the discoverer of the primordial fauna, which Emmons had previously published as being in the Taconic system. Barrande thus ranged himself, during the celebrated Taconic controversy, on the side of Dr. Emmons, and his principal supporter in this country, Professor Jules Marcou. One of M. Barrande's most remarkable discoveries related to what he has called 'colonies.' According to him, certain characteristic fossils appeared sporadically in the faunas preceding those to which they properly belonged; and he deduced from this the result that two faunas having some identical species, but existing in different parts of the world, were not necessarily contemporaneous because of this fact, but might, indeed, be very distinct in age. These views are strongly supported by Professor Jules Marcou in this country, who states that he has discovered similar colonies in the rocks of the Taconic, underlying the Potsdam at Swanton and Phillipsburg; and is opposed principally by English authors upon the grounds that the evidence was stratigraphically defective. Barrande's reply to this, which he was preparing at the time of his death, has not yet been published. The theory has the support of the geologists of Vienna, especially Haidinger, director of the Imperial museum, whom Barrande quotes upon the titlepage of each of his books upon the 'colonies.'

From 1846 to the present time, the smaller publications of this voluminous and accurate writer must have reached nearly a hundred. Of these, between seventy and eighty were made to learned bodies, and from sixteen to twenty were pamphlets and books of octavo size: some of these were abridgments of his larger volumes. In the latter series, his *études*, extracts, etc., he published over three thousand pages and twenty-nine plates. Of these, his 'Cephalopodes, études générales,' was the most important to the general student. His grand work, the publication of which was begun in 1852, and is not yet finished, has already reached, as we have said, the number of twenty-two quarto volumes. These treat of the Trilobites and Crustacea, 1,582 pages, 84 plates; Cephalopoda, 3,600 pages, 544 plates; Brachiopoda, 226 pages, 153 plates; Acephala, 342 pages, 361 plates; and he announces as having already completed over 100 plates of the Gasteropoda, which have not yet appeared. This makes the enormous number of 5,750 pages of text in quarto, and 1,148 plates already issued, which we estimate as containing about eighteen thousand figures of fossils of the finest execution.

Barrande published large editions of his smaller works, which he distributed with a free hand to many institutions and scientific men; but of his larger works, the edition, probably on account of the expense, was limited to two hundred and fifty copies. The larger number of these he also gave away to scientific institutions and to individual geologists, and it is estimated that he did not receive in return as much as the actual cost of three of the large volumes.

The Gasteropoda, Echinodermata, Bryozoa, and miscellaneous fossils still remain unpublished; though over a hundred plates of the Gasteropoda were completed, and the text was being printed, at the time of his death.

The number of species described amount to thirty-six hundred. When we reflect that each of these had to be studied, and handled over and over again many times, before reaching the final stages of classification, description, and illustration, we are amazed at the industry and capacity required to do all this scientific work single-handed. Barrande, unlike other voluminous authors, had no collaborators. With the exception of an amanuensis, draughtsmen, mechanical preparators, and mere collectors, he did all of this vast work. A careful and comprehensive system was followed in every volume, and in the descriptions of each species; so that, when one has mastered the intricacies of this, he can at once find every thing relating to the history, literature, structure, relations in time, and geographical distribution, of any species or group.

Finally, in the cephalopods, the parts and internal structures for which this fossil type is remarkable, as well as the embryo shells and their characteristics, are followed out in the same way. We will speak more at length of this type, partly because it was the favorite and most fruitful field of research of this eminent author, and was selected by him as the stronghold from which to attack the theory of evolution, and partly because we have no space to do justice to other departments, where he, however, made important discoveries; as, for example, among the trilobites. With infinite labor he succeeded in getting series showing the stages of growth of some species among these ancient Crustacea, and taught us that it was possible to study their development even in the Silurian period. Barrande's efforts have been frequently referred to as if he were one of what we might call the numismatic school of geologists, who study animal fossils as if they were medals, useful principally to verify the date and place of formations. On the contrary, his technical labors had a distinctly ideal purpose, — the investigation of the evidences for and against the theory of evolution. His education and consequent psychological condition placed him in opposition, and, in spite of his honest efforts to treat the subject fairly, controlled his classifications, and warped his judgment. The Cuvierian form of anthropomorphology was his faith; and he failed, as have most great executive men, in realizing the dangers of his own mental training, and the need of correcting the personal equation.

The facts, however, were strong enough even to meet his requirements in some of the groups he studied; yet he ended by admitting that evolution must, in part at least, be true. He believed that the different types were miraculously created, but that the smaller series which he had traced might have been evolved within certain well-defined limits, fixed according to the plans of an infinite intelligence, which it was hopeless to try to understand. He was also deficient in that sort of zoölogical knowledge which is acquired only by research among existing animals, and a familiarity with their modes of development, anatomy, and habits. This explains the apparent inconsistencies which show themselves in his text: — the continual admission of transition forms between different species and smaller groups, and yet the perpetual denial of the probable former existence of any such transitions between what he considered distinct types, whenever he could not actually find them; his comparisons between the Silurian and recent Nautili, which he supposed to be very similar, when in reality only their adults are similar, the young shells and their developmental stages being widely different; his singular opinion that species like these Silurian Nautili and other forms, which seemed to him out of place and also inexplicable on account of their structure, had been set in the geological record as intentional exceptions, to teach man the divine origin of this apparently modified chaos of gradations. Barrande understood, and gave a fair statement of, the ordinary views of evolutionary embryologists on p. 74 of his 'Études générales, Cephalopodes,' and represented a naturalist of this stamp investigating the embryos of the fossil Nautiloidea. After finding all the forms of the group from the Silurian to the present time with the same type of apex or young, he would then necessarily draw from this embryo a picture of the lost prototypical ancestor of all the Nautiloidea. In his next steps he would find the adults of transition forms from Nautiloidea to Ammonoidea, and set down his convictions that the Ammonoidea must have been derived from Nautilus through these transition forms, the gradations being Nautilini, Goniatites, Ammonites. Barrande then pictures this same naturalist as attempting to verify his apparently well-founded conclusions by opening a species of Goniatite with the anticipation of discovering within, at the apex, or young shell, an identical form and structure to that which he had been accustomed to find in the Nautiloidea, and his consequent confusion, and the overthrow of his theory, upon the exposure of a different form. Barrande's argument deals fairly with every point; and his facts are crushing refutations of the usual direct, simple modes pursued by embryologists in handling the question of the evolution of types. Barrande's work had no orators or lecturers to translate it; and the hypothesis of the embryologists, and even evolution itself, escaped an attack, which, if supported by powerful influences, might have shaken the popular faith in the new school of thought.

Hyatt has denied that there were such great and essential differences between the embryos of the Nautiloidea and those of the Ammonoidea; and they certainly seem to have been more alike than was supposed by M. Barrande. The fact, however, remains, that Barrande saw clearly that the embryos of these two nearly allied groups, which are united by most authors into one order, were, even in the Silurian, more easily separable from each other than some of the adult forms. When we can add to this, his discovery and thorough demonstration of the distinctness of the different types of fossils in the Silurian, and their sudden mode of appearance, we see clearly that he succeeded in doing the work which has thrown the greatest light upon the most obscure and interesting periods of the world's history, and which has furnished a temperate and healthy opposition to the theory of evolution. His faults of logic were unavoidable, with his mathematical and Cuvierian education, and strong feelings of loyalty to his masters in science; but these are only slight scratches upon the face of the vast monument erected by his labors, his discoveries, his eighty-three years of unblemished moral and faithful life, and his personal sacrifices for the advancement of science and the truth.

WHIRLWINDS, CYCLONES, AND TORNADOES.[1] — V.

CYCLONIC circulation has thus far been described as if it were effected in radial lines in to and out from the centre; but here, as in the whirlwind, perfect radial motion is impossible. A horizontal rotary motion would soon be established near the centre by the inequality of the inblowing winds. It is found, however, that all storms yet studied turn from right to left in the northern hemisphere, and from left to right in the southern (fig. 9). Such constancy points to something more regular than the accidental strength of the winds,—to some cause that shall always turn the indraughts to the right of the centre as they run in towards it in the northern hemisphere, and to the left in the southern hemisphere; and this cause is found in the rotation of the earth on its axis.

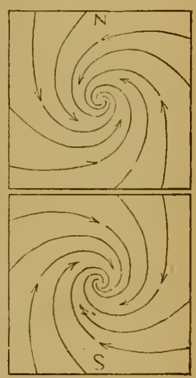

FIG. 9.

There is a force arising from the earth's rotation that tends to deflect all motions in the northern hemisphere to the right, and in the southern to the left; and this deflecting force varies with the latitude, being nothing at the equator, and greatest at the poles. It may be found that this statement differs from that generally made; namely, that moving bodies are deflected only when moving north or south, and not at all when moving east or west; for it is thus that Hadley (1735) and Dove (1835) explained the oblique motion of trade-winds, and that Herschel and others explained the rotation of storms. But this is both incorrect and incomplete; for a body moving eastward is deflected as well as when moving northward, and the actual deflective force is greater than that accounted for in Hadley's explanation.

[1] Continued from No. 43.

It is this deflective force, acting on winds from all sides, as was first shown by Tracy[1] (1843), that combines with the centripetal tendency of the surface-winds to give rise to the inward spiral blowing of the storm (fig. 10), — a constant feature of all cyclones.

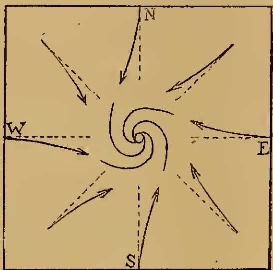

Fig. 10.

In all hurricanes, the winds greatly increase in strength as they near the centre of the storm, and at the same time their path becomes more nearly circular. A cause of this was briefly stated for the whirlwinds: but it now must be more fully analyzed; and it will be best to begin the attempt by resolving the motion of the wind at any point of its spiral track into two rectangular components (fig. 11), — one, along a radius toward the centre, *P R*, the centripetal component; the other, circular or tangential, *P T*. Only the first of these comes directly from the convectional circulation, already described as depending on the central warmth; and this one would never produce winds of devastating strength. The second, or tangential, arises first from the deflective force of the earth's turning. The higher the latitude, the less the friction at the bottom of the atmosphere, and the greater the distance from which the wind is derived, then the greater its right-handed departure from a radial path. Hence in a large storm at sea, where the friction is small, and the indraught has its source several hundred or even a thousand miles away from the centre of low pressure, the deflective tangential component becomes very considerable, and may, near the centre, outrank the centripetal.

Fig. 11.

But there is another and even more important cause of growth in the circular element of the wind's motion; namely, the increase of its rotary velocity as the radius of rotation decreases, in accordance with the law of the 'preservation of areas,' already mentioned. Let us suppose, that, when at a distance of five hundred miles from the centre, the inblowing wind has been turned to the right of its radial path by the earth's deflective force so as to have the moderate tangential or rotary velocity of one mile an hour; and, disregarding the further effects of deflection, let us consider the consequences of gradually drawing this mass of air towards the centre. The product of its radius and its rotary velocity must remain constant; and hence, as the radius is diminished, the velocity must increase, one quantity varying inversely as the other. The wind has no visible, material connection with the storm-centre; but it is slowly moving around that centre, under the control of central forces, derived from differences of temperature and pressure, that drive it inwards, or, in other words, shorten its radius of rotation: and consequently, when, in the case supposed, the radius has been diminished to five miles, the velocity must have been accelerated to one hundred miles an hour, — a violent hurricane-wind. The recognition of this important factor of the storm's strength is due to Ferrel (1856). The theoretical increase of velocity thus provided is never fully realized, for much motion is overcome by friction; but enough is preserved, especially in tropical storms, to give them the greatest share of their destructive strength. The total tangential component of the wind at any point must therefore be considered as the sum of the deflective and accelerative forces, minus the loss by friction. Near the storm-centre, where the velocity of the wind is very great, this tangential component is much greater than the centripetal, and the spiral path becomes almost circular; while the reverse relation holds for the outer part of the storm.

It will be easily understood, that a considerable centrifugal force will be developed by the rapid central rotations, as well as by the earth's deflective force; and, as a consequence, the centripetal force will be partly neutralized, and the winds will be held out from the centre. This must increase the depression already produced there by expansion and overflow; and, as a matter of fact, the low pressure of a storm-centre, especially in tropical latitudes, is chiefly the effect of this dynamic, and not of the earlier named static cause. But so long as the wind maintains its rapid motion, the additional

[1] See Science, i. 98.

depression is powerless to draw it towards the centre. Only when its velocity is decreased by friction does the barometric gradient, just before produced by the centrifugal force, urge the wind inwards to the middle of the storm. The additional gradient, therefore, represents potential energy, derived from the actual energy of the rotating winds, and all ready to be transformed into actual energy again, as soon as friction has destroyed some of the velocity of rotation.

The general interaction of the storm-forces may now be thus summarized: in obedience to a centripetal tendency, produced by differences of temperature or of pressure, or both, the air moves along the surface to the region of low pressure. On its way, the deflective force arising from the earth's rotation turns it continually to one side, and so gives it a more and more nearly circular path; and, in addition to this, its rotary velocity increases as much as its radius of rotation decreases: the tangential component of its spiral motion must therefore continually increase. With the increase of this component, and the decrease of the radius of rotation, the centrifugal force ($v^2 \div r$) must increase rapidly, and soon come to equal and counterbalance the original centripetal force, and at the same time greatly increase the barometric gradients. At this point the wind would blow in a circular path, were it not that friction with the sea or ground is continually consuming some of its velocity, and thus decreasing its centrifugal force, and allowing the potential energy of the steep barometric gradient to produce centripetal motion. This decreases its radius, and at once gives it new life, again to be partly destroyed and renewed as before. Absolutely circular motion can therefore never be attained, although it is approached very closely near the centre. At sea, where friction is small, and in tropical latitudes, where the strength of the storm is great, the wind is unable to reach the storm-centre; for, when the distance from the centre is reduced to only five or ten miles, the centrifugal force is so great, and the wind's course is so nearly circular, that it is carried aloft by the up-draught before it can enter noticeably farther: the central area is therefore left unprovided with violent winds, and is generally a comparative calm, known as the 'eye of the storm,' of which there will be more to say later. The general form of the storm-wind's spiral can be deduced from the preceding considerations. The angle between the tangential component and the actual path of the wind, which is called the inclination (fig. 11.), will vary with the relation of the circular and centripetal elements of the wind's motion; the tangent of the inclination will equal the radial divided by the tangential component: hence in the outer part of the storm the inclination will be large, and the wind will blow almost directly toward the storm-centre; but nearer the centre the inclination will become smaller and smaller, and the wind will blow in a more and more nearly circular path. It will also be understood, that the upper winds, less influenced by friction, will near the centre have a greater velocity and a less inclination than the lower ones. Moreover, the inward gradient which they produce will be effective and important in urging along the slower surface-winds, in a manner better illustrated in a tornado, where this action will be more fully described.

(To be continued.)

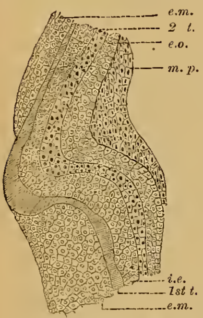
ON THE DEVELOPMENT OF TEETH IN THE LAMPREY.

The teeth in the myxinoid fishes are quite different from those of other vertebrates, and have hitherto been supposed to belong in an entirely different category. Nothing has been known with regard to their development, except a brief statement as to their mode of succession in Petromyzon by Professor Owen, in his 'Odontography.'

The teeth of the lamprey are horny, and of simple conical shape, disposed concentrically in the dome-shaped mouth. Besides these, there are horny lingual and palatal teeth.

The kindness of my friend Professor Benecke of Königsberg, who sent me a number of lampreys at the end of their metamorphosis from Ammocoetes, has enabled me to follow out the development of these horny teeth with unexpected results; for, as far as the essential part of the process is concerned, it differs but slightly from the normal course of true dental development. There is first formed a low conical papilla of somewhat reticulate tissue, belonging to the mesoblast (*m.p.*), and continuous with the dermis, which in this, as in other vertebrates, is of mesoblastic origin. Over this papilla the epiblast which lines the cavity of the mouth becomes extremely thick, and consists of very numerous layers of cells. All of these layers can be continuously traced into the other epiblast of the mouth, as well as that of the external skin. In the stage here figured there may be seen, immediately overlying the mesoblastic papilla, a layer of epiblastic cells irregularly columnar and polygonal in shape (*e.o.*). These cells are the homologue of the enamel-organ of the other vertebrates, and originate in the same way. So far, at least, the lamprey does not show an essentially different type of tooth-development from that known in other groups.

The cells of the 'enamel-organ' are rapidly proliferating, and have thrown off from their outer surface a conical cap of cells (*2d t.*), which are flattened, and which show an incipient formation of pigment among them. This hollow cone of cells is the rudiment of the youngest tooth, which in the stage here described is the second of the series. Outside of the rudimentary tooth is a cone of polygonal epiblastic cells, several layers deep (*i.e.*); and this is again followed by the first tooth, now almost completely cornified and pigmented, so that traces of cellular structure are but faintly discernible (*1st t.*). The tip of this tooth has just penetrated the skin of the mouth, and is elsewhere covered by the many-layered epiblast (*e. m.*).



Section through inner side of lip of metamorphosing lamprey. *e.m.*, epiblast of mouth; *1st t.*, oldest tooth; *2d t.*, youngest tooth; *e.o.*, enamel-organ; *i.e.*, intermediate epiblast-cells between successive teeth; *m.p.*, mesoblastic papilla.

We see, therefore, that the essential parts of the typical vertebrate tooth are here present; namely, the mesoblastic papilla, and the over-lying epiblastic enamel-organ. But the ordinary type of dental development is here greatly modified. The papilla is never ossified; and the enamel-organ secretes no enamel, but functions as a sort of tooth-gland, throwing off successive hollow cones of flattened and cornified epiblastic cells. The actual tooth of the lamprey is therefore not the homologue of the entire tooth of a selachian, but simply of the enamel-cap. It is not difficult, however, to understand how the process seen in Petromyzon could be derived from that in the selachian. In consequence of this change, another difference arises: as the papilla never ossifies or becomes protruded, it is no longer necessary that for every new tooth a new enamel-organ should be formed by budding from the old one; so each enamel-organ is converted into a permanent tooth-gland, functional throughout the life of the animal.

This view of the peculiarities of dental development in Petromyzon implies, of course, that this group of fishes was derived from ancestors possessed of teeth of the ordinary or selachian type. Further, as it is now very generally admitted that teeth are only modified placoid scales, it follows that the lampreys are descended, ultimately at least, from forms provided with placoid scales.

Such a conclusion, however, does not by any means commit us to the view that the myxinoids are degenerate descendants of some gnathostomatous group, as this is no more implied in the possession of ordinary calcareous teeth than in the presence of the horny teeth which the group has long been known to possess.

NORDENSKIÖLD ON THE INLAND ICE OF GREENLAND.[1]

In a series of letters to Mr. Oscar Dickson, Baron Nordenskiöld has given a detailed report of the leading incidents and results of his recent expedition, though it will still be some time ere we can learn what are the full gains to science. The leading novelty of the expedition was, of course, the journey into the interior of Greenland.

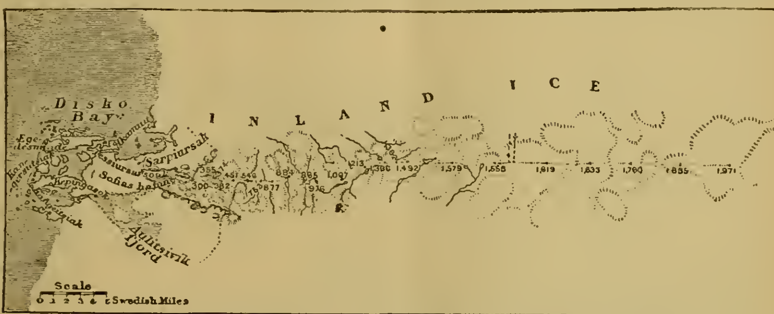
After landing Dr. Nathorst and his party at Waigatz Sound, Nordenskiöld went back to Egedesminde, which he reached on June 29. The following day he left for Auleitsivik Fjord, from which the expedition was to start. He then proceeds: —

On July 1 the Sophia anchored in the bay. We found here a splendid harbor with clay bottom, some seven fathoms deep, surrounded by gneiss rocks from six hundred to a thousand feet in height, the sides of which are in some places covered with low but close shrubs, or clothed with some species of willow, mosses, and lichen, which, when we arrived, were ornamented with a quantity of magnificent blossoms. From one of the slopes a torrent descended, the temperature of which was 12.3° C. The weather was fine, the sky cloudless, and the air very dry. July 1 to 3 were employed in making preparations for the ice-journey, while the naturalists made excursions to various places in order to collect objects relating to the conditions of the country. On the night of the 3d every thing was ready for a start; and, after some difficulty in reaching the spot where the baggage was, we were fairly off. The spot from which we set out on the journey was only five kilometres from the actual shore, and situated below a little lake into which a number of glacier rivers fell. We proceeded up the river in a Berton boat, purchased in England. On the night of the 4th we camped for the first time on the ice. The expedition consisted of nine men besides myself. After a great deal of hard work in getting the sledges over the ice, which was here very

[1] From *Nature*, Nov. 1 and 8.

rough, we found, on the morning of the 5th, that it was impossible to proceed eastwards, but were compelled to return to the border of the ice, and then continue to the north or north-east until finding smoother ice. This first part of the ice was furrowed by deep crevasses and ravines, causing us much trouble. We covered, however, a good distance that day, and pitched our tent near a land-ridge in the ice, two hundred and forty metres above the sea.[1] On July 6 I sent the Lapp Lars forward to reconnoitre; and he reported that it was still impossible to proceed eastwards, but, if we marched for a day or so to the north, we would find the country accessible to the east. As I feared, however, the impossibility of dragging the sledges with the weight on them over the rough ice, I selected provisions, etc., for forty-five days, and left the rest in a depot in the ice. We now resumed the march. It was very interesting to witness the great ease with which the Lapps proceeded among the ice-ravines, how easily they traced a road discovered, and with what precision they selected the least difficult track.

The Lapp Lars carried, instead of an alpenstock, a wooden club, with which he had slain more than twenty-five brown bears, full of marks from their teeth; and his eyes sparkled at the thought of encountering a white one. On the night of the 6th we held our third camp on the ice; and now several officers and men from the Sophia, who had accompanied us thus far, left us. Besides the most advantageous requisites for such a journey, we had with us a cooking-apparatus for petroleum: and here I beg to say that I found this kind of oil far more suitable than train or vegetable oils, which I had used on my former expeditions; and I recommend the same most warmly to arctic explorers. Of scientific instruments I may mention compasses, two chronometers, a circle by Pistor and Martin, a small sextant (in case of the former being damaged), a mercury horizon, three aneroid barometers, thermometers, magnets (for the study of the clay deposit in the snow), a topographical board, a photographic apparatus, blowpipes, flasks, nautical tables, etc. The sledges, 'kalkar,' six in number, were of the same kind as those on which Swedish peasant women bring their wares to market. The harness was made so strong that it would hold a man, in case of his falling into a crevasse. In addition to these things, we had a Manila rope specially spun for the expedition at the Alpine purveyor's in Paris. The food supplied per day may perhaps interest explorers. It was, — breakfast, coffee, bread, butter, and cheese (no meat or bacon); dinner, forty-two cubic centimetres Swedish corn brandy (*bränvin*), bread, ham or corned beef, with sardines; supper, preserved meat, Swedish or Australian. Sometimes preserved soup was served with dried vegetables. Five men were teetotalers, but there was no need of supplying them with extra rations. For cooking, 0.7 litres of spirits were consumed per day. Our whole baggage weighed a ton, — a weight which might easily have been drawn across a smooth snow or ice field, but which was very difficult of transporting over the rough and cut-up surface we had to traverse. Our daily march between July 7 and 9 was therefore not great, viz., five kilometres a day. In addition to the crevasses and ravines, we encountered innumerable rivers, swift, and with steep banks, which were difficult of crossing, which was generally accomplished by laying three alpenstocks across them. If I had not selected these of the toughest wood obtainable, we should often have had to make *détours* of many kilometres.



THE HEIGHTS ARE GIVEN PROVISIONALLY IN METRES. SWEDISH MILE = 6.64 ENGLISH MILES.

On these days we found, on several occasions, large bones of reindeer on the snow; and it was but a natural and pardonable conclusion to arrive at, that they were those of animals who had fallen in their wandering over the 'Sahara of the arctic regions.' But that good signs are not always true ones we soon discovered.

[1] The altitudes were ascertained by comparing three aneroid barometers, while observation was simultaneously made at Egedesminde with a splendid sea-barometer I had left there for that purpose. As the figures have, however, not yet been verified, they may be slightly altered. They seem, on the whole, too low.

During the entire journey, we had great difficulty in finding suitable camping-places. Thus, either the ice was so rough that there was not a square large enough for our tent, or else the surface was so covered with cavities, which I will fully describe later on, that it was necessary to pitch it over some hundred smaller and a dozen larger round hollows, one to three feet deep, filled with water, or else to raise it on a snow-drift so loose and impregnated with water that one's feet became wet, even in the tent. An exception to this was the place where we camped on July 9; viz., camping-place no. 6. We encountered here a small ice-plain, surrounded by little rivers, and almost free from cavities, some thirty metres square. All the rivers flowed into a small lake near us, the water from which rushed with a loud roar through a short but strong current into an enormous abyss in the ice-plateau. The river rushed close to our tent, through a deep hollow, the sides of which were formed of magnificent perpendicular banks of ice. I had the spot photographed; but neither picture nor description can give the faintest idea of the impressive scene, viz., a perfectly hewn aqueduct, as if cut by human hand in the finest marble, without flaw or blemish. Even the Lapps and the sailors stood on the bank, lost in admiration.

At first we had followed the plan of bringing the baggage forward in two relays; but, finding this very fatiguing, I decided to bring all with us at once. I found this to answer better. On July 10 we covered thus nine and a half, on the 11th ten, and on the 12th eleven, kilometres. The road was now much better than before, although stiff enough. An exception to this was, however, formed by the part we traversed on the 11th, when we proceeded alongside a big river, the southern bank of which formed a comparatively smooth ice-plain, or rather ice-road, with valleys, hills, cavities, or crevasses, some five to ten kilometres in width, and five kilometres in length. This plain was in several places beautifully colored with 'red' snow, especially along the banks of the river. It was the only spot on the whole inland ice where we found 'red' snow or ice in any quantity. Even yellow-brown ice was seen in some places; but, on the other hand, ice colored grayish-brown or grayish-green, partly by kryokonite, and partly by organisms, was so common that they generally gave color to the ice-landscape.

Even on July 12, between camps nos. 7 and 8, we found blades of grass, leaves of the dwarf-birch, willows, crackberry, and pyrola, with those of other Greenland flora, on the snow. At first we believed they had been carried hither from the interior; but that this was not the case was demonstrated by the circumstance that none was found east of camp no. 9. The only animals we discovered on the ice were, besides the few birds seen on our return-journey, a small worm which lives on the various ice algae, and thus really belongs to the fauna of the inland ice, and two storm-driven birds from the shore. I had particularly requested each man to be on the lookout for stones on the ice; but, after a journey of about half a kilometre from the ice-border, no stone was found on the surface, not even one as large as a pin's point. But the quantity of clay-dust ('kryokonite') deposited on the ice was very great, — I believe, several hundred tons per square kilometre.

We now ascended very rapidly, as will be seen from the subjoined statement of our camps: —

3d	camp,	300	metres above	the sea.
4th	"	355	"	"
5th	"	374	"	"
6th	"	382	"	"
7th	"	451	"	"
8th	"	546	"	"
9th	"	753	"	"

The 9th camp lay on the west side of an ice-ridge close by a small, shallow lake, the water from which gathered, as usual, into a big river, which disappeared in an abyss with azure-colored sides. From this spot we had a fine view of the country to the west, and saw even the sea shining forth between the lofty peaks on the coast; but, when we reached east of this ice-ridge, the country was seen no more, and the horizon was formed of ice only.

Through an optical illusion, dependent on the *mirage* of the ice-horizon, it appeared to us as if we were proceeding on the bottom of a shallow, saucer-shaped cavity. It was thus impossible to decide whether we walked up or down hill; and this formed a constant source of discussion between us, which could only be decided by the heaviness of the sledges in the harness. The Lapps, who seemed to consider it their sole business that we should not be lost on the ice, came to me in great anxiety, and stated that they had no more landmarks, and would not be responsible for our return. I satisfied them, however, with the assurance that I would find the way back by means of a compass and solar measurements. In spite of this, the Lapps easily traced our route and our old camps with an accuracy quite marvellous.

During our outward journey, I determined the site of each camp astronomically; and thus the distances which, when the determinations have been calculated, will be given on the map to be drawn of the journey, will be absolutely correct. But the distances covered by the Lapps have been made according to their own judgment. The kilometres we covered every day, including the numerous *détours*, were ascertained by two pedometers.

Up to the 9th camp we were favored by the finest weather, generally with a slight south-east wind, cloudless sky, and a temperature in the shade, three feet above the ice, of 2° to 8° C., and in the sun of even 20° C. The centre of the sun's disk sank in this spot for the first time below the horizon on July 15, and the upper rim, if allowance is made for refraction, on July 21. After the middle of July, when at an elevation of four thousand to seven thousand feet, the nights became very cold, the thermometer sinking to 15° and 18° below freezing-point of Celsius.

The constant sunshine by day and night, reflected from every object around, soon began to affect our eyes, — more so, perhaps, because we had neglected to adopt snow-spectacles at the outset of our journey; and snow-blindness became manifest, with its attendant cutting pains. Fortunately Dr. Berlin soon arrested this malady, which has brought so many journeys in the arctic regions to a close, by distributing snow-spectacles, and by inoculating a solution of zinc vitriol in the blood-stained eyes. Another malady — if not so dangerous, at all events quite as painful — was caused by the sunshine in the dry, transparent, and thin air on the skin of the face. It produced a vivid redness and a perspiration, with large burning blisters, which, shrivelling up, caused the skin of the nose, ears, and cheeks, to fall off in large patches. This was repeated several times, and the pain increased by the effect of the cold morning noon of July 13, with a heavy wind from south-east. It continued all the night, and the next morning turned into a snow-storm. We all got very wet, but consoled ourselves with the thought that the storm coming from south-east argued well for an ice-free interior. When it cleared a little, we strained our eyes to trace any mountains which would break the ice-horizon around us, which everywhere was as level as that of the sea. The desire soon 'to be *there*' was as fervent as that of the searchers of the Eldorado of yore; and the sailors and the Lapps had no shadow of doubt as to the existence of an ice-free interior; and at noon, before reaching camp no. 12,

Fissure in Greenland's inland ice, seen by Nordenskiöld on his visit in 1876. From a sketch by Dr. Berggren, published in *La Nature*.

air on the newly-formed skin. Any similar effect the sun has not in the tropics. With the exception of these complaints, none of us suffered any illness.

On July 13 we covered thirteen, on the 14th ten, and the 15th fourteen, kilometres (9th to 12th camps). At first the road gradually rose; and we then came to a plain, which I, in error, believed was the crest of the inland ice. The aneroids, however, showed that we were still ascending: thus the 9th camp lies 753, the 10th 877, the 11th 884, and the 12th 965, metres above the sea. Our road was still crossed by swift and strong rivers; but the ice became more smooth, while the kryokonite cavities became more and more troublesome. This was made more unpleasant by rain, which began to fall on the after- everybody fancied he could distinguish mountains far away to the east. They appeared to remain perfectly stationary as the clouds drifted past them, — a sure sign, we thought, of its not being a mass of clouds. They were scanned with telescopes, drawn, discussed, and at last saluted with a ringing cheer; but we soon came to the conclusion that they were unfortunately no mountains, but merely the dark reflection of some lakes farther to the east in the ice-desert.

In my report of the expedition of 1870, I drew attention to a clayey mud which is found in circular cavities, from one to three feet in depth, on the surface of the inland ice, not only near the shore, but even as far inland as we reached on that occasion.

My companion on that occasion, Professor Berggren, discovered that this substance formed the substratum of a peculiar ice-flora, consisting of a quantity of different microscopical plants (algae), of which some are even distributed beyond the clay on the ice itself, and which, in spite of their insignificance, play, beyond doubt, a very important part in nature's economy, from the fact that their dark color far more readily absorbs the sun's heat than the bluish-white ice, and thereby they contribute to the destruction of the ice-sheet, and prevent its extension. Undoubtedly we have in no small degree to thank these organisms for the melting-away of the layer of ice which once covered the Scandinavian peninsula. I examined the appearance of this substance in its relation to geology, and demonstrated, —

1. That it cannot have been washed down from the mountain ridges at the sides of the glaciers; as it was found evenly distributed at a far higher elevation than that of the ridges on the border of the glaciers, as well as in equal quantity on the top of the ice-knolls as on their sides or in the hollows between them.

2. That neither had it been distributed over the surface of the ice by running water, nor been pressed up from the hypothetical bottom 'ground' moraine.

3. That the clay must therefore be a sediment from the air, the chief constituent of which is probably terrestrial dust spread by the wind over the surface of the ice.

4. That cosmic elements exist in this substance, as it contained molecules of metallic iron which could be drawn out by the magnet, and which, under the blowpipe, gave a reaction of cobalt and nickel.

Under these circumstances, the remarkable dust which I have named 'kryokonite,' i.e., ice-dust, obtained a great scientific interest; particularly as the cosmic element, viz., the matter deposited from space, was very considerable. Even later students who have visited the inland ice have observed this dust, but in places surrounded by mountains, from which it might with more probability have been washed down. They have, therefore, and without having examined Professor Berggren's and my own researches of 1870, paid little attention to the same; while the samples brought home by Dr. N. O. Holst from South Greenland in 1880 were not very extensive.

But now Dr. Berlin brings home from a great variety of places ice algae, which, I feel convinced, will contribute fresh materials to our knowledge of the flora of the ice and snow. For my own part, I have re-examined my first researches of the kryokonite, and they are fully corroborated. Everywhere where the snow from last winter has melted away, a fine dust, gray in color, and, when wet, black or dark brown, is distributed over the inland ice in a layer which I should estimate at from 0.1 to 1 millimetre in thickness, if it was evenly distributed over the entire surface of the ice. It appears in the same quantity in the vicinity of the ice-border surrounded by mountains as a hundred kilometres inland; but in the former locality it is mixed with a very fine sand, gray in color, which may be separated from the kryokonite. Farther inland this disappears, however, completely. Gravel or real sand I have never, in spite of searching for them, discovered in the kryokonite. The kryokonite always contains very fine granular atoms, which are attracted by the magnet, and which, as may be demonstrated by grating in an agate mortar and by analysis under the blowpipe, consist of a gray metallic element; viz., nickel iron. In general, the dust is spread equally over the entire surface of the ice. Thus it was found everywhere where the snow from the previous year had melted away; while, to judge by appearances, there seemed to be little difference between the quantity found near the coast, and in the interior. The dust does not, however, form a continuous layer of clay, but has, by the melting of the ice, collected in cavities filled with water, which are found all over the surface. These are round, sometimes semicircular, one to three feet in depth, with a diameter of from a couple of millimetres to one metre or more. At the bottom a layer of kryokonite one to four millimetres in thickness is deposited, which has often, by organisms and by the wind, been formed into little balls; and everywhere where the original surface of the ice has not been changed by water-currents, the cavities are found so close to each other that it would be very difficult to find a spot on the ice as large as the crown of a hat free from them. In the night, at a few degrees below freezing-point, new ice forms on these hollows; but they do not freeze to the bottom, even under the severest frost, and the sheet which covers them is never strong enough to support a man, more particularly if the hole is, as was the case during half our journey, covered with a few inches of newly-fallen snow.

The kryokonite cavities were perhaps more dangerous to our expedition than any thing else we were exposed to. We passed, of course, a number of crevasses without bottom as far as the eye could penetrate, and wide enough to swallow up a man; but they were 'open,' i.e., free from a cover of snow, and could with proper caution be avoided; and the danger of these could further be minimized by the sending of the two-men sledges in front, and, if one of the men fell into the crevasse, he was supported by the runners and the alpenstock, which always enabled him to get up on the ice again. But this was far from being the case with the kryokonite hollows. These lie, with a diameter just large enough to hold the foot, as close to one another as the stumps of the trees in a felled forest; and it was therefore impossible not to stumble into them at every moment, which was the more annoying as it happened just when the foot was stretched for a step forward, and the traveller was precipitated to the ground with his foot fastened in a hole three feet in depth. The worst part of our journey was four days outward and three days of the return; and it is not too much to say that each one of us, during these seven days, fell a hundred times into these cavities, viz., for all of us, seven thousand times. I am only surprised that no bones were broken, — an accident which would not only have brought my exploration to an abrupt close, but might have had the most disastrous consequences, as it would have been utterly impossible to have carried a man in that state back to the coast. One advantage the kryokonite cavities had, however; viz., of offering us the purest drinking-water imaginable, of which we fully availed ourselves without the least bad consequences, in spite of our perspiring state.

On July 16 we covered thirteen, on the 17th eighteen and a half, and on the 18th seventeen and a half, kilometres. The country, or more correctly the ice, now gradually rose from 965 to 1,213 metres. The distances enumerated show that the ice became more smooth; but the road was still impeded by the kryokonite cavities, whereas the rivers, which even here were rich in water, became shallower but stronger, thus easier of crossing. Our road was, besides, often cut off by immense snow-covered crevasses, which, however, did not cause much trouble.

On the night of the 18th, when arrived at camp no. 14, the Lapp Anders came to me and asked if he might be permitted to 'have a run;' viz., to make a reconnaissance on 'skidor,'[1] to see if there was no land to the east. This granted, he started off without awaiting supper. He came back after six hours' absence, and reported that he had reached twenty-seven kilometres farther east; that the ice became smoother, but was still rising; but there was no sign of land. If his statement was true, he had, after a laborious day's journey, in six hours covered about sixty kilometres! At first I considered his estimate exaggerated, but it proved to be perfectly correct. It took us, thus, two whole days to reach as far as he had got, as shown by the track in the snow. I particularly mention this occurrence in order to show that the Lapps really did cover the estimated distance of their journey eastward, of which more below.

During these days we passed several lakes, some of which had the appearance of not flowing away in the winter, as we found here large ice-blocks several feet in diameter, screwed up on the shore; which circumstance I could only explain by assuming that a large quantity of water still remained here when the pools about became covered with new ice. The lakes are mostly circular, and their shores formed a snow 'bog' which was almost impassable with the heavy sledges.

On July 19 we covered seventeen and a half, on the 20th sixteen and a half, on the 21st seven, and on the 22d seven and a half, kilometres (15th to 18th camp). The ice rose between them from 1,213 to 1,492 metres. The distances enumerated fully show the nature of the ice. It was at first excellent, particularly in the morning, when the new snow was covered with a layer of hard ice; but on the latter days we had great difficulty in proceeding, as a sleet fell with a south-east wind in the night, between the 20th and the 21st. The new snow, as well as that lying from the previous year, became a perfect snow-bog, in which the sledges constantly stuck, so that it required at times four men to get them out. We all got wet, and had great difficulty in finding a spot on the ice dry enough to pitch the tent. On the 22d we had to pitch it in the wet snow, where the feet immediately became saturated on putting them outside the India-rubber mattresses. A little later on in the year, when the surface of the snow is again covered with ice, or earlier, before the thaw sets in, the surface would no doubt be excellent to journey on.

When we, therefore, on July 21, were compelled to pitch the tent in wet snow, as no dry spot could be discovered, and it was impossible to drag the sledges farther, I sent the Lapp, Lars Tuorda, forward on 'skidor' to find a dry road. He came back, and stated that the ice everywhere was covered with water and snow. For the first time in his life he was at a loss what to suggest. It being utterly impossible to get the sledges farther, I had no choice. I decided to turn back.

I wished, however, to let the Lapps go forward some distance to the east to see the country as far as possible. At first I considered it advisable to let their journey only last twenty-four hours; but as both Anders and Lars insisted that they were most eager to find the 'Promised Land,' and said they could do nothing towards discovering it in that short period, I granted them leave to run eastwards for four days and nights, and then return.

On leaving, I gave them the following written orders: —

"Instructions for Lars and Anders's 'skid' run on the inland ice of Greenland; viz., —

"Lars and Anders have orders to proceed on skidor eastwards, but are allowed to alter the course, if they may deem it advisable, to north or south.

"At the end of every third mile the barometer shall be read, and the direction run noted.

"The absence is to be four days, but we will wait for six days. After that, viz., on the morning of July 28, we return. If not returned, we leave behind, in a sledge, provisions, brandy, mattresses, etc.

"Lars is warned not to be too bold. Should land be reached, you are to collect as much as you may gather of blossoms and grass; if possible, several kinds (specimens) of each.

"Given on the inland ice in Greenland, July 21, 1883. A. E. NORDENSKIÖLD."

They were allowed to select what provisions, etc., they desired, and were furnished with two compasses, aneroid barometers, and a watch.

At 2.30 A.M. on July 22 they started. The days we waited for them were generally spent in the tent, as water surrounded us everywhere. The sky was covered with a thin veil of clouds, through which the sun shone warmly, at times even scorchingly. From time to time this veil of clouds, or haze, descended to the surface of the ice, and hid the view over the expanse; but it was, remarkably enough, not wet, but *dry*, — yes, so dry that our wet clothes absolutely dried in it. We have therefore, I consider, witnessed a

[1] The Swedish 'skidor' and Norwegian 'ski' are long strips of pine wood, slightly bent at the top, polished, and as elastic as if they were of the finest steel, with a strap for the feet in the centre, on which the Lapps and Scandinavians run on the snow with remarkable agility at a tremendous pace.

phenomenon on the inland ice of Greenland which is related to the 'sun-smoke' phenomenon of Scandinavia; viz., what Arago has described under the name 'brouillard sec.'

On the 24th, after an absence of fifty-seven hours, the Lapps returned. It was the want of drinking-water and fuel which compelled them to return. The surface had been excellent for their journey, and they had covered a distance out and back of two hundred and thirty kilometres, — an estimate which I consider perfectly reliable. During the march forward the barometer was read every third hour. It gave the point of return a height of two thousand metres.[1]

As to the run, Lars rendered the following report. When they had reached thirty miles from the camp, no more water could be found. Farther on, the ice became perfectly smooth. The thermometer registered −5° C. It was very easy to proceed on the 'skidor.' At the point of return the snow was level, and packed by the wind. There was no trace of land. They only saw before them a smooth ice, covered by fine and hard snow. The composition of the surface was this: first four feet of loose snow, then granular ice, and at last an open space large enough to hold an outstretched hand. It was surrounded by angular bits of ice (crystals). The inland ice was formed in terraces, thus: first a hill, then a level, again another hill; and so on. The Lapps had slept for four hours, from twelve midnight on July 23, in a hollow dug in the snow while a terrific storm blew. They had till then been awake for fifty-three hours. On the first day there was no wind; but next day it came from the south, and lasted thus until twenty-four miles on the return-journey, when it changed to west. On the return-journey, when forty miles from our camp, two ravens were seen. They came from the north, and returned in the same direction. The Lapps had for a moment lost the track of the 'skidor' in the snow. The ravens flew at first, they found, parallel with the track, and then turned to the north.

On July 25 we began the return-journey. It was high time, as the weather now became very bad; and it was with great difficulty we proceeded in the hazy air between the number of crevasses. The cold, after the sun sank below the horizon at night, also became very great; and on the morning of July 27 the glass fell to −11° C.

As to the return-journey, I may be very brief. The rivers now impeded us but little, as they were to a great extent dried up. The ice-knolls had decreased considerably in size too, and lay more apart; but the glacial crevasses had greatly expanded, and were more dangerous, being covered with snow. Even the cavities and the glacial wells, of which many undoubtedly leave a veritable testimony of their existence behind them in the shape of corresponding hollows in the rock beneath, had expanded, and increased in number. On a few occasions on the return-journey we saw flocks of birds, most probably water-fowl, which were returning from the north.

[1] I have as yet been unable to verify the barometer calculations, and the figures stated here may suffer some modification.

On July 31 we again sighted land, which was reached on the afternoon of Aug. 4, and proceeded to Sophia harbor, where Eskimos were, as arranged, waiting for us. For convenience' sake I now divided our party into two, one of which sailed in the lifeboat of the Sophia to Egedesminde, where the steamer was to take us on board; and the other, in which was myself, marched to that place across the low but broad promontory which separates Tessiusarsoak and South-East Bay, and then in two Eskimo 'kone' boats to Ikamiut and Egedesminde.

On Aug. 16 the Sophia arrived from the north, embarked us, and made for Ivigtut, where we arrived on the 19th.

Of the expedition carried out under Dr. Nathorst during my absence, he will himself make a report,[1] and I have no doubt that the results of the same will prove very important. Particularly will the very rich collections of fossil plants, which he has made with the greatest regard to the geological condition of the strata, be of great value to science, as they will furnish us with many new materials, and detailed illustrations of the flora of the far north during the epoch when forests of fig-trees, cycadi, gingko, magnolia, and tulip trees covered these regions. Dr. Forsstrand and Herr Kolthoff's collections and studies of the fauna of Greenland will also contribute to extend our knowledge of the naturalistic conditions of the arctic regions; while the careful researches made by Herr Hamberg, of the saltness, composition, and temperature of the sea, will, I am sure, greatly benefit hydrography. His researches have been effected in Davis Strait and Baffin's Bay too, the hydrographical conditions of which are but little known.

With regard to the results of my exploration of the inland ice, I may be permitted to say a few words. That we found no ice-free land in the interior, or that it does not exist between 68° and 69° latitude in Greenland, is due directly to the orographical conditions which exist in this part of the country, as referred to in my programme of the expedition.[2] The land has here the form of a round loaf of bread, with sides which gradually and symmetrically slope down to the sea; i.e., exactly the shape which I then pointed out was a necessary condition if the entire country should be covered with a continuous sheet of ice.

But, thanks to the Lapps, my expedition is the first which has penetrated into the very heart of the enormous Greenland continent, and which has thus solved a problem of the greatest geographical and scientific importance. It is the first exploration of the hitherto unknown interior of Greenland, the only continent in the world into which man had not penetrated.

A new means of locomotion, the 'skidor,' seems also to have been acquired for the arctic explorer of the future, which may greatly assist him in his work, and enable him to reach places hitherto deemed impossible of approach, but of the use of which the Lapp seems to possess, so to speak, the monopoly.

LETTERS TO THE EDITOR.

Osteology of the cormorant.

I WOULD make a couple of corrections to the article on the osteology of the cormorant in SCIENCE for Nov. 16.

First, the occipital style is figured as pointing upwards and backwards, and is spoken of as figured *in situ* for the first time. Having made several dissections of cormorants in past years, I would suggest that the bone is the ossified tendon of some of the extensor muscles of the neck, and that it points backwards, and, if any thing, downwards, as figured by Selenka (Bronn's Thierreichs, Vögel, figs. 5, 6, pl. viii.). As drawn in SCIENCE, it would project through the skin of the nape.

Secondly, the patella is spoken of as very large and as throwing "some light on such birds as Colymbus and Podiceps, where this bone becomes anchylosed with the tibia in the adult;" and Professor Owen is referred to as authorizing this statement. Now, Professor Owen describes the patella as 'co-existing with the long rotular process in the loon' (Comp. anat., ii. 83), and figures it as distinct from the process in fig. 34, *l*. In fact, the rotular process was regarded as the anchylosed patella until the time of Nitzsch. This celebrated ornithologist pointed out the co-existence of an enormous patella and rotular process in Podiceps, and showed the true nature of the process ('Osteogr. beitr. zur nat. der vögel.' Leipzig, 1811, pp. 98–101, pl. ii., figs. 13, 14). In fact, the rotular process of the divers is exactly the same in nature as in other birds, differs only in size, and in no wise represents the *co-existing* patella. In position and function the rotular process resembles the olecranon.

J. AMORY JEFFRIES.

Sense of direction.

Professor Newcomb's paper in SCIENCE of Oct. 26 opens an exceedingly interesting, if not a very important subject. It has exacted of me a good deal of thought, and this capricious sense has been a source of no little annoyance. I should like to give a little of my experience. With me the co-ordinates almost invariably revolve 180°. When a boy, I studied geography, and when at recitation sat with my face to the north. I thus had the whole world mapped out in my mind to correspond with my proper sense of the directions. Soon after this, my father moved to a new home; and there I found, to my great annoyance, that my co-ordinates had revolved 180°. My geography was in the greatest confusion. When I began to travel, I found that the co-ordinates would change in the most unexpected manner, first one way, and then the other. I could not trust my sense of direction.

When I came to Lebanon, I found myself with my original boyhood co-ordinates. I graduated, and went back to Arkansas. Upon my return to Lebanon a few months afterwards, the directions had revolved 180°, and I found myself practically in a new town. I had to learn it all over again; and to-day, if I desire to point to the north, my hand instinctively moves towards the south. In travelling I have found it useful to trust as little as possible to the sense, and be guided by the map. In an extended tour through Europe, I was in the habit of preparing myself, before entering each city, by a careful study of its map, — noting the position of the railway-station, direction of the streets etc. In this manner I was enabled to control the sense of direction. In only one or two instances did I fail to keep the directions right.

I make two practical suggestions: —

1. Students in geography should always sit with their faces to the north.
2. Travellers should prepare themselves, before entering a new place, by a previous subjective arrangement of the directions they are to find there.

Synchronism of geological formations.

In SCIENCE of Nov. 16, weekly summary, under above heading, Professor A. Heilprin is reported as having called attention to two conclusions of Huxley's on this subject, and to have maintained, that while the first-mentioned conclusion could be logically disproved, and the second derived no confirmation from the supposed facts, the opinion of the older geologists, that geological contemporaneity is equivalent to chronological synchronism, was therefore probably correct.

Professor Huxley, in his presidential address to the Geological society for 1862, supported the conclusions called in question by reasoning, which, so far as I know, has yet to be shown to be illogical. Neither am I aware, that, during the twenty-one years which have since elapsed, geological or paleontological research has tended otherwise than to maintain the logical basis on which he then rested.

If Professor Heilprin will but do what he is reported to claim can be done, he will earn the gratitude of all other geological students by helping to settle what has proved a vexatious question for the past half-century.

E. NUGENT.

Pottstown, Nov. 22, 1883.

From superstition to humbug.

Your editorial in the Nov. 16 issue of SCIENCE might very appropriately have contained an account of the 'magnetic springs' which underlie this portion of the state of Ohio. From my residence three of these springs may be seen, at one of which a large bath-house has already been erected, where, during the present season, an average of forty patients daily tested the curative effects of the waters. These springs are found along the bank of a small creek and at the base of a valley, perhaps twenty-five feet in depth. The water, which contains less than a sixth of one per cent of iron, is brought to the surface of the ground through an *iron* gas-pipe, and "becomes so highly charged with magnetism that it will impart its properties to a knife-blade." The village of Magnetic Springs, a few miles distant, has several large hotels, all of which are so crowded with guests, that rooms must be engaged weeks in advance. Change of residence, rest, and good nursing have together effected a number of cures, all of which, of course, are ascribed to the magnetic properties of the water. Many of the guests return to their home as disappointed as the little girl, who, after drinking a glass of the water, said, 'I do not feel one particle magnified, and I think these springs are a humbug.'

Delaware, O., Nov. 22, 1883.

Primitive visual organs.

The notice of Dr. Sharp's communication made before the Academy of natural sciences of Philadelphia, in No. 42 of SCIENCE [397], on the habits and on the peculiar visual organs of Solen ensis and S. vagina, between and at the base of the short tentacular processes along the external edge of the distal part of the siphons of these animals, reminds me that I have observed similar habits in other marine animals, and that possibly we may infer that similar visual cells exist in these cases. I now call to mind the cases of Ostrea and Serpula. When the former has its purplish tentacles extruded from between its valves, and the latter its crown of cirri extended from its tube, if the hand is made to move rapidly over the water in the aquarium in a strong light, so as to cast a shadow upon these organs, both these animals appear to be sensitive to the movement, and independent of any jars or vibrations. The oyster, under these circumstances, at once retracts its sensitive mantle-border; the worms, their cirri.

Upon examining the end of the siphon of Mya arenaria, lines of pigment are found about the bases of both the inner and outer circlets of tentacles, and the upper end of the siphon is pigmented for about an inch, both inside and outside. On the outside, however, there are scattered low, minute, pigmented papillae just under the epidermis and in the pigmented layer or true skin covering the siphon. The questions now arise, What is the nature of these organs? and do not the habits of Ostrea, as above described, justify us in expecting to find rudimentary end-organs on the mantles and siphons of mollusks, answering the purpose of eyes, as appears to be the case in the instance of Solen? Mya, like Solen, in life has normally the end only of the siphon exposed: and visual powers, developed to a certain degree, would therefore be useful to the animal; for, when the siphon is extended above the level of the sand, there are several fishes with mouths and teeth well suited to nip it off, and which would doubtless actually take advantage of the helpless clam, if it could not appreciate their approach.

I find fishes much more sensitive to sudden vibrations established in the water in which they live than to shrill or grave sounds made in the surrounding air near by. This may be due to special powers of perception which they may possess on account of the development of the singular end-organs of the lateral line.

The study of dermal, terminal nerve-endings, modified as more or less specialized sensory apparatuses throughout the different groups of the animal kingdom, is bound to yield many important results in the near future, in addition to what is already known; and the writer is glad that the matter has been taken up by such competent hands. John A. Ryder.

Nov. 27, 1883.

Probable occurrence of the Taconian system in Cuba.

Last year, while making two excursions across the mountains of eastern Cuba, between Baracoa and the southern coast, I had an opportunity to make some observations on the geological structure of these mountains. The rocks composing this end of Cuba fall naturally into three distinct groups, as follows: 1. Ancient, and for the most part coarsely crystalline, basic eruptive rocks; 2. Older stratified rocks, slates, schists, and limestones; 3. The post-tertiary limestones or elevated coral-reefs.

The eruptive rocks form the main mass of the mountains at most points. They appear on the shore in some places, and seem to be almost the only rocks found at greater distances than five or ten miles from the coast. The older stratified rocks occur principally in two irregular belts running parallel with the coasts, and lying one on either side of the great eruptive belt: hence they are found mainly on the flanks of the mountains. The stratified rocks, especially along their contact with the eruptives, are penetrated by numerous irregular masses and dikes of the latter. But that they are all older than all the eruptives is improbable, since the eruptives are themselves evidently of several distinct ages.

So far as I have observed, the stratified rocks are all alike unfossiliferous; and in consequence the precise determination of their stratigraphic positions is a difficult problem. I am satisfied, however, that some of them are widely separated in time. The newer beds, consisting chiefly of fissile slates, soft sandstones, and impure earthy limestones, are probably equivalent to the secondary and tertiary strata of San Domingo and Jamaica. These uncrystalline sediments occur chiefly on the northern slope of the mountains, and, although much disturbed and undulating, rarely exhibit high dips.

But on the south side of the dividing-ridge, or summit, I crossed a belt six to eight miles wide, reaching almost to the coast, of highly inclined crystalline schists. The stratification is usually distinct, the strike being parallel with the coast, or east-west. The schists are generally greenish, and are both hydromicaceous and chloritic. Associated with the schists are several immense beds of white crystalline limestone. The limestone undoubtedly belongs to the same series as the schists, and is often micaceous.

These rocks bear a strong resemblance to the Taconian system of western New England, and are essentially identical with the great series of semi-crystalline schists and limestones of Trinidad and the Spanish Main which I have elsewhere correlated with the Taconian.

The published reports on the geology of San Domingo and Jamaica show that the geologic structure of those islands is essentially similar to that of eastern Cuba. In each case there is a prominent axis of old eruptive rocks, flanked on either side by schists, slates, limestones, and other sedimentary formations, and by elevated coral-reefs. In San Domingo and Jamaica the eruptives are not wholly basic, but much granite occurs; and the metamorphic schists, which appear to be similar to those of Cuba, have been generally confounded with the cretaceous beds. I predict, however, that more careful study will show that they are distinct and vastly older, and that the Greater Antilles are similar in composition and structure to the southern coast of the Caribbean Sea, including the Spanish Main and Trinidad, except that the coral-reefs and the eruptive rocks are wanting in the latter region. We owe the coral-reefs largely to the great vertical movements of the Greater Antilles in recent times; and the eruptive rocks are but a continuation westward, and the older and more eroded portion, of the great Caribbee belt of volcanic rocks which begins a hundred miles north of Trinidad, and ends in Cuba, being about fifteen hundred miles long.

W. O. Crosby.

THE RESTORATION OF ANCIENT TEMPLES.

The Parthenon: an essay on the mode by which light was introduced into Greek and Roman temples. By James Fergusson, C.I.E., D.C.L., LL.D., etc. London, *Murray*, 1883. 8+135 p., 60 illustr., 4 pl. 4°.

Only a small portion of this book is devoted to the wonderful edifice from which it is named. It is in the main a reiteration of peculiar views concerning the lighting of ancient temples, — an amplification of theories advocated thirty-four years ago by Mr. Fergusson, in his 'True principles of beauty in art.' In a preface to the present volume, the author states his conviction that it is certain to prove offensive to specialists 'from the novelty of the views advanced;' but as these views are almost exactly those adopted in his earlier publication, and as this application of a clere-story to ancient temples can hardly be called original, — it having been suggested by Boetticher in 1847, two years before its first mention by Mr. Fergusson, — it would seem more natural to seek for some other explanation for the discontent of the critics.

It is certainly true, that more has been written, and more angry controversies have arisen, regarding the hypaethron, than with reference to any other feature, either constructive or artistic, in the temples of the Greeks; and after careful study the conviction forces itself upon the reluctant mind, that this last contribution, surpassing in extent and elaboration all others, does little toward the confirmation of that hypothesis in any of its varieties.

Mr. Fergusson adopts for the Parthenon, the temple of Zeus and that of Hera at Olympia, the temples of Aegina, Paestum, Selinous, — in short, for all regular Greek peristyles, — a clere-story sunk by two long openings in the roof at either side of the ridge, which remains unbroken over the central aisle of the naos. The height between the entablature of the upper order of interior columns and the inclined lines of the roof is that of his vertical windows. The drainage from this imperfect covering is effected by perforating the lateral walls of the cella with gutters, leading the rain-water into the pteroma, in which ceiled and protected colonnade such dripping must have been particularly undesirable. Contrary to the fundamental separation of roof and ceiling universally carried out in Greek architecture, he leaves the central aisle open to the inclined roof-surface, like the Bavarian Walhalla, and defends this feature with the surprising statement that flat ceilings, in either wood or plaster, were unknown in classical times. The argument adduced to prove this inclination of the ceiling, visible from within, is found by Mr. Fergusson in the well-known complaint of Strabo (viii. 3, 30, p. 353), — that the statue of Zeus at Olympia was so large, that, if the seated deity should arise, the roof of the building would be carried away. This passage is certainly not "the only hint in any ancient author as to how the roofs of Greek temples were constructed," and, what is worse, its application to the point in question is dependent upon a mistranslation. The words of Strabo, 'almost touching the ceiling with *the top of its head*,' are wrongly rendered by Mr. Fergusson, 'nearly touched *the summit of the roof*.' This misleading version is twice given in the present volume (pp. 2 and 111), and from it the non-horizontal form of the ceiling is directly deduced. It seems high time that this blunder, repeated by so many writers since its first commission by Quatremère de Quincy, should at last be eliminated from discussions of the subject.

As it would naturally have been impossible to surmount with a clere-story those smaller peripteral temples which were without columns in the naos, Mr. Fergusson is obliged to assume, against all evidence, that interior pillars or pilasters did originally exist, and that, while the Christian reconstruction of the Theseion obliterated the traces of these in that building, a figured mosaic pavement in the remarkably similar temple of Assos should be taken to indicate the position of such supports. The last example is certainly not favorable to the theory; for the bedding of the pavement in question is distinctly shown, by plan and text of the first report on the investigations at Assos,[1] to have extended to the very edge of the lateral walls, thus precluding the possibility of any columns or piers within the narrow hall.

The omission of galleries from interiors, which were provided with a double range of columns standing at some distance from the wall, is even less excusable. The assertion (pp. 8 and 73) that there were no galleries in the temple of Aegina is unwarranted. The only reason advanced for this, that the space between the shafts and the wall was only about one metre in width, is of no weight. To suppose that one order of columns was balanced upon another, with an intermediate entablature not tied to the wall by a floor, is unworthy our conception of the constructive wisdom displayed in Greek architecture. These galleries, known from literary sources to have existed in many temples, were actually found and measured at Paestum; and yet Mr. Fergusson omits them entirely from his section of that monument, without a word of justification (fig. 41). The notched architrave from the same site, in which he sees 'the most direct proof of the theory,' 'final in its correctness,' has really no bearing upon the question, being simply an example of the commonest method of construction, when adjoining horizontal ceilings were employed on different levels. This appears constantly in every kind of Greek buildings.

In one instance, however, the author must

[1] Rep. arch. Inst. Amer.

be admitted to have proved his case. The plan and interior arrangement of the temple of Bassae — which is in so many ways exceptional among buildings of its class — certainly point to some system of lighting by vertical windows above the interior ranges of pilasters. The curious position of these buttresses, which are awkwardly spaced so as to stand in the axes of the intercolumniations of the side colonnade, and especially the discovery of perforated tiles on the site, make it more than probable that this remarkably archaistic temple displays an intentional reversion to the manner of lighting the primitive, non-peripteral cella through open metopes. It is to be observed that the statue of the deity was not placed in the space thus lighted, which seems to have been considered as a sort of inner vestibule before the Holy of holies, — a hall decorated, like the exterior of the Parthenon, with a carved zophoros, intended to be seen by the general public. Mr. Fergusson is probably at fault in supposing the image at Bassae to have been a mere *simulacrum*, which had become sacred among the rude inhabitants of the mountain from some accidental cause. He gives no reason for such a belief, and of no temple of antiquity is the story of the dedication so well known. The deliverance of the Arcadians by Apollo Epikourios, from a prevalent pestilence toward the end of the fifth century, does not admit the assumption of a rude symbol, or even of a xoanon, within his fane.

The explanation of the roof-opening of the little cella upon Mount Ocha is good, as is also the concise treatment of the corrupt text of Vitruvius. The importance of both these points has certainly been greatly overrated by previous writers upon the subject. Mr. Fergusson advocates the change of *octastylos* to *decastylos*, and *et* to *est*, in the confused description of the Roman builder; and this appears plausible in view of the acknowledged corruption of the manuscripts, and the fact that the temple of Olympian Zeus at Athens, thus alone referred to, was the only building in Europe possessing all the peculiarities described. Having been without a roof at the time Vitruvius wrote, it certainly was *sub divo* and *sine tecto*, as he says. Mr. Fergusson's restoration of this temple is ingenious; but as it is not known that the structure was ever completed at all, and as even its plan is not yet ascertained, the attempt to delineate its roof is hardly of greater value than that dissertation 'on the use of the particle δέ in the lost plays of Menander,' which a German scholar is wickedly reported to have written.

And what are we to think of the disquisition on the Chaitya temple of Karlé, dragged in to lend weight to this restoration? That excavation in the native rock is lighted by a great window at the front, as it of course only can be: and yet in this feature Mr. Fergusson sees the direct influence of Greek and Roman architecture, felt after the incursion of Alexander into India, and the establishment of the Bactrian kingdom; making the system of illumination employed for the cave an imitation of that in the temple of Zeus at Athens by the argument that the appearance of light-openings on one side only must have been foreign to the wooden structures from which the Chaitya caves were in detail more or less imitated. Surely insistence upon precedent could be carried no farther.

The author's restorations of other temples are interesting, but hardly less improbable; the complicated makeshifts to which he is driven, by his various systems of windows in light-shafts, being too remote from the simple and straightforward methods of ancient building to please our imagination, or satisfy our practical sense of constructive fitness. A detailed consideration of all the temples treated of would here lead to undue length.

The account of the derivation and timbered prototype of the Doric style is inadequate; and the attempt to rehabilitate Falkener's proto-Doric capital unreasonable, after the well-known proof by Bergau and Erbkam of its wrong combination out of fragments of Egyptian bases. Incorrect, also, is the reiterated statement, that no Doric temples were built after the age of Alexander the Great. In certain parts of the Hellenic world other styles were but exceptionally employed, even in the latest epoch; as we know, for instance, from the ruins of Pergamon, where there is a complete Doric peripteros (that of Athena Polias), which certainly was constructed under the dynasty of the Attalidae. The comparison of the development of temple-architecture among the Greeks with Catholic church-building during the middle ages and during the reign of Queen Anne is misleading. Style among the ancients depended rather on geographical, or, to speak more correctly, on ethnographical, distribution than on passing fashions.

The description of the Parthenon is as thorough as any review antedating the recent investigations of Doerpfeld, which may not have been available at the time of writing. A model of the building, constructed by Mr. Fergusson on a generous scale, one-fortieth of real size, must be extremely interesting. Too much cannot be said in recognition of this interest in a branch of science not over-popular in these days, which has led the author to an expense of time and money hardly likely to be appreciated. Still, it is to be regretted that the chief attention devoted to this reproduction was evidently directed to an exemplification of an improbable method of lighting. A second gallery is added to the temple, the trenches sunk deeply in the roof being made accessible by stairs; and these *piombi* Mr. Fergusson sets apart for the females of the Athenian congregation, who must have been as uncomfortable there as the most confirmed misogynist of antiquity could have desired. The staircases, by the way, present in the section (pl. 3) a curiously impossible arrangement, approaching from either side as they ascend, so as to intersect at the level of the gallery, and leave no landing-place, — not a good instance of that application of common sense to the study of Greek architecture which Mr. Fergusson so warmly advocates. It has, moreover, been ascertained that the stairs in the Parthenon were situated where they might naturally be expected, — next to the entrance-door, not at the farther end of the naos.

A part of the book sure to be read with great satisfaction by students of archeology is the arraignment of Mr. Wood, the explorer of Ephesos, whose inadequate publications, and selfish hiding-away of the results of his richly endowed work, deserve all the asperity with which Mr. Fergusson treats them (p. 32).

The printing is careful. We notice few minor errors. Lagardette's folio is dated Paris, 1879, instead of 'seventh year of the republic (1799);' while 'M.' Boetticher's essay, published at Potsdam in 1847, is said to be without date.

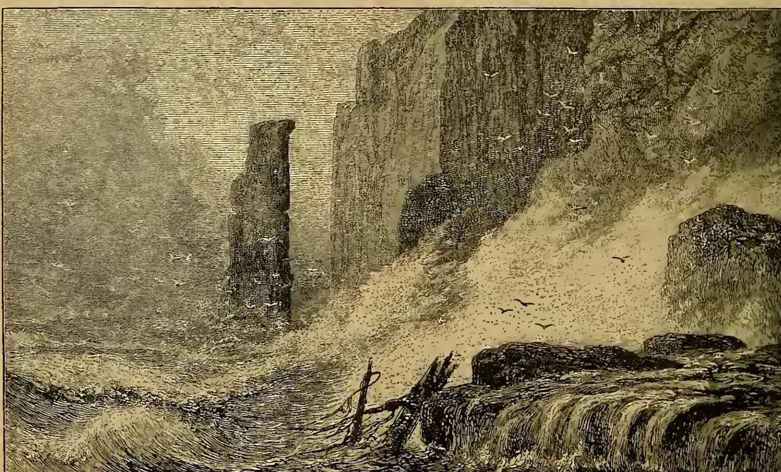
SCALLOWAY FROM THE NORTH-EAST.

THE ORKNEYS AND SHETLAND.

The Orkneys and Shetland; their past and present state. By John R. Tudor. London, *Stanford*, 1883. 29+703 p., illustr. 8°.

Mr. Tudor has collected and revised a series of letters published under the *nom de plume* of 'Old Wick,' in *The field*, the English sporting-journal, from 1878 to 1880, on the Orkneys and Shetland, and, with contributions from several scientific friends, has prepared a very entertaining book on these out-of-the-way islands. The general reader will find in it an interesting historical essay, embracing the period from Norse occupation to modern times, followed by local descriptions and numerous maps, that may well serve as a visitor's guide. Primitive old-fashioned ways have endured on these remote islands till recent times, and furnish many anecdotes to enliven the descriptive pages. The more scientific student, with a liking for botany, geology, mineralogy, or archeology, will meet with much worthy of his attention.

The two geological chapters, prepared by Messrs. Peach and Horne from their papers published in the *Quarterly journal* of the geological society and elsewhere, are of chief scientific value, and are well illustrated by neatly colored maps. The southern group is shown to be almost entirely covered by the various divisions of the old red sandstone; and, indeed, this formation once extended over a great area thereabouts, now broken up into ragged islands by dislocation, erosion, and submergence, so that only the smaller part of the original deposit remains. The topographic effect of former erosion at a higher level, followed by depression, is seen in the irregular shore-line and fringe of islands shown in the view of Scalloway. In their present attitude, the islands suffer most along their western coast, where the heavy waves of the Atlantic cut them back into imposing cliffs, such as are found on the western side of Hoy. Shetland includes a considerable variety of old metamorphic rocks, and numerous intrusives and eruptives. The relations of the latter to the adjoining masses is often finely exposed in the sea cliffs, and questions of age are not left to vague inference. Dikes, necks, intrusive sheets, and overflows are all well exhibited. But the geological interest culminates in the glacial question. These northern islands give the key to the movement of the combined Norwegian and Scotch ice-sheets, and show, as was first suggested by Croll, that they joined forces in the basin of the North Sea, and together moved north-westward, out into the Atlantic. The striae are of two dates. The later ones depend on the local topography for their direction, and are referred to a 'later glaciation,' though it is not shown that a non-glacial interval separated this from the greater or primary glaciation, during which the ice moved independently of local topography, over-riding all the hills and ridges. Only these are shown on the accompanying outline, which is traced and reduced from two maps of much larger scale in the original. On the Orkneys the scratches run north-west with much regularity. Marine shells and rocks derived from eastern Scotland are found in the bowlder-clay. On Shetland the approach of the ice was from the north-east,



RORAY HEAD AND THE OLD MAN OF HOY DURING A WESTERLY GALE.

COURSE OF GLACIAL SCRATCHES.

but the motion changed to north-west about the middle line of the group. The great variety of rocks in north and south strips gives abundant opportunity for determining this motion by the direction of dispersion of the bowlders from their parent ledges. No Scottish bowlders are found here, nor do marine remains occur in the drift. Raised beaches do not appear on any of the islands. It is concluded that Scandinavian ice covered Shetland, while Scottish ice advanced over the Orkneys; the original motion of both glacial sheets being changed where they coalesced, in the shallow North Sea, and turned to the line of least resistance, — north-west to the open ocean. There they must have ended in a great ice-cliff like that discovered by Ross in the Antarctic Ocean. It may be well to refer here to Helland's study of the Faroes a few years ago, when he showed that they bear no marks of continental glaciation, the few scratches he found there depending on local form for their guidance.

Our space forbids mention of the many other interesting topics that Mr. Tudor's book discusses, although few volumes contain so many pages of entertainment to the general reader; but attention should be called to the well-considered character of the work, only seldom marred by a remnant of newspaper style. In its table of contents, illustrations, glossary, bibliography, and index, the volume is all that can be desired.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Partial differential equations. — M. Darboux considers an arbitrary partial differential equation, defining a function, z, of any number of variables. Replacing z by $z + ez'$, developing according to powers of e, and equating to zero the coefficient of e, a new equation is formed, which the author calls the auxiliary equation. The auxiliary equation defines solutions differing infinitely little from a given solution; and so it has a signification which does not depend on the choice of variables, and which will remain unchanged by any arbitrary change of the variables. The equation, being linear, is easy to deal with, and conducts to many important results which are intimately connected with the given equation. The author considers especially two geometrical problems. First: having given a surface, Σ, attempt to find all the infinitely near surfaces which will form with Σ one family of a triply orthogonal system. This problem, which has already been studied by Prof. Cayley, is equivalent to either of the following problems: 1°, To find all surfaces admitting of the same spherical representation as Σ; or, 2°, To find all the systems of circles normal to the family of surfaces of which Σ is one. It follows at once, that, if the problem of the spherical representation of Σ is solved, the solution can be at once arrived at for the inverse surfaces to Σ, or the surfaces arrived at by the transformation by reciprocal radii.

The second problem considered by M. Darboux is one famed for its extreme difficulty; viz., to find the surfaces applicable to a given surface. Denote by δx, δy, δz, the increments taken by x, y, z, in passing from a point of the given surface, Σ, to the corresponding point on an infinitely near surface: then, expressing the necessary condition to the solution of the problem, — viz., that the small arc shall not change its length, — we have —

$$dx\, d\,.\,\delta x + dy\, d\,.\,\delta y + dz\, d\,.\,\delta z = 0.$$

Replacing δx, etc., by proportional quantities, — say, x_1, y_1, z_1, — this is $dx\,dx_1 + dy\,dy_1 + dz\,dz_1 = 0$; i.e., the corresponding elements on the surfaces Σ and Σ_1 are orthogonal. M. Darboux's problem is thus conducted back to a problem solved by M. Moutard. The surfaces for which the problem can be solved are divided into certain *classes*. M. Darboux gives the expressions for the co-ordinates of a point in terms of two parameters for the surfaces of the first class. — (*Comptes rendus*, March 19.) T. C. [441

ENGINEERING.

Theory of the screw-propeller. — Mr. J. N. Warrington, of the Stevens institute of technology, discusses the theory of the screw-propeller, and the methods of designing it. He first discusses the action of the screw in the water, investigates the conditions of maximum efficiency, and obtains expressions for the efficiency in terms of the angle of the blades, and the ratios of resistance of friction to pressures exerted. He finds, as does Froude, that the angle of maximum efficiency is forty-five degrees. It is found that a small amount of slip does not necessarily give good performance, — a conclusion already proven by experience. It is found that the action of the screw, in its most efficient operation, does not involve the sternward projection of a solid stream; and hence it follows that all investigations based, as is common, on that assumption, are inaccurate. Yet it is only the water that is thrown aft that gives propelling-power, and the nearer the stream is solid, the better. He obtains the equation of the curve of the developed screw from Thurston, and expressions for the magnitudes of diameter and thrust from Seaton. The second part of the paper is devoted to the designing of the screw according to the principles deduced in the first part. The shape of a blade upon which the water shall glide without shock, and from which it shall be thrown aft with a given velocity, acquiring that velocity by a uniform acceleration, is given by its equation as deduced by Warrington. The relation between the pressure and the acceleration is ascertained; the slip is assumed, and the total resistance is given; and the required size of screw is calculated. The magnitude of the losses of energy, and the efficiency, are determined, and the process is applied to the guide-blade propeller as well as to the common screw. Two wheels are drawn, — the one a U. S. naval-department screw, the other a screw designed on Warrington's plan. — (*Journ. Frankl. inst.*, Aug.) R. H. T. [442

Light prime motors. — President D. Napoli, of La société de navigation aérienne, in a communication to the *Aéronaute*, compares the weight of steam-engines and electric motors for use in aeronautics. He finds that the weight of fuel and water demanded by a steam-engine of twenty-horse power for ten hours' work would be not far from 1,600 kilos (3,527 lbs.), while the weight of an electric motor and its supplies would be about 1,400 kilos (3,087 lbs.); giving a decided advantage to the latter aside from the weight of the engine, which may be anywhere from two hundred and fifty to four hundred per cent greater than the weight of its supplies, according to style, which M. Napoli does not prescribe. — (*Chron. ind.*, June.) R. H. T. [443

Resistance of railway-trains. — Professor Franck has written a memoir on the resistance of trains, studying the earlier experiments of Vuillemin, Guebhard and Dieudonne, and of Rockl. He obtains the formula for resistance,

$$w = m + \frac{l F v^2}{Q},$$

in which w is the resistance in kilos per ton, Q is the weight in tons, m, l, and F are the coefficients, as follows: —

For	passenger-engines . .	$m = 0.0032$
"	freight-engines . . .	$m = 0.0038$ to 0.0039
"	the cars	$m = 0.0025$
"	all cases	$l = 0.1225$
"	passenger-engines . .	$F = 7$
"	freight-engines . .	$F = 8$
"	passenger & box cars,	$F = 0.5$
"	unloaded flat cars . .	$F = 0.4$
"	loaded flat cars . . .	$F = 1.0$

The author of the paper considers that this formula, used with this assortment of constants, will allow of very exact calculation of the resistance of trains. — (*Mém. soc. ing. civ.*, June.) R. H. T. [444

Dowson's gas for heating. — In 1882 the Messrs. Crossley put in a Dowson plant for making his gas. The trial of the system gave the following results: when the gas was made from Trimsaran anthracite, a gas-engine consumed 1.5 pounds (0.68 kilogram) per hour per horse-power; when using Garnant anthracite, the consumption was 1.4 pounds (0.64 kilogram). These results were so satisfactory that the Messrs. Crossley have adopted the gas-engine throughout their works, and are using some 200-horse power. The engine above referred to was of about 30-horse power. It is found that a larger engine, 40-horse power, uses but 1.2 pounds (0.54 kilogram). The process consists in passing a current of steam and air through a mass of red-hot carbonaceous materials. Coal-gas has nearly four times the heating-power of this gas, but the cost of the Dowson gas is so much less that it compensates this great difference. It is, however, intended to compete with the gas produced from coal-oils. The author of the paper calculates that the costs of operating a steam-engine, and of working a gas-engine driven by his gas, are as three to two, the engines being of 100-horse power each. — (*Proc. inst. civ. eng.*, 1883.) R. H. T. [445

AGRICULTURE.

Reversion of superphosphates in the soil. — Farsky shows, that, when a small quantity of water acts upon a superphosphate, the monocalcic phosphate which it contains is decomposed into dicalcic phosphate and free phosphoric acid. The same process seems to take place when a superphosphate is mixed with the soil. Subsequently the free acid appears to act upon the calcium, iron, and aluminum salts of the soil, forming dicalcic phosphate and soluble acid phosphates of iron and aluminum. The latter are not stable, and soon pass into insoluble combinations (compare SCIENCE, i. 825). — (*Biedermann's centr.-blatt.*, xii. 450.) H. P. A. [446

Fineness of superphosphates. — Farsky, both in pot-experiments with buckwheat, and in field-experiments with several other crops, found that coarse superphosphate gave a greater increase than fine. Exactly the opposite result was given by Wagner's experiments, reported in SCIENCE, i. 310. — (*Biedermann's centr.-blatt.*, xii. 453.) H. P. A. [447

Experiments on the continuous growth of wheat and barley. — These experiments by Voelcker, on the plan of the well-known Rothamsted experiments of Lawes and Gilbert, are in progress at Woburn, on a light soil, and are intended to supplement those at Rothamsted, which are on a heavy clay soil. The present report gives the results of the sixth year, viz., 1882. The most interesting of the results are those obtained on four plots, two of which had received mineral manures and nitrates or ammonia salts, and two stable-manure. Each plot was halved. One half received the same fertilizers as in preceding years; while the other remained unmanured (in case of the stable-manure plots), or received the mineral fertilizers of the preceding year, but no nitrogen. The mineral fertilizers alone gave no larger crop than was obtained from plots unmanured for six years, while the other half of the same plots, which received nitrogen, gave about thrice as large a crop. The evident conclusion was, that the plots were deficient in nitrogen, and that the large amounts of nitrates or ammonia salts, which they had received in previous years, had left no available residue of nitrogen in the soil. In the case of the plots which had received stable-manure, the unmanured halves showed that a portion of the manuring of previous years was still available, though the gain thus caused was small. In all the experiments of this year, sulphate of ammonia produced better results than an equivalent quantity of nitrate of soda. — (*Journ. roy. agric. soc.*, xix. 209.) H. P. A. [448

MINERALOGY.

Cuspidine. — This comparatively new mineral has been crystallographically examined by G. von Rath. It occurs at Vesuvius in very characteristic spear-head-shaped crystals, which are not to be confounded with any other mineral. The crystals were found to be monoclinic, the apparent rhombic form being the result of twinning. The axial relation is $a:b:c = 0.7243:1:1.9342$. $\beta = 89° 22'$. The measurements were made on a single small crystal, which showed no evidence of twinning; the symbols for seventeen different forms being obtained, cleavage parallel to the base, plane of twinning the orthopinnacoid. Sections from the mineral gave the optical properties of monoclinic crystals. Material pure enough for analysis could not be obtained, as the mineral is peculiarly liable to alteration. An analysis by E. Fischer, of impure material, showed that in addition to calcium fluoride the mineral contains the silicate Ca_2SiO_4.

A very few minute crystals of a mineral resembling cuspidine were found at Vesuvius, occurring in orthorhombic prisms, very much striated, parallel to the vertical axis, and terminated by an obtuse pyramid. An approximate axial relation, $a:b:c = 0.560:1:0.417$, was obtained; but the material did not admit of further investigation. — (*Zeitschr. kryst.*, viii. 38.) S. L. P. [449

Empholite. — This new mineral has been described by L. J. Igelström as occurring at Hörrsjöberg, Wermland, Sweden, in small, well-formed crystals and fibrous aggregates. The prisms, sometimes attaining a length of six millimetres, are brilliant, and resemble diaspore in form, the prismatic angle being about 123°–130°: with cleavage parallel to the brachypinnacoid; hardness, greater than six; color, white, changing to yellow on exposure, owing to the oxidation of the iron; before the blow-pipe infusible, giving a beautiful blue color with cobalt solution, and, in the closed tube, neutral water; scarcely attacked by acids. Two analyses, after correcting for sixteen per cent of gangue, yielded —

SiO_2	Al_2O_3	MgO. CaO. FeO.	H_2O	
52.3	30.5	3.4	13.8	= 100
48.8	33.3	3.3	14.6	= 100

The mineral is a hydrous silicate of alumina, and the formula $Al_2Si_2O_7 . 3H_2O$ is proposed; but the analyses are not correct enough to lead to any definite formula. — (*Bull. soc. min.*, vi. 40.) S. L. P. [450

METEOROLOGY.

Barometric maxima and minima. — The meteorological conditions which are characteristic of regions of high and low pressure have been studied by various investigators, notably by Mohn, Clement Ley, and Loomis. The latest contribution to this subject is made by Hildebrandsson, who bases his conclusions upon observations made at Upsala and other stations in northern Europe since 1873. He discusses the angle of the wind with the barometric gradient, the wind velocity, the direction of the upper and lower clouds, the air temperature, the amount of cloudiness and rainfall, the transparency of the air and fog, — all with regard to their relations to areas of maximum and minimum pressure. The conclusions are based wholly upon tabulations of the observations, and are primarily applicable to Upsala and vicinity, but are in general similar to those obtained for other countries. — (*La distr. élém. mét. autour min. et max. bar.*) W. U. [451

ZOÖLOGY.

Animal coloring-matters. — The application of the spectroscope to the determination and discrimination of coloring-matters from living organisms has opened an interesting field of research. Dr. C. A. MacMunn gives an extensive *résumé* of previous work, and the results of his own studies in this field. His article is a valuable presentation of our knowledge of the subject; but it necessarily contains many details, and is therefore unadapted to a brief abstract. The following points deserve special notice. Haematin may be prepared by a new method: "Fresh defibrinated blood is treated with a mixture of two parts of strong sulphuric acid to thirty-five of alcohol, and thrown on a filter, more alcohol being added to help the filtration; the filtrate is diluted with water, put into a separating funnel, and shaken up with chloroform. After standing some time, the chloroform is separated off, and filtered and evaporated. . . . The residue corresponds to haematin as it is usually described." By the action of strong mineral acids on this haematin, Hoppe-Seyler's haemato-porphyrin was obtained; it is practically identical with Thudicum's cruentin. When neutral dried cruentin is boiled with equal parts of rectified spirit and acetic acid, a five-banded spectrum was obtained, similar to if not identical with that of Preyer's iron-free haematin. Bilirubin is identical with haematoidin. There are several lutein pigments; for example, that of the hen's egg is different from that of the corpus luteum of the cow. Tetronerythrin is very widely spread, occurring in 'the roses' around the eyes of certain birds, in the skin of the red mullet, and in many invertebrates; it is apparently capable of performing respiratory functions, somewhat like haemaglobin. Its presence in the crust of lobsters and crabs is noteworthy. The various classes of invertebrates are taken up in succession, the following being the principal pigments described: chlorophyll, pentacrinin, cruentin (in starfishes), echinochrome, cochineal, aphidein, bonellein, haemocyanin (in blood of Octopus), aplysiopurpurin, dermolutein, etc. Numerous spectra are reproduced in the charts. In an appended note, it is stated that chlorophyll is found in the liver of mollusks: *cf.* Royal society's proceedings, April 5, 1883. — (*Proc. Birmingham nat. hist. soc.*, iii. 351.) C. S. M. [452

Mollusks.

Abyssal mollusks. — Dr. Jeffreys continues his valuable papers on the deep-sea mollusks of the Lightning and Porcupine expeditions. The last instalment includes the Scissurellidae, Trochidae, Turbinidae, and Littorinidae, with two fine plates on which are figured twenty-one new forms. Several new genera are described. Tharsis Jeffreys has a closed umbilicus and appressed peristome, which separate it from Cyclostrema: the type is Oystele romettensis Seguenza. Ganesa is like a very minute, delicate Lunatia, with a perforate axis. Cantrainea is suggested for Turbo peloritanus Cantraine. Hela Jeffreys, beside being pre-occupied, proves to be identical with the Japanese Cithna A. Ad. Iphitus Jeffreys is a minute form, resembling Fossarus or a miniature Tectarius, with a peculiar apex and subspiral operculum. — (*Proc. zoöl. soc. Lond.*, March, 1883.) W. H. D. [453

Further researches on nudibranchs. — Bergh prints an important paper, illustrated by five beautiful anatomical plates, as a supplement to his monograph of the family of which Polycera Cuvier is the typical genus. After a number of general notes on species and genera, among which is the description of Ohola, a new genus collected by the Challenger at Arapura in the South Seas, the author considers the Dorididae in general, with their divisions and probable phylogeny. The genus Heterodoris of Verrill and Emerton is considered as probably belonging to a different family. The Dorididae are separated into two very well marked groups by the possession of a single large retractile crown of gills or of numerous nonretractile branchia, cryptobranchiata, and phanerobranchiata respectively. The latter, connected with the typical Dorididae through Staurodoris, diverge in two lines, of which the more ancient forms are Notodoris and Akiodoris. The former culminates in Plocamophorus, with Ohola as a lateral branchlet. The latter passes through Acanthodoris, Goniodoris, etc., toward Ancula and Drepania.

The phanerobranchiate, non-suctorial Dorididae form the Polyceradae (better Polyceratidae) of Bergh, and the suctorial forms his Goniodorididae. Of these groups a full discussion is made, and a synopsis of their genera and species is given. They inhabit all seas, but are largest and most beautiful in the warmer regions. — (*Verh. zool. bot. ges. Wien*, März, 1883.) W. H. D. [454

Worms.

Development of Phoronis. — A. Foettinger has published an article on this subject in Van Beneden's *Archives de biologie* (iii. 679). He found in the morula stage, that the cavity contained a few spherical or oval corpuscles, sometimes surrounded by a fine granular substance filling the whole segmentation cavity. The important question he deems to be, whether these elements, which are clearly the first rudiments of the mesoderm, are derived from the endo- or the ecto-derm. Kowalevsky is in favor of the latter view, while Metschnikoff holds to their endodermal origin. If the larvae are treated with acetic acid, and immediately examined, evidence will be afforded as to the presence of the first mesodermic elements at a time when the ovum is still segmenting; and, indeed, indications of them were seen in two cases, where the developing ova consisted of only eight blastomeres, for there is in them a central corpuscle which appears to have a mesodermal significance. The author has no distinct opinion as to the origin of this cell, but inclines to doubt the explanation given by Metschnikoff. As to the still earlier stages, it is stated that the fecundated ova are developed outside the body of the parent, but that they remain attached to the branchiae for a certain time. After the appearance of four blastomeres, two divide, and so give rise to a six-celled stage, with two large and four smaller cells. (As to the origin of the mesoderm, compare Hatschek's researches on Sipunculus, to be given shortly in SCIENCE.) — (*Journ. micr. soc. Lond.*, iii. 509.) C. S. M. [455

Nervous system of Hirudinea. — Saint-Loup finds that the arrangements of the nervous system, which were thought to be peculiar to Clepsine, are very common among the Hirudinea. Commencing with Nephelis, he saw in the transparent tissues six capsules on the ventral surface of the ventral ganglia. Similar capsules were observed in Aulastomum and Hirudo. The author detected in all Hirudineae the intermediate or unpaired nerve first described by Brandt in the medicinal leech. Saint-Loup hopes to give a general account of the morphology of the nervous system of the group. — (*Comptes rendus*, xcvi. 1321; *Journ. micr. soc. Lond.*, iii. 509.) C. S. M. [456

Insects.

Classification of the larger groups. — From a study of the relationships of the lower insects, Packard has been led to a new arrangement of all the larger groups, and proposes the following scheme, in which the names proposed for what he terms super-orders are all new: —

Super-orders.	Orders.	Sub-orders.
Euglossata . . .	Hymenoptera.	
	Lepidoptera.	
	Diptera	Diptera (genuina).
		Aphaniptera.
		Pupipara.
Elytrophora . .	Coleoptera . . .	Coleoptera (genuina).
		Strepsiptera.
Eurhynchota . .	Hemiptera . . .	Homoptera.
		Heteroptera.
		Physapoda.
		Mallophaga.
Phyloptera . .	Neuroptera . . .	Trichoptera.
		Planipennia.
	Pseudoneuroptera .	Odonata.
		Ephemerina.
		Platyptera.
	Orthoptera.	
	Dermatoptera.	
Synaptera . . .	Thysanura . . .	Cinura.
		Symphyla.
		Collembola.

A mere outline is presented in this paper, which is only an abstract of his researches, to be published in full in the forthcoming report of the U. S. entomological commission. — (*Amer. nat.*, Aug.) [457

VERTEBRATES.

The function of body-equilibrium. — The central gray substance of the third ventricle, according to Bechterew's experiments, given in this paper, forms an organ of equilibrium in the same sense as the semicircular canals and the olivary bodies. His investigations were made chiefly upon the dog; although confirmatory experiments upon other animals, birds, and frogs, are given. The method of operating was to trephine a hole through the sphenoid bone at the sella turcica; and then, thrusting a small knife through the hypophysis into the third ventricle, a section could be made of the gray matter in any desired direction. Injury of any portion of the gray substance of the third ventricle was always followed by disturbances of equilibrium, similar, in a general way, to those caused by section of the semicircular canals. The author points out that the disturbances of equilibrium which have been noticed by other observers, after sections made in this region, but which were attributed either to the corpora striata or corpora thalami, were most probably caused by injury to the walls of the third ventricle. To explain how it is that the gray matter of the ventricle is affected by changes in equilibrium, he supposes that the cerebro-spinal liquid, which in this portion of the ventricle lies almost in a closed sac, assumes a rôle similar to that played by the endolymph of the semicircular canals. Changes in position of the body cause changes in pressure of the liquid upon the walls of the ventricle, giving rise to stimuli which act reflexly on the co-ordinating centres in the cerebellum. The preservation of body-equilibrium is brought about, according to Bechterew, by the action of three peripheral equilibrium organs; viz., the semicircular canals, the gray matter of the third ventricle, and the olivary bodies of the medulla. Disturbances of equilibrium cannot act as a stimulus to the olivary bodies by reason of any change in pressure of the cerebro-spinal liquid. The normal stimuli for this centre are found in the skin sensations, and perhaps muscle sensations, which reach the medulla from the spinal cord. Each of these three equilibrium organs, it is interesting to notice, is not only connected with the cerebellum, through which it acts on the muscles, but each is closely related also to one of the higher sense-organs, — the olivary bodies, to the skin; the semicircular canals, to the ear; and the gray matter of the third ventricle, as is shown in detail in the paper, to the eye. The intimate connection existing between the organs of sight and equilibrium is known to all; and this connection depends not so much on the visual sensations as on the position of the eyeballs. Injury to the centre in the third ventricle was always followed by marked changes in the direction of the axes of the eyeballs; and the author advances an ingenious theory to show that any change in the position of the eyeballs will act as a mechanical stimulus to this centre. Taken in conjunction with previous work by the same author, this paper makes an important addition to our knowledge of the much discussed question of body-equilibrium. — (*Pflüger's archiv*, xxxi. 479.) W. H. H. [458

Birds.

Sternum of Notornis. — In this paper Prof. Owen replies to a stricture on his plate of this bone, and makes many valuable remarks on the sternum in general. He distinctly adopts the Lamarckian theory for the loss of the keel, and again calls attention to the heterogeneous nature of the Ratitae. — (*Proc. zoöl. soc.*, 1882, 689.) J. A. J. [459

Pacinian corpuscles of birds. — Mlle. Joséphine Cattani has studied the corpuscles of Herbst in the leg of the fowl. The axis of the corpuscle is constituted by an extension of the nerve-fibre; the extension comprising not only the axis-cylinder, but also the medullary and Schwann's sheaths. At the point of entry the fibre is slightly constricted, and there is a Ranvier's node where the fibre reaches the corpuscle. Within the corpuscle the axis-cylinder becomes ribbon-like; the medullary sheath becomes thinner, and has a nucleus. The mass investing this terminal organ is composed of a web of fibres, with scattered ramified cells having oval nuclei; there are also two rows of cells with round nuclei along the nerve-fibre. The external envelope is a layer of connective tissue with very elongated nuclei. The nerve-fibre ends with a little flask-shaped dilatation, which has a granular matrix in which each fibrilla of the axis-cylinder ends in a little button. The author has also investigated the degeneration of these organs, after cutting the sciatic nerve; but this portion of her work lies rather in the domain of pathology. — (*Arch. ital. biol.*, iii. 326.) C. S. M. [460

Mammals.

The lingual sense-organs of Ornithorhynchus. — E. B. Poulton has continued his researches on the tongue (Science, i. 523) by studying that of Ornithorhynchus. The tongue is about two inches long, and has only a small part free. The posterior third forms a large rounded conical protuberance, pointing obliquely forwards, and bearing at its apex two corneous teeth. The anterior division is covered by horny papillae, and has numerous mucous glands. The posterior division is more complicated, bearing various organs on its dorsal surface: viz., numerous filamentous papillae; an arching fold, limiting the tongue behind; a median raphe, which does not reach the tip of the cone; and four gustatory pits, — one pair near together, in front; and one pair behind, widely separated.

The papillae upon the anterior division of the tongue are largest in front, and smaller (and more scale-like) towards the base of the tongue, and also extend over the inferior surface of the basal protuberance. Except a few in front, they are all cornified, pointed, and inclined backwards. In each of the interior of these papillae are lodged from one to four sub-epithelial sensory bulbs; a medullated fibre runs directly to each bulb, and there loses its sheath; while the axis-cylinder is continued into a spindle-shaped body within the bulb, which, for the rest, consists of a series of nucleated lamellar envelopes. Poulton compares these organs with the Pacinian corpuscles, and considers them tactile. The epithelium between the papillae is not cornified: in it are found the pore-like openings of the numerous mucous glands.

The epithelium of the overhanging ventral surface of the posterior protuberance is more specialized, in that four strata can be distinguished in it. Curiously, the outer stratum appears less corneous than that which it immediately overlies. The two teeth at the apex have a very thick corneous layer, which, however, does not cover their tips, but forms a ring around an apical spot of softer epithelium.

The dorsal surface of the protuberance is covered by a simple epithelium, with numerous hair-like papillae similar to those in Perameles (Science, i. 523). In all four of the gustatory pits is a ridge projecting from the base, and bearing the taste-bulbs under its surface. In the specimen examined the left posterior pit was (abnormally?) rudimentary. Each bulb lies in a papilla, which penetrates far into the epithelium, which is also pierced by a pore over each bulb. The terminal organ is the axial body (cell?) of the bulb, appended to the end of the nerve-fibre. The surrounding cells are sub-epithelial, and form a sheath around the axial body. This observation confirms the author's theory that the taste-bulbs arose as papillary sub-epithelial structures. The value of this theory was asserted in the abstract of the author's previous paper. Numerous serous glands open around the base of the gustatory ridges. Such glands appear to be very generally associated with the organs of taste. Around the pits are smooth muscles, which (at least, around the mouths of the anterior pair) distinctly form sphincters.

The gustatory ridges of Ornithorhynchus, if they rose to the surface and were shortened, would become like circumvallate papillae; if they remained long and became furrowed, they would resemble the foliate areas of rodents: hence Poulton considers that the ridges represent a primitive form from which both the principal types of elevated gustatory areas in mammals may have been derived. — (*Quart. journ. micr. sc.*, xxiii. 453.) C. S. M. [461

Lymphatic and blood vessels. — Dogiel describes the lymph-vessels of the renal capsule and gall-bladder of the dog. In the renal capsule two layers can be distinguished, the outer of which alone is vascular. Prof. Arnstein, in an appended note, states that the rudimentary homologue of the fatty envelope of other species is included in this outer layer. The lymphatics form a coarse network of large vessels, which are accompanied by blood-vessels, and spun over by a loose network of very fine capillaries, while in the meshes of the lymphatic network is an abundant collection of anastomosing blood-capillaries. Each mesh thus forms a vascular island. By this distribution the lymph-vessels are brought as far as possible from the blood-vessels, — an arrangement which is attained in various ways in other parts, and which is important for the perfect drainage of the tissues.

In the gall-bladder there are three sets of lymphatics, — a net for the mucosa, one for the muscularis, and a third for the serosa externa. These are all described and figured. — (*Arch. mikr. anat.*, xxii. 608.) C. S. M. [462

(*Man.*)

Branchial arches and clefts. — Cadiat publishes an article destined to serve as "an introduction to the history of the formation of the face and its different cavities: of the neck, thorax, pharynx, and lung;" also the peritoneum, pleurae, pericardium, respiratory cavities: and gills of fishes (!) The reporter regrets to have found in the article nothing but redescriptions of the pharyngeal apparatus of the embryo chick. As the facts have been familiar to embryologists for very many years, the object of the publication is not obvious. — (*Robin's journ. anat. physiol.*, xix. 38.) C. S. M. [463

Laws of dentition. — Magitot publishes a somewhat lengthy essay on this subject; but the article hardly contains original matter, and is written from a point of view too exclusively that of the dentist. — (*Robin's journ. anat. physiol.*, xix. 59.) C. S. M. [464

ANTHROPOLOGY.

Ancient Orkney-Islanders. — Dr. J. G. Garson has made a very thorough study of the crania and other remains of the ancient inhabitants of the Orkney Islands. His paper takes up in detail their dwellings, stature, limb-bones, and skulls, the last named with great detail, and expresses his results in elaborate tables. The author comes to the following conclusions: —

It is evident that in this series of skulls we have not a single pure race to deal with, but two distinct races, which have existed at probably three different periods. The first and apparently the ruder race seems to be the long-headed people, represented by the skulls from Skerrabrae and Saverough. We have next the round-headed race, which probably occupied the country for a considerable time. The time when these races inhabited the islands is quite uncertain. The abundance of deer-horn at Skerrabrae indicates the presence of these animals, which would probably be associated with forests. When the Romans visited the Orkneys, their historians tell us that there were no forests there. Also the absence of metals, and the rude implements, point to a people in the unpolished stone period. Some evidence is also found in the washing-away of the coast. The round-headed race seems to have lived just before or at the beginning of the bronze period. — (*Journ. anthrop. inst.*, xiii. 54.) J. W. P. [465

The Jutish type of face. — The peculiarity of the Jutish features consists in the form of the nose and mouth. There is no nasal point or tip, properly so called, as in the Danish, Cymric, and Iberian face, and their inter-crosses; nor is there any approach to the slight bulb which distinguishes the Saxon. The end of the nose is rounded off somewhat sharply, and the septum descends considerably below the line of the nostrils. The lips are less moulded or formed, and resemble the Iberian rather than the Saxon type. The lower lip, more particularly, is thick and deep. Mr. J. Park Harrison has been searching for specimens of the Jutish countenance in Kent, Isle of Wight, and in South Hants. — (*Journ. anthrop. inst.*, xiii. 86.) J. W. P. [466

Egyptian mechanical methods. — Petrie, who is the author of a treatise on ancient metrology, has lately turned his attention to ancient Egyptian processes. Though much labor has been bestowed on the literary remains of Egypt and the description of monuments, little attention has been given to finding out the tools and methods by which their results were reached. The first conclusion to which Mr. Petrie comes, is that the stone-cutting was performed by means of graving-points far harder than the material to be cut. These points were bedded in a basis of bronze; and in boring, the cutting action was not by grinding with a powder, as in a lapidary's wheel, but by graving with a fixed point, as in a planing-machine. From discovering spiral grooves in diorite and granite, at least $\frac{1}{10}$ of an inch in depth, the author supposes that an instrument was used of sufficient hardness to penetrate the material that far at a single turn. In this, however, he was corrected by Mr. Evans. The simplest tool used was a straight bronze saw set with jewels; but there is proof of one circular saw which must have been $6\frac{1}{2}$ inches in diameter. For hollowing the insides of stone objects, the inventive genius of the fourth dynasty exactly anticipated modern devices by adopting tubular drills varying from $\frac{24}{100}$ of an inch in diameter and $\frac{1}{30}$ of an inch in thickness, to 18 inches in diameter. Other drills, not tubular, were used for small holes, one measuring $1\frac{2}{10}$ inches long and $\frac{8}{100}$ of an inch in diameter. But this is surpassed by the Uaupes of South America, who drill holes in rock-crystal by the rotation of a pointed leaf-shoot of plantain, worked with sand and water. The writer of this note has seen, in Porto Rico, stone beads of the hardest material, 2 inches long, bored longitudinally with an orifice $\frac{1}{16}$ of an inch in diameter. The Egyptians understood rotating both the tool and the work. For the finishing of vases, a hook-tool must have been used; but the early Egyptians were familiar, not only with lathes and jewel-turning tools, but with mechanical tool-rests, and sweeping regular arcs in cutting. In addition to the tools mentioned, are to be noticed those for dressing out drilled cores, stone hammering and smoothing, saws with curved blades, mallets, chisels, adzes, and bow-drills. For marking and indicating the plane of the stone, red-ochre paint was used in a variety of ways, well studied out by Mr. Petrie. Rock-excavation, both for saving the stone and for the creation of vaults and chambers, was altogether an affair of drilling. Granite bowlders were utilized in the pyramids, but the best stones were taken from quarries. The method of handling these immense masses is not known. Mr. Petrie concludes with a sensible remark upon the oft-alleged inhumanity of the pyramid and temple builders. To require a man every six years to serve upon the public works, during the season when he could do nothing else, would certainly not be a great hardship. — (*Journ. anthrop. inst.*, xiii. 88.) O. T. M. [467

Navajo mythology. — The Navajos, says Dr. Washington Matthews, speak of five worlds, in four of which our fathers lived ere reaching this. In the first world were the first man, the first woman, and the coyote. In the second world were two other men, the sun and the moon people, and at the four corners were the people of the cardinal points. An amour of the sun with first woman led to the ascent of all to the third world, where they found another race of people living in the mountains. Here coyote stole the children of Ticholtsodi (he who seizes you in the sea), who caused a deluge to cover the earth. The emigrants ascended to the fourth world through the growth of a hollow reed. Here a disturbance arose concerning the relative value of men and women, which resulted in favor of the men. After the lapse of some years they were pursued hither by the giant looking for his cubs, which coyote still concealed. The floods rose, and they were let up into world five by the badger and the locust. The cubs were thrown down to the giant, and the waters subsided. Then came the fitting-up of the world for their abode. At this point of the myth are several very pretty origin-stories about the dry land, the mountains, the sun and moon, the making of climate, etc. Here is one. "On the fifth day the sun arose, climbed to the zenith, and stopped. Coyote said, 'The sun stops because he has not been paid: he demands a human life for every day that he labors.' At length a woman, the wife of a great chief, ceased to breathe, and grew cold. The sun travelled down the western sky, and passed behind the western mountain." There is a similar moon myth. Then follow the confusion of tongues, the making of the stars, the lengthening of the seasons, the forming of snow, the planting of corn. At this juncture, on account of the wickedness of mankind, first woman made the five great destroyers, — Yeitso, Tsinahale, Delgeth, Tseta-holtsil-tahli, and Binaye. She also took to rear a foundling girl, Estsanatlehi. The latter, impregnated by the sun, brought forth twins, who, by the aid of their father, slay the five great destroyers of mankind. The stories of these Herculean labors is charmingly told, and is full of theories about the causes of familiar things, such as the birds, the shunning of a mother-in-law. The mother of the giants repeopled the world, built pueblos, established the gentes. The giants may still be seen in the waters of the San Juan, and the mother continues to send to the Navajos the snow, the spring thaw, the soft rain, the corn, and the green grass. — (*Amer. antiq.*, v. 207–224.) J. W. P. [468

EARLY INSTITUTIONS.

A history of guilds. — A Mr. Waterford, barrister-at-law, is writing a history of English guilds. He has already described the aims and purposes of the guilds. He has also described their history, and the history of public opinion and legislation regarding them. He is now taking up their geographical distribution in the different counties and towns. Extracts are given from the records. The work promises to be one of interest and value. The history of trade unions is a subject which deserves especial attention in these days. It is a very difficult subject, however, and by no means mastered as yet. Contributions towards its elucidation are therefore very welcome. — (*Antiq. mag.*) D. W. R. [469

The Merovingian grants of immunity. — These grants, a chief source of feudalism, are not considered by M. Fustel de Coulanges to have been confined to ecclesiastics, as is usually assumed. The grants to ecclesiastics were no doubt the most numerous, and the documents are at any rate better preserved; but lay proprietors received precisely the same powers. The essential feature of the grant he regards as the exclusion of the public officials from the territory of the immunity, whether for judicial, fiscal, or military purposes. Exemption from financial burdens was a natural but not necessary nor universal consequence. In this he agrees with Heusler, differing from him, however, in holding that the grantee was absolutely removed from all relation to the public official, the count, and stood only under the king; while Heusler considers that he only became an intermediary between his tenants and the count. The result of these grants was to completely break up the administrative system of the Frank empire by removing great stretches of territory from the authority of the public official, and practically to make the proprietor an irresponsible master over his free tenants as well as his serfs. The same effects followed the grants of *mundiburdium*, or protection, by which the proprietor entered into a purely personal relation to the king, ceasing to be under the authority of the count. This substitution of a personal relation for the political one of subject and ruler is also of the essence of feudalism. It is not possible to decide whether the grants of immunity or those of *mundiburdium* were the earlier. Immunity, however, applying primarily to the land, necessarily included the personal relation; while *mundiburdium*, by an equal necessity, led to immunity. The article is written in the interesting style and with the characteristic lucidity of the author, and forms a most important contribution to the study of the origin of feudalism. — (*Rev. hist.*, July–October.) W. F. A. [470

NOTES AND NEWS.

A CABLE despatch was received Nov. 30, at Harvard college observatory, announcing the discovery of a small planet by Palisa at Vienna. Its position Nov. 28, 13 h. 20 m., Greenwich time, was, right ascension, 3 h. 19 m. 14 s.; declination, north, 15° 52′ 17″; daily motion in right ascension, — 48″; in declination, nothing. It is of the twelfth magnitude. The planet was readily identified at Harvard college observatory, and was observed by Mr. Wendell as follows: Nov. 30, 9 h. 30 m., Cambridge time; right ascension, 3 h. 17 m. 27 s.; declination, north, 15° 51.1′.

— While the revenue steamer Corwin was cruising on the coast of Alaska and in the north-west Arctic Ocean in 1881, Dr. Irving C. Rosse, her medical officer, found leisure to prepare a series of medical and anthropological notes, which have just been published by the Treasury department. The medical notes, although they exhibit the mind of a keen observer, are rather technical than racial: there is a short chapter on medical and surgical subjects, however, p. 25. The author holds that the marks of distinction between the Eskimo and the Chukchi are not very plain. At Kotzebue Sound many of the natives are tall and of a commanding appearance. Uniformity of features, so commonly attributed to the Eskimo, has frequent exceptions; many of the natives exhibiting countenances of Chinese, Jewish, Milesian, or even Mulatto cast. The experiments of strength and agility in rowing, racing, throwing stones, and lifting, given on p. 29, are valuable contributions to anthropometry. The popular notion regarding the great appetite of the Eskimo is one of the current fallacies, according to Dr. Rosse. As to the commercial connection between the two continents, natives cross and recross Bering Strait to-day on the ice and in primitive skin canoes, which have not been improved since the days of prehistoric man. With a view to finding out whether any linguistic affinity existed between the Japanese and the Eskimo, Dr. Rosse caused several Japanese boys employed on the Corwin to talk on numerous occasions to the natives, both on the American and Asiatic coast; but in every instance they were unable to understand the Eskimo, and assured him that they could not detect a single word that bore any resemblance to words in their own language. The language varies greatly from point to point. The interpreter taken at St. Michaels could with difficulty understand the natives of Point Barrow, while at St. Lawrence Island and on the Asiatic side he could understand nothing at all. The author happily likens spoken languages to those species of animals which are still in a plastic condition and are undergoing farther development. The Eskimo tongue is one of these, and yields with facility to almost any external influence.

Dr. Rosse speaks slightingly and flippantly of philological studies, and holds that the observation of habits in satisfying the demands of nature is a surer guide to racial affinities. The dietetic value of seal, bear, walrus, eider-duck, whale, and reindeer, is discussed; and we are led to believe that the Eskimo are by no means to be pitied for their miserable food. Says Dr. Rosse, "We dined occasionally on fresh trout, young wild duck, and reindeer. . . . There is scarcely any better eating in the way of fish than Coregonus, and certainly no more dainty game than young wild geese and ptarmigan." The cranberries and a kind of kelp are the only vegetable food. Eggs in all states are eagerly devoured, though the women will not take gull's eggs. Game is both plentiful and very tame.

Courtship and marriage are exceedingly simple, parturition is easy, families are small, and mortality among the new-born excessive. The description of the carrying of infants and the plays of children exhibit in the author a genuine sympathy absolutely necessary in an observer of natural history. The personal ornamentations are chiefly tattooing and wearing labrets. The native has no music in his soul, although rare instances of acquired facility in singing and playing are recorded. He is a born dancer or jumper, however, mingling this pastime with all his feasts. Dr. Rosse speaks in the highest terms of the Eskimo art talent and of the facility shown by some in learning the art of the higher race. Of the intelligence of the race the author has a high opinion. In speaking of their crania, Dr. Rosse confirms the results of Dr. Kohlmann, that there is no fixed Eskimo cranial type. As to character, uncontaminated, they are models of truthfulness and honesty; but as to chastity, Herder was far from truth when he wrote, "The blood of man near the pole circulates slowly, the heart beats but languidly: consequently the married live chastely, the women almost require compulsion to take upon them the troubles of a married life."

Owing to his hard life, the conflict with his circumstances, and his want of foresight, the Eskimo soon becomes a physiological bankrupt: and, his stock of vitality being exhausted, his bodily remains are covered with stones, around which are placed wooden masks, and articles that have been useful to him during life; or they are covered with driftwood, and the weapons and personal effects placed near by, in response to the sentiment commemorated by Schiller in 'Bringet hier die letzten gaben.'

— The Ottawa microscopical society held a conversazione on Nov. 20, at which nearly three hundred invited guests were entertained by the president and members. The admirable arrangement of the rooms allowed of a varied programme. Microscopes of various makers and models, and of highest grade, were set out in the upper story of the building; while the lower hall was devoted to music, elocution, the oxy-hydrogen microscope, and the stereopticon. In the hands of the Rev. Dr. Balland, of the College of Ottawa, the gas-microscope and gas-lantern charmed all by the novelty and brilliancy of the objects and views presented to them. The entertainment lasted nearly three hours, and a repetition is eagerly demanded.

The general meetings of the society will be held this winter on Dec. 18, Jan. 15, Feb. 19, and March 18, at eight P.M., in the offices of the Geological survey.

— In accordance with the vote passed at the public meeting of the Archaeological institute of America, reported in SCIENCE, No. 41, the Hon. Samuel C. Cobb and Messrs. Henry Lee, William Endicott, jun., Oliver W. Peabody, and John C. Phillips have been appointed a committee to solicit subscriptions for the publication of the report of the investigations at Assos and for the general work of the institute. Twenty thousand dollars are needed; and subscriptions may be sent to either of the members of the committee, or to Henry L. Higginson, Esq., treasurer of the institute, No. 44 State Street, Boston.

— At the third annual meeting of the Natural science association of Staten Island, held in the village hall, New Brighton, Nov. 10, Dr. A. L. Carroll was chosen president; Samuel Henshaw, treasurer; Charles W. Lang, recording secretary; Arthur Hollick, corresponding secretary; and W. T. Davis, curator. The society numbers seventy, and has a balance in the treasury. Objects of interest were exhibited at this meeting by seven members, and consisted very largely of specimens collected in the immediate vicinity, — the highest sign of activity.

— The editor of the *American monthly microscopical journal* announces that the office of publication will be removed to Washington with the beginning of 1884.

— The Russian academy of science held its centennary anniversary at St. Petersburg with much ceremony on the second of last month, under the presidency of Count Tolstoy, the Russian minister of the interior.

— The *Moniteur industrielle* announces that the International exhibition at Marseilles opened on the 15th of November, and remains open until April 31, 1884. The programme is extensive, and, on the whole, embraces much the same range of subjects as the London fisheries exhibition.

— After the electrical exhibition in Paris, a number of French electricians formed themselves into a club, which has met once a month for a dinner. From this small beginning there has developed an 'International society of electricians.' The society numbers more than nine hundred members from twenty nationalities. Information may be had from Georges Berger, 99 Rue de Grenelle, Paris.

— Mr. Charles A. Ashburner of the State geological survey is completing his surveys and examinations in Cameron, Elk, and Forest counties, Penn. Mr. Ashburner's report, to be accompanied by maps and sections, will be published late in the winter, and will contain much information of interest to the coal and oil operators in this section of the state.

— The next issue of the Library of aboriginal American literature, published by Dr. D. G. Brinton, Philadelphia, will be 'The comedy of Gueguence,' a play written and acted by the natives of Nicaragua. It dates from the seventeenth century, and is written in a curious dialect, half Aztec and half Spanish. It will be ready early in December.

— An itinerary has been issued of the first part of the map of the route of the Alaska military reconnaissance of 1883 by Lieut. Schwatka. The total length of raft-journey on the Yukon River from Lake Lindeman to Nuklakayet was 1,303.2 miles, being the longest raft-journey in the interest of geographical science. He gives the length of the Yukon River as 2,043.5 miles.

— At the meeting of the Engineers' club of Philadelphia, Nov. 17, Mr. Edw. I. H. Howell presented a sketch of the practice and peculiarities of the English machinists with regard to machine-tools. He also exhibited specimens of polished shafting, from $1\frac{1}{8}''$ to $2\frac{3}{4}''$ in diameter, cold drawn, like wire. The secretary, Howard Murphy, read an illustrated paper by Mr. G. T. Gwilliam, upon the methods of making and placing the mattresses and fascines at the extension of the Delaware Breakwater harbor. The secretary presented notes, by Mr. John J. Hoopes, to illustrate methods of computing tables by successive additions instead of separate calculations. Mr. John Haug presented illustrated notes upon boiler construction, touching especially upon what should be shown in drawings and specifications for boilers. Mr. George S. Strong exhibited specimens of cylindrical and corrugated flues; the former readily yielded to the pressure of the fingers, while the latter was trampled upon without injury. The secretary read, for Mr. C. J. Hexamer, a description of his experiments upon, with a discussion of the causes of, dust-explosions in mills. Mr. William A. Ingham considered that some explosions in coal-mines are probably attributable to the immense quantity of fine dust in the air; and Mr. T. Mellon Rogers, in response to Mr. Hexamer's comments upon the general absence of adjustable rolls in Philadelphia mills being a common cause of ignition by the friction of foreign metallic particles in the stock, spoke of their general use in the west.

— The mathematical section of the Washington philosophical society has resumed its sessions. At the meeting held Nov. 21, Mr. C. H. Kummell discussed the theory of errors as practically tested by target-shooting, in which he showed the effect of a difference of precision in the vertical and horizontal directions, and of taking account of the lost shots on the formulae employed.

— C. G. Stewart of St. Thomas's hospital, London, and Mr. G. Lathom Browne of the Midland circuit, have published the reports of various trials for murder by poisoning, from the trial of Tawell to that of Dr. Lamson. The book also gives directions for analysis, and points out difficulties that have occurred, or are likely to occur, in proving the presence of poison to a jury. The *Chemical news* considers the book "indispensable to all chemists who practise in toxicology, of great value to the medical profession generally, and doubtless no less so to solicitors and counsel who may be concerned in poisoning cases."

— The *Industrie-blätter* of Aug. 4 reports an ingenious fraud in jewelry. Thin plates of some precious stone, as for instance of emerald, have melted glass of the same color as the stone poured on one side. The real stone is set outside, so that, when tried, the jewel presents every appearance of being genuine and of the right hardness. These stones are called in the trade *pierres fines doublées*. The only test is to hold the stone edgewise, when, of course, the two sides will show different refraction. Any connoisseur will thus be able to detect the fraud; but, if set, this could hardly be done.

— The *Moniteur des fils et tissus* calls attention to a description of vegetable wool called kapoc. It comes from Java, and a specimen is on view at the Amsterdam exhibition. It arrives at Amsterdam in its leathery covering, being itself enveloped in the seeds. It is then freed from both, and is carded so as to make a very light mattress wool, worth about $8\frac{3}{4}d$ per pound. One of the houses engaged in this operation had made trials in spinning and dyeing this material; but the filaments are said to be like strings, and their industrial application consequently a matter of uncertainty.

— The *Industrie zeitung* gives a description of the source of the much advertised Hunyadi Janos water. Fourteen springs rise in a marsh near the town of Ofen in Hungary, which is the property of Herr A. Saxlehnes of Budapesth. Four of the strongest springs flow into a cement-lined cistern, whence the water is pumped into a second reservoir and cleared, then passed through other purifying-vessels, until it is bottled by an ingenious arrangement, ten bottles being filled at once. The yearly sale amounts to about three million bottles.

— Caillaud communicates to the Geographical society of Paris some statements in regard to a plant of the strychnine family, native to Tonquin, to which remarkable virtues are ascribed. It is called by the Annamites, who make use of it, 'hoangnan.' It grows in the mountains which separate the valley of Mekong from southern Tonquin, and is a vine whose bark, in which the active principle exists, is a violent poison. Its use was communicated by a native convert to the missionaries. M. Lesserteur, formerly a missionary in Tonquin, and now director of the seminary of foreign missions, has published a pamphlet, in which he recounts numerous cases in which a cure was effected. Dr. F. Barthélemy of Nantes has also made a special study of the drug, which appears to act as an alterative and antispasmodic. It is also under investigation by the medical school of Alfort. Cures of active hydrophobia are claimed for it, and several cases mentioned in detail. It is also said to be an antidote to the venom of serpents, and to relieve cutaneous diseases. While under the effect of the drug, it is said that alcoholic liquor or heating food must be absolutely avoided as liable to induce active poisoning. Altogether, while there may be a valuable medical agent in this new drug, the accounts given of it recall those which heralded the introduction of the notorious South-American 'cundurango.'

SCIENCE.

FRIDAY, DECEMBER 14, 1883.

THE SIGNAL-SERVICE AND STANDARD TIME.

It has been announced that the chief signal-officer has ordered his corps of observers to continue to be governed by the local time of their respective stations. It is difficult to understand this action on the part of Gen. Hazen. It would seem, that, next to the transportation companies, the weather bureau would be most benefited by the adoption of a system of time which would render all observations strictly and easily comparable with each other. The position taken by the service is all the more remarkable, when it is remembered that only two or three years ago its chief was himself a warm advocate of the new scheme, and declared his anxiety to further its introduction in every way in his power. It will be everywhere admitted that the adoption of standard time by all observers would greatly aid in securing its acceptance by the people generally; and it is to be hoped that it will be shortly done, unless some grave reason, which is certainly not apparent, exists for its rejection.

A SUGGESTION TO AUTHORS.

Authors who republish in a separate form papers originally printed in society transactions or journals should be careful to preserve the original pagination of the serial from which they are extracted, or to indicate the same in some clear way for purposes of ready and correct reference. It would really be worth calling a convention of our scientific societies for the purpose, if a reform could be effected in this matter. Time is too precious to be wasted in search, often fruitless, for an original source, when it could have been indicated, without additional cost, upon the separated copies. It would also be far better if the original page itself could be left intact without overrunning: otherwise errors of reference will be entailed on posterity, which will prove justly exasperating to the student obliged to consult the vast literature of that coming day. The reform cannot come too soon nor be too thorough.

EXPERIMENTS IN BINARY ARITHMETIC.

Those who can perform in that most necessary of all mathematical operations, simple addition, any great number of successive examples, or any single extensive example, without consciousness of a severe mental strain followed by corresponding mental fatigue, are exceptions to a general rule. These troubles are due to the quantity and complexity of the matter with which the mind has to be occupied at the same time that the figures are recognized. The sums of pairs of numbers from zero up to nine form fifty-five distinct propositions that must be borne in memory, and the 'carrying' is a further complication. The strain and consequent weariness are not only felt, but seen, in the mistakes in addition that they cause. They are, in great part, the tax exacted of us by our decimal system of arithmetic. Were only quantities of the same value, in any one column, to be added, our memory would be burdened with nothing more than the succession of numbers in simple counting, or that of multiples of two, three, or four, if the counting is by groups.

It is easy to prove that the most economical way of reducing addition to counting similar quantities is by the binary arithmetic of Leibnitz, which appears in an altered dress, with most of the zero-signs suppressed, in the example below. Opposite each number in the usual figures is here set the same according to a scheme in which the signs of powers of two repeat themselves in periods of four: a very small circle, like a degree-mark, being used to express any fourth power in the series; a long loop, like a narrow 0, any square not a fourth power; a curve upward and to the right, like a phonographic *l*, any double fourth power; and a curve to the right and downward, like a phonographic *r*, any half of a fourth power; with a vertical bar to denote the absence of three successive powers not fourth powers. Thus the equivalent for one million, shown in the example slightly below the middle, is 2^{16} (represented by a degree-mark in the fifth row of these marks, counting from the right) plus $2^{17}+2^{9}$ (two *l*-curves in the fifth and third places of *l*-curves) plus $2^{18}+2^{14}+2^{6}$ (three loops) plus 2^{19} (the *r*-curve at the extreme left); while the absence of 2^3, 2^2, and 2^1, is shown by the vertical stroke at the right. This equivalent expression may be verified, if desired, either

by adding the designated powers of two, from 524,288 down to 64, or by successive multiplications by two, adding one when necessary. The form of characters here exhibited was thought to be the best of nearly three hundred that were devised and considered, and in about sixty cases tested for economic value by actual additions.

In order to add them, the object for which these forty numbers are here presented in two notations, it is not necessary to know just *why* the figures on the right are equal to those on the left, or to know any thing more than the order in which the different forms are to be taken, and the fact that any one has twice the value of one in the column next succeeding it on the right. The addition may be made from the printed page, first covering over the answer with a paper held fast by a weight, to have a place for the figures of the new answer as successively obtained. The fingers will be found a great assistance, especially if one of each hand be used, to point off similar marks in twos, or threes, or fours, — as many together as can be certainly comprehended in a glance of the eye. Counting by fours, if it can be done safely, is preferable, because most rapid. The eye can catch the marks for even powers more easily in going up, and those for odd powers (the *l* and *r* curves) in going down, the columns. Beginning at the lower right-hand corner, we count the right-hand column of small circles, or degree-marks, upwards: they are twenty-three in number. Half of twenty-three is eleven, and one over: one of these marks has therefore to be entered as part of the answer, and eleven carried to the next column, the first one of *l*-curves. But since the curves are most advantageously added downward, it is best, when the first column is finished, simply to remember the remainder from it, and not to set down any thing until the bottom is reached in the addition of the second column, when the remainders, if any, from both columns, can be set down together. In this case, starting with the eleven carried, and counting the number of the *l*-curves, we find ourselves at the bottom with twenty-four, — twelve to carry, and nothing to set down except the degree-mark from the first column. With the twelve we go up the adjoining loop-column, and the sum must be even, as this place is vacant in the answer; the *r*-curve column next, downward, and then another row of degree-marks. The succession must be obvious by this time. When the last column, the one in loops to the extreme left, is added, the sum has to be reduced to unity by successive halvings. Here we seem to have eleven: hence we enter one loop, and carry five to the next place, which, it must be remembered, is of *r*-curves. Halving five, we express the remainder by entering one of these curves, and carry the quotient, two, to the degree-mark place. Halving again gives one in the next place, that of *l*-curves; and the work is complete.

It is recommended that this work be gone over several times for practice, until the appearance and order of the characters, and the details of the method, become familiar; that, when the work can be done mechanically and without hesitation, the time occupied in a complete addition of the example, and the mistakes made in it, be carefully noted; that this be done several times, with an interval of some days between the trials, and the result of each trial kept separate; that the time and mistakes by the ordinary figures in the same example, in several trials, be observed for comparison. Please pay particular attention to the difference in the kind of work required by the two methods in its bearing on two questions, — which of them would be easier to work by for hours together, supposing both equally well learned? and in which of them could a reasonable degree of skill be more readily acquired by a beginner? The answer to these questions, if the comparison be a fair one, is as little to be doubted as is their high importance.

Eight volunteer observers to whom this example has already been submitted showed wide difference in arithmetical skill. One of them took but a few seconds over two minutes, in the best of six trials, to add by the usual figures, and set down the sum, but one figure in all the six additions being wrong; another added once in ten minutes fifty-seven seconds, and once in eleven minutes seven seconds, with half the figures wrong each time. The last-mentioned observer had had very little training in arithmetical work, but perhaps that gave a fairer comparison. In the binary figures she made three additions in between seven and eight minutes, with but one place wrong in the three. With four of the observers the binary notation required nearly double the time. These observers were all well practised in computation. Their best record, five minutes eighteen seconds, was made by one whose best record was two minutes forty seconds in ordinary figures. The author's own best results were two minutes thirty-eight seconds binary, and three minutes twenty-three seconds usual. He thus proved himself inferior to the last observer, as an adder, by a system in which both were equally well trained; but a greater familiarity (extending over a few weeks instead of a few hours) with methods in binary addition enabled him to work twice as fast with them. Of the author's nine additions by the usual figures, four were wrong in one figure each; of his thirty-two additions by different forms of binary notation, five were wrong, one of them in two places. One observer found that he required one minute thirty-three seconds to add a single column (average of five tried) by the usual figures, and fifteen seconds to count the characters in one (average of six tried) by the binary. Though these additions were rather slow, the results are interesting. They show, making allowance for the greater number of columns (three and a third times as many) required by the binary plan, a saving of nearly half; but they also illustrate the necessity of practice. This observer succeeded with the binary arithmetic by avoiding the sources of delay that particularly embarrass the beginner, by contenting himself with counting only, and not stopping to divide by two, to set down an unfamiliar character, or to recognize the mark by which he must distinguish his next column. One well-known member of the Washington philosophical society and of the American association for the advancement of science, who declined the actual trial as too severe a task, estimated his probable time with ordinary figures at twenty minutes, with strong chances of a wrong result, after all.

These statistics prove the existence of a class of persons who can do faster and more reliable work by the binary reckoning. But too much should not be made of them. Let them serve as specimens of facts of which a great many more are to be desired, bearing on a question of grave importance. Is it not worth our while to know, if we can, by impartial tests, whether the tax imposed on our working brains by the system of arithmetic in daily use is the necessary price of a blessing enjoyed, or an oppression? If the strain produced by greater complexity and intensity of mental labor is compensated by a correspondingly greater rapidity in dealing with figures, the former may be the case. If, on the contrary, a little practice suffices to turn the balance of rapidity, for all but a small body of highly drilled experts, in favor of an easier system, the latter must be. This is the question that the readers of Science are invited to help in deciding. The difficulties attending a complete revolution in the prevalent system of reckoning are confessedly stupendous; but they do not render undesirable the knowledge that experiment alone can give, whether or not the cost of that system is unreasonably high; nor should they prevent those who accord them the fullest recognition from assisting to furnish the necessary facts.

Those who are willing to undertake the addition on the plan proposed or on any better plan, or who will submit it to such acquaintances, skilled or unskilled, as may be persuaded to take the trouble to learn the mechanism of binary adding, will confer a great favor by informing the writer of the time occupied, and number of mistakes made, in each addition. All observations and suggestions relating to the subject will be most gratefully received.

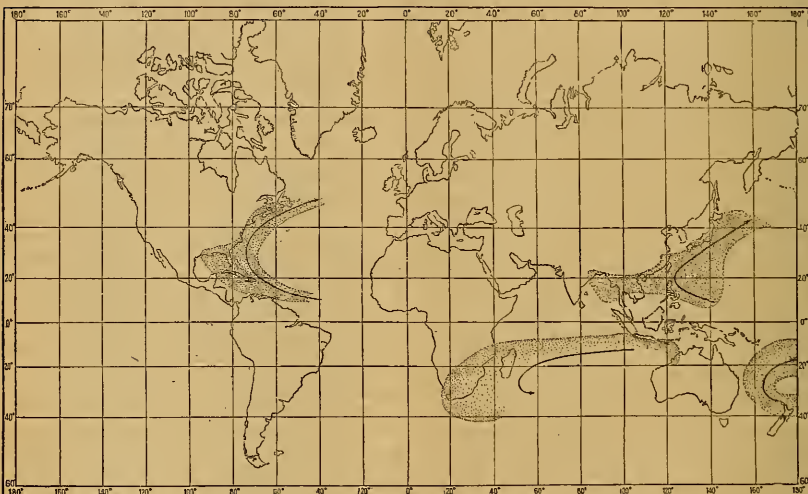
WHIRLWINDS, CYCLONES, AND TORNADOES.[1] — VI.

Having seen how storms arise, and examined the general motions of their spiral winds, we must next consider their progression from place to place. It is now a familiar fact, that storms do not remain stationary, but advance forth. The apparently lawless winds of a storm could be reduced to system if they were supposed to blow around a centre which itself has a progressive motion. In nearing the centre, the barometer falls, and the winds increase their strength. The manner and cause of the progressive motion must now be examined.

The four regions where tropical storms move into temperate latitudes — the seas south and east of India and China, and south-east of the United States, in the northern hemisphere; and those east of Madagascar and (probably) of Australia, in the southern hemisphere — are



THE REGIONS OF TROPICAL CYCLONES. (TAKEN FROM STIELER'S ATLAS.)

at a velocity of from five to fifty miles an hour along a line known as their track. Although perceived by Franklin about 1750, this, as well as their whirling motion, first found full and satisfactory proof at the hands of Dove of Berlin (1828), and Redfield of New York (1831). The latter gave the more numerous examples, and was the first to explain the motions of storm-winds at sea. The method of his discovery was simple enough. Information concerning the storm was gathered from all attainable records, and the condition of the winds and weather was plotted for certain hours. At once the result stood clearly all crossed by storm-tracks, running first westward near the equator, then turning toward the pole, and passing around the apex of a parabolic curve near latitude 30°, into an obliquely eastward course. The more numerous storms of temperate latitudes have less regular tracks, but are nearly always characterized by a strong eastward element in their motion; their chief variations to the right or left being dependent on thermal changes with the seasons, and on the configuration of land and water which they traverse. There have been four causes suggested to determine the progression of the storm-centre: namely, the general winds of the region, and especially the stronger and less

[1] Continued from No. 44.

variable upper currents; the supply of warm, moist air, and consequent occurrence of heavy rain; the relative strength of the inblowing winds; and a certain effect of the earth's rotation. All these causes of progression are variable in amount, and in relation to one another; and it is therefore natural to find their resultant inconstant.

The first-named cause is the most evident, the most powerful, and was the first recognized. The general or planetary circulation of the winds will require that any disturbance in the moving atmosphere shall partake of its motion, and be carried along in the direction of the current within which it is generated. Thus a storm arising in the equatorial calms is carried westward as soon as it attains sufficient height to reach the upper current, which must there move from east to west. No equatorial cyclone has ever been observed moving eastward. On approaching the western shores of the ocean, a part, at least, of the general winds, turns toward the poles, as may be seen on any wind-chart, and in latitude 25° or 30° passes from the region of the tropical winds into the system of the prevailing westerly winds of temperate latitudes. The storms have a strikingly similar course, and, on the western side of the oceans in these latitudes, never move towards the equator. Their further progress, and that of the many storms of the temperate zones, is easterly, with a leaning towards the pole while crossing the oceans, and a variable north-easterly or south-easterly advance on the continents. No storm has been found crossing the North Atlantic from east to west, or moving from our Atlantic coast to the plains beyond the Mississippi. Additional evidence of this style of bodily transference of storms will be given in considering the relative strength and the direction of their spiral winds on different sides of the centre.

The importance of the condensation of vapor and consequent rainfall in decreasing the cooling of the central up-draught, and so increasing its strength, has already been shown. In the explanation of this process, it was tacitly assumed that all the surface-indraught was equally warm and moist, so that condensation and rain would occur symmetrically about the centre of low pressure. It will now be seen, that, when a storm-centre is supplied from areas of unequal warmth and moisture, symmetrical cloud-forming and rain-falling on all sides will be impossible; there will be more rain, and hence less cooling, on one side than on the other; and just as the liberation of 'latent heat' aided in the formation of the first central barometric depression, so it will now tend to displace this centre to the side where the greatest amount of rain falls. If no other cause but this acted, the storm would advance regularly toward the region of heaviest precipitation: but this advance will not be like the bodily transference of the rotating winds effected by the general atmospheric currents; it will be rather the abandoning of one centre of attraction as a stronger one is created beside it, — the continual filling-up of one depression, and production of another. This may be illustrated by a modification of fig. 8, given here in fig. 12, in which the dotted lines show the gradients and winds established at a certain period of the storm. Let it be supposed that warmer, moister winds enter on the right, and cooler, drier winds, on the left. Where cooler, the air will be contracted, and the isobaric surfaces depressed: where warmer, from its own warmth, as well as from that of the condensing vapor, the air will be expanded, and the isobars elevated, as shown in full lines in the figure. The gradients will then be unsymmetrical about the original centre; and the previous motion of the winds will be accelerated at some points, retarded or reversed at others. As a result, the pressures at the surface will be changed from their previous arrangement to a new one, shown in fig. 13, in which the region of least pressure has moved to the side of the warmer winds and heavier rains. Any further inflow of the surrounding air must now be to the new low-pressure centre: in other words, the storm has advanced to the right. The process will be continuous as long as the winds on opposite sides of the storm are unlike.[1] Having thus

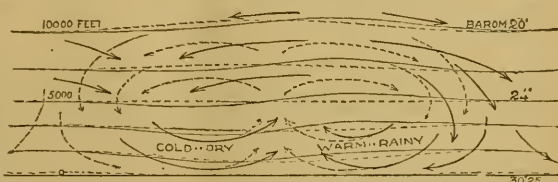


Fig. 12.

[1] Fig. 12 may serve further to explain the retarded arrival of the centre of low pressure at altitudes of a mile or more above

seen the general action of this cause of motion, it must now be applied more directly. There are two causes of rain in a cyclonic storm, — one from the expansion and cooling of the moist air as it enters the district of low pressure, and rises in the central up-draught; the other from the advance of the wind from a warmer into a cooler region. The first of these will generally be nearly symmetrical about the storm-centre, and hence not productive of any progressive motion: the second will as generally be unsymmetrical. In fig. 14, for the northern hemisphere, the parallel lines represent normal east and west isotherms, showing the usual decrease of temperature to the north. Of the several winds blowing inward to the storm-centre, *A* and *B*, which advance almost along the same isotherm, will not be seriously changed in temperature by their change of place; *C*, which comes from a cooler to a

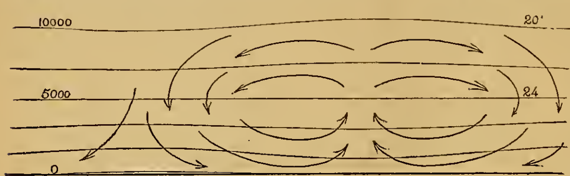

FIG. 13.

warmer district, will consequently increase its capacity for moisture, and be a clear, cold, drying wind; but *D* will be chilled, and must produce heavy clouds and strong rain somewhere about the shaded part of the figure; and the storm-centre will then be transferred toward the middle of this rainy district.

Standing on the warm side of the storm, the centre will appear to move nearly along the isotherms to the right. Actual isotherms seldom follow lines of latitude, and always vary their position with the seasons, especially along continental borders. Thus, over western Europe and the eastern margin of the Atlantic, the summer isotherms run to the north-east: so do the storms. In winter the isotherms run south-eastward, and the storms turn in the same direction. Figs. 15 and 16, illustrating this change, are based on diagrams in the 'Laws of the winds,' by Ley, who first, some fifteen years ago, called attention to the control of rain over storm-tracks. It should be noted that the change in the

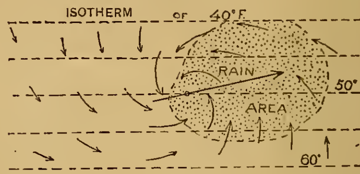

FIG. 14.

winter and summer prevalent winds would have a similar effect on the courses of European storms. In the United States, Professor Loomis has shown that the velocity, as well as the direction of advance, is closely dependent on the position and amount of the rain. In tropical storms the action of this cause of progression is not so clearly marked; for all the winds are moist, and almost equally warm. It is reported that the rainy area often extends farthest ahead of the storm; but it is not at once apparent why it should, for the front of the storm is occupied by winds from the north, which come from a slightly cooler latitude. It may be suggested, that, as their source in a region of high pressure (the 'horse latitudes') causes them to move faster, it also, probably, allows them a greater expansion and cooling, on entering the storm-area, than is permitted in the winds that come more slowly from the equatorial region of low pressure; but tropical storms probably de-

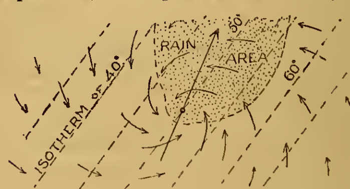

FIG. 15.

pend chiefly on the prevalent winds for their direction and rate of advance. In Austria none of the winds are very moist, and the rainy area has no definite relation to the advance of the

the surface. Observations on Mount Washington have shown the centre of low pressure there to be about two hundred miles behind that at sea-level (Loomis), and a similar retardation has been inferred in England from observations of cirrus-clouds (Ley). Fig. 12 shows this to be directly connected with rainfall; for, in this unsymmetrical storm, the former horizontal neutral plane is distorted, so that the centre of low pressure in the upper air is clearly behind, instead of vertically above, the centre on the surface of the earth.

storm: hence here, also, other causes than rain determine the general easterly progression. Whatever effect rain would have is overcome by stronger causes. The separation of a cyclone into two independent storms is probably aided by the irregular distribution of rain.

Inequality in the strength of the inblowing winds is a result of irregular distribution of barometric pressure in the regions around the storm; and the stronger indraught will come from the higher pressure, because the gradients will be steepest on that side. Thus, in the case of the West India hurricanes, the higher pressure is to the north or north-east in the 'horse latitudes' above named, and the lower pressure to the south, near the equator; and the northerly winds will therefore be stronger than the southerly. The stronger the wind, the greater its centrifugal force;

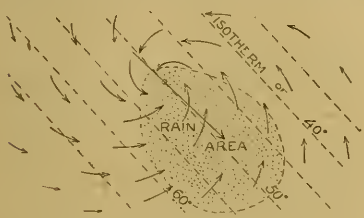

Fig. 16.

and, if this is not equal on all sides, the centre of lowest pressure will be drawn toward the point where it is strongest. This will be where it has to bend sharply around from its original direction, and may average about 135° from the source of the wind: hence, if the stronger wind come from the north-east, the storm-centre will move west: if from the east, north-west, as in fig. 17; and so on. Consequently, this cause will aid the first named in requiring the storm to describe a curved track in passing from the torrid to the temperate zone. It will also aid the coalescing of two neighboring storms, which has not unfrequently been observed; but, as a rule, it plays a subordinate part in determining the direction of advance. The slower advance of such of our storms as have extra strong winds on their western side (Loomis) is probably also due to this cause.

The fourth cause of a storm's advance is a peculiar effect of the deflective force arising from the earth's rotation. It has already been shown that this force increases toward the poles: it will therefore be greatest on the polar side of a cyclone; and the greater the

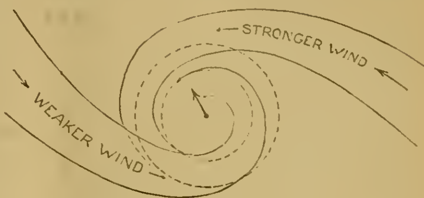

Fig. 17.

storm's diameter, the more marked the difference between the two sides. Its effect will be to make the centrifugal force on the two sides unequal, as in the previous cause; but the resultant motion will here be always from the equator. In the absence of other causes of motion, cyclones would therefore move along meridians: as it is, they nearly always have a more or less pronounced polar tendency, and their failure to move directly from the equator is due to the other causes of progression already mentioned.

(To be continued.)

A COMBINATION WALNUT.

A peculiar nut has recently been sent to me from Mr. S. L. Bingaman, Pughtown, Chester county, Penn. It was found on his lawn under a black-walnut tree (Juglans nigra). Mr. Bingaman says, "There is a pecan about sixty feet from it [the walnut-tree], and a shellbark some three hundred yards off." The nut is divided into two parts, as viewed upon the outside. There is a small portion at the base end, which has a covering similar to that of a black walnut. The upper and larger part of the nut has a covering closely resembling that of a shellbark (Carya alba). This exocarp is four-valved, and a partial separation has taken place at the upper end.

In its texture and adherence to the shell this covering is much like that of the ordinary black walnut. Upon cutting the nut in two, the shell (endocarp) is found thick, horny, and in all respects like that of J. nigra. The lower portion of the shell projects into the lower section of the nut, and resembles the point of a butternut. The engraving is from a carefully executed drawing, representing the nut of natural size.

The matter as above presented is left in the hands of those more familiar with subjects in teratology. There is no doubt that in the cross-fertilization of plants we may have a deviation from the parent form, even in the development of the seed thus fertilized, or in its surrounding parts. Some strawberry-growers are very careful what 'perfect' varieties are grown among their pistillate sorts to fertilize them. The fleshy receptacle, which is the edible portion of the strawberry, is more remote from the ovules which are fertilized on its surface than the covering of a shellbark or walnut is from the embryo within.

Hybridization between closely related genera is well established in several cases. Sachs mentions that it has been observed between species of Lychnis and Silene, Rhododendron and Azalea, Rhododendron and Rhodora, Azalea and Rhodora, Rhododendron and Kalmia, Aegilops and Triticum, and between Echinocactus, Cereus, and Phylocactus. The two genera Juglans and Carya compose a small order of closely related species. A study of the generic characters, as set down in the classification of these species, does not reveal any more striking difference than that shown in the exocarp. The male and female flowers are separated on the same tree (monoecious), and pollen must pass from flower to flower. This fertilizing-dust is produced in great abundance; and the distance between the black walnut and the pecan, or even the shellbark, is easily traversed by the pollen. There is probably no difficulty in the way of hybridizing from a difference of time in the flowering of the species. BYRON D. HALSTED.

New York, Oct. 26, 1883.

MANAYUNKIA SPECIOSA.

In a paper, illustrated with a plate, recently presented to the Academy of natural sciences of Philadelphia, Professor Joseph Leidy describes Manayunkia as a cephalobranchiate annelid living in fresh water, the only one of the order yet discovered not living in the ocean. It was found with the equally remarkable polyzoan Urnatella, with its tubes of mud attached to the same stones, in the Schuylkill River, at Philadelphia. It was first noticed, and a brief description given of it, in the Proceedings of the academy in 1858.

Manayunkia is nearly related to the marine genus Fabricia, with a species of which, described by Professor Verrill, the writer compared it, through specimens collected at Newport, R.I., and Gloucester, Mass. Manayunkia has not been observed elsewhere until recently, when it was found by Mr. Edward Potts, attached to a fragment of pine bark from Egg-Harbor River, New Jersey.

The tubes of Manayunkia are simple or compound, and in one instance five tubes branched and were pendent from a common stock in a candelabra-like manner. The little worm is very active and sensitive, and on the slightest disturbance withdraws into its tube. When quiet it protrudes its head, and spreads its cephalic tentacles or branchiae. The mature worm is three or four millimetres long, and is divided into twelve segments, including the head. The color is olive-greenish, due to the bright green blood circulating in the vessels of the animal. The head is furnished with a pair of conspicuous eyes, and supports a lateral pair of lophophores, each provided with sixteen cylindrical tentacles, invested with actively moving cilia, and closely resembling those of the polyzoa. The segments succeeding the head are provided with lateral fascicles of locomotive setae, and in addition, except the first one, are further provided with fascicles of pedal hooks.

The seventh segment is much larger than any of the others, and further differs from them in being greatly expanded in front; so that it gave rise to the idea that the worm undergoes division, though the process was at no time observed. The intestine is quite simple. The chief portions of the vascular system consist in a vast sinus enclosing the intestinal canal, giving off lateral pairs of branches to the segments, and a large vessel which extends from each side of the head into one of the tentacles, which is larger than the others. The blood is bright green, and is observed to be incessantly pumped into and expelled from the larger pair of tentacles. Ovaries occupy the segments from the fourth to the sixth inclusive. Organs supposed to be the testes extend from within the head into the third segment.

Manayunkia lays its eggs and rears its young within its own tube. The young, measuring about three-fourths of a millimetre, had the body divided into nine segments, and each lophophore provided with four tentacles.

In the species of Fabricia of our coast the number of segments of the body is the same as in Manayunkia; but the lophophores supporting the tentacles, instead of being simple, are trilobed or trifurcate. Fabricia has eyes in the tail, or last segment, as well as in the head, which is not the case with Manayunkia.

DRAINAGE SYSTEM AND LOESS DISTRIBUTION OF EASTERN IOWA.

These are described by Mr. W. J. McGee in a recent communication to the Philosophical society of Washington. The Mississippi River, where it forms the eastern limit of Iowa, flows somewhat to the east of south, and then as much to the west of south, giving the boundary an eastward angle in its middle part. The general strike of the rocks in eastern Iowa is south-east; and the dip, which is gentle, is south-west. The broadest outcrops are those of the Niagara and Hamilton formations. The Niagara, having resisted the prequaternary planation, holds an escarpment, the crest of which runs from the extreme eastern point of the state to a point on the Minnesota line fifty miles west of the Mississippi. From this line there is a somewhat rapid descent to the Mississippi, and a gentle slope south-westward to the broad, shallow depression marking the position of the Hamilton. From this valley the ascent is gentle to the water-parting between the Mississippi and Missouri. The general slope of the region west of the Niagara escarpment, considered as a whole, is with the dip to the south-west.

Beside the south-east trending depression marking the Hamilton outcrop, there is a gently sloped and indefinitely outlined but continuous and actual prequaternary valley, extending southward across the eastward projection of the state, and traversing diagonally the upper Silurian, Devonian, and carboniferous rocks.

The north-eastern angle of the state, from the crest of the Niagara escarpment to the Mississippi, belongs to the driftless region. The remainder of the state is covered with drift, and is affected by the undulations characteristic of drift topography.

The general directions of the rivers are from north-west to south-east; but their upper courses swerve a little toward the meridian, and their lower are deflected slightly toward the east, so as to give them a gentle curvature with concavity to the north-east. There is, moreover, a convergence northward, as though they radiated from some point in Minnesota. The variations from this normal system are so few that the drainage is almost unique in its regularity. It is likewise independent of the general topography; for not only do the principal streams flow at right angles to the prevailing slope, and cut through the elevated escarpment when it lies in their way, but, with a single exception, they preserve their courses across the ancient north and south valley.

In their relations to minor topographic features, they conform to two antagonistic laws, — first, they follow in general the ill-defined shallow valleys which characterize the drift-plains; and, second, they flow for one-third of their total courses in narrow gorges, following the axes of a system of elongated ridges which constitute the leading features in the local topography. Moreover, they have in many instances gone out of their direct courses, and deserted valleys seemingly prepared for them, to attain the anomalous positions assumed under the second law of association; and in every such case the gorges have demonstrably been carved by the streams themselves. The avoided valleys are evidently pre-existent: they have not been appreciably eroded since the quaternary, and there has been no recent localized orographic movement.

So the drainage is essentially independent of the general topography, though affected by local topography; and its relations to local topography are largely anomalous.

The loess of the region is continuous stratigraphically, but follows different laws of distribution in different districts. It constitutes the surface throughout the driftless region, and at the margin it overlaps the drift. In the northern part of the drift-covered area it forms narrow bands with a general north-west trend, each of which caps a ridge. Farther south it covers the entire plain, eminences and depressions alike. In the driftless area it rests on and merges into a thin stratum of water-worn erratic material. In the belts traversing the contiguous drift-plain it passes downward into sand, which may, or may not, merge into drift. Elsewhere it reposes on the drift, into which it graduates insensibly. The ridges in which the rivers have carved their anomalous cañons are always loess-topped; and, wherever streams avoid low-lying valleys for high-lying plateaus, the plateaus are of loess exteriorly.

So in its distribution the loess of eastern Iowa is intimately connected with the driftless region, with the drainage, and with the topographic configuration.

In the communication referred to, Mr. McGee offers no explanation, but merely sets forth the facts. His working hypothesis has, however, been published in an earlier paper (*Amer. journ. sc.*, Sept., 1882), and may properly be restated in this connection.

It is now many years since Powell first proposed to class all inconsequent drainage as either antecedent or superimposed; and no later writer has added to the number of categories. In *inconsequent* drainage the courses of the streams are independent of the dip and other structure-elements of the rocks across which they run. If the drainage is older than the rock-structure, — if, for example, the dip has been given to the rock after the establishment of the stream-courses, — the drainage is said to be *antecedent*. If the drainage was established by the configuration of an overlying and unconformable formation, which has disappeared by denudation, the drainage is said to be *superimposed*. In eastern Iowa, the superficial formation being northern drift, which lies with little modification as originally deposited, the hypothesis of antecedent drainage appears quite out of the question, while that of superimposed drainage in the ordinary sense is equally inapplicable. Mr. McGee's working hypothesis is, that the drainage was superimposed in an extraordinary manner; namely, by the ice-sheet. This, he finds reason to believe, was so thin in that region as to have its superficial configuration materially modified by the small inequalities of its bed. Where the ice was retarded by ridges underneath, more time was allowed for superficial waste by melting: so that hollows were produced, and the rivers of the ice-surface came to be established over the ridges of the glacier bed. With the disappearance of the ice, they were stranded upon the hill-tops.

G. K. Gilbert.

LETTERS TO THE EDITOR.

The reefs, keys, and peninsula of Florida.

The recent appearance of the admirable memoir of A. Agassiz on the reefs of Florida, which I have read with intense pleasure, furnishes me a proper occasion for calling attention to my paper, published in 1857, 'On the agency of the Gulf Stream in the formation of the peninsula and keys of Florida,' [1] and especially to the fact that the most important results reached in that paper have been substantially confirmed by subsequent observations. These results are as follows: —

1. The reefs of Florida are unique, and therefore were formed under peculiar conditions, and therefore, also, require a peculiar explanation.
2. The continuous growth of land by coral agency, in the case of Florida, is also wholly unique, and obviously connected with the peculiar conditions under which the reefs were formed.
3. The main peculiar condition in this case was the formation and southward extension of a submarine bank upon which the corals grew in successive reefs.
4. This bank was due to the agency of the Gulf Stream.

In addition, I supposed that the bank was built up by mechanical sediments brought by the Gulf Stream mainly from the Gulf rivers. In this I may have been mistaken, although no other explanation was conceivable at that time. The recent examinations of the course of the Gulf Stream, which, it seems, does not sweep about the Gulf, as was formerly supposed, and examination of the nature of the material forming the Florida bank, render this view no longer probable.

A. Agassiz in his memoir accepts the progressively formed bank, and also that it is due to the agency of the Gulf Stream, but thinks that it is formed, not by *mechanical* sediments, but by *organic sediments*, partly *brought* by the Gulf Stream from other coral banks (e.g., the Yucatan bank), *but mainly* formed *in situ* by the growth of deep-sea animals; the Gulf Stream bringing, not the materials, but only the conditions of heat and abundant food necessary for rapid growth.

This is certainly a very important modification of my original view; but the fundamental ideas expressed in the above four propositions still remain.

I ought to add, that, following L. Agassiz, I had exaggerated the probable amount of land added to Florida by the combined agency of Gulf Stream and corals. The recent investigations of Smith [2] on the geology of Florida show that the process cannot have commenced farther north than the north shores of the Everglades. Joseph LeConte.

Berkeley, Cal., Nov. 24.

Musical sand.

In the early part of the summer of 1883, the writer, in company with several others, was sent from Wood's Holl to Monomoy Point, Mass., by Professor Baird, to look after a whale reported to have been stranded there. Wandering around the island, we found an extensive tract of sand, which, when rubbed under the feet, produced that peculiar singing sound so often heard by the writer upon the beach at Manchester, Mass. The singing portion seemed to be confined to a narrow strip several hundred yards long, between the very dry sand above high-water mark and the sand moistened by the tides. Knowing that the phenomenon was a rare one, specimens of the sand were obtained; but I am not able to tell where they are at present. Monomoy Point is a long, narrow, sandy piece of land projecting out from the south-eastern end of the base of Cape Cod towards Nantucket Island. It is composed entirely of sand; and the blowing of the particles, as also the force with which they are blown, were well illustrated by the fact that all the windows of the fishermen's huts were ground so perfectly that nothing was visible through them. We paid one fisherman to break a square of glass for us. It had been there sixteen years. Even in cases where new glass had been put in within two years, nothing was visible through the panes. At a distance of thirty feet from the house on all sides, sand was piled up nearly as high as the tops of the cabins. The lighthouse-keeper upon the island would undoubtedly obtain specimens of the sand; the strip being found near the place where the whale lay, — in fact, just a few feet inland from it. The writer will be glad to give any further information desired upon the subject.

Rings of Saturn.

Apropos of the abstract on the 'Rings of Saturn,' published in Science for Nov. 16 (p. 660), it appears that Professor Alexander Winchell of the University of Michigan, in his work entitled 'World-life,' assumed and explained the gradual descent of the matter of the rings toward the planet, and also denied that the period of the inner satellite of Mars furnishes any objection to the nebular theory. The ultimate result of solar tides on the rotations of the planets is also referred to in the same work, though this has, I believe, long been an accepted conclusion by leading physical astronomers. W. B. T.

ARCHEOLOGY IN PORTUGAL.

Études préhistoriques en Portugal. Notice sur quelques stations et monuments préhistoriques. Mémoire présenté à l'académie royale des sciences de Lisbonne. Par Carlos Ribeiro, chef de la section des travaux géologiques, etc. Lisbonne, *Imprimerie de l'académie des sciences*, 1880. 88 p., 7 pl., and numerous engravings in the text. 4°. [Also in Portuguese.]

This publication, which has only recently been received by us, is the second instalment of a work the first of which appeared in 1878 (72 p., 21 pl.). We will accordingly give a brief account of the contents of both parts. Contrary to our expectations, we find in them no discussion of the important question of the alleged discovery of traces of the tertiary man in the valley of the Tagus; neither do they deal with quaternary times. They contain simply detailed accounts, with ample illustrations, of various discoveries, all belonging to the age of polished stone, made by the author in several localities in the immediate neighborhood of Lisbon, which are all laid down upon an accompanying map drawn to a large scale. The completed work will comprise six sections, three of which are contained in the two portions already published. Of these, the first describes the station of Licea, and the second, the megalithic monuments near Bellas; both of which places lie a short distance west of Lisbon. The latter also contains an account of the prehistoric remains at the Serra de Cintra, several miles farther west.

Licea is a little hamlet built upon the projection of an elevated plateau, of which two of the sides are naturally defended by deep ravines. In this respect it resembles other sites of human habitation in the age of polished stone, which were usually placed upon commanding positions, easily defensible, and having plenty of water. This naturally strong position was rendered more secure by having its sides sharply scarped in some parts; while in others, not so protected, there can still be seen remains of a wall built of huge unhewn stones. The whole area was thus converted into an intrenched camp of an oval shape, nearly half a mile long by half as broad. Within this space, excavations have brought to light various objects of the usual types belonging to the industry of the age of polished stone. There were numerous celts made of diorite or of basalt, some finely polished, well shaped, and with sharp cutting-edges, while others were of a ruder fabric; and also several hammer-stones. Knives, flakes, scrapers, arrow-heads, and lance-points abounded, made of different varieties of flint, many of which must have been brought from long distances. Rude clay vases, hand-made, and some of a large size, all baked in an open fire, together with a few bone implements, complete the catalogue of objects found. Associated with these relics were the remains of shell-fish, and the bones of several species of animals common in neolithic stations, such as the horse, ox, stag, goat, pig, wolf, and hare. There was also discovered a sepulchral grotto containing bones belonging to nine individuals of both sexes, half at least of which were those of very young children. We have good reason to believe that other similar caverns have been either destroyed, or filled up with the rubbish of the chalk-quarries that have been extensively worked in this locality. In the absence of a perfect cranium, nothing more could be determined than that the type was brachycephalic. From the general result of all the discoveries, the conclusion seems warranted that Licea was the habitation of a large population during the neolithic period. Signor Ribeiro, however, brings forward certain arguments to prove the existence of a second prehistoric civilization upon this same spot, belonging to the period of transition between the age of polished stone and that of bronze. But we must confess ourselves unable to perceive their pertinency; neither can we agree with him in thinking that any of the implements discovered here have 'a striking paleolithic appearance.'

In the vicinity of Bellas there still exist megalithic monuments, consisting of a half-dozen ruined dolmens, in which but little of importance was discovered, owing to their having been visited by previous explorers: nevertheless, two or three singular objects were found in them, which will be described later. Hard by, however, at Monte Abrahão, there is a covered alley in an excellent state of preservation, which has yielded important results. It is composed of a polygonal chamber some ten feet in diameter, and a gallery twenty-four feet long by six wide, extending in an easterly direction. The walls of the chamber are constructed of eight large slabs of hard gray limestone, rough, and entirely unhewn, planted more or less upright, and projecting some nine feet above the surface of the soil. It is evident, however, from the inclination at which the largest stone is placed, that it was not intended to be roofed over by a similar slab after the usual method of constructing such monuments. There had first been made with infinite toil, by the help of fire, an excavation in the solid limestone strata of the whole size of the chamber; and in this the large slabs were set. Of those with which the gallery was originally constructed, only three now remain in place; but the rows of smaller stones, by which they had been supported, were discovered when the surface-soil was removed, so that there can be no mistake as to the existence and extent of the gallery. It is admitted that dolmens and covered alleys were erected to serve as burial-places of the men of the neolithic age: consequently we are not surprised that Signor Ribeiro found this monument to contain human remains; but the number of them was quite unusual, amounting to as many as eighty individuals. This can be accounted for by the fact that certain circumstances seem to indicate that some of the remains had been interred elsewhere before they were removed to this resting-place. They were found in the gallery, as well as in the chamber; and it seems reasonable to suppose that there had been successive burials at intervals of time, and consequent disturbances of the soil, which would account for the situation in which many of the bones were found. Their condition was such as to allow but few inferences to be drawn as to their ethnic relations, no whole cranium having been found: sufficient, however, remained of one, to show it to be dolichocephalic, and one of the jaw-bones was prognathic. In this interment, however, was one peculiarity which we have never seen noticed before. Over the whole interior, but particularly at the eastern extremity of the gallery, there was spread a layer of rounded pebbles, covering the human remains. They ranged in size from an almond to a large apple, and were mostly of quartzite, though many were of limestone, and several of basalt. Evidently they had been brought from the beds of neighboring brooks lying some three hundred feet or more below the level on which the monument stood. That they were not intended merely to protect the bodies from wild beasts was plain, from the fact that the adjacent soil was filled with angular fragments of various rocks equally well adapted for that purpose. Here we have evidently a funereal custom analogous to the heaping-up of cairns over the dead by many primitive races.

Numerous objects of great beauty and interest were found accompanying the skeletons. Among them were only four celts; but there were no less than one hundred and twenty flint arrow-heads, very many of them of the choicest workmanship, and including all the well-known types which are figured in excellent woodcuts. There were found two very fine specimens of flint lance-heads, or more probably daggers, more than six inches in length, and of exquisite workmanship; and more than thirty knives, ranging in length from five inches down. There were also scrapers, numerous flakes, and fragments of worked flint of various sorts. Our author devotes an entire plate to a delineation of some twenty little instruments, some of which he thinks were "designed for delicate work, such as *the surgical operation of circumcision* (?), *and trepanning*." Another of larger size, disk-shaped, and terminating in front in a little point, and capable of standing upright on its base, his imagination has magnified into 'an idol, or some sort of symbol.' To our more prosaic vision the 'surgical instruments' are only ordinary little stone implements, which in this case happen to be made of transparent quartz; while 'the idol' is merely a piercer for making holes in skins, such as we have often found in our Indian shell-heaps.

There were half a dozen objects of unusual character, which Signor Ribeiro designates as 'war-clubs,' and two others, which he thinks were 'badges of authority.' They are quite similar in appearance, are of cylindrical shape, and made of limestone; and the largest is about a foot in length, and nearly two inches in diameter. A few bone implements were found, among them a button of a conical shape, and pierced at the base with two converging holes. The pottery consisted only of portions of some half a dozen small, rude vases. Two ornaments were found of considerable size, celt-shaped, and made of thin plates of gray argillaceous schist. One face was smoothed, and decorated with figures made by scratching lines upon it in the triangular pattern known by the name of the 'dog-tooth;' and it was pierced with a hole for suspension. Besides these, two smaller heart-shaped pendants were found, and more than a hundred beads of various shapes and sizes, made of different green minerals, out of which the author has reconstructed several tasteful necklaces. Taking every thing into consideration, this covered alley may be said to be one of the richest ever discovered; and we feel grateful to the author for his careful study and faithful delineation of it.

We have already stated that two or three peculiar objects were obtained from some of the ruined dolmens. They are made of thin plates of argillaceous schist, about a foot in length, and some two inches broad, and are shaped somewhat like the curved blade of a sword, having the end rounded, and pierced on the back side with a hole for suspension. Both surfaces are smooth, and are decorated with varying patterns of 'dog-tooth' ornamentation. Two similar objects have been previously discovered in Portugal; but we are confident they have never been met with elsewhere, and their use is entirely unknown. The third object is a sort of stone hoe, according to our author's opinion, shaped very much like a human foot, and having the lower portion of the leg for the handle, the top of which is sharp enough to be used as a scraper. Objects similar to this have been discovered in a cave a short distance to the south.

The Serra (or mountain) of Cintra lies due west of Bellas, and somewhat more distant than the latter place is from Lisbon. It is the most picturesque of all the mountains in the vicinity, and attains an elevation of over fourteen hundred feet. At the very summit is an artificial excavation in the porphyritic and granitic rock, divided into two portions. The inner chamber is circular, with a diameter of twelve feet, and height of nine; the other is a kind of open vestibule about eighteen feet square; and the two are connected by a short covered corridor, while the interior of the whole monument is lined with a wall of rough stones. In it were found a flint knife, or saw (an elliptical shaped implement, toothed around its whole exterior), and a few worked flakes. Fragments of clay vases of various shapes and sizes abounded, many of them having a 'herring-bone' pattern of ornament incised upon them. All of these objects evidently belong to the neolithic period; and the monument itself resembles a sort of combination of the dolmen and the sepulchral grotto.

But a novelty among neolithic interments seems to have been discovered at Folha das Barradas, a short distance to the north-east. This is excavated in the natural soil, a white limestone and green marl, and has almost the shape of a covered alley, twelve yards long, extending east and west. The circular chamber at the west was divided by pieces of thin flagstone into partitions intended to contain human remains, of which as many as twelve were found, but in so bad a condition as to be useless for study.

Accompanying the remains were a flint poniard, two very fine lance-points of unusual size, and seven large knives; also a long cylindrical stone 'war-club,' similar to those previously described, but more handsomely ornamented, and two of the 'badges of authority.' A flat pendant, like those already spoken of, and fragments of a few rude clay vases, completed the funeral furniture. But it should be noted, that both in this sepulchre, and the one last described, there was found a large number of the same kind of rolled pebbles as those which occur so conspicuously in the covered alley of Monte Abrahão.

In concluding this brief account of Signor Ribeiro's interesting researches, we can only express the hope that his recent death, which all lovers of knowledge must deplore, may not deprive prehistoric students of the publication of the remainder of the work.

THEORETICAL METEOROLOGY.

Theoretische meteorologie. Ein versuch die erscheinungen des luftkreises auf grundgesetze zurückzuführen Von Albert R. v. Miller-Hauenfels. Wien, *Spielhagen & Schurich*, 1883. 130 p. 8°.

The past twenty years have witnessed a great advance in the science of meteorology, viewed from a theoretical stand-point. Previous to this period, the laws deduced were derived empirically from the observations made; and this is largely true at the present time. The attempts to place the science upon a firmer basis by building upon well-established physical laws, and deducing conclusions by strict mathematical processes, have met with decided success. But this branch of meteorology is yet largely undeveloped: consequently there is no treatise that covers the ground satisfactorily, and there is a large gap between deductive meteorology and the inductive conclusions upon which meteorological text-books are based. The mathematical papers are scattered in the volumes of scientific journals, or published in separate form. Even if they were collected together, and their contents condensed into one treatise, the result would be unsatisfactory. It would be found that a large majority of familiar phenomena are yet unaccounted for, and that many of the conclusions reached by theoretical methods cannot be used for further investigations, on account of assumptions made for the sake of simplifying the work, but which are unwarranted by observed facts. The hope of meteorology as an exact science, however, lies in the success which will attend these theoretical investigations in the future; and therefore any treatise devoted to this branch of the science is welcomed, however fragmentary it may seem to the reader.

The latest publication upon theoretical meteorology is this octavo of a hundred and thirty pages, by Professor Miller-Hauenfels of Graz. It is confessedly incomplete, but seems to be worthy of the attention of the student. As its title implies, it is an attempt to refer atmospheric phenomena to fundamental laws. The author is not a practical meteorologist, but a mathematician, who treats the phenomena discussed as mechanical problems as far as possible, holding that the first thing necessary is to establish the fundamental laws of meteorology, and afterwards to build upon this secure foundation. In the first section the laws of Mariotte and Gay-Lussac are treated, the method giving essentially the same result as that deduced by Rühlmann in his well-known barometric formula. Passing then to the movements of the atmosphere, the author discusses first its general movement, and then the laws of the winds, the latter subject occupying a large part of the treatise. The laws of ascending currents as developed by Hann are briefly referred to, and the laws of moist air-currents also discussed, the formulae for which are based upon Hildebrandsson's exposition of Dalton's law. The fundamental laws of thermodynamics are the basis of the discussion of the disturbances of density giving rise to winds. Numerous theorems are laid down in connection with the phenomena of the winds, and it is recognized that differences of temperature are the original cause of them. The diurnal change of the barometric pressure is explained in a manner not unlike that usually followed, and the belief is expressed that the moon has an effect upon the atmosphere which would appear by a proper tabulation of barometric observations.

The above summary is sufficient to give an idea of the scope of the work. It is introduced to the public by Dr. Julius Hann, who remarks, with regard to deductive investigations, "Even where results derived deductively find no immediate application in nature, since the actual conditions are never so simple as those which must furnish the basis of the conclusions reached, yet they are of great interest and value in advancing knowledge, since they increase our insight into the nature of phenomena, and open the path upon which, in the course of time, we shall attain to their complete understanding."

The execution of the author's design, however, is not wholly satisfactory. On account of the fragmentary nature of the work, it is often difficult to understand the bearing of the subjects discussed, or to see what use can be made of the formulae derived. It is also not always easy to follow the author in his argument, and consequently the general effect upon the reader is one of disappointment. The treatise does not merit the title which is given it, though it may furnish useful suggestions to those who are investigating the subjects which it discusses.

HISTORY OF LAND-HOLDING.

The early history of land-holding among the Germans. By Denman W. Ross. Boston, *Soule & Bugbee*, 1883. 8 + 274 p. 8°.

This work of Mr. Ross starts from the principle of individual ownership and isolated farmsteads, as the primitive usage of the Germanic nations. The evidence for this the author finds in the sixteenth chapter of the Germania of Tacitus, in which he explains the *vici* to be villages, not of free tribesmen, as is generally assumed, but of serfs. Of community of ownership he finds no evidence, either in Caesar or Tacitus. In the period of the barbarian laws, too, the facts which have usually been understood to point to common or collective ownership he explains as meaning *undivided* property. He has no difficulty in proving the general prevalence of the principle of individual ownership at this latter period, so far as the laws and other documents of the period afford any evidence. That ownership is common wherever it appears in these documents, is as a rule temporary, and subject to individual claims, seems also fully established. The gap in the evidence is as to the two or three centuries which intervened between Tacitus and the barbarian codes, — a gap which is of no importance, if his interpretation of Tacitus is correct, but which leaves room, if that interpretation be not accepted, for the development of free village-communities in this interval, which may then, in some cases, have survived to a later period, by the side of the system of individual ownership which we must accept as the prevalent one for this period.

After developing these general principles, Mr. Ross proceeds (p. 26) to show how the isolated household may, in the course of a few generations, have developed into a clan-village; here, again, into a community of ownership which is not really corporate in character, but is on its way to divided and individual ownership (p. 38). The rules and usages of the inheritance and transfer of land are described with great fulness, after which the usages which appear to tell in favor of an original collective ownership — the rights of *vicini* to exclude strangers, to purchase in preference to strangers, and to inherit in case of lack of heirs — are discussed. Certainly these usages, which, it must be admitted, may accompany a system of private ownership, are, nevertheless, most easily explained on the assumption of a *previous* condition of collective ownership. We cannot think the explanation given on p. 52 to be wholly satisfactory.

The breaking-up of the clan-system is next considered, this being effected especially by female inheritance, adoptions, and alienations. An important topic is the founding of free colonies, off-shoots of the clan-communities, but modelled upon the serf-communities; and their organization and management are described with great fulness and lucidity. The relation between these free villages and the serf-villages — clan-villages of proprietors and of tenants — is discussed; and there is much here that would apply equally well to the village-community theory. They are indeed essentially the same in character with those assumed by that theory, only that they are represented by Mr. Ross as a later outgrowth instead of a primitive organization. The essay (which occupies 109 pages) ends with some brief considerations upon immunity, primogeniture, etc. The conclusions of the essay are supported by a mass of 'Notes and references,' occupying about 130 pages, and containing copious extracts from documents. There is a full index. This book is every way a thorough piece of work, which certainly places the village-community theory upon the defensive, and overthrows a considerable part of its assumptions; and, apart from its controversial character, as a 'history of land-holding' it possesses the highest value.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Hyperelliptic integrals. — The full title of this paper by M. Staude is "Geometrische deutung der additionstheoreme der hyperelliptischen integrale und functionen erster ordnung im systeme der confocalen flächen zweiten grades." Only a brief notice of M. Staude's paper is possible in this place, although its importance makes it worthy of a much more extended one. The paper is divided into five chapters. In the first chapter the author considers the geometric significance of the symmetric algebraic functions of two independent variables, and the differentials of the integral functions of an hyperelliptic form (*gebilde*) of deficiency (*geschlecht*). The second chapter treats of the representation of the *gebilde* in systems of confocal surfaces by aid of hyperelliptic functions, and opens by the introduction of certain transcendental parameters in place of the usual elliptic co-ordinates. An expression is also given of the homogeneous point co-ordinates in space in terms of products of the double theta-functions, and also of homogeneous plane co-ordinates in space by aid of products of two double theta-functions. The third chapter is of particular interest from a purely geometrical point of view. In this the author considers the relations of the addition theorem for hyperelliptic integrals to systems of confocal surfaces, treating particularly the reduction of given sums of three integrals to sums of two integrals of the same kind. The fourth and fifth chapters have not yet appeared, but the author mentions their contents. Chapter four is to treat of the ray-systems of common tangents to two confocal surfaces; and chapter five is to be devoted to a geometrical interpretation of Abel's addition theorem, by aid of which the reduction of the sum of any four of the integrals in question to the sum of two integrals of the same kind is arrived at by a purely geometrical process. — (*Math. ann.*, xxii.) T. C. [471

Discontinuous groups of linear substitutions. — The complete title of M. Picard's paper is "Sur une classe de groupes discontinus de substitutions linéaires et sur les fonctions de deux variables indépendantes restant invariable par ces substitutions." The theory of the elliptic functions has given the first example of a uniform function of a variable which does not change for a group of an infinite number of linear non-permutable substitutions effected upon the variable. The modular functions, i.e., the functions arising from considering the modulus as given by the ratio of the two periods, was for the first considered by M. Hermite. M. Poincaré has treated in his theory of the Fuchsian functions, in all its generality, the subject of functions of one variable which are reproduced by a group of an infinite number of linear substitutions. M. Picard, in the present memoir, proposes to consider functions of *two* independent variables which may be considered as analogous to the elliptic modular functions. He shows, first, that the Abelian functions do not conduct to functions entirely analogous to the modular functions, and illustrates this by the Abelian functions of the first order. But by taking the case of the Abelian functions of the second order, i.e., of three variables, he has found an indication of the desired extension, and hopes in a future paper to enter more fully into the subject of functions of two variables which are analogous to the modular functions. The present paper is interesting as pointing out the difficulties, and indicating the manner of overcoming them, in an entirely new department of the theory of functions. — (*Acta math.*, i.) T. C. [472

PHYSICS.

Target-shooting. — From Liagre's theory that errors in target-shooting are compounded of errors in sighting and in levelling, each of which follow independently the law of error, it was shown by Mr. C. H. Kummell that shots of equal probability are arranged in ellipses, which can be reduced to circles of shots uniformly distributed, the integration being much simplified by using the reduced distances and directions. Sir J. Herschel's 'even-chance circle' (ellipse, more generally), the one hit or missed with equal probability, can be deduced from the shots actually found in any given circle (ellipse), the most reliable result being given by the one containing the greatest number of shots, whose radius (mean semi-diameter) is the *most probable* shot. The number of shots falling within this ellipse should be about thirty-nine and one-half per cent. The equations between the even-chance shot (ρ), the most probable shot (ε), and the average shot (r_0), are —

$$\rho = \varepsilon\sqrt{2\,l\,2}, \quad r_0 = \varepsilon\sqrt{\frac{\pi}{2}}.$$

In determining these from the sums of squares of the vertical and horizontal co-ordinates of the separate shots, the number that miss the target should be considered. The probable position of centre and axes should not be calculated from the observations, unless the true positions are unknown. A target of ninety shots at eight hundred yards' range, by the Irish team at Creedmoor in 1874, gave discrepancies of less than five per cent between observation and theory, in the number of shots within successive rings. One of fifty pistol-shots, at fifty yards' range, showed a similar agreement. — (*Phil. soc. Wash., math. sect.; meeting* Nov. 21.) [473

ENGINEERING.

Honigman's fireless locomotive. — Mr. Honigman constructs an engine in which the steam is supplied by evaporation from a charge of water which is furnished to the boiler at the station, and there brought up to the required temperature and pressure. The shell of the boiler is surrounded by, or may enclose, another vessel, between which and the boiler a narrow space is left, which is filled with caustic soda. The exhaust-steam is discharged into this mass of soda, which at once absorbs it; and the absorption gives rise to a large amount of heat, which is in turn given out, and returned to the water in the boiler, where it produces an additional quantity of steam; and the latter, being exhausted into the compartment containing soda, gives rise to additional quantities of heat; and thus the process is continuous, and the locomotive continues to exert its power, until the solution of soda becomes so far saturated that it can no longer take up the exhausted steam, and supply heat to the boiler, with sufficient rapidity to enable the engine to do its work. When this state of affairs is reached, the engine is recharged, and is again sent out on the line. The soda removed from the exhausted engine is placed in an evaporator and deprived of its moisture, and is then again ready for further service. This seems to be the first attempt to make practical application of the now well-known principle discovered by Faraday sixty years ago, and probably even earlier known on the continent of Europe. It is reported to be tolerably successful, and likely to have practical use where the presence of a fired engine is not permissible. — (*Lond. engineering*, Aug.) R. H. T. [474

Compound locomotives in Europe. — Mr. Borries has read a paper before the Union of German engineers, relating the progress of the compound engine on German railways. They were first introduced by A. Mallet of Paris. There are now forty of these engines at work. They are worked either simple or compound, as desired. They are economical, and may be worked with a wide variation in the amount of power developed, but are somewhat complicated, do not distribute the steam in the manner sometimes found practically desirable in working, and the action of the steam during compression leaves something still to be desired. Mr. Borries has endeavored to obtain a system which should permit the use of double expansion at all times, should be simple, and should permit the proper adjustment of the ratio of expansion at any time, if possible. At starting, steam is admitted to both cylinders, reaching the large engine-cylinder through a 'reducing-valve;' but, after starting, the machine works as a compound engine. At all points of cut-off, he gets nearly equal work done in each cylinder. The engine works easily, and no spark-arrester is needed. The excess of weight and cost is about four per cent above that of other engines: the gain in power is six per cent, and in economy of fuel nine and a half per cent. The engine is considered a success. The best results are reported from passenger-engines thus constructed. — (*Lond. engineering*, Aug.) R. H. T. [475

Finishing rails. — M. Gazan writes to *La métallurgie*, saying that the chemical composition of the steel has very little to do with the strength of the rail: it depends more upon the temperature at which the rail is finished in the mill. Those finished at a high red heat, and which are recognizable by their blue tint, are more brittle and weaker than those which are finished at a lower heat. The latter are usually covered with a reddish colored layer of oxide. In the former case the fracture exhibits a granular, and in the latter case a good steely, surface. M. Gazan thinks that, in the former case, time is allowed for the formation of crystals which cannot be produced in the latter. If the red-hot metal be worked until it has fallen below the red heat, it does not exhibit crystallization. — (*Railway rev.*, Sept. 8.) R. H. T. [476

Compound engines and boilers. — Mr. M. Coryell, a member of the U. S. naval advisory board, writes that good results have been obtained from recent compound engines. Pressures rarely exceed 100 pounds per square inch (8 atmos. nearly, absolute pressures); but he thinks 150 (11 atmos., absolute) can be carried by adopting, instead of the 'Scotch boiler,' a boiler of but 6 feet diameter (1.8 metres), with cylindrical shell and set in brick-work, — a plan of which great distrust has hitherto been felt by engineers. He suggests a still better scheme, however, — a water-tube 'sectional' boiler, safe for 200 pounds. This would permit fire-surfaces of but a quarter-inch (0.6 centimetre) iron. The use of fire-brick furnace-walls is found to give some economy of fuel. He has found high pressures and great expansion to give good results, and states that at least one successful designer would exceed 20 expansions, — a proposal which is not looked upon with favor by leading engineers. Mr. Coryell would use the beam-engine for screw-ships on account of its perfect balance. He states that engines of 6 feet stroke are in use, making 60 revolutions per minute with 60 pounds (5 atmos.) of steam and a cut-off at 5 inches (i.e., a ratio of expansion of 14.4), and that these engines have been in successful use for nine years, making voyages of five days without detention and with economy. Engines of 88 inches (2.235 metres) stroke have averaged 58, and have sometimes made 71, revolutions per minute. He thinks 4 feet (1.22 metres) the shortest advisable stroke for marine engines, and believes that twice that length will ultimately become common. — (*Mech. eng.*, Sept. 29.) R. H. T. [477

CHEMISTRY.

(General, physical, and inorganic.)

Active oxygen. — For the purpose of testing the accuracy of his conclusion relating to the action of moist phosphorus on carbonic oxide, which seemed to be disproved by the results of Remsen and Kaiser (SCIENCE, i. **704**), E. Baumann has repeated his experiments, using apparatus closed with glass stoppers, and taking every precaution to avoid contact of the gases with organic matter of any kind. In one experiment, seven hundred cubic centimetres of carbonic oxide, diluted with air, after passing through the apparatus, in fifteen hours gave 36.6 milligrams of carbonic dioxide, or 2.6 % of the carbonic oxide was converted into carbonic dioxide. In a second experiment, thirty litres of air containing 2.45 litres of carbonic oxide, when passed through the apparatus, in twelve hours gave 64.6 milligrams of carbonic dioxide, or 1.3 %. The temperature varied between 20° and 26°. Baumann found, further, that hydrogen peroxide was not produced when air was passed over palladium hydrogen, although carbonic oxide was oxidized to a small extent. He concludes, with Hoppe-Seyler, that this oxidation is due to the presence of oxygen in its active condition. — (*Berichte deutsch. chem. gesellsch.*, xvi. 2146.) C. F. M. 478

Determination of the atomic weight of antimony. — J. Bongartz prepared metallic antimony from antimonious chloride, which had previously been purified by six or eight fractional distillations. The metal was separated by electrolysis according to Classen's method, and it was converted into the sulphide by heating with potassic sulphide. Determinations of sulphur in the purified sulphide were made by Classen's method; viz., by oxidation with hydric peroxide, and weighing the sulphuric acid thus obtained as baric sulphate. The mean of twelve determinations gave 120.193. — (*Berichte deutsch. chem. gesellsch.*, xvi. 359.) C. F. M. [479

AGRICULTURE.

Conductivity of soils. — Wagner has made a somewhat extended investigation of the thermal conductivity of various constituents of soils and of the effect upon it of alterations in the structure of the soil and in its moisture. The materials used were quartz sand, kaoline, precipitated calcium carbonate, ferric hydrate, peat extracted with acid and alcohol, and artificial humus prepared from sugar. The quartz was found to be the best conductor, and the humus the poorest, while the other materials occupied intermediate positions. The differences were small, however, and of little significance, compared with those due to differences of texture, compactness, and moisture. Experiments with two natural (calcareous) soils showed that heat was transmitted more slowly in a loose soil than in the same soil compacted, and that these differences were greater the greater the water-content of the soil. The latter factor, indeed, seemed to have more influence than any other. Its effect is due, according to the author, to the fact that it is a somewhat better conductor than the air which it replaces in the interstices of the soil. The heat was transmitted horizontally, so that there was little chance for the transmission of heat by convection. The effect of compacting the material was also studied on the six soil-ingredients mentioned above; and the compacted material was found to transmit heat better than the loose, in every case except the humus, of which the reverse was true. The conductivity was found to increase with the size of the particles or aggregates of which the soil was composed. Observations were also made on the daily variations of temperature at different depths in sand, clay, and peat. The variations were greatest, and extended to the greatest depth, in the sand. The peat stood at the opposite extreme, and the clay between the two: in these respects, their positions corresponding to their relative conductivity as previously determined. — (*Forschr. agr. physik.*, vi. 1.) H. P. A. [480

GEOLOGY.

Lithology.

The Maine building-stones. — It is well known, that, at the time Dr. Hawes was attacked by the illness which terminated so fatally, he was engaged in the microscopic study of the United States building-stones. It has been hoped that some one would be able to take up his unfinished work, and, in justice to his memory, render him credit for all that he had done. Whether this desirable work will ever be accomplished is a problem for the future. Meanwhile, the Maine building-stones collected for Dr. Hawes's work have been the subject of a recent paper by Mr. G. P. Merrill. These rocks, together with much data relating to their use, etc., were collected by Mr. J. E. Wolff, now of the Northern transcontinental survey.

Mr. Merrill classes these building-stones under biotite granite, biotite muscovite granite, hornblende granite, hornblende biotite granite, biotite gneiss, biotite muscovite gneiss, diabase, olivine diabase, and argillite or slate. Of the eighty-three quarries in Maine in 1880–82, seventy-four are of granite or gneiss.

The granites vary in color from a light to dark gray, and from a light pink to red. In texture they vary from fine, even-grained rocks, to coarsely granular ones, containing orthoclase crystals an inch or more in length.

The constituents are quartz, orthoclase, plagioclase, biotite, or hornblende, with or without muscovite, apatite, magnetite, zircon, epidote, sphene, rutile microcline, and iron pyrites.

The paper is accompanied by descriptions of the microscopic characters of the granites, which are of value to all interested either in lithology or building-stones.

The gneisses are similar to the granite, and, so far as the present writer's observations have gone, they are of the same origin.

Diabase, under the name of black granite, is quarried at three localities in Maine, — Indian River in Addison, Addison Point, and Vinalhaven. The first locality produces a nearly black rock composed of plagioclase, augite, magnetite, apatite, and secondary hornblende and mica. The other localities produce a similar rock; with the addition of olivine and chlorite.

It is a remarkable freak of fashion which renders rocks of such undesirable composition so much sought for, and extensively used, for polished monumental and ornamental work used out of doors, for which they are entirely unfit. This well illustrates the wide-spread ignorance, even among architects, of the properties of building-stones, even if New York and Boston, coupled with Harvard university, did not furnish striking examples.

Mr. Merrill's remarks on the properties of building-stones need to be received with caution, especially those regarding some of the red granites of Maine; for he has probably never seen them after their polished surfaces have been long exposed to the weather. — (*Proc. U. S. nat. mus.*, vi. 165.) M. E. W. [481

MINERALOGY.

Cassiterite. — W. P. Blake notes the occurrence of cassiterite as stream-deposit, as well as in place in the Black Hills, Dakota. It occurs in a coarse crystalline granite, yielding sheets of mica of commercial value, and large cleavage blocks of felspar. In addition, spodumene is found abundantly in gigantic crystals. — (*Amer. journ. sc.*, Sept.) S. L. P. [482

Lithiophilite. — Two analyses of this manganese variety of triphilite are given by S. L. Penfield, — one from a new locality in Norway, Me.; the other from Branchville, Conn. The analyses fully substantiate the formula of the species $LiMnPO_4$, in which a part of the manganese has been replaced by iron. — (*Amer. journ. sc.*, Sept.) S. L. P. [483

Augite. — The calculation of several augite analyses is given by C. Doelter, in which he shows, that in addition to the usual meta-silicate, $R''_2Si_2O_6$, the alumina and alkali, when present in various amounts, are united in molecules of the general formula, $R''R'''_2SiO_6$, of which he recognizes the following distinct molecules, which are isomorphous with each other and with the meta-silicate $R''_2Si_2O_6$: —

$MgAl_2SiO_6$	$MgFe'''_2SiO_6$
$Fe''Al_2SiO_6$	$Fe''Fe'''_2SiO_6$
$CaAl_2SiO_6$	$CaFe'''_2SiO_6$
$Na_2Al_2SiO_6$	$Na_2Fe'''_2SiO_6$

(*Min. petr. mitth.*, v. 224.) S. L. P. [484

BOTANY.

Hybridization of Zea. — Dr. Sturtevant writes, concerning the supposed direct manifestation of hybridization in the fruit of the first year, "We have as yet no station data whereby this belief can be verified." — (*Rep. N. Y. exper. stat.*, i. 1883.) W. T. [485

Fed and unfed sundews. — Büsgen briefly reviews the experimental efforts thus far made to determine the value of animal food for carnivorous plants, and gives the results of some feeding-experiments with Drosera rotundifolia carried on by himself at Strassburg.

To avoid the inequality certain to exist in plants gathered from their native habitat, containing unequal quantities of reserve material, and of different ages, Büsgen used seedlings, arguing that the slight weight (.02 mgm.) of the seed, and especially of its nutrient contents, renders the dry weight of all plants essentially equal at the beginning of the experiment. By averaging the results obtained from many plants, individual peculiarities could be eliminated for the most part; and, by subjecting the seedlings to fluid-cultures with different fluids, the necessity of nitrogenous compounds in the water absorbed by the roots was susceptible of determination.

All of these possibilities were not realized in the experiments reported, which extended through two seasons, since comparatively few plants were experimented upon, and these were cultivated on cakes of peat of unknown composition, saturated with the culture-fluid used. The results were measured by the size and vigor of the grown plants, their fruitfulness, and, finally, the dry weight of all their parts.

Without giving the details of the experiments, — which, though not perfect, appear to be the most satisfactory yet performed, — we may state that they seem to show quite conclusively that plants of this species, properly fed with animal matter (aphides) through their leaves, are individually stronger, more fruitful, and of greater weight, than those subjected to the same conditions but unfed; thus corroborating the conclusions of Francis Darwin, Rees and Kellermann and v. Raumer. It seems, however, as if the organic nitrogen cannot wholly replace that derived normally through the roots, but appears as useful for the plant only when supported by a certain quantity of nitrogenous salts (cf. Liebig, 'Die chem. in ihrer anwend. auf agric. u. physiol.,' i. 436). — (*Bot. zeitung*, nos. 35, 36.) W. T. [486

ZOÖLOGY.

Animal chlorophyll. — Th. W. Engelmann maintains that the diffuse green observed by him in certain Vorticellas is genuine chlorophyll, and not due to the presence of any vegetable matter. The species was found near Utrecht, and is related to V. campanula. The green coloring is diffuse, but is restricted to the ectoplasm. To study it, Engelmann employed the bacteria method, and found that the bacteria accumulated about the animalcule; whence he concludes that the green produces oxygen. Examined with the microspectroscope, the activity of the green Vorticella, as measured by the gathering of bacteria about it, varies in the same way, according to the wave-length of the light in which the animal lies, as does the activity of vegetable chlorophyll under corresponding circumstances. From these and other observations, Engelmann deduces the existence of true living chlorophyll, not of vegetable origin in this protozoon. The article is a contribution to the controversy concerning the existence at all of animal chlorophyll. [Engelmann relies upon the distribution of bacteria in the field of the microscope as a test for the distribution of oxygen. It is obviously hazardous to assign to living organisms whose peculiarities are most imperfectly known the value of a specific chemical test. We must look upon the 'bacteria method' with suspicion, because the idea, which is very ingenious, does not rest upon an established certainty. (*Rep.*)] — (*Pflüger's arch. physiol.*, xxxii. 80.) C. S. M. [487

Morphology of the primitive streak. — Repiachoff has confused the primitive mouth (urmund) with the blastopore. Owing to this, he attempts to disprove the connection of the primitive streak and groove with the primitive mouth by insisting upon the well-established point, that the blastopore is connected only with the posterior end of the primitive groove, overlooking the fact that the blastopore corresponds only to the posterior part of the primitive mouth, the edges of which unite all the way in front of the blastopore to make the primitive streak and groove, if the latter is present. There appears to be a wide-spread difficulty in comprehending the concrescence of the edges of the primitive mouth to form the axis of the vertebrate body. — (*Zool. anz.*, vi. 365.) C. S. M. [488

Coelenterates.

The life-history of American medusae. — Although Turritopsis is one of our most interesting hydromedusae, its metamorphosis has been entirely unknown. Brooks has added to McCrady's graphic description of the adult an account of the larva and of the changes through which the young medusa passes. The larva is very similar to Tubiclava Allman; and the medusa buds are carried upon short stems which grow out from the main stem, just below the hydranth. When set free, the medusa has eight tentacles and a short simple proboscis; but the endoderm-cells of the radial canals soon become thickened to form the great cellular peduncle, which is the most characteristic mark of the genus. Adult specimens of Turritopsis often contain the singular Cunina larvae which were discovered in this situation by McCrady.

Nemopsis Bachei is another very common medusa, the young stages of which have hitherto escaped observation. Brooks has reared it from a Bouganvilleia, and has traced the metamorphosis of the medusa.

Phortis gibbosa McCr. has been reared from a very singular campanularian hydroid which was washed ashore in great abundance at Fort Macon, on denuded Aglaophenia stems. Only one medusa escapes at a time, and this soon becomes larger than the entire gonotheca. The order in which the tentacles appear is shown in the following diagram.

The larva of Amphinema apicatum Haeckel is a Perigonomus, which grows upon the sand-tubes of Sabellaria. When set free, the medusa has no trace of the apical process, which is an adult feature, although it has usually been regarded as a larval characteristic. When five days old, the medusa begins to assume the adult form: the apical process is developed, the umbrella becomes like that of the adult, the oral folds appear, and the upper end of the proboscis becomes enlarged. — (*Stud. biol. lab. Johns Hopk. univ.*, ii. 465.) W. K. B. [489

Mollusks.

Extramarine mollusca of New Guinea. — Tapparone Canefri has undertaken a general work on the mollusca of New Guinea, of which the first part has just appeared in the shape of a fine octavo volume of three hundred pages and eleven plates. In proof-reading, typography, and illustrations, it presents a marked and favorable contrast to many Italian scientific publications. The second volume will contain the marine mollusks: the others find a place here. From such a region many novelties might be expected. The author, however, is conservative; and the divisions newly proposed are not numerous, though a considerable number of new species are described and illustrated. Bellardiella (Martensiana) from Port Dorey is a Pupinella in which the peristomal sulcus is replaced by a tube posteriorly directed, behind the lip. Sulcobasis and Cristigibba are sections of Helix, typified by H. sulcosa Pfr. and H. tortilabia Less. respectively. Cyclotropis (papuana) differs from Assiminea by its perforated base. Physastra resembles a thick-shelled reversed Limnaea with a dehiscent epidermis. We doubt if it should be referred to the Physidae. Lastly, the section Microdontia is proposed as a section of Unionidae for U. anodontaeformis, in which the anterior cardinal teeth are thin, compressed, and nearly parallel with the margin.

Besides full descriptions or synonymy of species, the work contains useful tables showing the exact distribution of each species and group of species, as far as known, and also dissections of the generative organs, and illustrations of the dentition of a number of species. The work will also appear as volume xix. of the Annals of the Museo civico of Genoa, and is provided with a good index. — W. H. D. [490

Structure of the oyster-shell. — Observations by Osborne show that the shell is formed by the crystallization of lime in the conchioline (not, as stated, chitinous) layer, as is generally believed. The structure of other species was found less easy of investigation; and the complexity of structure in many molluscan shells would indicate that the process of formation is not universally the same. — (*Stud. biol. lab. Johns Hopk. univ.*, ii. 4.) W. H. D. [491

Slime-spinning by Arion hortensis. — Mr. Roeback, having received a specimen an inch long, observed it crawling on a flat paper-knife, from which it projected in a horizontal position into the air, with only the end of its tail touching the knife. Emitting a thread of slime, it hung by it to a distance of four inches; and when, on reaching a support, the thread was severed, it immediately shrank into a minute, scarcely visible point of slime. — (*Journ. conch.*, July, 1883.) W. H. D. [492

Insects.

Distribution of the occident ant. — Rev. Dr. H. C. McCook made a communication on the geographical distribution of the occident ant, Pogonomyrmex occidentalis. The specimens upon which the communication was based were collected by Prof. J. E. Todd in Dakota. He reports that the species is confined to the bottom-lands along the Missouri River, and has not pushed eastward through the territory. This corresponds remarkably with Dr. McCook's conclusion, both from his own observations and those made under his direction by Dr. Horace Griffith of

Marengo, Io., that this ant does not dwell east of the Missouri River, in Missouri, Iowa, and Minnesota; that it avoids eastern while abounding in western Nebraska; and that it is not found in Kansas farther east than Brookville, which is near the site reported by Prof. Todd. The structure of the ant-hills, and the harvesting habits of the species, were described. Mr. T. Meehan, to whom had been referred a small quantity of the *débris* collected from one of the nests by Prof. Todd, reported that there were no seeds among the pebbles, but that there were a number of calices, or undeveloped capsules, of a leguminous plant, Dalea alopecuroides, which is common on the plains. Dr. McCook had been puzzled to explain why such intelligent creatures should be detected in harvesting immature seeds, until, upon inquiry, he found that leguminous plants have a succession of flowers; so that there may be mature seeds and flowers on a plant at the same time. It is evident that the ants were not harvesting out of season, but were occasionally deceived, and cast out to the refuse-heap the calices that contained no edible seed. — (*Acad. nat. sc. Philad.; meeting* Nov. 21, 1883.) [493

Dipterous maggots in man. — Dr. Samuel Lockwood exhibited a full-grown dipterous larva taken from the inner ear of a man at Paterson, N.J., Aug. 30. There was a perforation of the membrana tympani. The man had suffered seven days from its presence. The grub had entered the outer ear, but eluded an attempt to extract it by re-entering the drum. Appearing again in the external ear, it was extracted with forceps, and kept alive for several days. He referred to certain papers read to the society (one in 1880, and a sequel in 1881), in which he described specimens of dipterous larvae passed by a man in large numbers, and which he determined to be larvae of Sarcophaga carnaria and Anthomyia canicularis, which had come of eating tainted cold meat and cold boiled cabbage. He had also shown a larva, which he could not determine, which had been vomited by a girl. The larva taken from the man's ear he had determined to be the viviparous flesh-fly, Sarcophaga carnaria, and thought that the man had eaten meat on which were the freshly laid larvae, which, being very small, might easily be unperceived. If the man had coughed during the eating, he might have thus thrown one of the larvæ against the entrance to the eustachian tube, and it could readily ascend the epithelial walls, feeding upon the mucus on its way. The larva had attained full growth, and, about to pupate, was restless to find a nidus: hence the good fortune of its twice entering the outer ear from the rent in the tympanum. Dr. A. V. N. Baldwin remarked that he had recently found a cluster of grubs, hard-packed, in the external ear of a man in Bellevue hospital; to which Dr. Lockwood replied, "Probably the parent fly had oviposited there when the man was asleep, attracted by the fetid odor of a diseased ear." — (*N. Jers. micr. soc.; meeting* Nov. 10.) [494

Spinning-habit of Psocus. — Rev. H. C. McCook announced that the small neuropterous insect, Psocus sexpunctatus, had recently been found, for the first time in America as far as he was informed, on the Wissahickon Creek, Fairmount Park, Philadelphia, by Mr. S. F. Aaron. The family of the Psocidae is of peculiar interest in being the only true insects which spin webs in the imago state. The generally larval function of web-spinning might, perhaps, be correlated with the rank which zoölogists assign the Neuroptera as the lowest in the order Insecta. It is, however, a striking example of the diverging and independent lines along which life-forms have sprung up in nature, that a function which belongs to the larval stage of insects, and which appears in the imago stage only in the lowest type of the same, should appear as the most permanent and characteristic function of the spider, — an animal, which, although it is now commonly given a lower place in the same subkingdom with the insect, is certainly very differently and but little less highly organized. It would be a difficult task to trace, or even imagine, any evolutionary connection between the web-spinning spider, the web-spinning lepidopterous larva, and the web-spinning neuropterous imago. There is, indeed, the common factor, the spinning-function; but the physiologist fails to perceive any use or combination of the same which can unite the organisms in which it inheres. — (*Acad. nat. sc. Philad.; meeting* Nov. 27.) [495

VERTEBRATES.

Action of the respiratory movements on circulation. — Taljanzeff states, that, in violent breathing, partial or complete inhibition of the contractions of the right side of the heart may take place, without, however, any fall of arterial pressure resulting; the blood being forced from the right to the left side of the heart by the action of the breathing-movements on the heart, especially on the right ventricle. He has discovered, also, that if the branches of the vagus going to the lungs are cut, and their central ends stimulated, a decided reflex action on the heart and blood-vessels is obtained. In most cases the heart was slowed, giving the well-known 'vagus pulse,' and the blood-pressure lowered; though in one experiment there was a fall of aortic pressure without any change in either the force or rate of the heart contractions. — (*Centralbl. med. wiss.*, 1883, 401.) W. H. H. [496

Vaso-motor nerves of the leg. — In a brief preliminary communication, Bowditch and Warren give some of the results of an investigation upon the vaso-motors of the extremities. Their method of determining the contraction or dilatation of the blood-vessels was to enclose the limb in a plethysmograph, — a method undoubtedly very delicate and accurate, but possessing the disadvantage that it gives only the general result of the stimulation of the nerve on the blood-vessels of the limb as a whole, and furnishes no indication of local dilatations or constrictions which may take place. They find that stimulation of the peripheral end of the divided sciatic may cause either constriction or dilatation. When the induction-shocks followed in rapid succession (16 to 64 in a second), a constriction of the blood-vessels was the general result. When the stimuli followed more slowly (4 – 0.2 in a second), a dilatation was produced. With a medium rapidity of stimulation, a contraction was observed in the beginning, followed by a dilatation. The latent period of vaso-constriction was estimated at 1.5″; that of vaso-dilatation, at 3.5″. The vaso-dilator effects continued for some time after the cessation of the stimulus. — (*Centr.-blatt. med. wiss.*, 1883, 513.) W. H. H. [497

Mammals.

Birth of a mandrill in captivity. — A mandrill was born in the Hamburg zoölogical garden in July, 1882. It lacked the brilliant coloring of the face characteristic of the adult, and had but weakly developed face-wrinkles. The countenance and posterior callosities were flesh-colored. Only the upper and posterior portion of the head and a space on the median line of the back were dark. — (*Zool. garten*, xxiv. 1883, 235.) F. W. T. [498

The circulation in the kidneys. — This paper by Cohnheim and Roy furnishes an extremely important and interesting addition to our knowledge of the physiology of the kidney, and will undoubtedly, with the future work that is promised on the subject, throw much light also on the etiology of some of the diseases of that organ. The method which they employed in their investigation cannot be thoroughly understood without reference to the plates which accompany the article. It is sufficient to say that the organ was enclosed in a sort of plethysmograph, to which Roy has given the name of oncometer, by means of which variations in volume of the kidney can be registered. With regard to the normal circulation in the kidneys, it was found that both the respiratory and pulse waves were shown in the kidney tracing, as well as the Traube-Hering waves, when these occurred.

Stimulation of the vaso-motor centre directly by means of dyspnoea, as well as stimulation of the central end of sensory nerves, caused a strong and rapid diminution in volume of the kidney, owing to the contraction of its vessels. This diminution in volume occurs when both splanchnics are cut; but in those cases in which they succeeded in severing the kidney from all external nervous influences, the kidney, instead of contracting, showed an increase in volume corresponding to the general rise of blood-pressure.

The influence of the splanchnics on the kidney circulation was especially studied. Section of the splanchnics caused no increase in the volume of the kidney, so that the tonic influence which these nerves have been supposed to exert on the kidney-vessels is rendered very doubtful, though the authors do not care to make any positive statement with regard to this point. Stimulation of either the central or peripheral end of the divided splanchnics gave a strong diminution in volume of the kidney. The fact, that, after section of both splanchnics, stimulation of the central end of a sensory nerve still causes a contraction of the kidney, shows that vaso-motor nerves pass to this organ by some other path. In order to cut off the kidney from all external nervous connection, it was necessary to divide not only the nerve-trunks in the hilus, but also to destroy the external coat (tunica adventitia) of the blood-vessels. In cases in which this was successfully accomplished, they could obtain no distinct evidence of a vaso-motor tonus of the kidney-vessels. Stimulation of the nerves of the hilus showed the presence only of vaso-constrictor and sensory nerves: in no case did they obtain any evidence of vaso-dilator nerves.

The circulations in the two organs are, to a great extent, independent of each other. Clamping the renal artery on one side has no effect at all on the circulation in the other kidney, and the same may be said with regard to the closure of other large arteries of the body. Throwing ice-cold water, or water heated to 50° C., on the whole of the skin surface of the animal, has little or no effect on the kidney circulation; a fact which seems to indicate that the direct connection between the functions of the skin and the kidney is not so close as has been supposed. A future paper on the influence of the composition of the blood on the circulation in the kidney is promised. — (*Virchow's archiv*, xcii. 424.) W. H. H. [499

ANTHROPOLOGY.

Ethnology of Yunnan and the Shan country. — Mr. Colquhoun has traversed the region lying between Canton and Rangoon, including Yunnan, the south-western province of China. The details of his exploration have been published in the *Proc. roy. geogr. soc.*, Dec., 1882, in a volume entitled 'Across Chrysee,' or will appear in a work now preparing on the Shan country. From Canton westward the people were pure Chinese; west of that, to the Yunnan frontier, the people were mixed on the rivers; and aboriginal races were found inland. Throughout Yunnan the chief population consisted of Shans disguised under a great variety of tribal names. Lolo and Miao-tzu, aborigines and Thibetans under the name of Kutsung, were seen. Mr. Keane, commenting upon this paper, said that amongst the Yunnan tribes were the widely dispersed Lolo people, who seem to extend in isolated groups from Szechuen, Kwei-chew, and Yunnan, down to the Tonquin highlands, and who by some travellers had been described as physically more like Europeans than Indo-Chinese. — (*Journ. anthrop. inst.*, xiii. 3.) J. W. P. [500

North-eastern Papua. — During a period of six years, 1875–81, Mr. Wilfred Powell made frequent visits to the eastern coast of New Guinea. Torres Straits has become famous as a pearl-fishing ground, worked by fleets of large boats built for the purpose, and manned by natives from all parts of Polynesia. The most fever-cursed portion of the island is the low alluvial plain skirting the Gulf of Papua, opposite Queensland. Here is found the only cannibalism known to the author to exist on the island. The whole of the population here are of a lower type than those in the more elevated districts to the east. At Brumer Islands the two races meet and intermingle, — the darker and more barbarous type of the Gulf of Papua and the south-west coast, and the lighter colored and better featured type, more resembling the Polynesian, inhabiting the south-east and the eastern peninsula. The last-mentioned people are numerous and industrious. The women are respected, and irrigation is carried on by means of bamboo pipes joined with gum. Obsidian is used for many purposes, such as shaving their heads and faces, carving wood, etc. — (*Proc. roy. geogr. soc.*, Sept.) J. W. P. [501

The Masai people in East Africa. — Zanzibar is now a commercial centre, dominated over by British interests and British trade. It is therefore a matter of great importance to establish an expeditious caravan route over the range in which are Mounts Kilimanjaro and Kenia to Lake Victoria. In the way of this route are the Masai, a tribe reputed to be savage and aggressive. Last autumn Mr. J. T. Last, a physician missionary, made a journey to the Masai country, and reports much that is interesting to the ethnologist as well as to the geographer. The Masai seem to belong to the great Galla race. The extent of their country is very large. The majority are of average height, and the women are about as tall as the men. There is a marked difference in features between the pure and the mixed Masai, the former being of a much higher type. The author describes the scanty dress of the men, one article of which is the *olding'ori*, a heart haped piece of goat-skin, serving more for a seat than covering. The women are completely clothed and extravagantly ornamented. There is no iron in their country, nor do they know how to work it. Their domestic animals, weapons, mythology, burials, marriage, crimes, polygamy, and modes of building are all fully described, and a copious vocabulary closes the paper. — (*Ibid.*) J. W. P. [502

Serpent venom. — The destruction of human life by the bites of poisonous serpents is so great in many countries, that it becomes really an anthropological problem to ascertain the amount of damage, and to seek the remedy. Dr. Robert Fletcher has brought together much information, and a great deal of the literature, in a paper read before the Washington philosophical society in May last. Sir Joseph Fayrer states the average mortality from serpent-bites in India to be fully 20,000 annually. In 1869 the returns were obtained through official sources, from a large part of India, with unusual care and accuracy. In a population of nearly 121,000,000, representing an area of less than half the peninsula of Hindostan, the deaths were 11,416, or nearly one in 10,000. Of these deaths, there were caused by

Cobra	2,690
Krait (Bungarus ceruleus)	359
Other snakes	839
Unknown snakes	6,922
No details	606
	11,416

In 1880, 212,776 poisonous snakes were killed and paid for; and in 1881, 254,968.

Even in Europe the number of accidents from snake-bite is very large. In one department of France, La Haute-Marne, the government paid, in six years, for the destruction of 17,415 vipers. — (*Amer. journ. med. sc.*, July.) J. W. P. [503

Mythologic parallels. — Gaidoz, commenting the tendency to trace the myths and folk-tales of Europe to the Aryans on the high plateaus of India, remarks, "that we cannot rest upon those eminences, but must prolong our inquiry over the whole earth: they are not Aryan, they are human." The discussion of resemblances in culture seems to land us ever in a double corner between the supposition that humanity reproduces ever the same phenomena under the same conditions, and the theory that similarity proves contact of some kind. M. Gaidoz cites two very interesting but far remote similarities. Among the ancient Romans, driving a nail was a religious practice, oft resorted to as a remedy against certain maladies, or a preservative against enchantments. Numerous references to this practice will be found under the word 'clavus,' by M. Siglio, in his 'Dictionnaire des antiquités grecques et latines,' p. 1240–1242; and in the chapter upon the nail in the *cella* of the temple of Jupiter, in Preller's 'Roemische mythologie,' 2d ed., p. 231. The law demanded that the rite (*clavi figendi causa*) should be performed by one high in authority, and, in cases of great public calamity, by the dictator himself. Now pass beyond the Pillars of Hercules to the mouth of the Kongo River, and listen to the words of Charles de Rouvre (*Bull. soc. géogr.*, Oct., 1880, p. 323): "Finally there are the *n'doké* fetishes, under the care of priests called *gangazambi*, who are reputed to have the power to cause to speak. An offering is made to the *n'doké* of one or more pieces of cloth and tafia. A nail is then driven into the image, while the *ganga* or the suppliant formulates his demand." 'The barbarians are older than we,' said Plato; and this form of nail-driving into the heart of the image, in order that our prayer may pierce the heart of the god, is much older than the Roman custom. M. Gaidoz further connects this custom with votives on oratorios, on trees, on church-walls, etc., for many purposes. In conclusion, the author insists that the beliefs of classic antiquity are to be studied not only in ancient texts, but in a past far more remote. — (*Rev. hist. relig.*, vii. 5.) J. W. P. [504

Hypertrichosis. — The development of hair on abnormal parts of the body has received the names Hypertrichosis universalis when it occurs over the whole body, and H. partialis when only over limited portions or in patches. The abnormality may be the period of development, in which case it would be heterochronic. It may be sex, as the beard of certain females, where it would be heterogenic. In the first case mentioned above it is heterotopic. Dr. J. G. Garson of London has collected photographs of distinguished cases of hypertrichosis, and states his conclusions as follows: "As to the cause of abnormal hair-growth, the atavistic theory seems to me to be the most probable explanation, as here we would not have to trace the atavus far back, and in the normal body we have the atavistic germ present, though in a rudimentary condition. It would, therefore, be what Gegenbauer terms a paleogenetic form of atavism. — (*Journ. anthrop. inst.*, xiii. 6.) J. W. P. [505

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Geology. — According to Prof. L. C. Johnson, who has been at work on the geology of Alabama (in the southern part of the state), the tertiary boundary will have to be moved from six to ten miles north of the limits usually assigned it on the maps. The lignitic, a sub-Claiborne division of the tertiary, will therefore appear much extended northward (ten miles at Allenton, six at Camden, and seventeen at Butler Springs). Professor Johnson has collections of fossils to prove his position. He has also recently investigated the boundary-line between the rotten-limestone group and the Eutaw group of the cretaceous, and between the latter and the older formations, and has made large and interesting collections of mammalian and saurian remains from the southern part of Alabama, principally from Autauga county.

Prof. R. D. Irving, who is devoting his attention to the copper-bearing rocks of Lake Superior, reports, that, in connection with Professor Winchell, he has personally examined the quartzites of Nicollet and Cottonwood counties, Minn. One hundred and forty thin sections of rocks have been made, mostly of Huronian quartzites; and more than half of these have been examined, with the result of proving that the quartzites of the original or typical Huronian of Lake Huron, and of the Huronian regions of Marquette and the Menominee River in Michigan and Wisconsin, are fragmental rocks, and that they have never undergone any metamorphism other than that involved in the deposit of interstitial quartz among the clastic grains, of which they are in the main composed. Professor Irving has also begun a comparative study of the greenstones, cherts and flints, and jaspery iron ores of the various Huronian regions examined by him.

Prof. T. C. Chamberlin, who has charge of the morainic investigations in the eastern United States, has recently examined the border of the later drift, principally in Indiana, and subordinately in Ohio, and has completed the tracing of the line from the Scioto to the Wabash, and more fully demonstrated the peculiar association of the remarkable bowlder-belts of those states with morainic aggregations. Prof. J. E. Todd, one of Professor Chamberlin's assistants, has determined more exactly the character of the morainic loop in the vicinity of Alexandria, in southern Dakota. He also found in that neighborhood an exposure of the Sioux quartzite with glacial striae, the direction of which is in harmony with the previous observations. Professor Todd also examined the drift-bluffs in the vicinity of the Big Sioux River, where the loess comes in contact with the drift. In October, Mr. R. D. Salisbury, who is also assisting Professor Chamberlin, made a detailed and specific study of the border of the driftless area in Wisconsin, Minnesota, and Iowa. This had heretofore been examined only cursorily by various observers; and Mr. Salisbury made a critical and connected examination, which developed some interesting points, one of which is to give the outline a form more in harmony with the moraines of the later epoch that lie opposite it on either hand.

Chemistry. — Mr. Hillebrand, the chemist in charge of the field-laboratory at Denver, has been investigating the so-called basic sulphates from Leadville. They are an important constituent of the ore deposits of that region, and occur as a rule under the ore bodies, seeming to be a product of secondary decomposition of the original sulphuretted ores. They appear to be a mixture of the mineral jarosite and basic sulphate of iron with hydrated arseniate of iron, anglesite, and pyromorphite.

A short time ago Prof. F. W. Clarke, chief chemist of the survey, visited and examined the Gilmore mica-mine in Montgomery county, Md., about twelve miles north of Washington, and found it of remarkable mineralogical interest.

Publications. — A few advance copies of the third annual report have been issued without the complete set of illustrations. Besides the report of the director and the various administrative reports, it contains the following papers: Birds with teeth, by Prof. O. C. Marsh; The copper-bearing rocks of Lake Superior, by Roland D. Irving; Sketch of the geological history of Lake Lahontan, by Israel C. Russell; Abstract of report on geology of the Eureka district, Nevada, by Arnold Hague; Preliminary paper on the terminal moraine of the second glacial epoch, by Thomas C. Chamberlin; A review of the non-marine fossil Mollusca of North America, by Dr. C. A. White.

A monograph on the geology of the region adjacent to Golden, Col., by Mr. C. Whitman Cross, is almost ready for the printer.

Geographical field-work. — The following notes of the geographic work of the survey during the season of 1883 are furnished by Mr. Henry Gannett, chief geographer.

Appalachian division. — In the southern Appalachians, five topographic and two triangulation parties have been at work during the season, and are now about returning to the office in Washington. Prof. W. C. Kerr has been in charge of the triangulation. The area embraced in the survey was the mountain region of North Carolina, exclusive of that worked in previous years; the northern half of the valley of east Tennessee; the south-western portion of Virginia; and that part of West Virginia lying between the Kanawha and Big Sandy rivers. In addition to the territory thus enumerated, the western part of Maryland, and adjacent portions of West Virginia and Virginia, were surveyed.

The total area thus comprised will be not less than twenty thousand square miles for the season. Work in this region is necessarily difficult and somewhat slow, on account of the scarcity of salient topographical points, the thick growth of timber, and the heavy rainfall. The latter is a fact that is ignored on most of the rain-charts published during the past ten years.

This work will be published on a scale of four miles to the inch, with contours two hundred feet apart vertically.

Massachusetts division. — In July a survey of Massachusetts was begun, under the direction of Prof. H. F. Walling. In this work the triangulation of the coast survey and the old Borden survey, and the topographical work of the past, are being utilized wherever practicable. The maps will be comparatively detailed, as the published scale is to be two miles to the inch. It is hoped that the work may be completed in about two years. Thus far, during the present season, about two thousand miles have been surveyed, work having been begun in the western part of the state, and extended eastward from the high country as cold weather began to come on.

Rocky-mountain division. — Mr. Anton Karl has surveyed part of the Elk Mountains in Colorado, extending the map made by Hayden in 1874, and has also been engaged in re-surveying the Maxwell grant in northern New Mexico for the interior department.

Wingate division. — This division, in charge of Prof. A. H. Thompson, has its headquarters at Fort Wingate, N.M., and has been working in the plateau country, principally in north-eastern Arizona. Field-work was begun early in May, and is now practically finished for the season. One triangulation party and three topographic parties have been at work, and have surveyed twenty-two thousand square miles. The region they covered is one of the most dreary and desolate within the limits of the United States; and, when its arid condition and the difficulties of transportation through it are considered, it will be seen that this division has accomplished a remarkable amount of work.

California division. — Mr. Gilbert Thompson, who is in charge of this division, began work last year in northern California, and completed the survey of about four thousand square miles. This year the work was extended in all directions from Mount Shasta, reaching to the Coast Range on the west, and into the lava-bed country on the east and south-east. This region lies between the parallels 38 and 42, and meridians 121 and 123. Although the atmosphere was smoky a large part of the time, this division has had a successful season.

Division of the Great basin. — The topographic surveys in the Great-basin district have been confined mainly to detailed work for special maps illustrating Mr. G. K. Gilbert's investigations of the lake-basins of this region. The principal work done has been the securing of notes for a map of the drainage area of Mono Lake, and for a number of special maps of ancient moraines.

Yellowstone-park division. — Mr. J. H. Renshawe has just come in from the field. He has been engaged in work for a detailed map of the Yellowstone national park. He began work early in June, and has covered fifteen hundred square miles, making plane-table sketches on a scale of two inches to the mile. He also remeasured, at Bozeman, a base-line laid out by Wheeler's survey in 1877. Mr. Renshawe expanded this base-line last season, but was prevented from remeasuring it then by the weather.

In California Mr. John D. Hoffman has been carrying on the survey of the quicksilver-mines steadily for more than a year.

NOTES AND NEWS.

Last summer, at the Zurich meeting of the standing committee of the International geological congress, Professor Neumayr of the Vienna university presented, by request, a plan for the preparation of a 'Nomenclator palaeontologicus,' to be issued under the auspices of the congress. His project was well received, and only awaits final indorsement at the meeting of the congress next year at Berlin. The scheme contemplates the appointment of an editor-in-chief (for which post no better person than Professor Neumayr himself could be selected); an editing committee, under whose general supervision the work will be carried on; national collaborators, who are to give special assistance in the literature of their own country; and special compilers, to each of whom a particular section of the work will be confided, and who will be placed in special relation with some one member of the editing committee.

The work, when completed, will probably consist of fourteen or more large octavo volumes. The mollusks are expected to require at least two volumes; one each will be given to cryptogams, phanerogams, protozoa, coelenterates, echinoderms, worms and molluscoida, arthropods, and vertebrates; two volumes will be given to a systematic enumerator, and one to an alphabetical register.

The nomenclator proper will consist of citations of all species (the nominal species in special type) published in scientific works, in accordance with recognized rules, with their synonymes; and the citations will include, *a*, the first publication; *b*, later descriptions which have really advanced the paleontological knowledge of the species, particularly such as give for the first time a satisfactory illustration; *c*, the illustrations found in the best known and most widely circulated 'fundamental work.'

Critical notes and newly proposed names will not be admitted, and conventional signs will be avoided. Abbreviations in the citations will be so given as to be readily understood by every one possessing some knowledge of the literature; and, for serial publications, the use of those employed in the Royal society's Catalogue of scientific papers is recommended. The geological horizon and geographical distribution will be indicated, the former according to the scale of the congress. The language employed will be Latin.

The plan, as presented by Professor Neumayr, is excellently conceived, and, if carried out in the same spirit, will be an immense boon to paleontologists. But one minor criticism occurs to us: it seems a pity to perpetuate the awkward abbreviations employed in the Royal society's Catalogue, in which are too frequently violated the two cardinal rules of proper abbreviations, — the preservation of the order of words in a title, and, in ordinary cases, the abbreviation of words before the vowel of the second syllable. If those in charge of the compilation of that magnificent but exasperatingly incomplete work had but taken counsel of some of their better trained brethren of the Index society, the world would have had more to thank them for. As it is, their shortcomings seem likely to breed perpetual sorrow.

—On the 28th of July, about nine o'clock in the morning, a Mr. Ferry started from Dover to cross the English Channel on a water tricycle. The construction of the machine is well shown in the accompanying illustration, which we take from *La Nature*. It is evident, however, that the displacement must have been much greater than that indicated. Instead of the light wheels of steel, with tires of rubber, of the land vehicle, there are bulky paddle-wheels. The small wheel behind serves as a rudder. Ferry arrived at Calais in less than eight hours. The distance as a bird flies is twenty miles, but on account of the currents the exertion required was considerably increased.

TRICYCLE ON WHICH MR. FERRY CROSSED THE ENGLISH CHANNEL.

—Mr. Boyd Dawkins, who has long been familiar to American archeologists through his cave explorations, and his volume on early man in Britain, discusses in the *North American review* the question of the antiquity of man in our own country. The subject is treated as a portion of one great problem common to the old and the new world, when man lived in the same low stage of culture on both sides of the Atlantic, at a time when the hands of the geological clock pointed to the same hour over the greater part of the world. With reference to the absolute chronology of geological phenomena, the author makes a statement worth preserving: "The present rate of the retrocession of the Falls of Niagara, or of the deposit of Nile mud, or of stalagmite in caverns, or of the accumulation of rocks themselves, or of the movement of glaciers, has been formerly used as a natural chronometer, on the assumption that they have been going on at the same rate throughout the past, and have been warranted never to stop, or to want winding up, or to go faster or slower than at the moment the observer was looking at them." The chronology adopted in the present paper is that of the author's 'Early man in Britain.' In the light of Dawkins's system, Professor Whitney's pliocene man is found wanting. Skulls of Mexican mustangs and modern stone implements are taken from the same layers. The human bones in the auriferous gravels are indistinguishable from those of the red Indians.

With reference to Dr. Abbott's Delaware River finds, the author remarks, "The identity of the implements proves that the river-drift hunter was in the same rude state of civilization in the old and the new world, while the hand of the geological clock pointed to the same hour." This river-drift man was unmistakably a man, and not a 'missing link.'

—From advanced sheets of the Proceedings of the Anthropological society of Washington, Col. F. A. Seely, of the U. S. patent office, publishes a pamphlet entitled 'An inquiry into the origin of invention.' The author is accustomed, day by day, as new claims for patents come before him, to eliminate the successive steps in the classes of machinery until he reaches the fundamental idea. This is the plan pursued in tracing backward the whole subject of invention to its sources in the mind of primitive man. The subject is illustrated, first, by the story of the steam-engine, and then by the examination of the bow and arrow and other implements of the lower races. The author rejects Professor Gaudry's Dryopithecus, and affirms, "Obviously, archeology can find no trace of a remoter age than that of stone; but I mistrust that the thoughtful anthropologist will accept the evidence of earlier ages, one of which, taking one of its perishable materials as the type of all, we may call the age of wood. Still farther back must lie an age, as indefinite in duration as any, when man existed in his rudest condition, without arts of any kind, except such as he employed in common with lower animals; and this is the true primitive period."

— In the Bulletin of the *Société géogr. de Marseille* for June, Heckel gives new information, with a *résumé* of old, in regard to the African nut known as Kola, or Guru. This seed, which is hardly to be called a nut, has a kernel about two inches in length, somewhat like that of a peanut, with a groove instead of a projecting point at the germinal end. It may be white or red, or both, to the number of four or five, in the same rough brown pod. It is the product of a tree of the family Sterculiacea. The genus has been called Sterculia, Kola, etc., and there are several species or varieties. This nut, or seed, is remarkable on account of containing (beside glucose, tannin, and a bitter principle) caffeine and theobromine in large proportion. Among the African tribes it takes the place of tea and coffee or cocoa, — products of plants belonging to very different groups, but valued for the same essential principle. It has been used from time immemorial, and many singular stories have been current as to its effect upon the system, though little authentic information was at hand.

Kola is gathered twice a year, carefully shelled, and the bare meats are immediately despatched into the interior, carefully wrapped in green leaves to insure them from drying. They have to be carefully picked over every twenty or thirty days, and all defective ones thrown out. It is considered very important that they should be kept fresh and somewhat moist. However, as soon as they begin to shrivel and dry up, the caravan merchants dry them thoroughly in the sun, and pound them to a powder in a mortar. The seeds are worth twenty or thirty cents a pound at the place where gathered, near Sierra Leone; but they rapidly increase in value away from the original market. At Goree a single seed will be sold at six to ten cents, according to the state of the market. In the interior the tribes on the Niger pay as high as one dollar per seed, and in times of scarcity a slave has been given for one seed. In the far interior the Arab merchants frequently dispose of the powder for its weight in gold-dust.

The Kola is the stimulant of the African tribes, and is in order on every occasion. Among those peoples where the nut is not indigenous, nor yet too extravagantly dear, no transaction of any moment can take place without an exchange of Kolas. This is either in token of good will or to 'bind the bargain.'

If two tribes ally themselves, they exchange white Kolas, this color being always the token of good will and peace. If war is declared, the announcement is made by sending red Kolas to the enemy. A request for a wife is accompanied by the present of a white Kola from the lover to the intended mother-in-law. The response favorable is by a seed of the same color; a refusal, by a red one. The wedding present of the husband to his bride is incomplete without a certain proportion of Kolas. In the interior, where they are so valuable, the gift of one is considered a high attention, and, when given by a chief to a white traveller, takes the character of an assurance of protection. One of the chiefs of the upper Niger sent Zweifel and Mousteir red Kolas wrapped in green leaves as a sign that they would not be permitted to ascend certain sacred water-courses included in their programme.

In religious and judicial proceedings they are equally important. All oaths are taken on these seeds: the witness holds his hand over them, swears, and then eats them. An accuser demanding justice brings to the judge a little basket of rice with four or five Kolas upon it. The sorcerers lay great stress on the attractive qualities of this seed in drawing away evil spirits, sickness, and misfortune. Friends place with the dead some Kolas, that he may safely endure his 'long journey;' and, to crown all, the Mahometans declare it to be a fruit of divine origin, brought to earth by the Prophet himself.

The nut is chewed as if it were tobacco; the powder is eaten. The taste is sweet, astringent, and bitter in succession. Europeans as well as negroes are devoted to it. It not only sustains the system under the greatest fatigues, even without food and for long periods, but it is also a certain preventive of the dysenteries and deadly fluxes which render that region so unhealthy. The powder makes foul water drinkable and harmless. The negroes, without sufficient cause, regard it as an aphrodisiac; and for this reason, in Martinique, in the botanical garden, where there is a plant brought from Africa, the director has never been able to save a single seed for propagation.

— Apropos to Professor Leidy's interesting article in No. 43, a correspondent draws our attention to the fact that the botanists have not overlooked the crystals in the bark of forest-trees. See, for example, Gray's Botanical text-book, from second to fifth editions, in which those in the bark of the locust-tree are mentioned, and those of hickory figured.

— Dr. A. Graham Bell has reprinted in pamphlet form, from the 'American annals of the deaf and dumb,' a very interesting account of the method followed by him in teaching a boy, deaf from his birth, to read the written language and to write English himself. The child was five years old when the course of instruction described began, and had received only three weeks' private instruction from the principal of the Boston school for the deaf and dumb. About a year later he was able to write a letter to his mother, which, to be sure, contains many mistakes, and is not always readily intelligible in its sentences, but which yet shows that he could already communicate with others in writing. The author gives specimens of such letters written without assistance. One cannot read these few pages without a strong feeling of admiration for the ingenuity and patience displayed in producing such a result, which shows how much can be done for the early education of the deaf and dumb.

— Mr. Estaban Duque Estrada, a native Cuban, has made an extended investigation of the useful qualities of the best Cuban woods, with a view to exhibiting the resources of his country in this direction, and to the opening of our markets to his native timber. The research was made in the mechanical laboratory of the department of engineering of the Stevens institute of technology, and included the determination of moduli of resistance in tension, torsion, and compression, as well as for transverse loading. The woods are specified by their Cuban and by their botanical names, and can thus be identified. The first part of the work is now published; and the moduli of elasticity found for forty woods of sixteen distinct species are given, together with a full description of the apparatus, and the methods of test. These moduli are all high, and run very uniformly, usually above two millions. But one (Caoba) falls under a million and a half. The stiffest woods are the Dagame (Colycophyllum candidissimum) and the Jiqui Comun (Bumelia nigra), which have a modulus of two millions and a half.

The woods described are nearly all hard, strong, heavy, highly colored, taking a handsome finish, and excellent for constructive purposes. Some of them are not liable either to decay, or to injury by insects. They seem quite likely, should they become known through Mr. Estrada's work, to prove exceedingly valuable additions to the stock of available woods for the American market; and their introduction is likely to afford a valuable commerce, if it is properly encouraged by our own consular department and the Cuban officials. A full account of this part of the investigation is given in *Van Nostrand's magazine* for November.

—The Johns Hopkins university circular for November announces the resignation of Professor Sylvester from the chair of mathematics, and his early return to Europe. His loss to this country will be keenly felt by our mathematicians, for his presence and activity have given mathematical studies a remarkable stimulus in this country. We notice, in the December number of the *American journal of mathematics*, so long conducted by Professor Sylvester, the name of Dr. Craig given as assistant editor, which we trust indicates that it will be continued by the latter after Professor Sylvester's departure. The Johns Hopkins university has recognized the value of Professor Sylvester's services by electing him *professor emeritus*, and by passing resolutions in which the board of trustees "cordially extend to him its hearty thanks for the invaluable services which he has rendered to the university, and also its profound sense of the great ability, the conscientious fidelity and untiring energy, with which he has discharged the arduous duties of his chair, thereby elevating the science of mathematics to its proper plane, not only in this institution, but in this country."

The circular also announces the acceptance by Dr. Paul Haupt, professor of Assyriology in the University of Göttingen, of a call to the Johns Hopkins university as professor of the Shemitic languages. Dr. Haupt has already commenced his work, and has classes organized in Hebrew, Arabic, Assyrian, Ethiopic, and Sumero-Accadian.

— Killingworth Hedges described to the British association the fire risks of electric lighting, and is thus reported in *Nature*. There is a great difference between the electric currents which have been in constant use for telegraphic purposes and those which are to be supplied by the undertakers under the Electric-lighting act. The latter can be said to be free from danger only when the heat generated by the current is utilized in its right place, and not developed in the conductors or wires which lead the electricity to the incandescent lamps. The Fire-risk committee have already issued rules for guidance of users of electric light. These can hardly be said to embrace all the salient points of the new subject, which can only be arrived at after years of practical work. The necessity of proper regulations has already been recognized by the insurance-offices, both in the United States and Germany; and some of their special rules are given in this paper. The conductors must be properly proportioned for the current they have to carry. Whatever resistance there is in the conductor will cause a corresponding development of heat, which will vary with the amount of electricity passing, and inversely as the sectional area. As the temperature in Dr. Matthiessen's experiments upon the subject was not increased over 100° C., the author has made some further experiments, heating the wires by the electric current from a secondary battery to within a few degrees of their melting-point. Various materials were tried; the wires and foils having such sectional area, and being so arranged, that, on the current being increased by twenty per cent, they were immediately fused. The total length of each experiment was twenty-four hours, during which time the current passing through varied slightly. The results of the experiments were given.

— Mr. Joseph Thacher Clarke is giving a course of three lectures on classical archeology before the Johns Hopkins university, in one of which the recent work at Assos, under his direction, will receive special attention.

— On Nov. 13 the Arlberg tunnel, the third largest not only in Europe but in the world, was opened. It was not exactly the formal opening which took place Nov. 13 (this was celebrated Nov. 20), but the sounding-rod (three metres long) of the powerful boring-machine penetrated from the west side to the east gallery. A mass of rock sixty centimetres thick still separated the two galleries. One gallery was driven from St. Anton, on the Tyrolese side, and the other gallery from Langen in Vorarlberg. Both galleries sloped upward into the mountain; the Tyrolese rising two feet in a thousand, the steeper Vorarlberg fifteen feet in a thousand. When the Tyrolese section had penetrated 4,102 metres, it was continued downwards at the grade of the eastern end, the point of intersection lying nearer the west than the east mouth of the tunnel. As with the St. Gothard tunnel, there was but one mistake in the measurement, the length of the tunnel being three metres less than was computed.

The construction of the tunnel (10,263 metres long was begun June 22, 1880, by hand, and Nov. 13 of the same year, machines were introduced; so that an opening was made just three years to a day from the first time that the point of the drill, driven by compressed air, was forced into the gneiss of the Arlberg. The laying of the road is to be completed in six months, so that business may be conducted about the middle of May.

The St. Gothard tunnel is 14,900 metres long. The boring in Airolo and Göschenen began in 1873. After seven and a half years' work, the last layer of rocks was broken through Feb. 29, 1880; and June 1, after nine years and a quarter consumed in its construction, the road was opened to commerce. The Mount Cenis tunnel (12,323 metres long) was built in fourteen years and a quarter.

With the completion of the Arlberg tunnel by the union of the Adriatic Sea and Europe's granary, Hungary, a further connection is established with the heart of the continent. The Arlberg road, therefore, has not only for Austria-Hungary, but more especially for Switzerland, great commercial and political significance.

— Dr. H. Newell Martin, of Johns Hopkins university, gave, in November, four lectures on the minds of animals, before the Peabody institute of Baltimore, covering the subjects of instinct and reason, the emotions and moral sense, in animals.

— *La Nature* presents an illustration of the new form of equatorially mounted telescope, lately set up at the observatory of Paris, in which the tube of the instrument is bent at right angles; one portion of it constituting the polar axis of its mounting, and the other moving thus in the plane of the equator. The rays of light from any celestial object are brought to the eye of the observer after reflection from two mirrors, the loss of light from which is said to be inappreciable. This form of mounting does away with the customary dome covering the equatorial; and the observatory may be said to consist of two parts, — the movable one, covering the object-glass end of the telescope; and the fixed part, that in which the observer sits and makes his observations, completely protected against the weather. The new instrument is the most powerful one at the Paris observatory, and was built by MM. Eichens and Gauthier, and the brothers Henry. The form of construction is due to M. Loewy, and it has been built through the liberality of M. Bischoffsheim.

— In a late number of *Naturen*, Dr. Geelmuyden has a paper entitled 'Om Islaendernes gamle kalendere,' or the ancient calendars of the Icelanders, the chief peculiarity of which lay in the regarding of the week as the unit of measurement of time. There was also a year of fifty-two weeks, or three hundred and sixty-four days, as also twelve months of thirty days each; the last of these coming in the summer, and having the *Sumar-auke*, or summer addition of the four extra days. The half-years were called *misseri*, and were more frequently employed as a measurement of time than the full year itself. About the year 1000, when Christianity was introduced into Iceland, the calendar of that nation was modified into a near approximation to the Julian calendar; and early in the year 1700 the new style of reckoning was adopted in Iceland, at the same time with Norway and Denmark.

— The following persons, formerly connected with Johns Hopkins university, have received recent appointments: Edward Barnes, professor of the higher mathematics in the Rose polytechnic institute, Terre Haute, Ind.; William C. Day, professor of chemistry and physics in St. John's college, Annapolis; George S. Ely, professor of mathematics in Buchtel college, Ohio; Kakichi Mitsukuri, professor of zoölogy in the University of Tokio, Japan; William A. Noyes, professor of chemistry in the University of Tennessee; and William T. Sedgwick, assistant professor of biology in the Massachusetts institute of technology, Boston. It is also stated by the *Nation* that Dr. C. S. Hastings has received the appointment to the chair of physics in the Sheffield scientific school of Yale college, New Haven.

— Dr. John Rae writes in the *Athenaeum*, "In the *Athenaeum* of the 28th of July there is an extract from a letter of Capt. H. P. Dawson, to the following effect: 'On inquiry, I find that all the far-off Indians describe stone pyramids or altars on the tops of some of the hills far to the north and east of this, . . . composed of blocks of roughly hewn stone of a size such that the men of these days cannot lift. . . . The Indians look upon these remains with great dread, and will not go near them.' I do sincerely hope that Capt. Dawson may discover something new on these reported monuments of 'roughly hewn stone;' but I fear they will be found to be the well-known work of the Eskimo, who, where the country is hilly and rocky, delight in putting up stones of very considerable size — although not larger than a few men can lift — in all sorts of picturesque forms, especially in the neighborhood of a favorite camping-place. An excellent illustration of these Eskimo constructions may be seen in the narrative of Sir George Back (facing p. 378), describing his descent of the Great Fish River in 1834. The Indians, unless they are in great numbers, have a very wholesome and wide-spread fear of the Eskimo, and therefore have a 'great dread of going near these remains,' thinking they might meet the people who built them."

— Professor William Trelease, of the University of Wisconsin, will give four lectures in January, upon the fertilization of flowers, before the Johns Hopkins university.

— It is stated in *Nature* that the meeting of the Linnean society of London for Dec. 6 was to be exclusively devoted to the reading of a posthumous essay on instinct, by the late Mr. Darwin. The essay was said to be full of important and hitherto unpublished matter with regard to the facts of animal instinct considered in the light of the theory of natural selection; and, as the existence of the essay has only now been divulged, this meeting of the Linnean society must have been of an unusually interesting character.

— Prof. S. P. Langley, of Allegheny observatory, will give six illustrated lectures next February, on the sun and stars, before the Peabody institute of Baltimore.

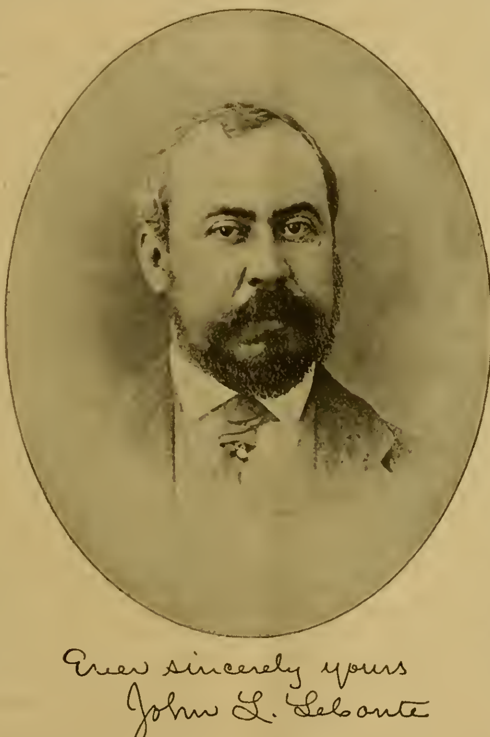
SCIENCE.

FRIDAY, DECEMBER 21, 1883.

JOHN LAWRENCE LECONTE.

American science has suffered a sad loss in the death of one of its best-known exponents. An advanced leader in his own department, profound and accurate in his labors, a cultured scholar, a genial companion and a true friend, — such a man was LeConte.

John L. LeConte, the son of Major John Eatton LeConte and Mary A. H. Lawrence, was born May 13, 1825, in New-York City. When but a few weeks old, his mother died, and the father thenceforward devoted himself to the care and development of his only child. The father died in 1860, having seen his son rise to a foremost place among the naturalists of his day.



On arriving at suitable age, he was placed in St. Mary's college, Maryland, from which he was graduated in 1842. The discipline of the school was severe, the training accurate and thorough. Early in his pupilage he exhibited decided tastes for natural-history studies outside of the scholastic course, greatly to the alarm of his tutors. The father, on being apprised of this, was greatly pleased, and directed that the tendencies should not be repressed, inasmuch as the boy exhibited no deficiency in his regular studies. His progress in the study of mathematics and languages was rapid and thorough, and doubtless laid the foundation for the accuracy and retentiveness of his memory, so marked in his maturer years. After the completion of the college course, he returned to his native city, and entered the College of physicians and surgeons of New York, receiving his medical degree in 1846.

For many years Major LeConte had been in correspondence with European entomologists, notably Dejean, and laid the foundation of the cabinet, now greatly enlarged, which made the basis of the future labors of the son. In 1844 the first essays of the latter in original work made their appearance, with unmistakable evidences of his youth and inexperience.

During 1849 he made several visits to the Lake-Superior region, once in company with Professor Agassiz, collecting largely, and publishing the results in Agassiz' work on that region. In the autumn of 1850 he visited California, remaining the greater portion of the following year, stopping for a while at Panama, collecting largely in many departments of natural history in a region in which nearly every thing was new to science, extending his explorations through the Colorado desert and as far east as the Pima villages. The material collected in these regions was carefully studied on his return, and the results published in the annals of the New-York lyceum. In 1852 the LeContes removed to Philadelphia, where the greater portion of the scientific labors of both have since been published. For a few months in 1857 LeConte accompanied the Honduras interoceanic survey, under the late J. C. Trautwine, publishing his observations in the report of that expedition. He visited at the same time the Fuente de Sangre, contributing an account of that phenomenon in Squier's 'Nicaragua.'

After these voyages, LeConte's scientific labor was uninterrupted until the breaking-out of the war. In 1862 he was appointed surgeon of volunteers, and shortly after made medical inspector with the rank of lieutenant-colonel; in which position he remained until 1865, exhibiting a capacity for organization and direction in a wider field than the cabinet to which he had hitherto confined himself.

During the summer of 1867 he acted as geologist of the survey for the extension of the Union Pacific railway southward to Fort Craig, under the command of Gen. W. W. Wright. His report, which in no way detracts from his reputation as an entomologist, was published as part of the report of the survey.

In the autumn of 1869 he started for Europe with his family, remaining abroad until near the close of 1872, visiting, in the mean time, Algiers and Egypt. His residence abroad interrupted somewhat his authorship, but not his studies. He visited all the accessible public and private museums; and his wonderful memory of the species of his own cabinet enabled him to settle many doubtful points of synonymy. Those who met him abroad were deeply impressed by his thorough scholarship, and his quick and accurate perception of the affinities of Coleoptera which he had never before seen. On his return he resumed his labors, which continued, with slight interruptions by ill health, until within a week of his death.

LeConte's career in science began in 1844 with his first paper in the proceedings of the Philadelphia academy, followed by others in other journals: these gave but little evidence of the future powers of the man, until, in 1850, his 'Monograph of Pselaphidae' appeared, in which an arrangement of these minute forms was proposed which remains at present the basis of the general classification of these insects. Shortly after appeared his 'Attempt to classify the longicorn Coleoptera of America, north of Mexico,' — a work of far wider application than indicated by its title, in which numerous suggestions of new characters and wider applications of old ones are found.

To follow his papers from this period would be a history of scientific coleopterology in America. Their importance and utility attracted attention abroad, and many were reprinted in whole or in part. As to their scope, they cover nearly every family in the order: and in every case his work is an improvement on what preceded it; he always left a subject better than he found it.

Several of his works require a special notice. His edition of the entomological writings of Say, in which he was assisted in their departments by Baron Osten-Sacken and Mr. P. R. Uhler, proved of inestimable value to students by placing within easy access the works of that pioneer of American science. The volumes appeared in 1859, have run through several editions, and are still in demand. Realizing that his favorite branch needed greater encouragement, he undertook, in 1860, the 'Classification of the Coleoptera of North America,' with the accompanying list of species, and descriptions of new forms. This work was never completed, but extended to the end of the Cerambycidae. The interruption of the work by the war made an interval of time in which the edition of the earlier-issued parts became exhausted, and, to a certain extent, antiquated from more recent studies. The results of this book are abundantly shown in the vast increase in the number of intelligent students and collectors, accompanied by a further demand for the exhausted edition, rendering a new one necessary.

Before the new edition could be prepared, it became imperative to study the Rhynchophora; and at this point LeConte made one of the boldest strokes of his career in the isolation of that series from other Coleoptera, and by proposing a classification of them as remarkable in novelty as it was true to nature. This was followed by the 'Species of Rhynchophora,' published as a separate volume by the American philosophical society.

The preparatory studies having been thus completed, LeConte looked forward with pleasure to an entirely new work to replace the old 'Classification,' and my co-operation was invited in the preparation of monographic essays. Two years ago, his health then slightly failing, he expressed the desire that the authorship of the new work should be equally divided; and in January, 1882, the work was begun. It was completed in March, 1883, in time for him to realize that it had been at least well received. To speak further of this work would, for obvious reasons, be inappropriate: suffice it to say, that his first edition made the ground-work of the second, and his spirit actuated the embellishment of the superstructure.

Since the completion of this work, his health has not admitted of much study; but he continued his work until within a few days of his death, and the incomplete manuscript will be published in the form he desired.

While LeConte's reputation will be based on his entomological writings, he by no means limited himself to this field. Mention has already been made of several important geological contributions. There are others of less moment. He has contributed a number of articles on vertebrate paleontology, and several on existing mammals. His 'Zoölogical notes of a visit to Panama' (*Proc. Philad. acad.*, 1852) illustrate the extent of his study in another direction. At least one article on purely social science has emanated from his pen.

In a general review of his writings, LeConte is found remarkably free from controversial tendencies. He gave to science the best results of his labor, knowing that what was worthy would in time be adopted. I know that he was better pleased to have errors of his own corrected than to correct those of another. He was above the limit of those petty jealousies which too often prevail between active workers in the same field. Those who sought his advice or assistance, either in person or by correspondence, were always made welcome; and the numerous cabinets determined by him gave evidence alike of his industry and liberality. The result of LeConte's labors has been the elevation of coleopterology in America from a traditional knowledge to a science with a permanent and distinctive literature.

LeConte was president of the American association for the advancement of science in 1874; and his address on retiring, regarding the relations of the geographical distribution of Coleoptera to paleontology, opened a new field for the thoughtful student.

No prominent public position was ever held by LeConte. He was urged by his friends for the position of commissioner of agriculture; and, while he received an indorsement of which any man might be proud, the choice of President Hayes gave it to another. That his eminence as a naturalist was recognized is shown in the numerous societies, at home and abroad, of which he was elected a member. Of the entomological societies of London, France, and Berlin, he was made an honorary member, — a distinction attainable by few, from the limited number allowed by the societies' rules. At the time of his death he was president of the American entomological society, and a vice-president of the American philosophical society.

In 1861 Dr. LeConte was married to Helen, daughter of the late Judge Grier, who, with two sons, survives him.

Dr. LeConte died Nov. 15, 1883, and was buried in West Laurel Hill cemetery, in the vicinity of Philadelphia. His death is an irreparable loss to American science, and a calamity in his special department.

George H. Horn.

THE WEATHER IN OCTOBER, 1883.

The monthly review of the U. S. signal-service gives in copious detail the weather conditions which prevailed in October. The peculiar features of the month were the deficiency in temperature and excess in rainfall in the greater part of the country. The former was most strongly marked in the Missouri valley and New England, the mean temperature falling below the average 3°.7 and 3°.6 respectively in these districts. In Tennessee, Florida, the Rio Grande valley, the South Atlantic and Gulf states, however, the mean temperature was from 2°.5 to 4°.3 above the average; so that the distribution of temperature was rather irregular. One instance of a maximum temperature of 100° was noted, while the frosts were frequent.

The distribution of rainfall is indicated by the following table: —

Average precipitation for October, 1883.

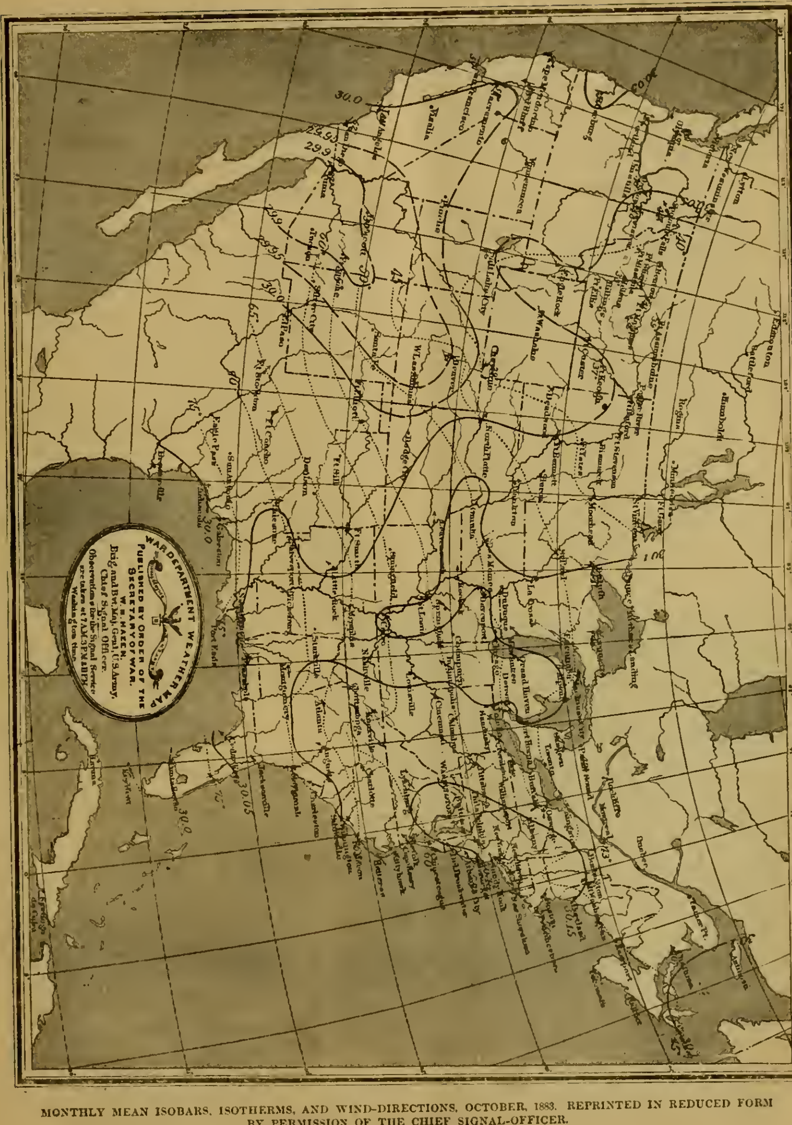
Districts.	Average for October. Signal-service observations.		Comparison of October, 1883, with the average for several years.
	For several years.	For 1883.	
	Inches.	Inches.	Inches.
New England	3.82	6.23	2.41 excess.
Middle Atlantic states .	3.07	5.13	2.06 excess.
South Atlantic states . .	4.77	3.14	1.63 deficiency.
Florida peninsula . . .	6.27	9.09	2.82 excess.
Eastern gulf	3.79	2.51	1.28 deficiency.
Western gulf	3.75	5.23	1.48 excess.
Rio Grande valley . . .	3.86	0.94	2.92 deficiency.
Tennessee	3.42	5.60	2.18 excess.
Ohio valley	3.04	6.75	3.71 excess.
Lower lakes	3.12	2.86	0.26 deficiency.
Upper lakes	3.80	3.62	0.18 deficiency.
Extreme north-west . .	2.01	2.93	0.92 excess.
Upper Mississippi valley,	3.19	4.82	1.63 excess.
Missouri valley	2.01	4.12	2.11 excess.
Northern slope	0.81	1.94	1.13 excess.
Middle slope	1.26	3.40	2.14 excess.
Southern slope	1.57	2.98	1.41 excess.
Northern plateau . . .	2.50	1.64	0.86 deficiency.
Southern plateau . . .	0.67	0.84	0.17 excess.
North Pacific coast. . .	4.45	3.49	0.96 deficiency.
Middle Pacific coast . .	1.11	1.71	0.60 excess.
South Pacific coast . . .	0.33	1.16	0.83 excess.

The drought in New England and in some portions of the Southern States was broken by the copious rains of the month, but still continued in other sections.

The storms of the month present some noticeable features. The weather over the North Atlantic Ocean was generally stormy, being attended by a succession of strong westerly breezes. There were seven depressions charted on the ocean, all of which moved in a north-easterly direction. Of these, four were continuations of storms in the United States, one of which moved to the British coast; and one was a tropical hurricane which gave evidence of its presence off the Atlantic coast by high winds at coast stations, and which moved north-eastward as far as the twentieth meridian. Nine depressions were charted in the United States; all, with one exception, moving north-easterly, and but one being a severe storm. This occurred on the 17th and 18th, causing violent gales on Lake Michigan, though few casualties were reported. One depression moved in quite an unusual path: it was reported at Yuma, Arizona, on the 2d, and moved in a northerly direction into British America. There is reason to believe that it was a tropical hurricane which crossed Mexico in the latter part of September from the Caribbean Sea, and, recurving in the Pacific, entered the country in Arizona as a weak depression. All of the tropical hurricanes of this season have run their courses mainly in the ocean. Though they have been fully as numerous and as severe as usual, their ravages have been confined to the islands in their path and to the vessels exposed to their fury.

Sunspots continue to be numerous. There was only one brilliant aurora in October, and this was observed principally in New England and northern New York. Severe shocks of earthquake were experienced in San Francisco on the 9th and 10th, causing considerable alarm, but no material damage. A new volcano has made its appearance, bursting out in Bering Sea: it has been exceedingly active, having already formed an island eight hundred to twelve hundred feet high. On the 20th a shower of mixed sand and water fell at Unalashka, sixty miles east of the volcano, which may have come from it.

The accompanying map represents the mean pressure, temperature, and wind-directions. The former is worthy of note because of the regular increase of pressure from west to east. Usually there are two high areas in October, — one near the eastern coast, and the other in the north-western territories. The latter was wanting in October of this year.



MONTHLY MEAN ISOBARS, ISOTHERMS, AND WIND-DIRECTIONS, OCTOBER, 1883. REPRINTED IN REDUCED FORM BY PERMISSION OF THE CHIEF SIGNAL-OFFICER.

A NEW RULE FOR DIVISION IN ARITHMETIC.

THE ordinary process of long division is rather difficult, owing to the necessity of guessing at the successive figures which form the divisor. In case the repeating decimal expressing the *exact* quotient is required, the following method will be found convenient.

Rule for division.

First, Treat the divisor as follows: —

If its last figure is a 0, strike this off, and treat what is left as the divisor.

If its last figure is a 5, multiply the whole by 2, and treat the product as the divisor.

If its last figure is an even number, multiply the whole by 5, and treat the product as a divisor.

Repeat this treatment until these precepts cease to be applicable. Call the result the *prepared divisor*.

Second, From the prepared divisor cut off the last figure; and, if this be a 9, change it to a 1, or, if it be a 1, change it to a 9: otherwise keep it unchanged. Call this figure the *extraneous multiplier*.

Multiply the extraneous multiplier into the divisor thus truncated, and increase the product by 1, unless the extraneous multiplier be 7, when increase the product by 5. Call the result the *current multiplier*.

Third, Multiply together the extraneous multiplier and all the multipliers used in the process of obtaining the prepared divisor. Use the product to multiply the dividend, calling the result the *prepared dividend*.

Fourth, From the prepared dividend cut off the last figure, multiply this by the current multiplier, and add the product to the truncated dividend. Call the sum the *modified dividend*, and treat this in the same way. Continue this process until a modified dividend is reached which equals the original prepared dividend or some previous modified dividend; so that, were the process continued, the same figures would recur.

Fifth, Consider the series of last figures which have been successively cut off from the prepared dividend and from the modified dividends as constituting a number, the figure first cut off being in the units' place, the next in the tens' place, and so on. Call this the *first infinite number*, because its left-hand portion consists of a series of figures repeating itself indefinitely toward the left. Imagine another infinite number, identical with the first in the repeating part of the latter, but differing from this in that the same series is repeated uninterruptedly and indefinitely toward the right, into the decimal places.

Subtract the first infinite number from the second, and shift the decimal point as many places to the left as there were zeros dropped in the process of obtaining the prepared divisor.

The result is the quotient sought.

Examples.

1. The following is taken at random. Divide 1883 by 365.

First, The divisor, since it ends in 5, must be multiplied by 2, giving 730. Dropping the 0, we have 73 for the prepared divisor.

Second, The last figure of the prepared divisor being 3, this is the extraneous multiplier. Multiplying the truncated divisor, 7, by the extraneous multiplier, 3, and adding 1, we have 22 for the current multiplier.

Third, The dividend, 1883, has now to be multiplied by the product of 3, the extraneous multiplier, and 2, the multiplier used in preparing the divisor. The product, 11298, is the prepared dividend.

Fourth, From the prepared dividend, 11298, we cut off the last figure, 8, and multiply this by the current multiplier, 22. The product, 176, is added to the truncated dividend, 1129, and gives 1305 for the first modified divisor. The whole operation is shown thus: —

```
        1883
           6
       -----
       1129|8
        176
       ----
       130|5
       110
       ---
        2|40
       88
       |90
     -----
     19|8
    176
    ---
     19|5
    110
    ---
     12|9
   198
   ---
    2|10
   22
   --
   24
```

We stop at this point because 24 was a previous modified dividend, written under the form 240 above. Our two infinite numbers (which need not in practice be written down) are, with their difference, —

$$
\begin{array}{r}
\dot{1}0,958,90\dot{4},058 \\
\underline{\dot{1}0,958,90\dot{4},109.58904\dot{1}0958904\dot{}} \\
51.58904\dot{1}095890\dot{4}
\end{array}
$$

Hence the quotient sought is $5.\dot{1}5890410\dot{9}$.

Example 2. Find the reciprocal of 333667. The whole work is here given: —

```
  33366|7                        7
 233567                    1634969
                          2102103
                          226559|9
                         2102103
                         232866|2
                         467134
                         700000
```

Answer, $.\dot{0}0000299\dot{7}$.

Example 3. Find the reciprocal of 41.

```
Solution. —  41                     9
            37|9                   33|3
                                  111
                                  144
                                 148
                                 16|2
                                 74
                                 90
```

Answer, $.\dot{0}243\dot{9}$.

C. S. PEIRCE.

URNATELLA GRACILIS, A FRESH-WATER POLYZOAN.

A PAPER on this polyzoan, by Professor Joseph Leidy, has been recently published, with illustrations, in the *Journal of the Academy of natural sciences of Philadelphia*. Urnatella was originally discovered in 1851, and briefly noticed in the Proceedings of the academy the same year, and also subsequently in 1854, 1858, and 1870. It was found in the Schuylkill River at Philadelphia, but has not been seen elsewhere, except a dried but characteristic specimen on the shell of a Unio from Scioto River, Ohio.

Urnatella is an interesting and beautiful form, living in association with Plumatella and Paludicella, and having similar habits, but is very different from them or any other known fresh-water polyzoan, and is most nearly related with the marine genus Pedicellina. It is found attached to the under side of stones beneath which the water can flow. As commonly observed, it consists of a pair of stems divergent in straight lines, or rather gentle curves, from a common disk of attachment. The stems slightly taper, and are beaded in appearance, due to division into segments alternately expanded and contracted. The segments commonly range from two to a dozen, proportioned to the length of the stem, which, when longest, is about the eighth of an inch or a little more. The stems terminate in a bell-shaped polyp, with an expanded oval or nearly circular mouth slanting to one side, and furnished with about sixteen ciliated tentacles. The stems also usually give off a pair of lateral branches from the second segment succeeding the polyp, and frequently likewise from the first segment. The branches consist of a single segment or pedicle supporting a polyp, and usually also give off similar secondary branches. The first and second segments are cylindroid, highly flexible, and mostly striated and colorless, and appear mainly muscular in structure. The succeeding segments are urn-shaped; the body of the urn being commonly pale brown, ringed with lines, and marked with dots of darker brown. The neck and pedicle of the urns are black. The different colors give the stem a beaded and alternately brown and black appearance. Through the lighter colored body of the urns a central cord can be seen, extending through the length of the stem. The urn-shaped segments exhibit lateral pairs of cup-like processes, which correspond in position with the branches from the terminal pair of segments of the stem, and apparently indicate branches which have separated from the parent stem to establish themselves elsewhere as new polyp-stocks.

A series of specimens of Urnatella — from such as consist only of a simple cylindrical, flexible pedicle, supporting a polyp, to those with long stems, consisting of a dozen segments — indicates the urn-shaped segments to be formed successively through segmentation of the originally single simple pedicle. The segments, therefore, do not correspond with what were polyps; but the terminal polyp is permanent, and the segments originate by division from its neck, very much as the segments of the tape-worm arise from its head. After the destruction of the head, the segmented stem remains persistent; but what becomes of it ultimately has not been determined. Probably the segments may serve the purpose of the statoblasts of other fresh-water polyzoa, but the question has not

FIG. 1. — Urnatella gracilis. The one on the left with the polyps expanded; that on the right in the condition assumed when the animal is disturbed.

been ascertained. A common mode of propagation of Urnatella appears to be by budding, the formation of branches with their terminal polyps, and the detachment of these branches to establish stocks elsewhere. The different specimens apparently indicate this process, though it was not actually observed.

Though the stem of Urnatella is invested with a firm, chitinous integument, it still retains its flexibility; so that, when the polyp is disturbed, it not only closes its bell, and bends its head, but the entire stem bends, or even becomes revolute. Sometimes the polyps suddenly twist the stems from side to side, as if they had become wearied of remaining longer in the same position.

Fig. 2. — Urnatella gracilis, with the main stem of four segments, and a terminal expanded polyp. Branches are given off by the third segment, and a bud from the fourth.

The interior of the polyp is mainly occupied by the alimentary apparatus. From the mouth of the bell a funnel converges as the pharynx; and the tube of the former, as the oesophagus, occupies the shorter side of the bell. At the bottom of the latter the oesophagus opens into a capacious retort-like stomach, which occupies two-thirds of the capacity of the polyp. The stomach towards the mouth of the bell has an alembic-like pylorus, from which a short intestine turns ventrally to expand in an oval colon. From this a short rectum opens about the centre of the mouth of the bell. The pharynx, oesophagus, and stomach are lined with ciliated epithelium. The ventral side of the stomach has the epithelium colored brown, indicating, as in other polyzoa, an hepatic function. The polyp feeds on vegetable particles mainly, including diatoms, desmids, etc.; and the food may be observed in an incessant whorl in the axis of the stomach, induced by the action of the cilia lining the latter. The polyp is almost constantly infested with parasites, often in large numbers, which mingle with the food, and accompany this in its movement. The parasite is a ciliated infusorian, distinguished with the name of Anoplophrya socialis. From time to time, remains of the food are passed into the colon, and here accumulated into an oval pellet, which is then quickly discharged from the mouth of the bell.

Generative organs, or provision of any kind for the production of ova, were not detected, nor were eggs observed.

Urnatella differs from the marine genus Pedicellina mainly in not having an attached and creeping rootstalk, and in having free, pendent, and jointed stems, instead of simple pedicles.

THE PHYLOGENY OF THE HIGHER CRUSTACEA.

The class Crustacea is one of the dominant groups of the animal kingdom, and it includes a very considerable proportion of our living animals. Its representatives are extremely diversified in structure; and a single order, such as the Decapoda, includes a much greater variety and diversity of forms than the whole class of insects. It is very rich in primitive and transitional forms; and when we add to this, that there is no group in which our embryological knowledge is more rich and varied, or in which the embryological history of the individual throws so much light upon the evolution of the race, its importance as a means for tracing the actual history of the evolution of species is obvious. In fact, most of the problems in the logic of morphological reasoning, are, in great part at least, problems in the morphology of the Crustacea.

Since the awakening in natural science which followed the publication of the Origin of species, many naturalists have attempted to disentangle the story of the phylogeny of the Crustacea. Some of these attempts, such as Müller's 'Für Darwin' and Huxley's 'Crayfish,' are familiar to all; while others, such as Claus' 'Crustaceen system,' are known to none except specialists. The latest attempt in this field ("Studien über die verwandtschaftsbeziehungen der Malakostraken," by Dr. J. E. V. Boas, *Morph. jahrb.*, viii. 4, 1883) is, to say the least, a very valuable addition to crustacean morphology, as well as an interesting study in scientific logic. Its results seem to be a close approximation to the true natural classification of the higher Crustacea, and it should therefore receive the careful attention of all naturalists, and of all who wish to be informed regarding the methods of thought in morphology; but as it is from necessity filled with minute details, which would be formidable to all except specialists, the general reader must be contented with a summary of the results.

The proof that the crabs are descended from long-tailed decapods is familiar to all naturalists; and no one can doubt, that, among these, the swimming decapods, such as Penaeus, are the most primitive. So far, the phylogeny of the decapods may be regarded as definitely settled, and Boas proposes no modification of the accepted view; but his opinion regarding the origin of the swimming decapods from the lower Crustacea is novel, and the evidence which he furnishes seems to be conclusive. The Decapoda are generally regarded as the modified descendants of the schizopods; but Boas points out that the order Schizopoda is not a natural group, since the animals which have been included in it belong to two widely separated orders.

According to this author, the Euphausiacea and the Mysidacea are not at all intimately related. The latter are not in the line which leads to the Decapoda, and there is no natural group Schizopoda. He therefore divides the group into two orders, — the Euphausiacea and the Mysidacea: the former including the primitive unspecialized forms through which the Decapoda have been evolved from the lower Crustacea; and the latter containing highly specialized forms, which have been evolved from the Euphausiacea along an independent line, and which have no direct relationship to the Decapoda. He holds, that the Euphausiacea are a synthetic group of Crustacea which has given rise to several divergent groups of descendants. Of these, the decapod stem has undergone the least modification. A second stem, the Mysidacea, has diverged in an entirely different direction, has departed very widely from the primitive form, and has, in its turn, given rise to the Cumacea, and through these to the amphipods and isopods, the latter being the most highly modified of the Malacostraca. A third line of descent from the Euphausiacea has given rise to the Squillacea.

The recognition by Boas of the fact, that the group Schizopoda is not a natural one, and the discovery that the animals which have been thus associated may be divided into a very primitive group, the Euphausiacea, and a highly specialized group, the Mysidacea, seems to be a very great advance in crustacean morphology.

He gives the following definition of the Euphausiacea: —

Malacostraca, with the mid-body and abdomen compressed, with a well-marked bend in the abdomen; carapace well developed; the last segment of the mid-body a complete ring; eyes stalked; antenna with a large scale; mandible simple; first maxilla with broad, one-jointed palp, and with well-developed exopodite; second maxilla with a similar palp, and with exopodite, and a cleft lacinia interna. The appendages of the mid-body or cormopods all have a well-developed exopodite, and an epipodite which is subdivided in all except the first pair, where it is simple. The endopodite is thin and weak, and it does not end in a sharp point: it is more or less rudimentary on the last two pairs. The first cormopods are not specialized as maxillipeds, but are like the others. The abdominal feet are powerful swimming-organs, with an appendix interna. In the male the first or most anterior ones are specialized as copulatory organs. The tail-fins are well developed. The liver is composed of a great number of small lobes. The heart is short and wide. The halves of the reproductive organ are united by a transverse unpaired portion. Spermatophores are present, and the spermatozoa are simple round cells. There is an antennary gland. The young leaves the egg as a free-swimming nauplius, and the carapace of the older larva is a great phyllopod-like mantle.

It is easy to trace the relationship between this group and the decapods, on the one side, and, on the other side, through Nebalia, to the phyllopods and lower Crustacea.

The Decapoda natantia resemble the Euphausiacea in many conspicuous and highly important particulars. In these two groups alone, among the Malacostraca, we have a free-swimming nauplius; and in both the carapace of the larva is a great mantle. The abdomen is bent in both, and the integument is horny. The carapace, the abdominal appendages, the large tail-fin, and the pointed telson, are alike in both. The endopodite of the first pleopod is a copulatory organ in the decapods as well as in the Euphausiacea; and spermatophores are almost universal in these two groups, while they are found in no other Malacostraca.

The close relationship between these two groups can hardly be questioned; nor is it difficult to show that the Euphausiacea are the primitive, and the Decapoda the derived, form. In the presence of simple epipodites, and of a four-jointed palp on the first maxilla, the Penaeadae are nearer to the phyllopods than Euphausia; but in all other respects Euphausia is the most primitive, and it shows its close relationship to the lower Crustacea by many characteristics, among which are the following. The terminal joint of the cormopods is rounded and blunt, as it is in Nebalia, instead of being pointed, as it is in all the Malacostraca except Nebalia. There are no specialized maxillipeds; but the first cormopod is like all the others, as it is in Nebalia, and all the cormopods are furnished with exopodite and epipodite: while in all other Malacostraca there are true maxillipeds; and either the exopodites or the endopodites, or both, are absent on some or on all the cormopods. The antenna has a well-developed exopodite; and in the young this is flabellum-like, and very similar to that of the adult Limnadia or Estheria. This feature of resemblance to the lower Crustacea is shared by the young of the Decapoda natantia. The first maxilla has a large exopodite; while this is rudimentary in the Decapoda and Mysidacea, the only other Malacostraca where it occurs at all. The pleopods are much like those of Nebalia: they are efficient swimming-organs, and they are provided with an appendix interna. The spermatozoa, like those of the phyllopods, are simple round cells without tails; and this is true of no other Malacostraca except the squillas.

While the Euphausiacea are thus seen to be very much like the phyllopods in so many important features, they are true Malacostraca; and they have deviated greatly from their phyllopod ancestor, and have acquired a small carapace, differentiated cormopods with long slender endopodite, small exopodite divided into shaft and flabellum, and an epipodite which is purely respiratory. They also differ from Nebalia in the possession of that distinctively malacostracan organ, a tail-fin, made up of a telson and a pair of swimmerets.

The relationship of Nebalia to the Malacostraca on the one hand, and to the phyllopods on the other, has long been recognized, and Claus has even gone so far as to hold that this form is a true malacostracan; but Boas believes that it is neither a true malacostracan, nor the phyllopod from which the Malacostraca originated, but simply the nearest living ally of this ancestral form.

He believes that the presence of a great mantle-like carapace, of eight unspecialized, broad cormopods with leaf-like exopodites, of a furcated abdomen without tail-fins, and of eight abdominal somites, show that it is not a malacostracan, but a phyllopod. As many phyllopods, such as Limnetis and the Cladocera, have, like the Malacostraca, an exopodite on the second antenna, we must believe that the Malacostraca have inherited this feature from their phyllopod ancestor; and, as it is absent in Nebalia, this form cannot be the direct ancestor of the Malacostraca. So, too, the fifth and sixth pairs of abdominal feet are rudimentary in Nebalia, while they are well developed in nearly all Malacostraca. As most of the phyllopods, and some of the Malacostraca, leave the egg as a free-swimming nauplius, we must believe that this was true of the phyllopod ancestor of the Malacostraca; but as Nebalia does not pass through a free nauplius stage, but leaves the egg in a more advanced condition, it cannot be in the direct line of evolution. Boas therefore concludes that Nebalia is a true phyllopod, and that the Malacostraca have originated from a form somewhat different, although Nebalia is the closest living ally of this ancestral form.

Having thus traced the decapods back through the Euphausiacea to a phyllopod ancestor very similar to the recent Nebalia, we have now to trace the ancestry of the other Malacostraca. Boas holds that the squilloids are a branch from the Euphausiacea, and that the Mysidacea have been derived from the Euphausiacea along still another line of descent, and have, in their turn, given rise to all the remaining groups of Malacostraca.

The Mysidacea differ from the Euphausiacea and the decapods in many features which they show in common with the Cumacea and the amphipods and isopods; and it is not difficult to show, that, in these points of difference, the Euphausiacea are the primitive group, and the Mysidacea the modified group.

In Euphausia, as in the swimming decapods, the body and abdomen are compressed; while they are flattened and rounded in the Mysidacea, and the tip of the abdomen is directed backwards, lacking the peculiar bend of Euphausia and Penaeus.

The structure of the mandible is very instructive. In Mysis, as well as in the Cumacea and amphipods and isopods, the mandible is forked, the cutting part being widely separated from the crushing part; and between the two there is a row of setae, and a peculiar accessory appendix. In Euphausia and the decapods the appendix and row of setae are absent, and the chewing part is hardly separated from the crushing part. In Mysis, as in Cuma and the amphipods and isopods, the palp and exopodite of the first maxilla are absent, and the laciniae are turned forwards as well as inwards; and in all these forms the laciniae of the second maxilla are directed forwards. They overlap, and the lacinia interna is undivided. In Euphausia, the decapods, and squillas, there are no brood-pouches; but these structures are present in Mysis, as well as in the Edriophthalmata, and they are formed in essentially the same way in all, — by plates which are developed on the basal joints of certain of the cormopods. In all these forms the young pass through a long metamorphosis within these pouches. The liver is comparatively simple. There are no spermatophores, and the spermatozoa have tails. The Cumacea are regarded by Boas as a greatly modified offshoot from the Mysidacea; and the amphipods and isopods are derived from an ancestral form somewhat like, but more primitive than, the living Cumacea.

As regards the position of the amphipods and isopods, Boas's view is directly opposite to that which has been generally accepted; as he regards these as the most highly specialized and divergent of the Malacostraca, instead of low and primitive forms. The conspicuous segmentation of the nervous system, the absence of a carapace, the sessile position of the eyes, the great number of similar somites, the worm-like shape of the body, and the elongation of the heart, — all seem at first sight to show that these forms are ancient and low. Boas points out that the nervous system gives no proof of a primitive condition, as there are as many independent ganglia in Mysis as there are in the sessile-eyed Crustacea. It is true that the heart is longer than it is in Mysis; but there are only three pairs of ostia, and the length of the heart, as compared with that of the mid-body, is no greater than it is in Mysis. As the eyes are stalked in Nebalia, the nearest ally of the Malacostraca, all of the latter must have inherited stalked eyes from their phyllopod ancestors, and the sessile eyes of the Edriophthalmata must be due to secondary modification. So, too, regarding the absence of a carapace. As the Malacostraca inherit this structure from the phyllopods, those forms in which it is absent must have lost it by secondary modification. The same thing is true of the absence of a scale on the antenna. There is, therefore, no proof that these animals are primitive; and the many points of resemblance to the Mysidacea which we have just noticed show the close relationship between these groups. But as the Mysidacea, like Euphausia and the decapods, have stalked eyes, a carapace, and a fused mid-body, exopodites in first maxillae, exopodites and palpi in second maxillae and on cormopods, and as a seventh abdominal segment is present, we must believe that the Mysidacea are the more primitive group, and the Edriophthalmata their recently modified and highly specialized descendants.

Boas believes that most of these differences are due to the fact that the Edriophthalmata have become adapted for running instead of swimming; and he thus explains the loss of the exopodites of the cormopods, the strengthening of the endopodites, the shortening of the abdomen, the loss of power in the pleopods, the flatness of the body and abdomen, the thickening of the integument, and the loss of eye-stalks and of the antennary scale. The respiratory function of the pleopods he attributes to the loss of the carapace, and the thickening of the integument.

The general conclusions of this highly suggestive and interesting paper may be summarized as follows.

The Malacostraca are descended from the phyllopods, among which Nebalia is their nearest relative.

The Euphausiacea are the most primitive Malacostraca. The decapods originated from the Euphausiacea, although the most primitive decapods, the Natantia, are now widely separated from this ancestral form. The Squillacea stand by themselves, their nearest, although distant, allies being the Euphausiacea. They show in certain points a more primitive condition than any other Malacostraca; although, as a whole, they are highly modified.

The Mysidacea are also derived from the Euphausiacea; although they are so different from them that they must be placed in a distinct order, and the group Schizopoda must be abandoned. The Mysidacea have no close relationship to the decapods.

The Cumacea arise from the Mysidacea, and the amphipods and isopods from a form between the Mysidacea and the Cumacea. The amphipods and isopods are not a primitive group distantly related to the Podophthalmata, but they are the most highly specialized of the Malacostraca.

He gives the following as his phylogenetic classification of the Crustacea: —

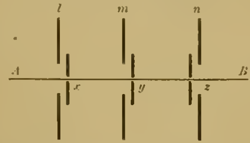
LETTERS TO THE EDITOR.

Radiant heat.

Mr. Fitzgerald has favored me with a paper [1] in which he takes exception to my views respecting radiant heat,[2] wherein he says, —

"Suppose that two regions, *A* and *B*, be separated by three parallel screens, *l*, *m*, and *n*, having apertures in them, *x*, *y*, *z*, capa-



ble of being opened and closed from the centre, so as to make everything perfectly symmetrical round the line *AB*, perpendicular to the screens. Now, if *x* be opened for a very short time, a certain quantity of radiant energy will escape out of *A* into the region between *l* and *m*; and if *y* be opened when this heat reaches *m*, it can certainly be let on into the region *mn*; and if *z* be similarly opened when it reaches it, this radiant heat will get into *B*. While *z* was open, however, some heat left *B*; but, as Dr. Eddy observes, *y* may be closed so as not to let this even get through the screen *m*, and it can be all returned into *B* by reflection through *z* or some other aperture. So far I entirely agree with Dr. Eddy, and so far it seems as if the result had been to transfer heat from *A* to *B* without *B*'s losing any heat by having it transferred to *A*. As I warned Dr. Eddy when I heard his paper, there are, however, other bodies and regions to be considered besides *A* and *B*. There are more than two bodies considered: there is the region of the screens. Consider what happens when the heat that escaped out of *B* into the *mn* region tries to get back into *B*. Some door must be opened to let it pass; and, while it is passing in, an at least equal amount of heat will be passing out of *B* into the *mn* region, so that you can never really get the heat that has once left *B* back into *B* again. This is true, whether you adopt doors over fixed apertures, such as I have supposed, or moving apertures, such as Dr. Eddy proposed. What really takes place is this: a certain quantity of heat escapes out of *A* and reaches *B*; and a not less quantity of heat leaves *B*, and is kept entangled in the region of the screens, and it is only possible to let the heat pass from *A* to *B* by means of this third region. Hence this only really comes to the same thing as letting *A* radiate some of its heat into the screen region, while *B* is kept closely shut up. Now, be it observed that Dr. Eddy practically postulates that this screen region is at least colder than *A* — in fact, he assumes it to be perfectly cold, i.e. to contain no radiant heat except what is admitted from *A* and *B*, so that it is by no means contrary to the theory of exchanges that *A* might cool by radiating into this region."

Now, Mr. Fitzgerald has stated only two of the three things which occur while the door *z* is open. He omits to state, that in my process a certain amount of heat which has come from *A* also passes through the door *z* every time it is opened, into the region *B*; and this is all which is proposed to be accomplished by the process which is at all unusual or peculiar. Thus the fact remains, that although a definite amount of heat from *B* remains entangled in the region *mn*, which is not increased with the lapse of time, there is a continued passage of heat through this region into *B*, that being the very object sought to be accomplished by my process. It is not easily seen how the arrangement of screens and apertures proposed by Mr. Fitzgerald could be so manipulated as to bring the heat coming from *A* into a position such

[1] On Dr. Eddy's hypothesis that radiant heat is an exception to the second law of thermodynamics. By George F. Fitzgerald, M.A., F.T.C.D., *Sc. proc. roy. Dubl. soc.*, iv. pt. 1.

that it would be in readiness to pass into B at the same time as the heat which originally came from B is returned to B, though my arrangement of moving screens readily accomplished this, as was admitted by Prof. J. Willard Gibbs in his criticism of my paper.[1]

Area of a plane triangle.

In the *Mathematical magazine* (Erie, Penn.) for April, Mr. James Main publishes, as a matter of curiosity, a collection of ninety-four expressions for the area of a plane triangle. In *Mathesis* (Gand, Belgium) for June this list is republished; and in the August number of the same journal the subject is taken up again by M. Ed. Lucas, who extends the collection, and classifies into five groups. In the first group are eleven '*unique*' expressions for the area, i.e., expressions that do not admit of other similar expressions by permuting the letters; in the second group are nine expressions, each admitting of two other similar expressions by permuting the letters; in the third group are eleven expressions, each admitting of three other similar expressions; in the fourth group are seven expressions, each admitting of five similar expressions; and, last, the fifth group consists of a single formula, admitting of eleven similar expressions. Thus we have a hundred and thirty-six expressions for the area of a plane triangle in terms of the sides, angles, perpendiculars, semiperimeter, and radii of the circumscribed, inscribed, and escribed circles. M. Neuberg adds also three other unclassified formulae, with the statement that many other such may be found. The total number of expressions for the area of a plane triangle, in this collection, is therefore a hundred and thirty-nine, making it, perchance, the most complete collection that has been published. M. B.

The Dora coal-field, Virginia.

In the November number of *The Virginias* is contained a review of the report on the mineral resources of the United States, recently published by the U.S. geological survey, which contains the following: — "In Mr. Charles A. Ashburner's report on anthracite coal, p. 32, is this statement concerning the Dora coal-field: 'Of one of the reported anthracite localities in Virginia, that in Augusta county, recent tests with the diamond-drill would seem to prove the presence of anthracite,'" etc. In explanation of the above, I would like to state, that, by referring to the report reviewed, on p. 24 will be found a footnote as follows: "Mr. Ashburner's contribution and statistics end here." I only stand responsible for a *portion* of the statistics relating to the anthracite region in Pennsylvania (pp. 7 to 24 inclusive). I desire to make this explanation public from the fact that I do not wish to be held accountable for *questionable data* relating to a coal-field of a very uncertain character, and which I have never examined.

Charles A. Ashburner,
Geologist in charge Penn. anthracite survey.

Philadelphia, Penn.

Synchronism of geological formations.

In Science of Dec. 7 your correspondent, Mr. Nugent, takes issue with me as to my conclusions bearing upon the relative ages of geological formations, and contends that the geological and paleontological researches of the last twenty-one years (i.e., during the period that has elapsed since the publication of Professor Huxley's address referred to in my communication before the Philadelphia academy of natural sciences) have only tended 'to maintain the logical basis' on which the distinguished English naturalist rested. As the subject is a very important one, and one that has not, it appears to me, received its full measure of attention or discussion, I trust that you will permit me a little space for fuller explanation, even at the risk of repeating what has already been said in your valuable columns.

Professor Huxley, in his anniversary address delivered before the London geological society in 1862 (*Quart. journ.*, xviii. p. xlvi), maintains substantially, —

I. That formations exhibiting the same faunal facies may belong to two or more very distinct periods of the geological scale as now recognized; and, conversely, formations whose faunal elements are quite distinct may be absolutely contemporaneous: e.g., "For any thing that geology or paleontology is able to show to the contrary, a Devonian fauna and flora in the British Islands may have been contemporaneous with Silurian life in North America, and with a carboniferous fauna and flora in Africa" (*loc. cit.*).

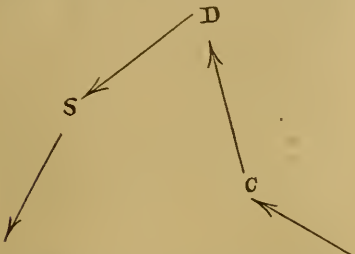
II. That, granting this disparity of age between closely related faunas, all evidence as to the uniformity of physical conditions over the surface of the earth during the same geological period (i.e., the periods of the geological scale), as would appear to be indicated by the similarity of the fossil remains belonging to that period, falls to the ground. "Geographical provinces and zones may have been as distinctly marked in the paleozoic epoch as at present; and those seemingly sudden appearances of new genera and species which we ascribe to new creations may be simple results of migration."

Now, without wishing to enter into the minutiae of the question, I believe a little reflection will clearly show, that if, as it is contended, several distinct faunas (i.e., faunas characteristic of distinct geological epochs, and separated in age from each other by possibly millions of years) may have existed contemporaneously, "evidences of inversion," to quote my own words, "in the order of deposit, ought to be common; or, at any rate, they ought to be indicated somewhere, since it can scarcely be conceived that animals everywhere would have observed the same order of direction in their migrations." Given the possible equivalency in age, as hypothetically claimed, of the Silurian fauna of North America with the Devonian of the British Isles and the carboniferous of Africa, or any similar arrangement, why has it never happened, it may be asked, that when migration, necessitated by alterations in the physical conditions of the environs, commenced, a fauna with an earlier life-facies has been imposed upon a later one, as the Devonian of Great Britain upon the carboniferous of Africa, or the American Silurian upon the Devonian of Britain? Or, for that matter, the American Silurian may have just as well been made to succeed the African carboniferous. Reference to the annexed diagram, where D represents a Devonian area, say, in Europe, S a Silurian one in America, and C a carboniferous one in Africa, — all contemporaneous, — will render this point more intelligible.

Now, on the proposition here stated, reasoning from our present knowledge of the antiquity of faunas, and accepting the doctrine of migration, as maintained by Professor Huxley and others, to account for the possible contemporaneity of distinct faunas, it may be assumed that S (or America) will receive its Devonian fauna from D; D (Europe), its carboniferous from C; and C (Africa), a later fauna from some locality not here indicated. In other words, a migra-

[1] Science, i. 160.

tion, as indicated by the arrows, would set in from D to S, one from C to D, one from S to some possibly South American Cambrian locality, and one, bringing a Permian or some later-day fauna, from an unknown locality towards C. Were this order of migration to continue here, or at other portions of the earth's surface, in this or in a similarly consecutive manner, the results obtained would be in perfect consonance with the facts presented by geology. But is there any reason whatever for the continuance of this order of migration? Surely no facts that have as yet been brought to light argue in favor of a continued migration in one direction. Why, then, it might justly be asked, could not just as well a migration take place from S to D, and impose with it a Silurian fauna upon a Devonian? What would there be to hinder



a migration from S to C, placing the American Silurian fauna upon the carboniferous of Africa? Why, as I have asked, has it just so happened that a fauna characteristic of a given period has *invariably* succeeded one which, when the two are in superposition all over the world (as far as we are aware), indicates precedence in creation or origination, and *never* one that can be shown to be of a later birth? Surely these peculiar circumstances cannot be accounted for on the doctrine of a fortuitous migration. And it certainly cannot be claimed that through a process of transmutation or development, depending upon the evolutionary forces, a fauna with a Silurian facies will, in the course of a possible migration toward a carboniferous locality, have assumed a carboniferous or Permian character.

The facts of geology and paleontology are, it appears to me, decidedly antagonistic to any such broad contemporaneity or non-contemporaneity as has been assumed by Professor Huxley; and their careful consideration will probably cause geologists to demur to the statement that "all competent authorities will probably assent to the proposition that physical geology does not enable us in any way to reply to this question: Were the British cretaceous rocks deposited at the same time as those of India, or are they a million of years younger or a million of years older?"

THOMSON AND TAIT'S NATURAL PHILOSOPHY.[1] — II.

Before proceeding to an account of the rest of the work, we shall add a few more words of explanation upon the harmonic solutions of the differential equation (6), expressed in polar co-ordinates. On attempting to integrate this equation, it is found that there is an infinite number of particular solutions, as was before stated must necessarily be the fact; and each of these solutions is the product of three factors. One factor is an arbitrary constant; another factor is the radius vector raised to any integral power, positive or negative; and the remaining factor is a function of the angular co-ordinates, dependent for its form upon the exponent of that power of the radius vector by which it is multiplied. It is this last factor, or coefficient, which gives the name of 'spherical harmonics' to the solution: indeed, these functions of the angular co-ordinates are themselves surface-harmonics.

If we restrict ourselves, as is usually done, to real integral powers of the radius vector r, positive and negative, then, from the well-known principle that a general solution is obtained by taking the sum of particular solutions, we should have the most general possible solution by taking the sum of a series of particular solutions, such as have just been described, in which the powers of r have all integral values between $+\infty$ and $-\infty$. But since it is found, upon computing the functions of the angular co-ordinates which constitute their coefficients, that the coefficients of r^i and $r^{-(i+1)}$ are identical, it will be more convenient to write the general solution in the form —

$$V = a_0 f_0(\theta,\phi) + (a_1 r + b_1 r^{-2}) f_1(\theta,\phi) + (a_2 r^2 + b_2 r^{-3}) f_2(\theta,\phi) + \dots + (a_i r^i + b_i r^{-(i+1)}) f_i(\theta,\phi) + \dots \quad (8)$$

In applying this to any given case, either all the arbitrary constants a vanish, or all the constants b; thus giving rise to the two general forms of solution before mentioned, in which there is a series of terms, either in ascending integral powers of r, or of descending integral powers of r.

A value of V consisting of several terms is a compound spherical harmonic of the degree (positive or negative) of its numerically highest power of r. A value of V consisting of a single term is a simple harmonic.

Returning, now, to the consideration of chapter vii. p. 98, entitled 'Statics of solids and fluids,' the subject of rigid solids is disposed of in the course of thirty pages, nearly half of which is occupied with inextensible strings in the form of catenaries of various kinds.

The authors hasten on to the more intricate matter of elastic solids. As is well known to students of this subject, the general problem

[1] Concluded from No. 36.

of finding the displacements in all parts of an elastic solid of any figure subjected to the action of known forces applied to its exterior surfaces, even when the solid is uniform in texture in all directions (i.e., isotropic), transcends at present the powers of analysis, though considerable progress has been made toward a complete theory. An important contribution to this theory by Sir William Thomson is found on pp. 461 to 468 in Appendix C, entitled 'Equations of equilibrium of an elastic solid deduced from the principle, energy.'

By reason of the incompleteness of the general theory, those simple cases are first treated which are most completely amenable to analysis. The forty pages succeeding p. 130 treat the special case of the elastic wire, whose fundamental equations were first thoroughly investigated by Kirchhoff in 1859. This treatment, which is of interest both to the mathematician and engineer, investigates not only the spirals which elastic wires of circular and of rectangular cross-section assume under the action of direct forces, and of couples producing bending and twisting, but also goes into several important side-issues, one of which is the so-called kinetic analogy. A simple case of this, which is discussed at length, exists between the plane curves assumed by a thin flat spring, and the vibrations of a simple pendulum which it graphically represents. Another important side-issue is found in the discussion of the common spiral spring, in which the force resisting elongation is mostly due to torsion of the wire. Very curiously, the theorem of three moments of a straight beam is omitted, although the principles to be employed in establishing it are fully given.

Another important elastic solid which is fully amenable to analysis is the thin elastic plate. The treatment of the thin plate, which occupies thirty pages, discusses the flexure of a plane plate under all combinations of forces tending to produce either a state of synclastic stress (i.e., a state in which the curvature at every point is convex) or a state of anti-clastic stress (i.e., one which tends to cause the surface to become saddle-shaped). Kirchhoff's boundary conditions for a plate are also demonstrated at length. These are of importance in most practical cases, — as, for example, that of the flat steam-boiler head; for evidently any plate must have some kind of support or fastening at its boundary.

The general subject of elastic solids is reached at p. 204, and occupies a hundred pages, in which, after the general equations of equilibrium between the applied stresses and the resulting strains are established, several special cases are treated at length. The first of these is the celebrated torsion problem published by St. Venant in 1855; in which the distribution of the stresses and strains throughout a right prism of any cross-section whatever, under the action of forces applied to its ends, is completely determined. This is perhaps the most complicated problem which has been entirely worked out in the subject of elastic solids, and twenty-four pages are devoted to it. The flexure of beams having rectangular cross-sections is discussed, especially with reference to the distortions which are suffered by these cross-sections. The distortions can be easily exhibited by bending a thick rectangular piece of rubber, when the upper and lower surfaces will become saddle-shaped.

The general problem is then further treated by investigating the case of an infinite elastic solid under various suppositions as to the force applied through limited and through unlimited portions of it. The spherical and cylindrical shells are then treated by the help of harmonic analysis.

The concluding hundred and sixty pages of the work, beginning at p. 300, are devoted ostensibly to hydrostatics; but the first twenty-five pages finish those parts of the subject included under that title in ordinary treatises, and the remainder relates to the physics of the earth as dependent upon its fluid condition, past or present. The first great problem in this department of inquiry is to determine what figure will be assumed by a rotating liquid mass under the influence of centrifugal force and of the mutual gravitation of its parts. That an oblate spheroid is a figure of equilibrium for such a mass is commonly known, having been shown to be such by Newton; but that an ellipsoid with three unequal axes is also such a figure is not so commonly known, though this was discovered to be the fact by Jacobi in 1834. There are other possible figures, stable and unstable; but which of all these is the one which will actually be assumed in any given case? In reply to this question, the authors state, that "during the fifteen years which have passed since the publication of the first edition we have never abandoned the problem of the equilibrium of a finite mass of rotating incompressible fluid. Year after year, questions of the multiplicity of possible figures of equilibrium have been almost incessantly before us; and yet it is only now, under the compulsion of finishing this second edition of the second part of our first volume, with the hope for a second volume abandoned, that we have succeeded in finding any thing approaching full light on the subject" (p. 332). Then follows an enumeration of the possible forms of equilibrium, including the single and multiple rings into which an ellipsoid would be changed when rapidly rotated, and the detached portions, nearly spherical, into which an elongated ellipsoid must separate when rapidly rotated about its shorter diameter.

Now, on the supposition that the figure of the earth is approximately an oblate spheroid, the next matter of importance is to show how to compute the alterations in figure due to local inequalities in its density, and irregularities in the distribution of the material composing it. This at once raises the question as to what we are to consider as the surface of the earth at any point which forms part of its figure. The true figure of the earth may be taken to be the water-surface when undisturbed by tides. Whenever it is desired to find such surface on land, a canal could be supposed to be cut from the ocean to the place under consideration. Of course, a plumb-line is everywhere perpendicular to such a surface, whose outline is evidently affected by all existing inequalities of density and distribution of the substance of the earth. For example: it is computed that a set of several broad parallel mountain chains and valleys, which are twenty miles from crest to crest, and seventy-two hundred feet above the bottom of the valleys, would cause a corresponding undulation of the water-surface whose crests would be five feet above the bottoms of the hollows. This statement is equivalent to saying, that the plumb-line is deviated from its mean direction by the attraction of the mountain chains. Deviations of nearly 30″ have been actually observed near the Alps and near the Caucasus Mountains. The comparatively small deflections observed near the vast mass of the Himalayas in India — which, according to Pratt's calculations in his treatise on attractions, etc., should be vastly greater than any thing actually observed — indicate that extensive portions of the globe under those mountains are less than the average density. Localities have been found in flat countries also, notably in England and Russia, where the deflection of the plumb-line exceeds 15″, which is, of course, due to underlying material of great density. From this it appears, that the true figure of the earth is nearly as diversified as the contours of its hills and valleys, and does not correspond to any known geometrical figure; although, to be sure, these undulations are of small amount. Now, as a first rude approximation, the figure of the earth can be taken as a sphere, having the same volume as the actual earth. The earth at the equatorial regions will then project beyond the figure, and at the poles lie within it.

A second and better approximation can be made by taking the figure to be that of an oblate spheroid; and this is the basis upon which our present geodetic and astronomical measurements are based. Of course, it is possible to find an ellipsoid having three unequal axes which will coincide still more nearly with the results of observations upon the true figure of the earth; and this will furnish a third still closer approximation. This is what has been done by Capt. Clarke in his various publications. A summary of his results is given upon pp. 367 and 368.

It is evident, when the astronomical latitude is determined at any point of the earth's surface by measuring the elevation of the north pole above the horizon, as given by the spirit-level, that that determination will be in error by the entire amount of the local deviation of the plumb-line, which error may be as much as 30″, or more than half a mile, although the observations are made with all possible precision; and the outcome of geodetic triangulation may show that any such station whose position was supposed to have been determined astronomically to single feet really occupies a position, when referred to the spheroid, which at present furnishes the basis of all our astronomical and geodetic work, which is a considerable fraction of a mile from its position as so determined.

The last grand subject treated in the work is that of the tides on the corrected equilibrium theory, and matters closely connected with it. To explain what is meant by this, we shall briefly sketch the rise and progress of the theory of the tides.

Sir Isaac Newton, whose Principia appeared in 1687, showed that universal gravitation would not only account for the motions of the heavenly bodies in their orbits, but would also account for the tides, — phenomena whose cause had not, before his day, been traced to any simple law of nature. He showed that there would be a tide due to the attraction of the sun, and another to that of the moon, the latter being in general the larger; and that the actual tide would depend upon the relative position of those bodies, so that the highest or spring tides would be due to their combined effect, and the lowest or neap tides would occur when the tide due to the sun partially neutralized that of the moon. He showed how other known variations in the tide could be accounted for by the declinations of the sun and moon, and their greater or less distance from the earth.

. The cause of the tide may be roughly stated, according to the equilibrium theory, thus: the sun or the moon attracts the water on the side of the earth nearer to it more than it does the earth itself, and attracts the earth itself more than the water on the farther side; the consequence being that water is heaped up on the sides of earth away from and toward the attracting body. Or, more exactly, we may imagine

" The rise and fall of the water at any point of the earth's surface to be produced by making two disturbing bodies (moon and anti-moon, as we may call them for brevity) revolve around the earth's axis once in the lunar twenty-four hours, with the line joining them always inclined to the earth's equator at an angle equal to the moon's declination. If we assume that at each moment the condition of hydrostatic equilibrium is fulfilled, — that is, that the free liquid surface is perpendicular to the resultant force, — we have what is called 'the equilibrium theory of the tides'" (art. 805).

Newton made a modification of this theory, which was intended to take into account the rotation of the earth, by supposing that the full effect of the attraction was not exerted immediately under the attracting body, but that the tide was of the nature of a wave, and by its inertia lagged behind the place where it should have been found in case the earth was not rotating. This retardation he thought might be more than a whole day in some cases. He was not able to submit the whole theory to rigorous computation for lack of sufficient data as to the mass of the moon and the height of the tides; but, from the tidal observations then available, he computed the mass of the moon necessary to produce them according to his theory, and obtained a result which we know to-day to be about twice too large.

In 1738 the French academy proposed the problem of the tides as the subject of a prize-essay, and elicited important essays on the subject from Bernouilli, Maclaurin, and Euler, to each of which was awarded a prize, and in each something of importance was added to Newton's theory; but the foundations of an exact and complete theory were first made in the 'Mécanique céleste' by Laplace, in five volumes, 1799–1825.

The science of mathematical analysis had not been greatly developed at the time Newton wrought upon this subject. His work is expressed in geometrical forms in which his genius is unapproachable. But the new methods of analysis founded upon the calculus, the principles of which were discovered equally by Newton and by Leibnitz, received a rapid and wonderful development during the seventeenth century at the hands of Lagrange and the continental mathematicians. It was to the then existing state of advancement in this particular that the great success of Laplace was due, which enabled him to unravel to so remarkable a degree the intricate interactions of the bodies of the solar system, and give for the first time the fundamental equations of the tides on correct principles. But it must be admitted that Laplace, in integrating his differential equations, seems to have become involved in intricate formulae whose full significance he has not correctly interpreted.

At about the same time, Dr. Thomas Young made an important investigation of the action of the tides, which was published in the Encyclopaedia Britannica, where it has been republished in succeeding editions to the present day. The special point of importance in his investigation was the discussion of the effect of friction upon the tides, which he showed to be such as to explain many difficulties, and that its magnitude might be such as to completely change the character of the tide at certain places so as to make low water take the place of high water, and *vice versa*, — a result hitherto unsuspected, and of prime importance.

The next great step in the theory of the tides was due to Airy, in his article on 'Tides and waves' in the Encyclopaedia metropolitana. He gave in new and concise form a most useful *résumé* of Laplace's theory, and made an original investigation of the effects of friction. He also made valuable additions to the theory as applied to shallow seas and rivers, a subject hitherto untouched.

The labors of Lubbock and of Dr. Whewell have added much to our knowledge of the relations of the theory to the observed tides; but the two foremost cultivators of this branch of science now living are Thomson and Ferrel. The former, who is chairman of the committee appointed by the British association for the advancement of science, for the purpose of the extension, improvement, and harmonic analysis of tidal observations, has done much, by his improved methods of observing tides and discussing them, to separate their components from each other, and render the exact comparison of theory and observed facts possible. Laplace assumed that the fortnightly and semi-annual tides due to the movement of the moon and sun in declination move so slowly that the equilibrium theory applies to them with exactness. But even if that be admitted, it can be shown that the theory needs correction to take account of the relative amount of land and water, as well as the contour of the continents. These have a controlling influence upon the tides, and this discovery is Thomson's great improvement and correction of the equilibrium theory.

The diurnal tide has been usually explained, in accordance with the equilibrium theory, as a wave existing under nearly static conditions, and following the moon and sun around the earth, but interfered with by friction, and changed in direction by the contour of the land. Though this was the view of Newton, Young, and others, and is incorporated in our ordinary text-books, it is quite inadequate; and the kinetic theory of Laplace must be put in its place, which treats the water as a moving fluid body, subject to the disturbing influence not only of the sun and moon, but of itself also.

The kinetic theory of the tides was to have been developed at length in vol. ii.; and that intended development is more than once referred to by the authors, — as, for instance, on p. 382, where an incidental comparison is made of the results of the two theories.

This part of the theory has been treated by Ferrel in his 'Tidal researches,' published as one of the appendices to the U. S. coast-survey report for 1874, in which work he has put in practical shape all the theoretical work heretofore accomplished, and also deduced therefrom important consequences. Until the publication of this work, it was not possible to apply the correct theory to the discussion and prediction of tides by reason of the unmanageable formulae employed by Laplace; and the discussions were, perforce, made by some modification of the equilibrium theory. Indeed, Laplace himself resorted to that method in his famous discussion of the tidal observations in the harbor of Brest. But, thanks to Ferrel's labors, this most intricate branch of computation has been systematized, and applied to an extensive series of tidal observations in Boston harbor.

The concluding pages, from 422 to 460, treat the question of the rigidity and solidity of the earth as a whole, especially as related to the tides. The final sentence (p. 460) is, "On the whole, we may fairly conclude, that, whilst there is some evidence of a tidal yielding of the earth's mass, that yielding is certainly small, and that the effective rigidity is at least as great as that of steel."

Four important papers on subjects related to those just mentioned are added to the work as appendices. The titles of these papers are, 'Cooling of the earth,' 'Age of the sun's heat,' 'Size of atoms,' 'Tidal friction.' The last three of these were not in the first edition.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Fuchsian functions. — A previous paper by M. Poincaré on this subject has already been noticed in these pages (i. 535). In the present most important memoir, M. Poincaré assumes the results arrived at in the former memoir, and proceeds to more fully develop them and the consequences flowing from them. In the previous paper the author showed that it was possible to form discontinuous groups by substitutions of the form

$$\left(z, \frac{a_i z + \beta_i}{\gamma_i z + \delta_i}\right)$$

by choosing the coefficients $a_i, \beta_i, \gamma_i, \delta_i$, in such a way that the different substitutions of the group should not alter throughout the interior of a certain circle called the fundamental circle. In the present paper the author assumes that the fundamental circle has its centre at the origin, and its radius unity; so that its equation can be written as mod. $z = 1$.

He then considers one of these discontinuous groups, which he calls Fuchsian groups, and which he denotes by G. To this group corresponds a decomposition of the fundamental circle into an infinite number of normal polygons, R, all congruent among themselves. The author then demonstrates that there always exists a system of uniform functions of z, which remain unaltered by the different substitutions of the group G, and which he calls Fuchsian functions. M. Poincaré's memoir is too long to be reviewed here as it deserves. It is certainly a most important addition to the modern theory of functions, and is rendered particularly valuable by the historical note at the end, in which the author gives a brief account of the labors of Hermite, Fuchs, Klein, Schwarz, and others in this field. The two memoirs, with very little amplification, would constitute a really valuable treatise on this subject, — a subject of great importance, and on which there exists absolutely no text-book or treatise of any kind. — (*Acta math.*, i.) T. C. [506

ENGINEERING.

Steam-whistles. — Lloyd and Symes give a statement of experiments with a locomotive whistle having a bell $4\frac{1}{16}$ inches diameter, $3\frac{3}{4}$ inches long inside, and over an annular steam opening $\frac{1}{16}$ of an inch wide. The bell was of cast brass of medium character; and the lip was chamfered to a thin edge, and set exactly over the steam-opening. Sixty pounds pressure of steam gave E natural; 80 pounds, F sharp; 90 pounds, G; 110 pounds, A; and 125 to 130 pounds gave C sharp in alt. The distance from steam-opening to edge of whistle was 1½ inches. When it was increased to 2 inches, the power of the sound was sensibly lessened, but the pitch was altered relatively but half a tone. If the distance were decreased to 1 inch, or to ⅞ of an inch, the whistle would sound only supertones. The notes above were clear, even 'reedy,' and could be heard six miles. A bell of brass tubing, annealed, hammered, and then heated again, gave sounds of somewhat greater intensity and pitch. An iron bell was unsatisfactory. — (*Railr. gaz.*, Aug. 31.) C. E. G. [507

Economy of pumping-engines. — Mr. P. A. Korevaer compares the economy of the scoop-wheel, the Archimedean screw, the pump-wheel, the suction or bucket pump, the double-action pump, and the centrifugal pump, and reports the results to the Dutch institute of engineers. In the Netherlands the pump-wheel is used for lifts less than 2.5 metres (8.3 feet), and the screw for about 4.25 metres (12.5 feet); while the lift and volume delivered by the ordinary forms of pump are unlimited. The economical lift for a centrifugal pump is taken to be as a maximum at about 30 or 40 feet. Its cost in Holland is rather greater than that of a scoop-wheel. The latter gives an efficiency of 64 to 69.5 % on lifts varying from 4 to 6 feet (1.2 to 1.8 metres). The double-acting pump gives an efficiency of 67 to 73 % on lifts between 6.66 and 10 feet (2 to 3 metres). The centrifugal pumps tested gave from 17 to 70 % (averaging 45) in one place, and 40 to 49.3 (averaging 44) in another case. The coal used amounted to from 0.9 to 1.2 kilogr. with scoop-wheels for the drainage of one hectare and a lift of one metre, 1 to 1.17 with double-acting pumps, and 1.56 to 2.19 with centrifugal pumps. The author concludes that a decided gain is obtained by the use of other methods of pumping rather than by the use of the centrifugal pumps,— a conclusion which we may be allowed to agree in, with the qualification that the results would bear a somewhat different complexion if the comparison were with efficient centrifugal pumps, which should be capable of giving an efficiency of at least 66 %. — (*Abs. papers inst. civ. eng.*, 1882–83, iii.) R. H. T. [508

Electric head-light for locomotives. — The Sedlaczek head-light was exhibited at Munich at the late exhibition. It was made by Messrs. Sedlaczek & Wilkulill, as a modification of the lamp of Lacassagne & Thiers, of 1856. The current is supplied by a dynamo placed on the top of the boiler behind the smoke-stack, and driven by an independent engine. The lamp is arranged to turn automatically on curves so as to light the track at all times. The light was visible at a distance of 2½ miles (4 kilometres). The report of the committee intrusted with the observation of the action of the lamp states that the intensity (4,000-candle power) was so great that the guards reported that it dazzled their eyes to such an extent that they were unable to make the observations prescribed by the regulations. The committee express a fear that it may frighten horses. Their apprehensions remind us of the same difficulties as they presented themselves to the opponents of the railway itself. A report made on this lamp in 1881, when used on the Northern railway of France, stated that the experiment proved that the lamp was not extinguished by the jar of the train, and that it did not in any way affect the visibility or the appearance of colors in signals. Engineers of trains were not dazzled by it unless by looking at it persistently, and were not prevented, even then, from seeing the signals. It is proposed to apply the same system of lighting to the cars. — (*Railway rev.*, Oct. 6.) R. H. T. [509

CHEMISTRY.

(Organic.)

Constituents of petroleum from Galicia. — In the oil from this locality Br. Lachowicz has found a normal, and an iso-pentan, two hexans, one heptan, one nonan, and two decans. Other hydrocarbons of this series were present in smaller quantity. No members of the ethylen series were detected. Of the aromatic hydrocarbons, benzol, toluol, isoxylol, and mesitylen were identified. The quantity of 'Wreden's hydrocarbons' — hexahydrobenzol (C_6H_{12}), hexahydrotoluol (C_7H_{14}), and hexahydro-isoxylol — in the Galicia petroleum lies between that of the Caucasus and the American oils. — (*Ann. chem.*, 220, 168.) C. F. M. [510

Compounds of the indigo group. — In the course of his investigations upon the constitution of indigo, A. Baeyer has tried several reactions to determine the position of the hydrogen atom which is not in the benzol ring. If the formula

$$\begin{array}{l} C_6H_4 - CO \\ \;\;| \qquad\;\; | \\ \;N \;=\; COH \end{array}$$

is assigned to isatin, the isomeric form called by Baeyer pseudo-isatin would have the form

$$\begin{array}{l} C_6H_4 - CO \\ \;\;| \qquad\;\; | \\ HN - CO \end{array};$$

and the form of pseudo-indoxyl isomeric with indoxyl,

$$\begin{array}{l} C_6H_4 - COH \\ \;\;| \qquad\;\; \| \\ HN - CH \end{array},$$

would be

$$\begin{array}{l} C_6H_4 - CO \\ \;\;| \qquad\;\; | \\ HN - CH_2 \end{array}.$$

Baeyer draws the following conclusions from his results concerning the structure of indigo: —

1. It contains an imido group.
2. The carbon atoms have the arrangement

$$C_6H_5 - C - C - C - C - C_6H_5.$$

3. It is formed only from compounds in which the carbon atom next to the benzol ring has attached to it an oxygen atom.

4. In its formation and properties it is closely related to indirubin and the 'indogenides' of ethyl-pseudo-isatin.

5. The latter results from a union of the α-carbon atom of pseudo-indoxyl with the β-carbon atom of pseudo-isatin.

The formation of indigo may therefore be shown by the equation —

$$\begin{array}{ccccccccccc} C_6H_4 - CO & & CO - C_6H_4 & & C_6H_4 - CO & & CO - C_6H_4 & & \\ | \quad\quad | & + & | \quad\quad | & = & | \quad\quad | & & | \quad\quad | & + & H_2O. \\ HN - CH_2 & & CO - NH & & HN \quad C & = & C - NH & & \\ \text{Pseudo-indoxyl.} & & \text{Pseudo-isatin.} & & & \text{Indigo.} & & & \end{array}$$

— (*Berichte deutsch. chem. gesellsch.*, xvi. 2188.) C. F. M. [511

AGRICULTURE.

Maintenance of fattened animals. — Kellner having observed that simple maintenance-fodder was sufficient to prevent fatted sheep from losing weight, Vossler has tried the same proceeding with sheep and oxen, and confirmed Kellner's observation. — (*Biedermann's centr.-blatt.*, xii. 612.) H. P. A. [512

Relation of manure to quantity of seed. — In experiments on the drill-culture of barley, Märcker finds, that, as the distance between the drills is increased, the yield decreases, unless more nitrogenous fertilizer is applied. — (*Ibid.*, xii. 620.) H. P. A. [513

Seed-potatoes. — In an experiment with potatoes at the New-York agricultural experiment-station, single eyes gave better yields in proportion as they were located near the terminal portion (seed-end) of the tuber. — (*N. Y. agric. exp. stat., bull.* lxiv.) H. P. A. [514

Potato-culture. — Previous experiments having led to the hypothesis that the most favorable conditions for the growth of potatoes are coolness and moisture for the roots, and warmth and dryness for the tubers, an attempt was made to test the hypothesis by planting potatoes on ridges, and mulching the intervals. The season, however, was very wet, so that the desired conditions for the tubers were not attained. As it was, the parallel plots under ordinary culture gave decidedly greater yields. — (*Ibid.*, lxv.) H. P. A. [515

Fertilizers for tobacco. — Nessler has repeated part of his well-known experiments on the effect of various salts upon the quality of tobacco. The present experiments consisted of a comparison of the chloride, sulphate, and nitrate of potassium in this respect, as well as of a few other fertilizers. The results were essentially the same as those previously reached: the sulphate and nitrate improved the burning qualities, while the chloride, except in one case, caused them to deteriorate. The chloride also increased the percentage of chlorine in the ash. The author recommends applying phosphatic and potassic fertilizers to the preceding crop, and only nitrogenous fertilizers directly to the tobacco. — (*Landw. vers. stat.*, xxix. 309.) H. P. A. [516

Glutamin in beet-juice. — In an earlier investigation, Schulze and Urich obtained glutaminic acid and ammonia by boiling beet-juice with hydrochloric acid, and from this fact concluded that the juice contained glutamin, a substance which had then never been prepared. Schulze and Bosshard have now succeeded in preparing glutamin from beet-juice. The juice is first treated with lead acetate. The filtrate from this precipitate is treated with mercuric nitrate, and the resulting precipitate decomposed by means of hydrogen sulphide.

Glutamin crystallizes from aqueous solution in fine, white, anhydrous needles, soluble in hot water and dilute alcohol. It is readily decomposed by acids or alkalies into glutaminic acid and ammonia, the decomposition taking place gradually, even in the cold or on simple boiling with water. Consequently ammonia cannot be determined in vegetable extracts containing glutamin, either by Schlösing's method or by boiling with magnesia. — (*Ibid.*, xxix. 295.) H. P. A. [517

GEOLOGY.

Correlation of Cambrian rocks. — Mr. Charles D. Walcott, of the U. S. geological survey, has recently reviewed the great Cambrian sections of North America. He defines the Cambrian as the formation characterized by the 'first fauna' of Barrande.

In New York, on one side of Lake Champlain, near Chazy, the formation is constituted by the Potsdam and calciferous; and the biologic transition to the Silurian, as represented by the Chazy, is abrupt. In Nevada there is a gradual passage from the Potsdam fauna to the Silurian; and beneath the Potsdam are rocks containing the Olenellus fauna. In northern Arizona the section exhibited by the Grand Cañon of the Colorado shows at bottom the Grand Cañon and Chu-ár groups, which contain barely fossils enough to characterize them as early Cambrian. These were greatly eroded before the deposition of the Tonto with a profuse fauna equivalent to that of the Potsdam. The Silurian is absent, and the Devonian rests on the Tonto. In Wisconsin the Potsdam is underlain unconformably by the faunaless Keweenawan, and overlain conformably by the Silurian. In Vermont the Potsdam rests on the Georgian group containing the Olenellus fauna. In Tennessee the upper Cambrian is represented by the Knox shale, and the lower by the Chilhowee sandstone and the Ocoee conglomerate. In New Brunswick the St. John's group, and in Massachusetts the Braintree argillites, exhibit the Paradoxides fauna. At the Straits of Belle Isle the section is not continuous, but appears comparable with that of Nevada. The anomalous relations reported at Point Levis, in Canada, are attributed to error in the interpretation of the stratigraphy.

The Tonto group of Arizona and the Knox group of Tennessee are recognized by Mr. Walcott as the equivalents of the Potsdam of New York, Vermont, and Wisconsin. The Olenellus horizon of Nevada is correlated with the Georgian group of Vermont. The Grand Cañon and Chuar groups of Arizona are provisionally correlated with the Keweenawan of Wisconsin, and are regarded as older than the Georgian. The St. John's group of New Brunswick is held to be older than the Georgian, and probably younger than the Keweenawan and Chuar. The Chilhowee and Ocoee groups of Tennessee are provisionally assigned to the horizons of the Georgian and St. John's.

The paper marshals the stratigraphic evidence only, leaving the paleontologic to form the subject of a future communication. — (*Phil. soc. Washington; meeting* Nov. 24, 1883.) [518

PHYSICAL GEOGRAPHY.

Influence of climate on vegetation in Alaska. — In his remarks on glaciers in Alaska, Mr. Thomas Meehan remarked, that, on the top of what are known as 'totem-poles' in some of the Indian villages, trees of very large size would often be seen growing. These poles are thick logs of hemlock or spruce, set up before the doors of Indian lodges, carved all over with queer characters representing living creatures of every description. These inscriptions are supposed to be genealogies, or to tell of some famous event in the family history. The poles are not erected by Indians now, and it is difficult to get any connected accounts of what they really tell. At a very old Indian village, called Kaigan, there are a large number of these poles, with few, or, in some cases, no carvings on them, among many which are wholly covered; and these all had one or more trees of Abies sitkensis growing on them. One tree must have been about twenty years old, and was half as tall as the pole on which it was growing. The pole may have been twenty feet high. The roots of the tree had descended the whole length of the poles, and had gone into the ground from which the larger trees now derived nourishment. In one case the root had grown so large as to split the thick pole on one side from the top to the bottom; and this root projected along the whole length, about two inches beyond the outer circumference of the pole. Only in an atmosphere surcharged with moisture could a seed sprout on the top of a pole twenty feet from the ground, and continue for years to grow almost or quite as well as if it were surrounded by soil. He had seen a bush of Lanicera involucrata which was of immense size as compared with what he had seen in Colorado and elsewhere. The plant was at the back of an Indian lodge, and beside a pathway, cut against the hillside. The stems near the ground were as thick as his arm, and the whole plant was covered with very large blackberries. Stopping in admiration to look at and admire the specimen brought numbers of Indians to see what was the subject; and these smiled indulgently on being made to understand that only the sight of a huge bush had attracted the travellers' attention. — (*Acad. nat. sc. Philad.; meeting* Nov. 6.) [519

BOTANY.

(*Fossil.*)

Australian coal flora. — A memoir prepared with great care by Rev. J. E. Tenison-Woods is valuable to science, not only for the clear and detailed description of the fossil plants, but for the discussion upon the geological distribution of the coal-bearing measures of Australia.

The first notice in regard to the Australian fossil flora was given by Prof. Morris in 1845. In 1847 McCoy gave an elaborate paper on the flora and fauna of the rocks associated with the coal of Australia, and came to the conclusion that a wide geological interval probably occurred between the consolidation of the fossiliferous beds underlying the coal, and the deposits of the coal-measures, as he found no real connection between them, and as they were referable to widely different geological systems.

In 1848 Rev. Mr. Clarke dissented from the above conclusions, maintaining that there is no break whatever between the various beds containing the remains of plants described. His assertion was based upon his own discoveries, and the researches of Jukes and Dana.

After recording the long discussion between McCoy and Clarke, the progress made on the subject by Daintree, Feistmantel, etc., the author gives a clear exposition of the Australian coal-formations, as far as they are known at the present time, considering not only the remains of plants and animals found in connection with the strata, but the composition of the measures, and the localities where the strata have been examined. He gives the formations in the following series: —

1. Upper Devonian, with three species of plants.
2. Lower carboniferous, six species, among them three of Lepidodendron.
3. Permian (?), five species, among them two of Glossopteris.
4. Newer coal, trias (?) (Newcastle), fourteen species; of these, seven of Glossopteris, of which Glossopteris Browniana is most common, and also found in No. 3.
5. Rhaetic.
6. Upper lias (?), with two species.
7. Jurassic, with twenty-two species.

In recording the plants and their distribution, the author describes ninety-three species: twenty-seven are new. The plates are photographs of specimens. The remains of plants are very indistinctly and insufficiently represented. — (*Proc. Linn. soc. N. S. Wales*, viii. 37.) L. L. [520

ZOÖLOGY.

Reconstruction of objects from microscopic sections. — Born gives an elaborate description of his method of modelling, which is really very simple as well as ingenious. The sections are made with great care, all of the same thickness: they are next drawn with the camera, and the outlines transferred to wax plates, the thickness of which is chosen so as to correspond in relation to the thickness of the sections, as do the outlines to the superficial dimensions of the sections; or, in other words, each wax plate is cut out so as to represent the actual section equally magnified in all three dimensions. — (*Arch. mikrosk. anat.*, xxii. 584.) C. S. M. [521

Preservation of soft tissues. — Dr. Benjamin Sharp called attention to Prof. Semper's mode of preparing dried specimens of soft animals, and exhibited a couple of snails as illustrations of the admirable results of the process. The tissues are first hardened by being steeped in chromic acid, which is afterwards thoroughly washed out in water. The specimen is then allowed to remain in absolute alcohol until the water is perfectly extracted, when it is placed in turpentine for three or four days. It may then be dried and mounted. Specimens prepared in this way retain their characters in a very satisfactory degree, and are strong and flexible, the examples shown resembling kid. If the surface be treated, after drying, with a solution of sugar and glycerine, the natural colors will be restored; but the specimens must then be kept in hermetically sealed glass cases to preserve them from the dust. The objection to this mode of treating large specimens is the expense of the absolute alcohol: otherwise there is no reason why the largest animals should not be preserved by this process. — (*Acad. nat. sc. Philad.; meeting* Nov. 21, 1883.) [522

Preservation of protozoa and small larvae. — Hermann Fol recommends an alcoholic solution of ferric perchloride to kill small animals without injury to the tissues. It is diluted with water down to two per cent, and then poured into the vessel holding the animals. These then sink to the bottom. The water is poured off, and seventy per cent alcohol substituted. Change the alcohol, and add to the second dose of it a few drops of sulphuric acid: otherwise the iron may remain in the tissues, and cause them to overstain with coloring-reagents. The alcoholic washing should be thorough. Even larger animals (medusae, Doliolum, etc.) may be perfectly preserved by this method. The tissues may be subsequently stained by adding a few drops of gallic acid (one-per-cent solution) to the alcohol containing the specimens. The nuclei are stained dark, the protoplasm light brown, in twenty-four hours.

Fol also describes some new injection masses, which offer the advantage that they may be readily kept without spoiling. — (*Zeitschr. wiss. zool.*, xxxviii. 491.) C. S. M. [523

Fossils of Pachino. — The Marquis de Gregorio has published a brochure of twenty-five pages on the fossils of this locality. They comprise cretaceous forms of the horizon of Hippurites cornucopiae, and tertiary species of the horizon of Carcharodon megalodon Ag. The work is in octavo, and illustrated by six excellent phototypic plates representing corals, echinoderms, and a few mollusks. Simpulorbites, a new genus of Foraminifera allied to Orbitolites; Escharopsia, a new genus of Polyzoa; and Proteobulla, a form represented by casts, recalling Buccinulus, but with three strong horizontal plaits on the column, — are described and figured. — W. H. D. [524

Mollusks.

Spicula amoris of British Helices. — Charles Ashford contributes an interesting and comprehensive paper on the 'darts' found in connection with the reproductive apparatus in certain Helices. The dart is contained in a short ventricose pouch opening into the lower part of the vaginal tube, a little above the common vestibule, on the right side of the neck. There is usually one: if two are present, the second sac is on the opposite side of the tube from the first. The sac may be simple, or bilobate. At the bottom of the cavity of the sac is a conical papilla, which serves as a basis for the dart, which is attached to it by its posterior end. The apparatus is a development of adult life, and especially of pairing-time, but is indifferently present or wanting in species otherwise closely allied. The dart itself is a tubular shaft of carbonate of lime, tapering to a solid, transparent, sharp point, enlarging at or toward the base, where it assumes the form of a subconical cup. The sides of the shaft are sometimes furnished with blade-like longitudinal buttresses, which serve to strengthen it. They are rapidly formed, may be secreted in six days, and differ in form in different species. They are supposed to serve the purpose of inducing, by puncture, the excitement preparatory to pairing. They are too fragile to do more than prick the tough skin of these mollusks, but sometimes penetrate the apertures of the body, and are found within. A new weapon is formed after the loss of the old one. It is best extracted for study by boiling the sac in caustic potash. — (*Journ. conch.*, July, 1883.) W. H. D. [525

Shell-structure of Chonetes. — John Young, in the course of an examination of C. Laguessiana Kon., finds on the ribs a series of wide-set tubular openings, perhaps bases of spines, which do not extend to the interior of the shell; also a row of very minute close-set pores, placed along the central line of each rib, but which disappear after descending a very short distance into the shell-substance; a series of raised tubercles, which appear on the interior surface of the valves arranged between each pair of ribs in single rows, and which send rather distant tubules obliquely outward and backward as far as the middle layer of the shell; lastly, in the thickened cardinal edge of the ventral valve, corresponding to the spines with which it is ornamented, a series of tubes which open with round orifices on the interior, and which converge toward a point near the apex of the beak, but at the surface are continuous with the hollow of the tubular spines which point away from the beak in a direction nearly at right angles with their previous course. In a note on this communication, Mr. Thomas Davidson mentions that in Chonetes plebeia, tenuicostata, sarcinulata, and the Devonian C. armata, Mr. Young finds no trace of the external perforations described above in C. Laguessiana, although small perforations or tubules extended nearly to the middle shell-layer from the interior of the valves, slanting toward the beaks. In Productus (with a doubtful exception in the case of P. mesolobus), also, Mr. Young finds the perforations extending only part way from the interior, and never visible on the unabraded external surface of the shell. The same fact has been determined by him for the genera Strophomena and Streptorhynchus. — (*Geol. mag.*, Aug., 1883.) W. H. D. [526

VERTEBRATES.

Mammals.

Aortic insufficiency and arterial pressure. — Both Rosenbach and Cohnheim have stated that sudden insufficiency of the aortic valves, produced artificially, has no effect on arterial pressure. Goddard, on the other hand, from experiments made upon rabbits, says, that after perforation of the aortic valves, there is an important fall of pressure. De Jager has repeated these experiments, using both dogs and rabbits. Upon dogs he finds that perforation of the valves has little or no effect on arterial pressure; whereas, with rabbits, a considerable and permanent fall of pressure is the result. It appears from these experiments that the compensatory power of the heart-muscle is greater in the dog than in the rabbit, although de Jager thinks that the results may be partly explained by the fact that the injury to the valves in the case of the rabbits was generally more extensive than in the case of the dogs. — (*Pflüger's archiv*, xxxi. 215.) W. H. H. [527

Structure of the placenta. — Ercolani has renewed the advocacy of his views on the mammalian placenta, according to which, after conception, the mucosa of the uterus falls off, and a new cellular decidual layer is formed, and after delivery the mucosa is re-formed. ports some new observations, particularly on the dormouse and on woman, by which he endeavors to strengthen his position. He writes in the form of letters addressed to Prof. Kölliker at Würzburg. Dr. H. O. Marcy, in the *New York medical journal* (July 28 – Aug. 4), gives an account of these letters, but adds nothing original. The difficulty as to Ercolani's views is threefold: he leaves in obscurity the exact histolytical and histogenetical changes in, 1°, the assumed shedding of the mucosa; 2°, the appearance of the new-formed decidua; 3°, the regeneration of the mucosa. For the present, Kölliker's view, that the maternal decidua is the metamorphosed mucosa, has at least an equal claim for acceptance with Ercolani's theory. — (*Rendic. accad. sc. ist. Bologna*, Jan. 28, 1883.) C. S. M. [528

Touch-corpuscles and other nerve-endings in man and apes. — W. Wolff has investigated the corpuscles of touch in Cercopithecus, the chimpanzee, and man. The corpuscles are essentially the same in all. They have an oval form, and are distinguished by having the connective-tissue envelope thrown into folds parallel with their long axis, the folds being delicate and close together. The content of the capsule is a granular, coherent fluid. According to Wolff, the supposed nerve-filaments seen in gold preparations are really precipitates formed in the folds of the capsule.

The author questions whether the nerves have any terminations in epithelium. His principal objection is, that, if the cornea of small animals is macerated for several hours in weak gold solutions, the epithelium falls off as a distinct membrane. Now, as gold fixes the nerves, if any filaments ran to the membrane, they would hold it down, and the epithelium would not separate. The author confuses fixing the optical form of the nerves and fixing their coherency. There is no reason against, but, on the contrary, many reasons for, assuming a maceration of the nerve-filaments in weak solutions of gold. In view of the very numerous positive observations of nerve-endings in epithelia, Wolff's argumentation is weak, and it appears unnecessary to follow his further deductions; viz., that since glands are modified epithelia, and epithelia have no nerve-endings proper, therefore the gland-cells have no nerve-endings. Such attempts to set aside a vast body of evidence on account of a few imperfect observations ought not to be countenanced. — (*Arch. anat. physiol., anat. abth.*, 1883, 128.) C. S. M. [529

The action of digitaline on the heart and blood-vessels. — The authors of this paper, Donaldson and Stevens, have made a careful and thorough study of the action of digitaline on the heart and blood-vessels, and have arrived at results differing from those usually accepted. The evidence obtained by previous investigators is summarized by them as follows: "Investigations on the frog's heart show an increase of work; investigations on the arterioles have led to contradictory results, with the weight of evidence in favor of a constriction." In their own work they made use of frogs and terrapins. The heart was completely isolated from the rest of the body, and kept alive by defibrinated blood supplied to it from the venous side; while the outflow of blood from the ventricles, in the method used, could easily be determined at any time, and the relative amount of work done by the heart, when pure blood or blood containing digitaline was fed to it, estimated. The conditions under which the heart worked were made, as far as possible, the same as those existing during life. The result of these experiments was that digitaline causes a decrease in the work done by the heart. On the other hand, digitaline injected into the living animal in moderate doses increases the blood-pressure. This increase of blood-pressure cannot be caused by the heart: it must result, therefore, from a constriction of the arterioles. Experiments were made in which the arterial system was supplied with normal salt solution at a constant pressure, and the outflow collected from the large veins emptying into the heart. The heart was thus excluded from the problem. It was then found, that, when digitaline was added to the circulating liquid, there was a diminution in the outflow from the veins; and this diminution could only be caused by a constriction of the arterioles. The result of their work, then, is that digitaline causes a decrease in the work done by the heart, but increases mean blood-pressure by constricting the arterioles. — (*Journ. of physiol.*, iv. 165.) W. H. H. [530

(*Man.*)

Cilia in the human kidney. — That a large portion of the renal tubules in cold-blooded vertebrates is ciliated has been known for some time. It has also been known, from the observations of Bowman and others, that the neck of the Malpighian capsule in mammals is ciliated. A. H. Tuttle found, from the examination of a large number of sections of human kidneys, that the convoluted tubule is very extensively, if not generally, ciliated. Where the flat lining-cells of the capsule approach the neck, they become cuboidal and ciliated also. The cilia in the kidney are from 3.5 to 5 μ long, very fine, numerous, and closely set. Confirmatory observations were made on the kidney of a kitten. The cilia are probably present in all mammalia, and serve to propel the urine outwards or towards the ureter. — (*Stud. biol. lab. Johns Hopk. univ.*, ii. 453.) C. S. M. [531

ANTHROPOLOGY.

Man's place in nature. — One hears now and then the assertion that man is not the highest animal. In proof of this assertion, it is urged that this animal is far more specialized in one direction, and that animal in another. Mr. Lockington takes the ground that specialization is not in itself any proof of advance. Now, the real progress is not to be sought in the specialized offshoots of any series, but in the growing stem from which it is parted. The highest specialization is that based upon perfection of the greatest number of parts, not upon the great development of one part at the expense of others. "We need not ask morphologists or embryologists whether man is the highest animal: we have the proof of it every hour before our eyes. His powers of mind are the resultant of his structure, and have enabled him to conquer all other beings in the struggle of life. That animal is highest which possesses the widest range of faculties. This man undoubtedly does. No other animal has the power, by voice or pen, to exaggerate or depreciate its own importance; no other animal can use the powers of nature as he; no other can produce works which are proportionately comparable to his: and if, therefore, morphology or embryology contradict the facts of life, then are those sciences unsafe guides, as they certainly are only partial ones." — (*Amer. naturalist*, Oct.) J. W. P. [532

Notation of kinship. — In the study of kinship many schemes of graphic representation have been devised. A perfect system should exhibit three ideas: It should, 1. Identify each place in the series; 2. Classify kindred for each people; 3. Exhibit affinity or marriage, as well as kinship. Mr. Francis Galton presents us with a new scheme, identifying the members of the series and sex, in which arithmetical notation takes the place of letters or pictographs. — (*Nature*, Sept. 6.) J. W. P. [533

Curare. — M. Couty has made extended observations and experiments on the curare poison, and has given the benefit of his studies in a course of lectures in the museum of Rio Janeiro. The investigation closes with a modest confession of ignorance. "The *curare*," says M. Couty, "demands fresh physiological studies to comprehend the nature of its relation to the muscles and the nerves, and also the real significance of the various phenomena of excitement and paralysis which it occasions, before we should attempt to comprehend the intimate mechanism of its intoxicating influence." — (*Rev. scient.*, 1882, 587, etc.) J. W. P. [534

Color-words in the Rig Veda. — Geiger wrote, 'The men of that time [of the Rig Veda] did not and could not call any thing blue.' Mr. Edward W. Hopkins reviews the deductions of Geiger, and not only questions the facts adduced by him, but also doubts whether his application of the statements be admissible, even if proved to be facts. The use of color-words is not unlike that in other poetic literatures. Mr. Hopkins concludes: 1°. Non-mention of the colors green and blue is not proved for the Rig Veda literature; 2°. That the sky is not called blue, nor the fields green, rests on reasons which have nothing to do with the development of the retina; 3°. We cannot admit that either color-words or color-perception of those who composed the Rig Veda were inexact or imperfect; for the cause of the apparently inexact employment of words lies in the variable and uncertain color of the objects to which the color-terms are applied.

If the Vedic literature fail to support the theory of the late development of the color-sense, one of the strongest of the negative proofs is withdrawn; and even the absence of certain colors in Homer may be deemed, perhaps, of less significance than has been claimed when we consider that the Niebelungenlied exhibits, twenty centuries later, the same absence of corresponding colors, and a like ratio in the greater use of terms denoting red and yellow. — (*Amer. journ. phil.*, iv. 166.) J. W. P. [535

The Yuma linguistic stock. — In the year 1877 Mr. A. S. Gatschet brought together in two papers all that was then known with reference to the Yuma stock of languages spoken around the mouth of the Colorado of the west. Recently he has come into possession, through the Bureau of ethnology and private correspondence, of new and important material, and has been compelled to publish an appendix to his former papers. This consists of information respecting the names and characteristics of the tribes belonging to this stem; comparative vocabularies of the Yavapai, Ni Mai, and the Seri; the Yavapai vocabulary of Dr. W. H Corbusier; and the Tonto vocabulary of Dr. John B. White. — (*Zeitschr. ethnol.*, xv. 123.) J. W. P. [536

The tempering of bronze. — No doubt, native copper attracted the attention of primitive man before any of its alloys; but the difficulty of working it for a long time prevented its general use. How the metal came to be associated with tin in various forms is entirely unknown to us. Arms and implements of bronze in Egypt, Greece, and Gaul, present a constant proportion of tin, — twelve per cent. The bronze of cannons is eight to eleven per cent; of bells, twenty to thirty per cent. Recently, at Réalon (Hautes-Alpes), a peddler's pack of bronze objects has been unearthed, showing eighteen per cent of tin.

The founders of prehistoric times seem to have had three methods of procedure: —

1°. The alloy was poured into a mould of stone or metal in two pieces. The ridge formed by the junction was afterwards hammered down.

2°. A model of wood was pressed upon a layer of sand in a box, to obtain a negative of one side: a corresponding operation gave a mould of the other side. The two boxes fitted together completed the mould. There were still seams requiring to be hammered.

3°. A model of wax was surrounded with soft clay. The clay was then heated to harden it and to melt the wax. The metal was introduced at the opening left for the escape of the wax.

Soldering was unknown to the men of the bronze age: mending was done by riveting. The art of softening bronze was known to the ancients. Proclus says (Works and Days, line 1842) that "in ancient times men used bronze in cultivating the ground just as they use iron now; but that copper being soft in its nature, they hardened it by immersion." Eustathius also says (Iliad, book I., line 236) that they tempered the bronze when using it in place of iron. The chemist Darcet, at the end of the last century, showed: 1. That pure copper, heated to redness and plunged into cold water, is neither hardened nor softened; 2. Bronzes having only tin alloy, and that less than thirty per cent, heated and cooled in air, become weak and brittle; 3. The same bronzes, heated and cooled in water, are softened, and become very tractable.

It is nearly certain that the men of the bronze age tempered their implements in taking them from the mould. Those destined to stand a blow were left in this state. Arms and tools needing more temper were heated over, and cooled in the air.

Another prehistoric art, rediscovered by the engineers of Alexandria, and recently again brought to light from the orient, is rendering bronze flexible. This property of flexibility is certainly possessed by some very ancient specimens. The engineer Philo, who lived in the century before our era, describes, in his 'Treatise on artillery,' the fabrication of springs of bronze needed in some of his machinery.

The author from whom the foregoing notes are taken, A. de Rochas, will soon publish, through Masson at Paris, a volume on the origin of industry, and the first application of the sciences. — (*Rev. scient.*, Sept. 22.) J. W. P. [537

Seamy side of the Vedas. — Max Müller tells us in his recent work, 'India, what it can teach us,' that in the Vedas we have a nearer approach to a beginning, and an intelligible beginning, than in the wild invocations of Hottentots and Bushmen. Mr. Andrew Lang holds the mirror up to this assertion by showing that a highly civilized people are farther from the beginning in their religion than races which have not evolved nor accepted society. Again: there is nothing particularly wild in some of the invocations of the Bushmen (*Cape monthly*, July, 1874), nor of the Papuans (*Journ. anthrop. inst.*, Feb., 1881). Compare the prayer of Odysseus to the Phaeacian king. And, finally, the faith of Vedic worshippers was very near akin, in the wildness of its details and its mythology, to the faith of Bushmen and Hottentots. In the Rig Veda human sacrifice has left its traces, the practice enduring in symbols and substitutes which point back to something 'nearer the beginning.' The ninetieth hymn of the tenth book of the Rig Veda tells how all things were made out of the limbs of a giant, Purusha. A similar legend is found among Scandinavians, Iroquois, Egyptians, Greeks, and Tinneh. It would be easy to show that Vishnu, in the shape of a boar bringing up the world from the waters, is equivalent to the North American coyotes and muskrats performing the same feat. The origin of species from Purusha is matched only by the metamorphoses and amatory pursuits of Zeus, Kronos, Demeter, and Nemesis. Indeed, we seem to have a nearer approach to a beginning in the Vedic hymns, in those very portions in which they resemble the primitive philosophy of Bushmen and Navajos. The gods in the Vedic religion are deified nature; and we frequently see gods in animal form fighting with animals, afraid of enemies, behaving like the half anthropomorphic, half theriomorphic deities of the Australians, Hottentots, and Bushmen. The gods are begotten of heaven and earth, and are not necessarily immortal. The birth of Indra is very similar to that of Heitsi-Eibib, the supreme god of the Hottentots; and some of his feats have parallels in Scandinavian, Thlinkit, Murri, and Californian myths. Speaking of the other Vedic gods, Mr. Lang quotes the language of Racine respecting the deities of the Greeks: "Burning was too good for most of them. . . . If any one wishes to see at a glance how much savage thought persisted till the age of the Brahmanas, let him compare the myths of the constellations (*Sacr. books of the east*, xii. 282) with the similar myths in Brough Smyth's 'Aborigines of Victoria.' Except upon the hypothesis that the Aryans came civilized into the world, they must have descended from savage ancestors. That they retained savage practices, such as human sacrifices, and much worse things, is universally admitted. Why should they not have retained savage ideas in religion and mythology, especially as of savage ideas Aryan mythology and religion are full to the brim?" — J. W. P. [538

Anthropology at Berlin. — The organ of the Berlin society of anthropology has just completed its fifteenth year, and contains matter of interest not only to the local but also to the general student. Part iv. opens with a paper by Ernst Bötticher on the analogies of the Hissarlik finds. Dr. Schliemann's 'owl-faced' vases are characterized as *canopus* vases, and thus connected in type with the various art productions of Egypt, in which the bird-face predominates. The ornamentation of funereal urns with a bird-face, — be it that of a falcon, owl, or sparrow, — and the occurrence of the same custom from the Baltic to the Nile banks, are worthy of remark. Until historic evidence clears up the subject, the learned must move their opinions back and forward in the alternation of independent evolution and social contact. —— Prof. Arzruni reviews the jadeite and nephrite discussion, quoting and criticising the writings of Meyer, Damour, Janettaz and Michel, Fischer, Beck, and v. Muschketow. The author carefully excludes from the discussion minerals which have been confounded with those above named, and also mentions the fact that they have different characteristics in different localities. In Europe, up to this time, neither jadeite nor nephrite has been found *in situ*. Prof. Arzruni closes his paper with the citation of those localities in each continent which have furnished the minerals or their products. —— M. Kulischer speaks of the handling of children and youth upon the lower culture steps. He broaches a very ingenious theory, which seeks to include infanticide and all sorts of torture and ordeals in a common category of helping the survival of the fittest. In savagery, intimates the author, two children are as many as the parents can raise: they knock the surplus on the head. They subject their sons and daughters to frequent vigils, fastings, fatigues, and pains, mourning for them meanwhile as dead. Indeed, many die under the treatment, but the fittest survive. Very many scraps of information, gathered here and there, are brought within the range of the author's theory. In this connection, one should not fail to consult Ploss: 'Das kind in brauch und sitte der völker.' —— Mr. Aurelius Krause read a paper upon the relationships existing among the peoples of the Chukchi peninsula. Are the coast Chukchi and the reindeer Chukchi the same people? —— In speaking of the 'footsteps of Buda,' — a gigantic track found in the ruins of the most hallowed shrine of Buddhism at Gaya, in southern Bihar. — M. Grünwedel calls to mind, that in every part of the world are to be found, in solid rock, impressions made by the feet of gods and heroes. —— Gen. von Erckert sends to the society from Petroosk measurements of the weight, length of body, and length of limbs, taken from Russian peoples, — Wotjaks, Great Russians, Little Russians, Volga Tartars, Meshtsheraks, Poles, Bashkirs, Tscheremis, and Jews. — (*Zeitschr. f. ethnol.*, xv. pt. 4.) J. W. P. [539

The London anthropological institute. — The unlimited resources of British anthropologists lead one always to expect something good from the journal of the institute. The first paper in the current number is by F. Bonney, on some customs of the aborigines of the River Darling, New South Wales. Mr. Bonney resided on a sheep-range from 1865 to 1880, and therefore knew the Bungyarlee and Parkungi tribes 'before they were spoilt by civilization.' The aboriginal population, owing to periodic droughts of great severity, could never have exceeded 100 on an area of 2,000 □ m. Epidemics also have told upon the people. There is a typical similarity among all Australian aborigines; but, to a close observer, each tribe has its own peculiarities. The oft-repeated statement that they are the lowest type of humanity is a libel. Mr. Bonney describes their parturition customs, systematic infanticide, child-rearing, initiation of youth, class-marriage, courtesy, charms, sucking-cure, diseases, blood-cure, burials, and mourning. —— Mr. Tremlett writes of stone circles in Brittany, by which is meant two concentric rings of rude stone masonry, covered by a mound. One, called Nignol, was undoubtedly a cremation mound; since, exterior to the outer circle, cinerary urns were found, as well as between the walls. The inner circle consisted almost entirely of ashes and charcoal. Two others were similarly constructed, — one at Coët-a-touse, the other at Kerbascat. —— The subject of group-marriage is reviewed by Mr. C. S. Wake, and an attempt made to show its origin. The author assumes two fundamental rights, — the individual, or sexual; and the tribal, or self-protective. The origin of the Australian four-class division is to be sought in the separation of the original marrying group into two grades, a parent and a child grade. —— Major H. W. Fielden exhibited a series of South African stone implements. —— The Rev. James Sibree, following up the investigations of Col. Garrick Mallery, U.S.A., reports a number of gestures from Madagascar as a contribution to the study of comparative sign-language. —— Mr. A. W. Howitt reports some Australian beliefs, commencing with a delightful paragraph or two on synonymy, which we should like to quote. The superstitions described relate to the physical universe, the human individual here and hereafter, and Ghost-land. —— On the 19th of June a special meeting was held at the Piccadilly hall, by invitation of Mr. C. Ribeiro, who exhibited five Botocudo Indians and a collection of implements. —— Mr. A. H. Keane read a paper on the Botocudos. Their home is the province of Espiritu Santu, in Brazil; their name, probably from the Portuguese *botoque* (a barrel-plug), alluding to their labrets. The Tembeitera, or lip ornament, and the immense ear-plugs, give rise to an extended notice of the geographical distribution of these objects. The Botocudos are of Guarani stock physically, although of non-Guarani speech. Their physical characteristics are elaborately set forth by Mr. Keane, and extended references made to their culture, sexual relations, dwellings, industries, tribal organization, burials, religion, and language. — (*Journ. anthrop. inst.*, xiii. no. ii.) J. W. P. [540

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Geology. — Mr. J. S. Diller, an assistant of Capt. C. E. Dutton, who has charge of the investigation of the volcanic rocks in the division of the Pacific, made a geological reconnaissance of the Cascade Range, during the early part of the season, in exploring the eastern side of the range; going as far north as the Dalles, and thence to Portland, finally coming down on the west side to Red Bluff, California. He and his party travelled some twenty-five hundred miles. They were unable to do any topographical work on account of the smoke, which also interfered with the work of Mr. Gilbert Thompson (chief topographer of the California division) in the neighborhood of Mount Shasta.

Paleontology. — During the past season Mr. Charles D. Walcott received at the office, for the use of the National museum collections, a series of typical specimens, representing seventy-eight species described by Mr. U. P. James, from the Hudson River group in southern Ohio. These are the gift of Mr. James, and have been recorded. Mr. Walcott has also received, from Cornell university, for study and illustration, the type specimens used by Prof. C. F. Hartt, in Dawson's 'Acadian geology,' in his descriptions of the fossils of St. John, N.B. All the species described by Professor Hartt will therefore now be illustrated for the first time.

Prof. O. C. Marsh, in charge of vertebrate paleontology for the survey, has had parties working in Wyoming during the past season, and also in the Jurassic of Colorado, and reports to the director that they have made large additions to the collections, and very important discoveries, the results of which will be reported later.

Chemistry. — The chemical division of the survey will hereafter occupy the laboratory of the U. S. national museum, where work will be begun at once on material that has been accumulating in the hands of the chief chemist, Prof. F. W. Clarke.

Professor Clarke has been appointed honorary curator of mineralogy in the U. S. national museum. At the New Haven laboratory, Dr. Carl Barus and Dr. William Hallock are conducting thermo-electric investigations. They find that thermo-electric couples containing nickel behave anomalously at temperatures above 400° C., but that couples of platinum, with palladium or iridium, are available for the measurement of high temperatures. With such couples, temperatures as high as 1200° may be measured as exactly as with the air-thermometer.

Fresh-water shells from the paleozoic rocks of Nevada. — The bed of calcareo-argillaceous strata containing this unusual fauna is situated near the base of the great lower belt of carboniferous limestone of the Eureka mining district, Nevada. The argillaceous layers pass into calcareous strata above, that contain a few plates of crinoidal columns, and fragments of brachiopods, and besides these a fauna of forty or more species that is purely marine, and closely related to that of the lower carboniferous fauna of the Mississippi valley.

Although there is now a large collection of material from the band containing the fresh-water shells that was collected subsequent to the geologic field-work, during which the specimens now to be mentioned were collected, it will not be studied until after the publication of the report on the Eureka district. This brief notice is to call attention to the occurrence of fresh-water shells in the paleozoic rocks, and also to state that more is to be presented when the paleontologic collections shall have been thoroughly worked over and studied.

The first species discovered was a Physa, — a form of the genus so characteristic that there is no need of making any other generic reference; judging, of course, from the shell, and not presupposing that any variation existed in the animal inhabiting it. For this species I have proposed the name Physa prisca (fig. 2). The second is a species so Ampullaria-like that a reference is made to that genus (fig. 3). The operculum is shelly, calcareous, concentric (fig. 3*a*). If not generically identical with Ampullaria, it certainly belongs to the group in a closely allied genus. The name Ampullaria? Powelli is proposed for it. The third species is a pulmonate shell that appears to be closely related to Auricula, and for which the name Zaptychius carbonaria (*nov. gen. et sp.*) is proposed.

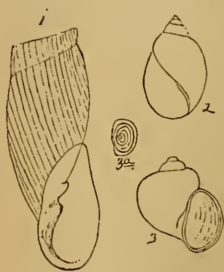

FIG. 1. — Zaptychius carbonaria × 5. FIG. 2. — Physa prisca × 2. FIG. 3. — Ampullaria? Powelli × 2. FIG. 3*a*. — Operculum of A.? Powelli.

A small lamellibranchiate shell that may be a Nucula, Corbicula, or Cyrena, probably one of the two latter, is associated with the above, and also fragments of twigs and small cones that may be referred to the Coniferae. The land-shells thus far described from the paleozoic series are all referable to the sub-order Geophila or terrestrial pulmonates, and comprise six species; viz., Pupa vetusta, P. Bigsbyi Dawson, P. vermilionensis, Dawsonella Meeki Bradley, Zonites (Conulus) priscus Carpenter, Anthracopupa ohioensis Whitfield (from the horizon of the coal-measures), and one species (Strophites grandaeva Dawson) from the erian plant-beds of St. John, N.B. To these we now add two species of the Limnophila (Physa prisca and Zaptychius carbonaria), and one species of an operculated fresh-water shell (Ampullaria? Powelli). It may be said of these species, as Principal Dawson has said of Pupa vetusta, they are remarkable not only for their great antiquity, but also because they are separated by such a vast interval of time from other known species of their race.

CHARLES D. WALCOTT.

PUBLIC AND PRIVATE INSTITUTIONS.

Williams college, Williamstown, Mass.

The natural-history department. — Through the liberality of friends, the college has secured a permanent table, with the necessary facilities for its use, in the museum of the U.S. fish-commission at Wood's Holl. The table will be occupied every summer by the department. The college has also leased for a series of years a table at Professor Dohrn's international zoölogical station at Naples, from the use of which it is hoped that permanent benefits will inure to this department. The conditions of the gift of the late Dr. William J. Walker make provision for a scientific expedition every fourth year.

NOTES AND NEWS.

THE extensive collections of American Coleoptera made by the late Dr. J. L. LeConte, containing an immense number of original types, become the property of the Museum of comparative zoölogy at Cambridge, Mass.

— We reproduce by photo-engraving, from *The photographic news*, a cut prepared from nature by the Luxotype process of the English firm of Brown, Barnes, & Bell. It should be mentioned that considerable clearness has been lost in the reproduction on account of the fineness of the stipple in the original, and the acknowledged hasty printing of the *News*. *The photographic news* has given during the last few months a number of separate imprints from plates made by processes similar to that of Mr. Ives of Philadelphia; that of Sara Bernhardt, in the issue for Nov. 23, being possibly the most satisfactory. Any one interested in the advances in the methods of making relief-plates for printing with type will find much in this series of articles of great interest. The portrait of Dr. LeConte, in this number of SCIENCE, was made by the Ives process, no hand-work having been used in the preparation of the plate from a photograph.

— While we are prosecuting our researches among the mounds, shell-heaps, and pueblos, of our own territory, we must not forget the thorough work going on in India under the patronage of the British government. For about ten years, an archeological survey of the ancient cave and rock-hewn temples of western India has been in operation, and, previously to the present year, three handsome quartos, profusely illustrated, have been published. The third volume treated more especially of the cave-temples of India.

During the present year, volumes iv. and v. have been issued, and complete the report of the survey, extending from 1876 to 1880. These volumes are about the size of the Smithsonian contributions, and are printed on fine paper, and elegantly bound. In volume iv. are forty heliotype plates and twenty-five woodcuts, and in volume v., sixty-one plates and eighteen woodcuts. It is not necessary here to enter into a minute description of these temples, since that has been done by Mr. Fergusson and Mr. Burgess, in their 'Cave-temples of India,' published in 1880. The method pursued is purely technical, "enabling the architect and the student to form a tolerably correct idea of the style and character of the plans and ornamentation. The facsimiles and translations of the inscriptions will afford fresh materials of a trustworthy character for the epigraphist and philologist." The principal group of rock-temples of western India is the magnificent series at Elura, consisting of splendid representatives of the three classes, Baudha, Brahmanical, and Jaina cave-temples. The village of Elura is in the Nizam's territory, about fourteen miles west of Aurangâbâd. Of this group, M. Baudrillart says, "All commentary grows pale before these magnificent ruins. Here the development of the plastic arts and of public religious luxury amongst the Hindus receives the most striking attestation in the magnificence of these temples, in the infinite diversity of their details, and the minute variety of their carvings."

— The Ottawa field-naturalists' club held the first *soirée* of their winter course on Thursday, Dec. 6, when the president, Dr. H. B. Small, delivered his inaugural address. After remarks on the past operations of the club, and suggestions as to its future management, he gave an excellent summary of past and present systems of the classification of the animal kingdom. The necessity of a knowledge of this character was strongly urged, in order that a just conception might be obtained of the relations of the different members of our fauna, and narrowness be avoided by those pursuing special studies. In his opinion, many persons who commenced the study of natural history abandoned it after a short time solely because, through ignorance of the relations of various objects, they failed to become imbued with that love of nature which the more carefully educated student possesses. An interesting discussion ensued on the address, in which several members shared. His excellency the Marquis of Lansdowne, governor-general of Canada, has consented to become patron of the club.

— At the annual meeting of the Boston zoölogical society, held Dec. 4, 1883, the following officers were elected for 1884: president, F. C. Bowditch; vice-president, F. H. Brackett; secretary, R. Hayward; treasurer, A. C. Anthony; librarian, H. Savage.

— In the Iowa weather bulletin for November, attention is called to "The most beautiful phenomena of the entire month. . . the varying and brilliant tints of sunset during the last five days of the month." These brilliant sunsets seem to have been noticed over the whole country.

The prediction is made, that "the winter now beginning will probably be a moderate or mild winter for Iowa and the adjacent parts of the northwest. The observations of the past ten years make the above probability very high, and, taking into account the entire series of forty years' observations, the chances for this winter proving a severe one are less than one in twenty."

— One of the most excellent of the familiar British museum catalogues is that lately published of the Batrachia, Gradientia, and Apoda, in the British museum, by Mr. George A. Boulenger. This work is called a 'second edition' of the catalogue of the same animals, published in 1850, by Mr. John Edward Gray; but it is a second edition only in name, as very little of Gray's work remains in it. The material studied by Boulenger (comprising ninety-seven of the one hundred and thirty-three species recognized, instead of forty-three) is far greater than that at Gray's disposal, and the character of the work done by the younger author is far higher.

The classification adopted by Boulenger agrees in many respects with that of Professor Cope; but some of the families and genera adopted by the latter are here given lower rank. The commonly accepted rules of zoölogical nomenclature are carefully followed by Mr. Boulenger, who evidently does not consider his own whims or prejudices, or even the traditions of the British museum, as forming a law higher than the law of priority.

Among the changes of current nomenclature considered necessary by Mr. Boulenger, we may note the substitution of the generic name 'Molge Merrem' for the later 'Diemyctylus' or 'Notophthalmus,' for our common red or green newt or 'evet;' of 'Cryptobranchus Leuckart' for the 'hellbender,' instead of the later 'Menopoma;' and of the name 'Necturus maculatus Raf.' for the 'mud-puppy,' instead of 'Menobranchus' or 'Necturus lateralis.'

An instructive discussion is given of the geographical distribution of the Batrachia, the geographical divisions with that group coinciding very closely with those recognized in the distribution of the fresh-water fishes.

— The Society of naturalists of the eastern United States will hold its second meeting at Columbia college, New-York City, Dec. 27, at ten A.M.

— Gen. Richard D. Cutts, first assistant superintendent of the U. S. coast-survey, died at Washington, Dec. 13, at the age of sixty-six. Gen. Cutts was born in Washington, and was connected with the coast-survey the greater part of his life. During the war he served on the staff of Gen. Halleck.

— On the 25th and 26th of October, there fell at Hilo, Hawaii, $17\frac{15}{100}$ inches of rain in twenty-two hours, by rain-gauge.

— The December number of *Van Nostrand's engineering magazine* contains an announcement, that, as the publication of the magazine has continually entailed a loss, the magazine will not be continued after the coming year, unless an increased support should justify it. That a magazine of such great merit should succeed is most heartily to be wished.

… SCIENCE.

FRIDAY, DECEMBER 28, 1883.

THE CHIEF SIGNAL-OFFICER'S REPORT.

The report proper of the chief signal-officer of the army for the year ending June 30, 1883, has been published in advance of the complete volume, which will contain the usual appendices. When compared with those of previous years, it presents a marked and most gratifying contrast. The useless and tiresome repetition of much that has appeared regularly since the organization of the service is no longer indulged in; and, in fact, the present report is brief, fresh, and vigorous. It is pleasant to see, that, among the various topics discussed, the first place is given to 'Instruction in meteorology.' Although somewhat crippled by lack of sufficient appropriation, this work has not been allowed to retrograde; and the encouraging fact is noted, that, out of a hundred and seventy-two enlistments made during the past two years, fifty-three were college graduates.

Gen. Hazen argues ably and pointedly against the inadequate provision made by the last Congress. The separation of the signal-service from the army proper, as far as its support from the general appropriation goes, undoubtedly left the service in a worse condition, even, than was intended by those who sought to reduce its expenditures. The result has been, that a number of stations have necessarily been closed, and much important work of the weather bureau has been suspended. It is certainly to be hoped that it may receive more generous treatment at the hands of the present Congress.

An interesting *résumé* of the scientific work of the weather bureau is given, which indicates a commendable activity in that direction. One of the most important announcements is, that a new standard of thermometry has been adopted "which no longer agrees with that of the Yale college observatory, but approaches more nearly to that of the International bureau of weights and measures." Another is, that steps have been taken to inaugurate in the immediate future a series of elaborate observations upon atmospheric electricity. The continuation of the publication of 'Professional papers' by members of the scientific corps is noted, one of the most important of which is that on 'Movements of the atmosphere,' by Professor Ferrel. It is gratifying to observe throughout the report, that scientific meteorology is receiving a recognition to a degree much greater than formerly.

A brief history of the unfortunate Greely expedition is presented, and the statement made that it is intended to apply for an appropriation to enable another relief expedition to be sent out in 1884.

The report covers twenty-two pages, instead of three or four times that number, as was the case in previous years; but, as a report of progress for the year, it is much more valuable than its predecessors. A similarly judicious treatment of the appendices and meteorological summaries, which will follow this report, would bring the whole into a much more useful and manageable form, and would not be the least important of the many reforms introduced into the service by its present chief.

ROMALEA MICROPTERA.

Should the return of spring be early, and the winter just passed an open one, a rambler in the meadows of southern Louisiana is very likely, during the middle of February, or perhaps even earlier, to have his attention drawn to curious little colonies of red and black grasshoppers.

These are the young of Romalea microptera. Until this summer I never saw a living adult specimen of this handsome insect, and my examination of it had been confined to a few individuals in alcohol. No sooner, however, had I thoroughly examined one of these little red and black colonists, than it struck me that they must be the young of the great black grasshopper I had seen in spirit. This was subsequently confirmed for me through the kindness of Mr. L. O. Howard, of the Agricultural department at Washington. One day last March, during the first part of the month, while on one of my collecting excursions in this country, my way lay through an extensive cypress-swamp. The only good footing was along a low, straight embankment, that had been made by the earth thrown out to dig a canal, to which it now formed the bank on one side. It was composed of a dry, black soil, upon which the new spring grass and the earlier plants had just commenced to make their appearance. It was here that I first came across a family, or brood rather (for no old ones are to be found at this time of the year), of the young grasshoppers in question. They extended obliquely across my path in nearly a straight line, about half a yard in length, and from three or four to a dozen or more individuals in width. Where small dry twigs occurred, or blades of grass, in their course, they completely covered them, and were so packed together that in some parts of the group they crowded each other a good deal. When first discovered, little or no activity among them was apparent; but no sooner did I commence to lay in a store of specimens than the survivors of my attack immediately began to hop off in all directions, obliging me very soon to make single captures. At this stage of their growth, these insects are about of the same size, having an average length of a centimetre; their general color being a deep, shiny black. This is set off by fine lines of brilliant vermilion, occurring at different places on the body. One strip extends mesiad, the entire length of the dorsal aspect, from a point between the antennae to the posterior extremity of the abdomen; another bounds, on either side for a short distance, the hinder margin of the prothorax; while the same is found behind the whole length of each of the hind-femora. The lower and posterior angle of the epicranium is also bordered by the same color as is its inferior margin in front, and a line that extends down from the eye on either side to join it. Finally we observe that each abdominal ring is emarginated in the same way, along the ridges of the pleurite portions, below the spiracles. At this age the antennae are half as long as the body.

A few weeks later, when they are about double the size I have just described, we begin to observe in these collections, which are apparently all of the same crop, some specimens considerably larger than the general run. These may be females, but this I cannot positively assert: though, as the insect grows, these larger ones maintain their size over the others; and later in the year we find them to be females, notwithstanding the sexes at these times seem to be pretty equally divided in numbers.

In the middle of June, a field in the vicinity of New Orleans, where the grass had grown to be about waist-high, was covered in one or two places of no great extent with these grasshoppers. They now ranged from four to five centimetres in length, and could be seen at several hundred feet distance. Other varieties of plants were covered with them; but I found none on the ground, unless they were accidentally knocked down, or jumped down when one failed in his efforts to capture them.

At these times they are very sluggish, emitting no sound or note that I ever heard, and do not seem to be feeding on the vegetation upon which they congregate. Their colors are now somewhat changed; and, though the black is as deep and shiny as ever, the red gradually fades to a brilliant orange, and a small pair of dull black wings commences to make its appearance.

In the country about New Orleans, Romalea seems to attain its full growth some time in the early part of July. This is denoted by the general appearance and habits of the insect: certain parts of his exoskeleton have become firm and hard, and all his structures and organs bear evidence of maturity. They are no longer found in groups in the meadows and forests, but dispersed, and occurring in all sorts of localities. Hundreds of them are found invading the cow-paths and roadways: others climb on fences and trees. Many still are yet observed, though now usually singly, on high grass and plant-stalks; and these we may easily discern at a long distance in the open fields. Even our houses are not altogether exempt, at this season, from this black-mailed vagrant. Many are killed by being trodden upon, or accidentally crushed in other ways; for they are slow to get out of one's road, and disinclined to jump much, — a feat in which the males, from their lighter weight, far exceed the larger and heavier females.

It is about this time of the year that we first begin to notice any thing approaching an *affaire d'amour* on the part of this now truly handsome insect. We now see many couples apparently regardless of those who behold their awkward and highly fantastic addresses. The only sound that I have ever heard this grasshopper give vent to, is now indulged in by the male. It consists simply of a series of peculiar hisses (this word expresses it better than any thing else), and is only heard when we seize and handle one of them, or during their mating. The sound seems to be produced largely by the wings; for these members are elevated at this time, as I have shown them in my plate, where the male exhibits his beautiful hind-wings, — a relief to his otherwise sombre tints that is only to be experienced on such occasions.

I am of the impression that Romalea does not confine itself to any particular diet, but is rather a general feeder, choosing such plants as happen to fall in its way. Some of them, that I kept alive for several days in a large box, fed upon almost any thing in the shape of vegetable growth that I offered them.

This view seems to be sustained by the report of Mr. L. O. Howard, who saw them in August in immense numbers in the rice-fields about the city of Savannah; 'yet they seemed to do little damage to the rice.' [1]

This observer tells us in the same report, that they are known in that locality among the people as the 'lubber grasshopper,' whereas, throughout this section of the country, they are called by every one the 'devil-horse.' Perhaps, if at one of their grand councils they had a choice in the matter, it would be hard for them to decide which was the prettier name, and no doubt they would vote unanimously to select some other one.

It has never been my fortune to find examples of the black variety of the female in southern Louisiana, as observed by entomologists elsewhere.[2]

On the 28th of last July, while engaged in looking for a specimen of the prothonotary warbler, which I had just brought down with my cane-gun from a magnolia under which I stood, my attention was attracted by a large female Romalea, with part of her abdomen buried in the ground, and evidently in the act of depositing her eggs. A chapter in the history of this insect at once flashed across my mind; and, in my undue eagerness, I removed her at once from the little excavation she was in on the ground; but the most careful search afterwards was not rewarded by the discovery of a single egg. However, the satisfaction was afforded me, at the subsequent *post mortem* of the specimen in question, of finding her ovaries containing upwards of fifty bright-yellow, spindle-shaped eggs, each about a centimetre long.

[1] Report commiss. agric., 1881–82, p. 138. [2] *Ibid.*, p. 138.

This circumstance convinced me that Romalea microptera deposits its eggs in the ground; and from that time I did not allow an opportunity to slip in searching for them. My interest in this matter was only increased by receiving a letter, a few days afterwards, from Mr. Howard, in which he informed me that it was not known where this grasshopper laid its eggs. I am sorry to say that I have not had the opportunity to examine the reports made by Glover upon this insect, in the report of the Department of agriculture for 1872, kindly called to my attention by my correspondent, nor the mention made of it in Ashmead's 'Orange insects,' also referred to by him.[1]

My search was, however, afterward rewarded; for on the 15th of August, while passing through a long, flat meadow a few miles from New Orleans, I came, at one end of it, to a little low mound about ten yards in extent, composed of a dry black earth, that was cracked and fissured in many directions by a sun that streams down here almost as mercilessly as in the tropics. Many tall weeds and grasses surrounded this miniature hillock, and others grew upon it.

Romalea had made this elevation its headquarters, and it was at the same time a rendezvous for many couples who had apparently postponed their honeymoons. The importance of the occasion was evident; for there was not a male on the ground, to say nothing of the majority who were perched up in the weeds, but was strutting about in the most business-like manner, or trying to do so on their perches in the latter. Whatever part of the entertainment these sable gentlemen entered into, they constantly kept up a very audible buzzing racket with their wings, which they elevated and lowered at few seconds' intervals, showing the inferior carmine pair each time they did so, with telling effect. At these times they assume the position in which I have drawn one in the plate, walking about in a stilted manner, but bearing, withal, a dignified mien, rattling their wings, and paying their court to the quieter and more sedate opposite sex.

Some of the females kept apart, and bore the appearance of being dejected, tired of the gayeties of the season, and otherwise bored by the proceedings that were going on everywhere about them. It was the sight of these satiated dames that soon brought the thought to my

[1] I have since ascertained that Mr. Charles R. Dodge, of the Agricultural department of Washington, has raised the young of Romalea from eggs that were laid by specimens he kept in confinement. He published his observations in the *Rural Carolinian* (April, 1874, p. 363, vol. v., no. vii.), Charleston, S.C.; and subsequently in the *Field and forest* (ii. 1877, p. 160), Washington, D.C.

mind, that perhaps they laid their eggs here too; and acting immediately upon this, as well as the suggestive fissures in their camping-ground caused by the sun, I proceeded to investigate those likely places in which they might deposit their ovicular treasures. These rents presented every stage of being filled in from one cause or another; and I had hardly commenced to scratch out the earth from one that was partially in this condition, than I came across masses of their eggs. They were not easily observed at first, as I turned them out with the stick I used in searching for them, from the fact that they resembled lumps of earth, as this substance adhered to their entire surface, either dusted over, or in little fragments, which latter rendered the resemblance still more deceptive. My plate represents one of these masses, that has been well cleaned off, in the lower right-hand corner (marked *A*). I have four before me that were collected at the time of my observations, and one of these is that figured in the plate.

The first of these masses that I pick up contains about thirty-five eggs, of a like size and shape to those removed from the body of a female several weeks before. They are in one rather irregular layer, being placed roughly parallel to each other, and entirely incased by the pellets of earth that have adhered to the mass. No true egg-pod was observed to enclose them; but, judging from the way in which the eggs of other large grasshoppers are laid, no doubt further observations will prove its existence. The eggs of this lot are all sound, and in an apparently safe condition till the time of hatching, as they were several inches below the surface of the ground. In the next collection the mass is of a circular form, with the eggs arranged pretty much as we found them in the first lot. Here, however, they are quite distinct, being simply dusted over with a little earth; and I find several of them have been opened at the sides, and their contents removed, apparently by ants or other insects. The two remaining masses are essentially of the same description as those we have just described. One is a little different in shape, being oblong instead of circular. This form may have been forced upon it from the narrowness of the fissure in which the eggs of this lot were laid. Of these four deposits, we may say that they contain an average of thirty eggs apiece; and this statement, no doubt, will be very near the correct one for the usual number found in such masses.

Examining one of these eggs under a two-inch objective, we find it composed of an outer coat, brown in color, fibrous in texture, and about 0.1 of a millimetre in thickness. The little fibres are placed side by side, and vertical to the surface of the egg. This coat fractures off in small pieces quite easily, and, in so doing, exposes the thin membranous and transparent inner coat, which allows one to see through it the amber-colored contents of the egg proper, which are of a viscid character and of about the consistency of old olive-oil.

This was the only occasion upon which I ever succeeded in finding any of the eggs of this grasshopper; and I am unable at the present writing to say how many times they deposit during a season, or how often Romalea moults during the same period.

It was my intention, when I commenced this paper, to enter to some extent upon the anatomy of this insect; but the idea was eventually abandoned from the fact that the anatomy of locusts and grasshoppers has been very ably and extensively worked up by many entomologists: so, to enter upon this subject at all in the present case would entail a minute study of details and comparisons that would result in carrying my paper much beyond its intended limits. Then, too, so far as the external appearance of Romalea is concerned, I have made every effort to convey a correct idea in my plate, both of the male and the female; and this work has been most carefully and beautifully reproduced by my engravers, Messrs. T. Sinclair and Son of Philadelphia, — a firm to whom our scientific men are under so many obligations for faithful reproductions of their work. This sketch, in its present form, then, is offered to the readers of Science as a contribution to the life-history of Romalea microptera; and it is hoped that in it at least a few facts will be discovered that will prove of interest to entomologists.

R. W. Shufeldt,
Captain Medical corps, U.S.A.

RESOLUTIONS OF THE INTERNATIONAL GEODETIC COMMISSION IN RELATION TO THE UNIFICATION OF LONGITUDES AND OF TIME.

The seventh general conference of the International geodetic association held at Rome, and at which representatives of Great Britain, together with the directors of the principal astronomical and nautical almanacs and a delegate from the Coast and geodetic survey of the United States, have taken part, after having deliberated upon the unification of longitude by the adoption of a single initial

Science [illegible]

R W Shufeldt del

T Sinclair & Son, Lith Phila

ROMALEA MICROPTERA

meridian, and upon the unification of time by the adoption of a universal time, has agreed upon the following resolutions: —

1°. The unification of longitude and of time is desirable as much in the interest of the sciences as in that of navigation, of commerce, and of international communications. The scientific and practical utility of this reform far outweighs the sacrifice of labor and the difficulties of re-arrangement which it would entail. It should, then, be recommended to the governments of all the interested states to be organized and confirmed by an international convention, to the end that hereafter one and the same system of longitudes should be employed in all institutes and geodetic bureaus, for general geographic and hydrographic charts, as well as in astronomical and nautical almanacs, with the exception of those made to preserve a local meridian; as, for instance, the almanacs for transits, or those which are needed to indicate the local time, such as the establishment of the port, etc.

2°. Notwithstanding the great advantages which the general introduction of the decimal division of a quarter of the circle in the expressions of the geographical and geodetic co-ordinates and in the corresponding time-expressions is destined to realize for the sciences and their applications, it is proper, through considerations eminently practical, to pass it by in considering the great measure of unification proposed in the first resolution.

However, with a view to give satisfaction at the same time to very serious scientific considerations, the conference recommends, on this occasion, the extension, by the multiplication and perfection of the necessary tables, of the application of the decimal division of the quadrant; at least, for the great operations of numerical calculations for which it presents incontestable advantages, even if it is wished to preserve the old sexagesimal division for the observations, for charts, navigation, etc.

3°. The conference proposes to governments to select for the initial meridian that of Greenwich, defined by a point midway between the two pillars of the meridian instrument of the observatory of Greenwich; for the reason that that meridian fulfils, as a point of departure for longitudes, all the conditions wished for by science, and because, being at present the best known of all, it offers the most chances of being generally accepted.

4°. It is suitable to count the longitudes, starting from the meridian of Greenwich, in the sole direction from west to east.

5°. The conference recognizes for certain scientific wants, and for the internal service in the great administrations of routes of communication, — such as the railways, steamship-lines, telegraphic and post routes, — the utility of adopting a universal time, along with local or national time, which will continue necessarily to be employed in civil life.

6°. The conference recommends as the point of departure of universal time and of cosmopolitan dates the mean noon of Greenwich, which coincides with the instant of midnight or with the commencement of the civil day, under the meridian situated twelve hours, or a hundred and eighty degrees, from Greenwich.

It is agreed to count the universal time from 0 hour to 24 hours.

7°. It is desirable that the states which, with a view to adhere to the unification of longitudes and of time, find it necessary to change their meridians, should introduce the new system of longitudes and of hours as soon as possible.

It is equally advisable that the new system should be introduced without delay in teaching.

8°. The conference hopes, that, if the entire world agrees upon the unification of longitudes and of hours by accepting the meridian of Greenwich as the point of departure, Great Britain would find in this fact an additional motive to make, on its part, a new step in favor of the unification of weights and measures by adhering to the *Convention du mètre* of the 20th of May, 1875.

9°. These resolutions will be brought to the knowledge of the governments, and recommended to their favorable consideration, with an expression of a hope that an international convention — such as the government of the United States has proposed — for confirming the unification of longitudes and of time should be decided upon as soon as possible.

ORIGIN OF THE MESODERM.

The origin and composition of the mesoderm has been the subject of perhaps more discussion than any other single point in the whole range of embryology. Observers have given the most conflicting statements, for the most part due to incomplete observations; but now we are at last in a position to eliminate many of the false descriptions and to harmonize fairly well those we must regard as correct.

The first important advance was accomplished by His, who made the fundamental discovery that the mesoderm is not homogeneous, but double, in its origin. The ectoderm, entoderm, and part of the mesoderm, he distinguished under the common name of 'archiblast,' from that portion of the mesoderm which is related to the connective-tissue group (connective tissue proper and endothelia), and which he supposed to grow from the yolk (in the chick) into the archiblastic tissue or cells, which, from the first, are constituent elements of the embryo. His maintained that the parablast-cells were derived from the white elements of the yolk, but in that respect he is believed to be in error; nevertheless to His belongs the great honor of having first insisted upon the duplex development of the middle germ-layer. This knowledge is the key to the solution of one of the fundamental problems of animal morphology.

The researches of Professor His have been confined to vertebrates. One cannot but feel that his views would have been modified in many details, if he had included the lower types, also, in his investigations. The discoveries of others, however, have gradually made it clear that among invertebrates, also, the twofold composition of the mesoderm exists. The path to this generalization may be said to have opened out upon the announcement by Alexander Agassiz that in echinoderms the lining of the body-cavity and water-vascular system is derived from the entoderm. Selenka and others have since shown that the rest of the mesoderm is derived from scattered and isolated cells, which are thrown off from the other layers into the space between the ectoderm and entoderm. It was thus clearly shown that in this class of animals the mesoderm primitively consists of two epithelial evaginations and of scattered and independent cells of amoeboid character. The fundamental importance and the far-reaching significance of this discovery were unfortunately not appreciated at the time.

For several years past I have been accumulating materials for a work on 'Comparative histology,' and have meanwhile directed my attention chiefly to the classification and genesis of tissues. These preliminary studies led me to various conclusions, among which was the conviction that amoeboid cells were the primitive representatives of the mesoderm, and that from them was derived a large part of the mesodermic tissues. This view I published in 1879;[1] but the article has, so far as I am aware, been entirely overlooked by subsequent writers, and I therefore venture to call especial attention to it now, as the opinion I then advocated has since become a current embryological generalization. To the cells I gave the name of 'mesamoeboids.'

The investigations of Hatschek, whose brilliant discoveries have not yet received their deserved recognition, have revealed that in Bryozoa, Mollusca, Annelida, and Amphioxus, the mesoderm arises, 1, from cells, such as we have seen may be classed under the head of mesamoeboids; 2, from two paired masses of cells, his 'mesodermstreifen,' whose origin from the entoderm is rendered probable in all cases, and certain in some, by known characteristics. These stripes either have from the first, or soon acquire, a distinctly epithelial structure. Hatschek appears to have recognized the bearing of his observations nearly as we conceive it now; and to him, I think, we should accord the honor of having first clearly and definitely recognized the dual histogenesis of the mesoderm.

F. M. Balfour, in his writings, particularly in his 'Treatise on comparative embryology,' made the next important step by pointing out that the vertebrate mesoderm probably arose as a pair of diverticula from the gastrula cavity; and he gave a new meaning to, and justification of, this theory, by insisting upon the homology between the blastopore of the Ichthyopsida and the primitive streak of the Amniota; for from the walls of the former, as well as from the substance of the latter, the paired outgrowths of the middle layer arise. The deficiency in Balfour's presentation of the subject lies in his failure to recognize the importance of the mesamoeboids.

The brothers Hertwig have published a series of contributions to the solution of the problem, and have embodied their general results in an article entitled the 'Coelomtheorie.' As we have shown, their predecessors had pretty well established the necessity of regarding the mesoderm as consisting of two parts, — *first*, the paired epithelial portion derived from the entoderm, forming the lining of the body-cavity, and giving origin to the peritoneum, muscle-plates, genital glands, etc.; *secondly*, scattered cells, giving origin to the connective tissue, the endothelia, vessels of the circulation, the blood, and lymph. These conclusions, however, had never been systematically collated and coherently presented. The brothers Hertwig performed this task with characteristic ability and success. Guided by their own important original researches on several animal types, and utilizing the results of others, they succeeded in demonstrating the prevalence of the same composition of the mesoderm in the

[1] Minot: Preliminary notice of certain laws of histological differentiation. *Proc. Boston soc. nat. hist.* xx. 207.

majority of animals. Their own most important addition to our knowledge appears to me to be their analysis of the morphology of muscular tissue, by which they removed the most important difficulty against the final acceptance of the generalization. While we thus recognize the great services rendered by the brothers Hertwig, we are impelled also to express our regret that they have not been more generous in their acknowledgment of the achievements of previous investigators; for their theory was mainly the result of a judicious combination of what had been before published. To them belongs the merit of ripening the fruit which was already formed.

To the mesamoeboid portion of the mesoderm the Hertwigs gave the very appropriate name of 'mesenchyma.' For the epithelial portion no satisfactory name has yet come into use: therefore I venture to propose 'mesothelium.'

In applying this generalization which we have been considering to vertebrates, difficulties and objections were encountered. To set these aside, Professor Oscar Hertwig has published two special researches, the second of which appeared recently, and is reproduced in abstract below.

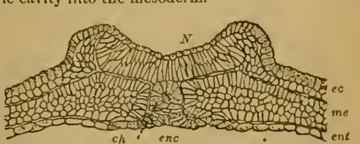
In this review, only a few salient points of the history of this most important of recent embryological discoveries are given; but I cannot close without a strong expression of my regret at being unable to notice many valuable contributions to the subject, — a pleasure which the limited space at my disposal compels me to unwillingly forego.

In continuation of the extended researches on the origin of the mesoderm previously given to the world by his brother and himself, Oscar Hertwig now publishes the results of his investigations on the development of the middle layer in the frog, adding a discussion of its origin in other vertebrates. The early stages in the frog are described with great minuteness, and with far less concision and directness than we should have anticipated in any of Professor Hertwig's writings.

The essential points brought forward are the following. In the first stage, while the blastopore still appears as a round white spot, the primitive *darm* (urdarm) has the well-known form. Its inferior and lateral boundaries are the cells of the entoderm; but along the dorsal line the cells offer a different histological character, being pigmented, and consisting of three or four rows of small cells. In Triton, however, there is a single row of high cylinder cells. This dorsal band includes the *anlage* of the notochord, and is named by Hertwig 'chorda-entoblast.' Around the blastopore the mesoderm is already present, forming a paired extension running forward as a lateral mass on either side, and a median division lying below the blastopore. Around the edges of the blastopore all the layers are united: throughout the remainder of its extent the mesoderm is separated by a narrow space from both ectoderm and entoderm. The mesoderm and the chorda-entoblast are both histologically similar to the ectoderm; and Hertwig, on that account, believes they are both derived from the outer germ-layer. (This conclusion we think is founded upon an insufficient basis.)

In the next stage the blastopore remains merely as a white point, and the medullary folds and median dorsal furrow appear. The notochord is developed under the dorsal furrow as a thickening of the median portion of the chorda-entoblast, which butts against the ectoderm, so that the mesoderm is excluded from the axial line. Ultimately the lateral portion of the chorda-entoblast enters into the formation of the intestinal wall; but in Triton the whole of this peculiar band is changed into the chorda, which, being formed by an invagination, exhibits a slit in transverse sections of early stages. No such slit is seen in frogs. There is a fold formed at the lateral junction of the chorda-entoblast with the rest of the entoblast; and along that fold the entoderm is fused, without demarcation, with the mesoderm. Around the blastopore the three layers still present essentially the same arrangement as before; the mesoderm has grown out around the whole ovum, except a small area on the ventral side, where the ectoderm and entoderm (yolk) are in immediate contact.

In the next stage, when the whole length of the broad medullary groove is clearly marked out, and indeed in later stages also, the absolute independence of the notochord of the mesoderm, and its development out of and gradual separation from the chorda-entoblast, are to be clearly recognized (see the accompanying figure). In the region of the blastopore, where the mesoblast is continuous with the other layers, there are two projecting lips, on one side formed by the entoderm proper, on the other by the chorda-entoblast. These lips enclose a fissure between them, which is a small evagination of the enteric cavity into the mesoderm.



Frontal section through a frog ovum in which the medullary ridges have begun to appear. *Ent*, entoderm; *enc*, chorda-entoblast; *ch*, notochord; *me*, mesoderm; *ec*, ectoderm; *N*, nervous system.

In a later stage the anus is developed *behind* the blastopore as a simple ectodermal invagination, the bottom wall of which breaks through. No such relations between the germ-layers have been found here, or elsewhere, as around the blastopore.

The points, then, of special importance, brought out by Hertwig, are, 1°, the existence of the median dorsal band of cells, the chorda-entoblast, entering into the formation of the entodermic wall, but resembling in character the ectodermal cells; 2°, the development of the mesoderm as a paired outgrowth from the blastopore. In part second of his paper, Hertwig reviews the published investigations on the embryology of other classes of vertebrates. He accepts the homology of the primitive streak in Amniota with the blastopore. He is fairly successful in proving the same relations of the germ-layers to exist in all vertebrates. He also discusses the various objections advanced against the *coelomtheorie*, according to which the mesoderm is an epithelial layer, bounding the body-cavity. He draws from his observations and arguments the following conclusions: 1. The mesoblast grows as a continuous mass from acknowledged epithelial layers; 2. In all vertebrates there early appears a fissure in the mesoderm, limited parietally and viscerally by epithelium, as can be especially well seen in elasmobranch embryos; 3. From this epithelium are derived true epithelial membranes in the adult, from which are developed the peritoneum, kidneys, sexual glands, etc.; 4. The primitive mode of origin of the mesoderm is probably that described by Kowalevsky and Hatschek in Amphioxus, —an invagination of an epithelial membrane (entoderm); 5. In the true vertebrates the mesoderm grows out as a solid mass, in which the fissure appears later. This must be regarded as a secondary modification, for we frequently find hollow organs making their first appearance as solid *anlagen;* e.g., the central nervous system of teleosts, many sense-organs, and most glands. These considerations lead collectively to the final conclusion that the mesodermic plates are morphologically epithelial evaginations homologous with those of the invertebrates.

CHARLES SEDGWICK MINOT.

ACOUSTIC ROTATION APPARATUS.

In a recent number of the *Zeitschrift für instrumentenkunde*, Dr. V. Dvořák gives an account of the various forms of apparatus which have been devised to show attraction or repulsion due to sound-waves, or to gain a continuous rotation.

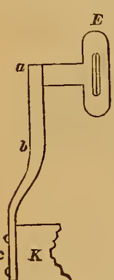


Fig. 1.

Such experiments require a good volume of sound for success. That this may be obtained, not only should the tuning-fork be in accord with the resonator-box on which it is placed (the most convenient form of sounding-body for the purpose), but also the elastic system, consisting of tuning-fork and box, should be capable of vibrating in unison with the fork and the air in the resonator. The three sounds are called the fork, the air, and the wood tone. In order to get the last, the resonator should be stuffed with cotton-wool, and a piece of cork put between the prongs of the fork; then, by rapping on the top of the fork, the whole system is vibrated very much as it would be by the up-and-down motions of the lower part of the fork when free. By cutting away the walls of the resonator to make them thinner, the system may readily be brought to the right pitch. In most of the resonators in common use the wood tone is too low, owing to the wood being already too thin.

The fork used by Dr. Dvořák was *G*, having 392 vibrations per second. It weighed 265 grams. As a resonator, an ordinary pine box was used, about 13.5 cm. long, 11 cm. broad, and 10.5 cm. high. In one side a round hole was cut, large enough to make the air tone of the right pitch. The wood was 8 mm. thick. From the top and bottom it was shaved off for the purpose explained above. The dimensions of the box were entirely accidental, but proved to be good.

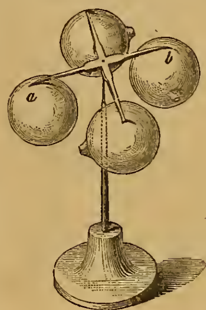

Fig. 2.

By using an electro-magnet to keep the fork in continuous vibration, the results are naturally more sure. The form of magnet which has proved satisfactory is shown in fig. 1. *E* is the magnet, with a core made of iron plates. This magnet is placed between the prongs of the fork, and is held by the wooden arm *a c*, to the lower end of which is fastened the resonator *K*. At *b* the arm is bound to a firm support, so that the system of fork and resonator is perfectly free.

The resonator-wheel (fig. 2) is the first form of rotating apparatus described. It consists, as shown in the illustration, of four glass resonators on the four arms of a wheel. For a fork of 392 vibrations, the spheres should be about 44 mm. in diameter, with openings 4 mm. across. Rotation was obtained with the fork 40 cm. away.

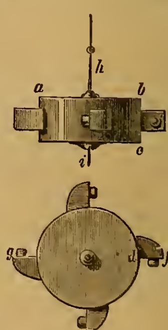

Fig. 3.

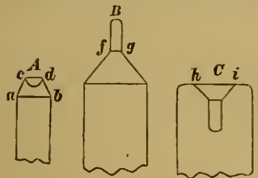
As a modification of this wheel, a rotating resonator (fig. 3) may be made of a flat cylindrical pasteboard box, having a number of side-openings, each ending in a short piece of tubing of size to make the resonator respond to the fork. When suspended by a silk thread, *h*, such a resonator can be easily put in rotation ; *i* is a needle to rest in a hole in a piece of lead, to prevent oscillation. The dimensions given are: *a b*, 70 mm.; *b c*, 36 mm.; *d f*, 19 mm. The tubing openings were 8 mm. long and 6 mm. in diameter.

The sound-radiometer (fig. 4) is readily made. In cardboard about 8 mm. thick, holes are punched at intervals of 6 mm. with the punch of the form shown at *A*. When prepared in this way, the cardboard will be repelled if presented to the resonator with the small ends of the holes toward it, and attracted when reversed. To make these effects more marked, the punch and die shown at *B* and *C* may be



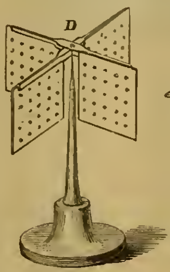


Fig. 4.

used on moistened cardboard to form conical holes with cylindrical ends. The conical holes alone show no effects. By arranging the pieces of pasteboard as in *D*, or better as in *E*, a rapid rotation may be obtained. The apparatus shown in fig. 5 is called a sound-wind-mill. A Helmholtz resonator, *a b*, is placed before the opening of the box-resonator. Out of the smaller end, *a*, a stream of air will be blown when the fork is vibrated, and its existence shown by the rotation of the windmill, *h k*. The dimensions of the Helmholtz resonator for *G* are : diameter, 80 mm. ; the opening at *b*, 16 mm. ; at *a*, 2 mm. This last is very important. It seems odd that the resonator with two openings may be replaced by such as shown at *R* with only one. The opening may face in any direction, provided the windmill is suitably placed, and still the mill will turn. When the opening is turned toward the resonator-box, the distance between the

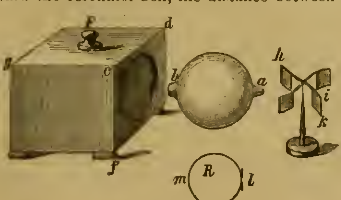

Fig. 5.

resonators may be as great as half a metre. The dimensions and form of the ball are important. A suitable one may be made by grinding off the top of a glass globe 50 mm. in diameter, and covering the opening with a very thin metal plate in which there is a hole 3.5 mm. across. The puffs of air coming from the opening *l* are vortex-rings, which may easily be shown by filling the ball with smoke.

By putting one of the wings of the sound-radiometer before the box-resonator with the larger ends of the holes facing it and at a distance of 2 cm. from it, the mill may be made to rotate by the puffs of air coming through the holes, which should be numerous.

AURORAL EXPERIMENTS IN LAPLAND.

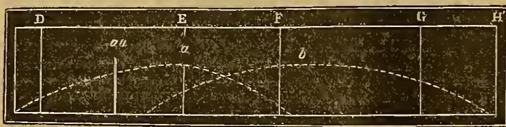
MR. J. RAND CAPRON gives a brief account (*The observatory*, Sept.) of Professor Lemström's experiments, quite similar to that which has already appeared in SCIENCE. He thinks that Professor Lemström's conclusion, that the height of auroras "has been generally over-estimated may probably open a lively discussion, as undoubtedly his dictum will that 'measurements of an aurora on a long base must be erroneous, as the observers never see the same aurora.'" He thinks, too, that the relation Professor Lemström believes himself to have proved, between movements of atmospheric electricity and the 'variations of the magnetic elements,' may be only apparent.

Mr. Capron believes that the experiments described did "collect and make apparent to the eye a true auroral glow, its spectroscopic character being at the same time tested and defined by experienced observers." He adds, "Yet one cannot help feeling something of regret that, if only for further assurance, the wave-length of some one line seen was not (as far as we are aware) absolutely determined, on some occasions at least, and that the observations appear to rest only on a small instrument presumably without scale."

Mr. Capron's article is important mainly for calling renewed attention to the phosphorescence, or fluorescence, theory of the principal (yellow-green) line of the aurora spectrum. This theory, first proposed by Angström, was advocated in the *Philosophical magazine* for April, 1875, by Mr. Capron, who is inclined to attribute the line to phosphorescence, apparently on the following grounds: 1°. The 'phosphorescent appearance' of the aurora ; 2°. The fact that phosphorescence is capable of giving quite sharply defined spectral lines, as shown by his observations with a phosphorescent vacuum tube ; 3°. The fact that the auroral line belongs to 'the principal region of phosphorescent light;' 4°. 'The observed circumstance that the electric discharge has a phosphorescent afterglow.'

Mr. Capron observed, moreover, that the auroral line lies in the region of a certain bright band in the spectrum of a phosphoretted hydrogen flame, though somewhat nearer the red end of the spectrum than is the brightest part of this band, as shown in the accompanying figure.

"In this diagram (of a normal spectrum), curve *a* [which Mr. Capron calls the phosphorescence curve] is deduced from the spectrum of phosphoretted hydrogen, curve *b* from Professor Angström's spectrum of the violet pole of air-vacuum tubes; *a u* is the principal auroral line." This figure is apparently intended



to represent the facts under ordinary laboratory conditions; but Mr. Capron states, that according to Lecoq de Boisbaudran, when the flame of phosphoretted hydrogen is artificially cooled, the bands of the spectrum become intensified, and in such a way that the brightest portion of each band is shifted toward the red end of the spectrum. Mr. Capron appears to think, that, under the intense cold of the auroral regions, one of these bands might become the line *a u*.

E. H. HALL.

LETTERS TO THE EDITOR.

Secular increase of the earth's mass.

THE thoughtful and suggestive researches of Ebelmen and T. Sterry Hunt, on the chemical and geological relations of the earth's atmosphere,[1] have led me to some further deductions, which seem to increase the interest in this field of inquiry. The general tendency of these studies is to show that the chemical transformations in progress upon the earth involve the fixation of a larger volume of atmospheric constituents than could probably have ever existed in the atmosphere at one time, and that they must consequently have arrived from interplanetary space.

1. *The carbonates.* — It is generally agreed, as first shown by Hunt, that the carbonates of lime and magnesia have arisen chiefly through the interactions between carbon dioxide of the atmosphere, the decomposing silicates of the earth's crust, and the chloride of calcium of the ocean. The carbon dioxide has therefore been contributed by the atmosphere. To what does this contribution amount? We may assume, without material error, that the carbonates here in question are all calcium carbonate, with a specific gravity of 2.72. Then, the mean pressure of the atmosphere being about 14.7 pounds avoirdupois on a square inch, a little calculation shows that an amount of carbon dioxide in the atmosphere sufficient to double its pressure would yield only 8.627 metres of limestone. An amount sufficient to cause a pressure of 80 atmospheres would suffice for the formation of limestones equal to only a fortieth (.02265) of the hundred thousand feet which, for this purpose, may be assumed as the thickness of the stratified rocks. But a pressure of 80 atmospheres at a temperature of 30° C. produces liquefaction of carbon dioxide. The actual proportion of limestones and dolomites in the earth's crust is about one-eighth, as I have shown by recent studies. This amount would yield, by the liberation of all its carbon dioxide, a pressure of 441.6 atmospheres. If we consider the limestones and dolomites formed since the period of the coal-measures, the proportion required to yield, on the liberation of its carbon dioxide, a pressure of 80 atmospheres, would be only a twenty-second (.04469) of all the post-carboniferous strata. The actual proportion is about one-eighth, as for the whole stratified crust; and this would yield sufficient carbon dioxide to cause a pressure of 223.8 atmospheres.

It is not credible that such amounts of carbon dioxide have ever existed in the atmosphere at one time. During the larger part of the aeons of carbonate formation, animal life has existed in great abundance upon the earth; and this would have been impossible with 200 to 400 atmospheres of carbon dioxide present. As the proportion of this gas in the existing atmosphere is only 4½ parts in 10,000 by weight, 200 atmospheres of the gas would be 444,000 times the present proportion. It is scarcely more credible that the pressure of 200 to 400 atmospheres would have been compatible with either vegetable or animal organization, so similar as it was fundamentally to modern organization. As this large amount of carbon dioxide cannot be supposed derived from the earth's crust, it must have been derived from interplanetary space. This would imply an addition to the earth's mass of .0003806, which is about $\frac{1}{2636}$ part of the present mass.

2. *The kaolinization of felspars.* — Hunt has shown that the kaolinization of a layer of 51.66 metres of orthoclase, or its equivalent of quartzo-felspathic rocks, would result in 23.7 metres of kaoline, and would use up 10,333 kilograms of carbon dioxide per square metre of surface. This is the weight of the atmosphere. Now, the whole amount of felspathic decomposition during the sedimentary ages must much exceed 500 metres in vertical thickness of kaolinic deposits. But 500 metres of kaoline represent 21.1 atmospheres of carbon dioxide; and, assuming the mass of the atmosphere at $\frac{1}{1200000}$ in relation to the earth, the carbon dioxide fixed in the processes of kaolinization would be .0000175826 of the total mass of the earth.

3. *Decay of hornblende, pyroxene, and olivine.* — According to Hunt, the decay of 10⅓ metres of such minerals, or their equivalents in hornblendic and pyroxenic rocks, would yield carbon dioxide equal to 1 atmosphere: hence, if the earth's crystalline rocks have afforded 500 metres of hornblende and pyroxene, they must have fixed 48.387 atmospheres of carbon dioxide. This, in relation to the earth's mass, is .0000403209.

4. *Conversion of ferrous into ferric oxide.* As Ebelmen states, the conversion of 21,357 kilograms of ferrous oxide into 23,750 kilograms of ferric oxide would consume the whole of the 2,376 kilograms of oxygen in the atmosphere (more exactly, 1.007 atmospheres) covering a square metre. If, then, we suppose the existence over the earth of 1,000 metres of sediments derived from the decay of crystalline rocks containing only one per cent of ferrous oxide, weighing, according to Hunt, 25,000 kilograms, this is 1.052 times the amount requisite to fix the oxygen in 1.007 atmospheres; that is, 10 metres of ferric oxide represent the fixation of 1.059 atmospheres of

[1] See a memoir by T. Sterry Hunt in *Amer. journ. sc.*, May, 1880, where references are given to numerous other publications.

oxygen. This, in relation to the earth's mass, is .0000008825.

5. *Unoxidized carbon.* — This occurs not only in coal-beds, but in pyroschists and petroleum. We find that the oxidation of a layer of carbon 0.7123 metre in thickness would use up all the oxygen in the atmosphere. A layer 2.252 metres thick, and having a specific gravity of 1.25, if converted into carbon dioxide, would exert a pressure of one atmosphere. This would amount to 2,267,000 tons of 2,240 pounds each on a square mile. Mr. J. L. Mott calculates that the amount of unoxidized carbon per square mile cannot be less, and is probably many times greater, than 3,000,000 tons. If we adopt this determination, it will imply a depth of 0.982 metre, and the proportion of the earth's mass will be .00000036318. This is the amount of carbon dioxide which must be decomposed to yield a layer of carbon over the earth only a trifle over three feet in thickness, while it is probable that the carbonaceous deposits of the earth's crust exceed this. Now, it will hardly be maintained that the uncombined carbon of the earth's crust was derived from any other source than the atmosphere, and mostly through the agency of vegetation. The earth's atmosphere must therefore have contained all this amount of carbon dioxide. With the fixation of the carbon, the freed oxygen, it may be said, might have been employed, as far as it would go, in the formation of ferric oxide, whose demands upon the atmosphere have just been computed; but, as it would only satisfy $\frac{1}{309}$ of those demands, it is hardly necessary to consider the question.

6. *Meteoric contributions.* — If, as commonly assumed, 400,000,000 meteors enter our atmosphere daily, an average weight of ten grains each would amount to a yearly addition of 93,170 tons. This, in 100,000,000 years, would amount to .000000001542 of the earth's mass, and would form a film .292, or nearly $\frac{3}{10}$, of an inch thick, having a density of 2.5.[1]

Gathering together these various contributions to the earth's mass during 100,000,000 years, we have the following: —

1. CO_2 represented by the carbonates . . .	.0003896
2. CO_2 fixed in kaolinization of felspars . .	.0000175826
3. CO_2 fixed in decay of hornblendic and augitic rocks	.0000403209
4. O fixed in conversion of ferrous oxide . .	.0000008825
5. CO_2 represented by uncombined carbon .	.00000036318
6. Meteoric contributions	.000000001542
Aggregate	.000439750722

This is an addition of $\frac{1}{2274}$ to the earth's mass; and, in the present state of knowledge, it does not appear on what grounds assent can be withheld from the result, or some result of similar purport. It must be left with the astronomer to determine what relation this increase may sustain to the moon's acceleration in its orbit and to other phenomena. It may be noted, however, that the remote secular recession and retardation of the moon, which G. H. Darwin has recently brought to view, would have been delayed by the cause here considered, and the time required for the attainment of the moon's present relations would have been prolonged, but to what extent remains to be determined.

The evidences disclosed by these recent researches, of the slow accession of gaseous and solid matters to the earth, possess a profound interest. It would almost seem that the earth's atmosphere is only so much of the intercosmical mixture of gases and vapors as the earth's mass is capable of condensing around it, and that the proportions of these gases are determined separately, each by its own weight and elasticity and by its relative abundance in space; so that, as any one becomes diminished by fixation in the planetary crust, new supplies arrive to keep the ratio constant. As under this view it is apparent that an atmosphere should be accumulated around the moon, even after the saturation of the pores of its rocks, it may be said that the moon's mass and volume are such that her atmosphere would possess only $\frac{1}{36}$, or, according to Neison, $\frac{1}{50}$, the density of the earth's atmosphere; and this degree of tenuity might reduce the lunar atmospheric refraction to the small value actually observed.

ALEXANDER WINCHELL.

[1] The value given for this film in a note, p. 14, in my 'World-life,' should be multiplied by 365¼.

Regulation of electromotive force.

In one of the articles — the first, I think — recently published in SCIENCE (ii. 642) upon the subject of the electric light on the U. S. fish-commission steamer Albatross, the writer tells us that the brilliancy of the Edison incandescent lamps is kept constant, when other lamps upon the circuit are lighted or extinguished, by placing an adjustable resistance in the circuit of the field-magnets of the dynamo-electric machine, 'whereby the internal and external resistances are balanced.'

The importance of the subject scarcely seems to warrant any more space being devoted to it than already has been. But the point that I bring up is not an immaterial one, such as whether the engine is on the port or the starboard side of the vessel: it is a question which involves interesting and important physical principles.

The reason an adjustable resistance is required in the field-circuit of an Edison dynamo, in order to maintain a steady incandescence of the lamps, results from the fact that the armature has some resistance. This resistance is quite small, to be sure, but it has a considerable effect, nevertheless.

In order that a multiple arc system should be perfect, so that the dynamo or generator would require no adjustment or regulation when lamps were turned on or off the circuit, it would be necessary that this generator should have absolutely no resistance: for, if it were possible to reduce the internal resistance to zero, then there would be no fall of potential within the machine itself; that is, the fall of potential would all be in the external circuit, and the difference of potential between the poles of the generator would be equal to the total electromotive force of the circuit. In that case, all that is necessary is to keep the electromotive force constant; and then it follows, that any number of the lamps in the system may be lighted or put out without producing any fluctuation whatever in the light of the other lamps, because the incandescence of a given lamp depends only upon the electromotive force with which it is supplied. Now, we know that the electromotive force generated by a dynamo is constant, provided that the speed of rotation of its armature, and the intensity of the field-magnetism, are kept constant. The armature is maintained at a constant speed because it is driven by a steam-engine furnished with a governor, the function of which is to secure a constant speed;[1] and the field-magnets have a constant strength because the current which excites them is constant, since this current, like the current in the lamps, is produced by an electromotive force, which, by hypothesis, is constant.

Let us now consider the case where the resistance of the armature is not zero (to which, of course, it

[1] The speed would remain constant, but the *power* required would increase with the number of lamps in circuit.

never could be reduced), but is some small fraction of an ohm (say, .2 ohm), and suppose that there is a single lamp of 140 ohms' resistance in circuit, and that the electromotive force is 100 volts: then $\frac{140}{140.2} \times 100 = 99\frac{6}{7}$ volts will be the fall of potential in the lamps, and only $\frac{1}{7}$ volt in the armature. But suppose that there are 70 lamps of the same resistance (140 ohms) in circuit, instead of a single one: then the external resistance will be reduced to $\frac{140}{70} = 2$ ohms, and the fall of potential in the lamps will only be $\frac{2}{2.2} \times 100 = 90\frac{10}{11}$ volts, and $9\frac{1}{11}$ volts in the armature.

Thus we see, that, when the number of lamps in circuit is increased from 1 to 70, the difference of potential available in the lamps is decreased from $99\frac{6}{7}$ to $90\frac{10}{11}$ volts, a reduction of almost one-tenth; in consequence of which the candle-power of the lamps would be lowered at least one-third, and probably one-half. Of course, variations in the brightness of the lamps of one-third, or one-tenth, or even one-twentieth, would not be permissible: therefore, in order to maintain the required steadiness of the light, it is necessary to raise the electromotive force of the dynamo as more lamps are put on, and to lower it as lamps are taken off. This is done by increasing or diminishing the strength of current in the circuit of the field-magnets by means of a resistance-box interposed in the circuit. This regulation of the electromotive force of dynamos by controlling the resistance of the field-circuit may be, and in fact has been, made automatic; but up to the present time it has more generally been done by hand.

In what has gone before, I have said nothing about the resistance of the conductors which convey the current from the dynamo to the lamps. The effect of the resistance of any conductor which is *common to two or more lamps* — one of the main conductors, for example — is precisely the same as the effect of the resistance of the armature, which has been discussed above; but when a conductor supplies only a *single* lamp, then it does not have this effect. Of course there is a loss or fall of potential due to the resistance of the individual conducting-wires of each lamp; and of course the fall of potential in the lamp itself, and consequently its brightness, are thereby reduced. But this resistance does not introduce any *irregularity:* its effect in diminishing the light of the lamps is constant.

Let us suppose that a conductor having a resistance of 140 ohms feeds a single lamp of 1.4 ohms' resistance: then the loss in this conductor will be 1% of the useful fall of potential. But suppose that we now put 10 more lamps in circuit: then the loss in the conductors will be increased to over 10%; and assuming the useful fall of potential to be 100 volts, with a single lamp in circuit, it will only be about 90 volts with 11 lamps. The candle-power of the first lamp would drop at least 25% or 30% when the other 10 lamps were added. Thus it is, that, in a multiple arc system of electric lighting, any resistance which is common to a number of lamps, whether in the armature or the conductors, causes fluctuations in the light of the lamps when other lamps are put on or off; whereas the resistance of the individual conductors of each lamp produces a loss of potential which is a constant fraction of the total potential, but does not introduce any unsteadiness.

F. B. CROCKER.

Osteology of the cormorant.

With respect to Mr. Jeffries' criticism (SCIENCE, ii. 739) of my paper on cormorants, I beg to say that the occipital style of the cormorant is not an ossification in the tendon of any muscle; that he is entirely wrong in his view of the homologies of what I call a patella; and that, furthermore, I find myself misquoted more than once.

R. W. SHUFELDT.

A dog plans and executes with reference to the future.

Six weeks ago Prof. J. B. Thayer of this place returned from Ree Heights, Dakota, bringing with him one of a litter of eight pups raised by a slut of the setter breed. The story which he relates to me of this pup's mother is, it appears to me, worthy of record.

The good mother appears to have discharged her arduous duties as only a mother can, and arrived with her eight babes at the time when they should be weaned. At this juncture, judging from the events reported to have followed, she seems to have conceived the idea that too many dogs were occupying the same claim, and that a distribution was desirable. Accordingly, she started one morning with three of her pups, and was observed by Miss Rosa Cheney, now of this place, running in the road toward their claim at a rate which made it impossible for the pups to keep pace with her. The dwelling where she lived, and another shanty on the adjoining corner of another claim, are situated one mile and three-fourths from the dog's home. The mother reached the claims in advance of her babes, but no sooner had they arrived than she hurried on at her best pace. Miss Cheney reports that "the puppies came up all out of breath, and apparently too tired to continue; but the smallest of the three followed on." Another claim was reached three-fourths of a mile beyond; and here Miss Cheney observed the mother stop until her panting babe came up, when she immediately set off again. A quarter of a mile beyond the last claim, the mother was observed to make a third halt as before, and then to pass on beyond the range of vision, towards Ree Heights, with the puppy still following her. Two days later the persistent mother, with her more persistent babe, was observed coming back; and Miss Cheney tells me that the little puppy appeared almost dead from fatigue.

Some days later the dog led off two more of her pups, and succeeded in leaving them both; but in the mean time the two puppies left the first day were returned. A pup was also left at Professor Thayer's claim, but was returned, and exchanged for another. Both Professor Thayer and Miss Cheney assure me that other efforts of the same kind were made by this dog, but with what results they are unable to say.

After the puppies had been distributed, they were not forgotten; for the old dog used often to go and play with them. Professor Thayer mentions one instance of her coming and playing with the puppy left at his claim until it was very tired, when she lay down by the side of it; but, after it had gone to sleep, she quietly walked to the opposite side of the house, and then hurried away in the opposite direction from home for a distance of about forty rods, when she turned and went directly there, thus showing quite clearly that the thought of distributing her puppies was still uppermost in her mind.

What events may have awakened this desire on the part of the mother, or what reasons she had for her acts, we do not know; but in her own mind I have no doubt the case was urgent and the way clear, if not also just. It would appear, not only that this dog must have thought her plan through, but that she must also have held it definitely in mind for several days while she executed it, thus indicating quite unequivocally, it seems to me, that one animal at least, ranked lower than man, possesses the power of looking into the future and of executing plans deliberately laid with reference thereto; "man is the only animal which has the power of looking into the future," to the contrary notwithstanding. F. H. KING.

Method for making electrical signals.

When I first became connected with the Alabama agricultural and mechanical college, the recitation signals were made by means of electric bells, one in

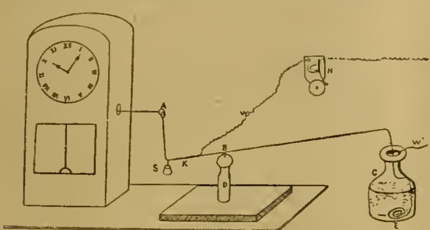

FIG. 1.

each professor's room. These were rung separately by pressing in succession as many push-buttons as there were bells. In order to complete the system, it was necessary to have one wire for each bell, and a return-wire running through the whole length of the system; and therefore only *one* bell could be rung at once. In the circuit there were twelve bells, about one-half mile of wire, and twelve one-gallon cells of Watson's battery. One of the cadets of the college was delegated to sound the signals at the end of each fifty minutes, which was the length of the recitation hours. Sometimes he would ring too soon, and at other times several minutes too late. This was frequently annoying, particularly when an interesting

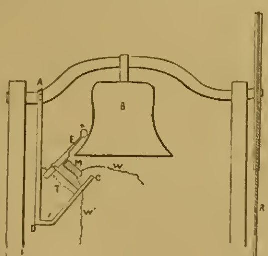

FIG. 2.

and important lecture was in progress. In the attempt to obviate this difficulty, the plan that I am about to describe was suggested to my mind.

We have an excellent compensated clock that can be made to strike twice any multiple of five minutes. After adjusting this clock so as to make it strike every fifty minutes, I insulated it on a square of plate glass. I then made an oblong opening in the side of the woodwork about one inch long. This slit was made on a line with the ball of the striker. Through this hole I passed a copper wire, and fastened it securely to the hammer of the gong. In the end of the wire outside of the clock I made a loop, as shown at *A*, Fig. 1.

A second wire, *A B C*, was attached to the first, as shown in the figure. A loop at *B* fits in a slit in the upright *D*, and a pin is inserted at *B* to hold the wire in position and at the same time allow the ends *A* and *C* to work up and down when the hammer of the clock strikes. The bottle *C E* is partly filled with mercury. From this mercury-cup a wire, *E W″*, runs to one pole of the battery. The other pole connects at *K* with the wire *W′*, after passing through all the bells of the system. *S* is a weight to counterbalance the arm *B C*. It will be readily seen that the outward stroke of the hammer will throw the end of wire *A B C* into the mercury, thus completing the circuit, and causing all the bells to ring. The blow of the hammer against the gong of the clock will raise the end *C*, and break connection. All but one of the bells must be single stroke: otherwise it will be impossible to obtain satisfactory results. By using one bell, with attachment for breaking and closing the circuit, the ringing will continue as long as the wire at *C* is in contact with the mercury.

The above system has been in operation for one year, and has given satisfactory results.

It has occurred to me that our large bell, weighing nearly two thousand pounds, can be made to strike the hours for the benefit of the town by placing it in the system just described, with the following adjustment. Procure a soft iron horseshoe magnet six or eight inches long, and secure it at *M* on the iron rod *A D C*, Fig. 2. This becomes magnetized when the clock completes the circuit. The armature *X Y* is attracted, and the ball *X* strikes the bell. The elasticity at *E* raises the ball immediately from contact, and allows a clear and distinct ring. The tension-spring *T* raises the armature from the magnet, and the current ceases to flow. If it is desirable at any time to ring the bell in the ordinary way by means of the rope *R*, the adjustment of the system may be sustained by making the supporting rod *A D C* secure to the bell-shaft at *A*, and thus permitting the magnet and fixtures to swing with the bell.

GEIKIE'S GEOLOGY.

Text-book of geology. By ARCHIBALD GEIKIE, LL.D., F.R.S., director-general of the Geological survey of Great Britain and Ireland, etc. With illustrations. London, *Macmillan & Co.*, 1882. 971 p. 8°.

TEXT-BOOKS in science once held a rather low place in the estimation of scientific men. Labor of this sort was long relegated to the book-makers, who, copying statements and illustrations one from another, gave the student more of the errors of by-gone days than of the knowledge of their own. But in our own time all this has been greatly bettered. Now a man of science is likely to look forward to text-book making as a source of honor as well as of remuneration; as a task that may not only help others on their way, but aid himself to a broader and more careful view of his own field of labor. The text-books of Lyell, Jukes, and Dana in geology are among the admirable works of these great authorities, and were doubtless helpful to them in their careers, as they have been vastly advantageous to those who have been trained by them. From a purely literary point of view, text-book making has no mean value to their makers. To collect the stores of learning of a science, to take that which has general value from the mass of details, to secure a due proportion and perspective to the parts of the work, — this is a task indeed.

Mr. Geikie has proven himself strong enough for this burden. His store of facts is far larger than has hitherto been gathered in any one book on geology. They show a large general reading, not only in the vast geological literature of his own island, in the making of which he has had a large share, but in the work done in other lands, — a praise that can be given to few of his countrymen. In his list of authorities he gives more names of scientific men of other countries than of British geologists; and this although he professedly desires to take his illustrations as far as possible from his own ground.

Besides the peculiarly large amount of well-gathered fact that marks this work, we may note among its peculiarities the considerably wider range in the method of treatment of the subject. In his first book he gives twenty-four pages to the cosmical relations of the earth, and under this heading presents the fullest and most satisfactory statement of the general condition and history of the earth as a member of the solar system that has yet been given in a popular treatise. With the same freedom of treatment, he does not hesitate to give a much fuller discussion of mineral veins than has hitherto found its way into any text-book. So, too, with those portions of the text that treat of river-action, volcanic phenomena, and the other leading manifestations of the geological forces. The author evidently feels a sense of freedom in making his book that is to be commended even if it gives him in the end near a thousand pages of text.

The paleontological part of the work is carefully done, but it is in the nature of the subject that it should be less commendable than the other parts of the book. There is a radical difficulty in treating paleontology, especially in its department of historical geology, in any text-book fashion. Even within the ample limits given by a thousand pages of print it comes down to a list of specific names that can only convey a meaning to the masters of the science; while the first principle of a text-book should be, that any statement should have a free comprehensibility within itself, without recourse to libraries or collections. Page after page of specific names hinders rather than helps the beginner.

This is the only criticism that can be made on the historic geology of the book, and it is one that lies against all the text-books that have thus undertaken to treat a subject that is so essentially unfit for this use. The essays on the divisions of the rock series are admirable. Especially to be commended is that on the old dispute concerning Cambrian and Silurian. It is pleasant to find a successor of Murchison in the directorship of the British survey who can do even-handed justice to the famous dead who fought this great battle over the division of the lower paleozoic section.

At several other points in the series of rocks we find an excellent spirit of discrimination applied to the problems of stratigraphic geology. We note the following. In discussing the relations of Permian to carboniferous rocks, the author notes the important fact, that, while in Europe there are discordances and sharp contrasts between the Permian and the carboniferous series, there is no such trenchant line in America. In the same spirit the indistinctness of the line between the triassic and the Jurassic series in North America is carefully pointed out. We find, also, that the doubt concerning the position of the Flysch series of the Alps is well presented; the ground being taken that the lower part of this series is upper cretaceous, the higher portions, eocene. This is the best brief presentation of this important problem that is known to the present writer. The only important exception that we can take to this admirable presentation of the stratigraphic problems concerns the author's general treatment of the triassic period. He notes that the European triassic series, with its reddish sandstones and shales, with connected gypseous and rock-salt beds, is essentially local in character, and that this aspect of the series cannot be expected in foreign lands. To this no objection can be taken; but he fails to assert the equally important fact, that reddish sandstones and shales have a singularly wide distribution in other lands. This general character of the trias constitutes it one of the most puzzling portions of the geological section, and it should be given its due prominence in any general account of the series.

The last eighteen pages of the book are given to the chapter on physiographic geology.

This matter belongs in close relation to the earlier chapters of the book, and seems somewhat isolated in its position. It is not so completely treated as the other parts of the book; but it is, nevertheless, a fair condensation of the most material points of the subject. The illustrations of this subject are rather limited, but a diagram of the Colorado Canyon by Mr. Holmes (p. 923) gives a peculiar value to the set of diagrams.

It is hardly fair to quarrel with the title of so good a book, but it would have been better to have given it the name of a manual rather than a text-book. It is not fitted for the ordinary use of schools; being far too rich in matter, and calling for too much collateral knowledge for classroom work. It belongs in association with Dana's classic manual of geology. For American students it cannot replace that admirable book; but, taken along with the American work, it will give the student a very complete encyclopaedia of geologic science.

The book is fairly well made. The type is bolder-faced than in Dana's manual; so that the total amount of matter is about the same in the two books, despite the somewhat larger page of Geikie's volume. An admirable feature of the book is the free use of footnotes referring to authorities, which is a distinct advantage the book has for the student. The figures are well chosen, and finely serve their purpose; though there are not quite half so many as in Dana's work.

The index is voluminous and well made.

HAECKEL'S CEYLON.

Indische reisebriefe. Von Ernst Haeckel. Berlin, *Paetel*, 1883. 13+356 p. 16°.

A visit to Ceylon. By Ernst Haeckel. Translated by Clara Bell. Boston, *Cassino*, 1883. 8+337 p. 16°.

In his 'Voyage of the Beagle,' Darwin has shown that an acquaintance with nature does not in the least detract from the interest of a traveller's adventures. Haeckel, in his new book on Ceylon, has still further given evidence that a love for nature's treasures adds an indescribable charm to one's wanderings in a strange land. In the 'Indische reisebriefe' we find a charming account of a scientific pleasure-excursion which the author made during the six months following October, 1881. The journey included a brief stay at Bombay, and a much longer series of travels through Ceylon, covering a space of four months.

Upon reading the book, the first impression we get is, that Haeckel must be a most pleasant travelling-companion, so delighted is he with every thing. He starts, he tells us, on a trip he has been longing for all his life, and evidently with the expectation and intention of having a delightful excursion. Nor will he allow any thing to frustrate his intention. It makes no difference where he is, or who are his companions: his good nature is unbounded. Every one, he seems to think, treats him with more than kindness; the roads he travels are models of comfort; and even the elements conspire in his favor. The country he passes through calls forth the whole wealth of the German language to find adjectives sufficient to express his boundless admiration. Officials give him every assistance; private homes open to him with the kindest hospitality; and even the natives take great interest in him, and are ever ready to give him aid which is at least kindly intended. When he establishes his laboratory at Belligam, he is supplied with servants, to whose excellency he can only do justice by naming one Socrates, and a second Ganymede. Belligam, the name of the town where he established his laboratory, means 'sand-village.' This name, however, does not suit Haeckel's general delight; and he calls it Bella gemma, considering it as 'a choice jewel in nature's casket.' An ordinary trip in the tropics is thus, by good nature and enthusiasm, transformed into a glowing journey through fairy-land. Indeed, one almost imagines, as he reads, that he has found an American advertisement of a pleasure-excursion. So full of pleasure and good fortune is the whole trip, that the reader soon grows weary, and wishes that some slight accident might happen, to break the monotony. It is certainly a relief to find the admission that the fauna of the island is disappointing; and we are quite reconciled to the fact, that the scientific laboratory was not quite so successful as had been hoped.

Haeckel's style in this book, as indeed in all his writings, is a most happy one. He gives what may be called a confidential description of nature where it is most lovable. The reader gets the impression that it is being given him in person by the author, for the purpose of enjoying once more the pleasures of the journey, and having a quiet laugh at the people. He cannot keep himself out of his descriptions, — indeed he does not try to do so: and what we see on every page is not a picture of Ceylon, but a picture of a man, making a journey through

Ceylon. He begins by telling us that he is getting to be an old man, and it is now or never with him as regards a journey in the tropics; but when, in the next breath, he informs us that his advanced years number eight and forty, we are quite amused at his premature old age. When he tells us, in the first chapter, how the Berlin academy refused to give him any aid on account of the challenge he had thrown to it on evolutionary speculations, we laugh with him. We see his amusement as he writes upon seeing wild apes for the first time: "Comparing them with the dirty and naked begging priests at our feet, they seemed to me a highly respectable ancestry for them." His German nationality, too, is ever apparent. Now we see it when he describes his German companions, or more frequently when he delights in his allusions to 'the indispensable black tail-coat and white necktie' of old England, or to the English 'chimney-pot' (*cylinderhut*), which he considers, 'of all head-coverings, the most hideous and insufficient.' He enjoys telling of English gluttony as compared with German temperance, of the Englishman's love for money with his exorbitant prices, and finally ends with the terse statement, 'Unsonst ist in Indien nur der tod.' But even his admiration for Germany does not prevent him from giving tribute to the faculty which England has exhibited as a colonizing power.

The scientific results of the Ceylon journey are not apparent. He travelled quite extensively through the island, continually swelling his collections, and finally established a rough laboratory at Belligam, where he worked hard for six weeks, filling his large cases with specimens from land and sea. But beyond the statement that the fauna of Ceylon agrees closely with that of the Philippine and Fiji group, the zoölogist gets little scientific knowledge. His account of the botany of the island is more extensive; but even this is largely made up of artistic descriptions of the magnificent vegetation which so vividly impresses a traveller in the tropics. That the journey was made by Haeckel is, however, sufficient proof that it was more than a pleasure-excursion. He brought back large cases of specimens, of which he says little, but which will, in years to come, undoubtedly be a source of much valuable information to the scientific world.

The book is not intended to be a scientific production, but rather a pleasant account of a naturalist's travels; and as such it is a success. A book of travels is usually dry and uninteresting after the first few chapters; for, however interesting new places may be to the traveller, to keep up a novelty in description soon becomes an impossibility. Haeckel has not entirely overcome this difficulty, but he introduces variety in the shape of personal anecdotes and observations. He is successful, too, in selecting most interesting points for description; and this, together with his boundless love for nature, which is so evident in every line, makes the closing chapters of his book much less wearisome than is usual with books of like nature. He reserves his account of the people until toward the end, and thus gives a series of bright chapters as the close of his stay at Belligam; and, by the continual introduction of people and incidents, he succeeds in keeping the reader's attention better than is customary. But, in spite of all, the last chapters of the book will invariably be glanced over in a hurried and cursory manner.

The translation by Clara Bell is on the whole good, though she has evidently been hard pressed to find expressions which will translate Haeckel's superfluity of adjectives. In some cases she seems to have been unable to find English expressions which give any idea of the German. One hardly gets the idea from the phrase 'worthy and fair reader,' which is conveyed by the German, '*Du, geneigter leser, und noch mehr, vererhte leserin.*' Though she has not followed the German very closely in her translation, yet she has succeeded in conveying to the English reader a tolerably good idea of Haeckel's flowing, free, and confidential style. The wonderful success of Haeckel's writings has proved that his method of writing and dealing with scientific subjects is a most attractive one; and this edition of his visit to Ceylon, partly on account of the freedom of the translation, but more largely because of the nature of the subject treated, will give to the English reader a better idea of his style of writing than any other of his translated works.

REMSEN'S THEORETICAL CHEMISTRY.

Principles of theoretical chemistry with special reference to the constitution of chemical compounds. By Ira Remsen. Revised edition. Philadelphia, *Henry C. Lea's Son & Co.*, 1883. 242 p. 12°.

In preparing this new edition of his little book upon 'Theoretical chemistry,' Professor Remsen has extended quite materially the second part, which treats of the constitution of chemical compounds, and which forms its most distinctive and attractive feature. Many of the alterations, however, will hardly be regarded as improvements by those who believe that a clear and definite presentation of chemical theories is quite essential to their proper comprehension. While it is manifestly highly important that the student should not only be acquainted with the facts upon which chemical theories rest, but should also appreciate fully the nature of conclusions reached by inductive reasoning, still a constant reiteration of the doubts, uncertainties, or conflicting evidence, which surround the various hypotheses, seems to us ill advised in an elementary text-book.

Although structural chemistry in a certain sense is independent of the valence hypothesis, still this hypothesis was one of the earliest and most natural inductions resulting from the study of the constitution of chemical compounds, and is so interwoven with the present theories, that any attempt to exclude it rigorously from a discussion of the subject merely adds an unnecessary complication. We confess that we do not think the ordinary student will read with much interest the pages devoted to structural formulae, or 'proofs' of their correctness, if he chances to see beforehand the opening sentence of the retrospect which follows (p. 232).

"A study of the preceding chapters on constitution will show that no absolute meaning is to be attached to the word. Constitutional formulas are those which suggest certain reactions, and recall analogies. The formula $CH_3 - OH$ does not mean that hydroxyl (OH) is necessarily present in the compound, or that CH_3 is present, but that the different parts of the compound bear such relations to each other that when the compound is decomposed, it acts as if the parts were united as the formula indicates. The formula suggests possibilities; it may not represent realities."

If the author be correct, and "it cannot be denied that we are now in a period of chemistry which may fairly be called one of *formula worship*" (p. 100), it is very certain that formula worship has been of vastly greater service to chemistry than agnosticism is ever likely to be.

We fail to see that any advantage is gained by the introduction of new conventional signs in place of those already in common use, to represent the linkage of the carbon atoms in the olefinet and acetylen series (pp. 202, 206): nor can we understand why the double linkage of the nitrogen atoms, which the author apparently accepts, since he uses the old sign (=) in his formulae for the azo- and the diazo-compounds (p. 222), stands upon any more trustworthy experimental basis. Furthermore, we cannot help expressing our surprise that the author should have ventured the statement, "Of the substitution products of benzene, which contain three substituting groups, more than three varieties have been observed" (p. 208), which seems a bit of rashness hardly consistent with the caution elsewhere displayed.

THE CORNELL MATHEMATICAL LIBRARY.

Cornell university library. Special lists, No. 1. Mathematics. Ithaca, N.Y., 1883. 92 p. 8°.

This classified list of works, with index, includes some twenty-five hundred titles relating to mathematics, and such allied subjects as astronomy, engineering, and physics. These books form what is known, from the name of the donor, as the 'Kelly mathematical collection.'

An examination of the list shows that it consists of books actually purchased within the past few years, with good judgment, and a conscientious endeavor to cover, so far as practicable, the immense field of mathematical research, past and present, as evenly as possible.

It comprises, besides many rare and valuable works not readily accessible to American students, the collected works of the great masters of analysis, and the more important mathematical journals.

The mathematical capabilities of American youth are quite equal to those of Germany or England; but the facilities offered them by our universities for the study of this grandest of sciences are in general far behind those found abroad. When the professors and teachers of mathematics in this country shall themselves become lifelong cultivators of mathematical pursuits, and shall have the same average proficiency as those abroad, there will be no difficulty in accomplishing results in the mathematical training of college students fully equal to any attained elsewhere. But such professors and such students cannot be without libraries such as this is the beginning of. We can but express our deep satisfaction with this good work in the interest of sound learning.

WEEKLY SUMMARY OF THE PROGRESS OF SCIENCE.

MATHEMATICS.

Kummer's surface. — Professor Cayley, in a brief note 'on the sixteen-nodal quartic surface,' remarks, that Riemann's theory of the bitangents of a plane quartic leads at once to a very simple form of the equation of the sixteen-nodal quartic surface; viz., if ξ, η, ζ, denote linear functions of the co-ordinates (x, y, z, w), such that identically

$$x + y + z + \xi + \eta + \zeta = 0,$$
$$ax + by + cz + f\xi + g\eta + h\zeta = 0$$

(where $af = bg = ch = 1$), then the quartic surface,

$$\sqrt{x\xi} + \sqrt{y\eta} + \sqrt{z\zeta} = 0,$$

is a sixteen-nodal surface. Prof. Cayley has previously given the equation of this surface under the form

$$\sqrt{x(X - w)} + \sqrt{y(Y - w)} + \sqrt{z(Z - w)} = 0,$$

where $X = a(\gamma'\gamma''y - \beta'\beta''z)$, etc., and $a + \beta + \gamma = 0$, etc.; the other relations being obtained by cyclical interchange of the letters, and by advancing the accents. The object of the present paper is the direct identification of these two forms of the equation of the surface. — (*Journ. reine ang. math.*, xciv.) T. C. [541

Elliptic functions. — M. Hermite has given a simple and direct demonstration of an interesting relation discovered by Prof. Cayley. The relation is as follows: if u, v, r, s, are four quantities connected by the relation $u + v + r + s = 0$, then we have —

$$-k'^2 \,\text{sn}\, u \,\text{sn}\, v \,\text{sn}\, r \,\text{sn} s + \text{cn}\, u \,\text{cn}\, v \,\text{cn}\, r \,\text{cn}\, s - \frac{1}{k^2}\text{dn}\, u \,\text{dn}\, v \,\text{dn}\, r \,\text{dn}\, s = -\frac{k'^2}{k^2}.$$

This remarkable relation is shown by M. Hermite to be easily derived by means of certain formulas which he has long used in his course in the Sorbonne. The formulas are those which give the decomposition into simple factors of the three quantities $\text{sn}\, x \,\text{sn}\,(x + a)$, $\text{cn}\, x \,\text{cn}\,(x + a)$, $\text{dn}\, x \,\text{dn}\,(x + a)$. The decomposition of the first of these products is a known fundamental relation between Jacobi's Z-functions: the decomposition of the other two products is given by M. Hermite; and by aid of them Prof. Cayley's formula is proved. — (*Acta math.*, i.) T. C. [542

ENGINEERING.

The two-cylinder compound engine. — Professor S. W. Robinson furnishes *Van Nostrand's magazine* a paper on the working of steam in this engine in its various forms, and traces the method of distribution in the two cylinders and the effect of such methods on the theoretical efficiency. He gives the general method of representing the action of steam graphically, and shows how diagrams made from the two cylinders are combined. The effect of the receiver is exhibited, and the result of the introduction of various conditions, as clearance, etc. — (*Van Nostrand's mag.*, Oct.) R. H. T. [543

Spherical steam-engines. — Messrs. Heenan & Froude of Manchester, G.B., recently exhibited at the Engineering and metal trades exhibition, London, their 'Tower' spherical engine, driving an Edison dynamo. The steam-cylinder is a sphere having two cylindrical projections cast upon it. Each of these carries a shaft, only one of which transmits power from the engine, the other having merely to guide the hinged piston nearest it. The pistons divide the interior of the sphere into four portions, which at times are four equal quadrants of the sphere, but which are capable of variation of volume with change of piston position; and, this being effected by the action of the steam which is let into the several spaces at proper times by the action of the rotating valves which are set in the cylindrical projections, the shafts are turned, and power is produced and transmitted to the mechanism of transmission.

The engine worked silently and well, and indicated 18-horse power at 600 revolutions per minute, with steam at 80 pounds ($6\frac{1}{3}$ atmos.). Its diameter was but 7 inches (17.8 centimetres). — (*London engineer*, July.) R. H. T. [544

Steel castings. — Mr. W. Parker has collected facts bearing upon the value of steel castings in marine-engine construction. He observes that forged iron shafts and other heavy parts are very unsafe, and that mild steel is taking the place of wrought iron for all such uses. About a hundred and twenty steel ships are in progress in Great Britain, constructed of low steel. The testimony of steel-makers and tests of the material show that steel castings can be made of homogeneous character and thoroughly reliable. Jessop & Co. use crucible steel for this purpose, and think that good castings can only be obtained with certainty by the crucible process. Spencer & Sons use both crucibles and the open-hearth process, and get equally good results from both. The Steel company of Scotland use the Siemens furnace and process, and adopt the silicide of manganese as a flux to insure soundness. The internal stresses due to variation in rate of cooling are avoided either by very slow cooling or by annealing. Pourcel of Terre Noire, France, tempers in oil, with, as is claimed, very great advantage. The tenacity is thus increased sometimes thirty per cent, and the elongation at rupture remains unreduced, while the grain of the steel is greatly improved. Sir Joseph Whitworth compresses his ingots of steel, while solidifying, by applying the pressure of a large hydraulic press. Messrs. Vickers & Co. make many large crank-shafts for steamships, adopting a mild steel of a tenacity of about fifty-five thousand pounds per square inch. The castings are improved by hammering or rolling, thirty per cent. — (*Scient. Amer.*, Oct. 20.) R. H. T. [545

CHEMISTRY.

(General, physical, and inorganic.)

Bleaching. — 'Oxygenated water,' a common name for peroxide of hydrogen, has within the last few years attracted a good deal of attention as a bleaching and purifying agent, and has been successfully employed as a substitute for chlorine. It is now stated that Mr. P. Ebell of Pfungstadt, near Darmstadt, has succeeded in preparing economically a product, pure, stable, and of constant strength, capable of being easily transported for long distances, and kept for years without losing its bleaching-properties. Among other applications of this product, that of the decoloration of animal fibres is the most important, as it does not contain some of the disadvantages of other bleaching-agents. For wool or silk, it is advisable, before bleaching, to cleanse the materials thoroughly, so as to eliminate all the greasy substances and impurities. For this purpose, Mr. Ebell recommends a bath in a solution of five parts carbonate of ammonia to one hundred of water, this bath being followed by a soaping, and thorough washing with water. The bleaching itself is performed either by immersing the materials in the solution of oxygenated water, and leaving them there at a temperature of from 20° to 30° C., until the decoloration is complete, or the materials are impregnated, when they are wrung out and exposed in a room heated to about 20° C.: they are then left to dry. — (*Engineer*, July 20.) [546

Molecular volume of liquids. — In the determination of the molecular volume of liquids, R. Schiff proposes to make the observations at the boiling-point of the liquid and in a special form of apparatus. The latter consists of a small flask capable of holding about one hundred grams of mercury: it is drawn out to a narrow neck which is graduated to ten divisions, each of which corresponds to 0.01 of a cubic centimetre; and each of these divisions is divided into five parts, making each of the final divisions equal to 0.05 of a cubic centimetre. The volume is accurately determined by weighing the flask filled with mercury to the zero-mark. To determine the specific gravity of any liquid at its boiling-point, the flask is filled with the liquid, placed within a jacket-tube which contains a little of the same liquid, and the latter boiled until the liquid in the flask is heated to its boiling-point. By means of a capillary tube the liquid is withdrawn from the flask until it stands at the zero-mark, and the flask is corked, cleaned, allowed to cool, and weighed. The specific gravity of the liquid is referred to water at 4° C., and it may be calculated by means of the formula —

$$D^t{}_4 = \frac{P}{V_t\left(1 + K(t - 4)\right)},$$

in which P = the corrected weight of the liquid in the flask, V_t = the apparent volume which the liquid occupies at t°.

By this method the molecular volume of many of the paraffine and aromatic hydrocarbons, their halogen substitution products, alcohols, etc., were determined, and results were obtained which agreed closely with those of other experimenters. — (*Ann. chem.*, 220, 71.) C. F. M. [547

AGRICULTURE.

Aves guano. — A new phosphatic material under this name has lately been imported into Germany from the Aves Islands, in the Caribbean Sea, near the coast of Venezuela. Analyses of it by Märcker and by Heiden show it to contain about seventy-two per cent of calcium phosphate, four to nine per cent of calcium carbonate, seven per cent of organic matter, and twenty-five hundredths of one per cent of nitrogen. The material consists of a fine powder, with more or less fragments up to the size of a pea or larger. Among the coarser portions, shells and coral fragments are often found. The extent of the deposit is said to be great. — (*Biedermann's centr.-blatt.*, xii. 582.) H. P. A. [548

Comparison of nitrogenous fertilizers.—Märcker reports the results of pot-experiments by Albert on the relative value of various nitrogenous fertilizers for oats. Leather, either unprepared or fermented, gave as good as no increase of crop. The others ranged in the following order, the best being placed first: horn-meal, nitrate of soda, fermented dried blood, sulphate of ammonia, fermented steamed bone, steamed bone, dried blood. The horn-meal is prepared by treating horn-refuse with superheated steam. In previous experiments it produced almost as good an effect as nitrate of soda. It is to be observed, that several of the materials used contained other fertilizing ingredients than nitrogen, of whose possible effect no account seems to have been taken. An experiment in the following year with the pots manured with leather showed no noticeable effect from the latter. — (*Biedermann's centr.-blatt.*, xii. 584.) H. P. A. [549

Effect of fertilizers on composition of oats — In the experiments reported in the preceding abstract the composition of the oats produced by the aid of the various fertilizers was determined. Those manured with leather and those without nitrogen contained 8.7 % to 10.7 % of proteine; those manured with nitrate of soda and sulphate of ammonia, 11.2 % and 11.1 %; those manured with the blood or bone manures, 11.6 % to 13.6 %. The proportion of crude fibre and ash was greatest in those manured with leather and those without nitrogen: the others showed only slight differences. The nitrogenous manures delayed the ripening of the grain in some cases. Märcker divides them into three groups: 1°, those which allow the grain to ripen at the normal time, their nitrogen being assimilated during the early stages of growth (nitrate of soda, sulphate of ammonia); 2°, those which delayed the ripening somewhat (steamed bone, and the same fermented); 3°, those which delayed the ripening considerably, and rendered it irregular (horn-meal, dried blood). The last decompose slowly in the soil, and furnish a continuous supply of nitrogen until late in the autumn. — (*Biedermann's centr.-blatt.*, xii. 587.) H. P. A. [550

Nutritive value of amido-compounds.—Weiske has already shown that the asparagine which is found in various fodders, along with other amides and amido-compounds, can partially take the place of proteine in nutrition. Zuntz has repeated his observations on asparagine and other amides, with the same result. — (*Biedermann's centr.-blatt.*, xii. 602.) H. P. A. [551

Sunflower cake as fodder. — This material has been tested as fodder for milch-cows by Schrodt and von Peter with very favorable results. Slightly more milk was produced by its aid than by that of an equivalent quantity of palm-nut meal; and the proportion of fat in the milk was slightly increased, as has sometimes been the case in feeding palm-nut meal. No injurious effects on the health of the animals were noticed. — (*Biedermann's centr.-blatt.*, xii. 609.) H. P. A. [552

GEOLOGY.

Lithology.

Lithology of the District of Columbia. — According to Mr. G. P. Merrill, the prevailing rock of this district is an extremely variable hornblendic, chloritic, or micaceous schist, sometimes somewhat gneissoid. This rock is used for building-purposes in its finer varieties, which are composed of quartz and biotite, with a silvery white mica, magnetite, apatite, etc. Besides the quartz and biotite, the coarser varieties frequently contain plagioclase, hornblende, chlorite, apatite, epidote, pyrite, magnetite, garnet, and rutile. The biotite is frequently more or less altered to chlorite, and contains apatite, magnetite, and sometimes infiltrated calcite. — (*Proc. U. S. nat. mus.*, vi. 159.) M. E. W. [553

The bismuth deposits of Australia. — These deposits are found in irregular quartz veins or 'reefs' in gray granite, and near its junction with the surrounding porphyritic and schistose rocks. The veins are composed of irregular segregations of quartz, holding bismuth, both native and as a sulphide, gold, molybdenite, smoky quartz crystals, etc. These veins occur only in circumscribed patches in the granite, which has here been decomposed to a soft, friable rock, the mica and felspar being much altered. The native bismuth occurs in irregular bunches and nests throughout the quartz, or in fissures traversing the veins. These bunches vary in weight from a half-pound to fifty pounds; and the metal is particularly found associated with and incasing the crystals of smoky quartz. Sometimes it is in needles in the quartz. The walls of the segregations are charged with from thirty to fifty per cent of oxide of bismuth for a distance from the vein of from eight inches to two feet.

Mr. Robertson, from whose paper the above account is condensed, states that the entire sale of bismuth has for years been monopolized by a few London brokers, "known as the 'Bismuth ring,' — a close and conservative institution formed for the purpose of controlling the supply and price of bismuth." The present consumption of the metal is about seventy tons yearly; and it is stated that these deposits could easily produce that at a small expense. In 1882 the market-price of bismuth was 6s. 8d. per pound in London. — (*Trans. geol. soc. Glasgow*, vii. 127.) M. E. W. [554

MINERALOGY.

Halite. — B. Wittjen and H. Precht have endeavored to find the cause of the blue color in some varieties of halite, and have arrived at the conclusion that it is dependent upon some optical phenomena, possibly connected with the presence of minute gas inclusions. — (*Berl. berichte*, xvi. 1454.) S. L. P. [555

Rubellan. — This micaceous mineral has been investigated by M. U. Hollrung, and shown to be very various in its properties. It occurs mostly as a decomposition product of magnesian micas. It is by no means homogeneous, and cannot be classed as a distinct mineral. By means of the microscope it could be seen that crystals of the ordinary biotite form were composed of lamellae of different degrees of decomposition, showing all stages from pure mica to wholly decomposed material. — (*Min. petr. mitth.*, v. 304.) S. L. P. [556

Parallel growth of zinc blende and tetrahedrite. — Specimens from Kapnik, Transylvania, have been studied by F. Becke. The minute crystals of tetrahedrite are deposited only upon the dull faces of the blende crystals, and are of a later growth. They have been deposited according to the following law: the principal axes of the two minerals are parallel, and the first or principal tetrahedron of tetrahedrite is parallel to the second tetrahedron of blende. The development of the tetrahedrite crystals is dependent upon their location on the blende, being most symmetrical if deposited on a dodecahedron face, and flattened if on a cubic face. A parallel growth of these two minerals has been previously noted, but with the first tetrahedron of tetrahedrite parallel to the first tetrahedron of blende. — (*Min. petr. mitth.*, v. 331.) S. L. P. [557

Iolite (cordierite). — A. von Lasaulx has described twin crystals occurring in a cordierite gneiss from Laacher See. Twins of this species are of unusual occurrence, and have been observed with the prism ∞ P for composition face. The author finds, in addition to twins according to the old law, compound twins, part of the individuals being united according to the old law, and part according to a new law with $\infty \breve{P} 3$ for composition face. Twins united wholly according to the new law were not observed. — (*Zeitschr. kryst.*, viii. 76.) S. L. P. [558

GEOGRAPHY.

(Arctic.)

Arctic land. — F. Schmidt discusses the claims of different persons, and especially Wrangell, to the discovery of land north of eastern Siberia. Discovery is hardly the proper word to apply to the record of reports by the aborigines of that region. In fact, as Professor Schmidt admits, Wrangell had his doubts as to the accuracy of the report; and his opinion was expressed, sometimes with more, sometimes with less, confidence, at different times. The first civilized man to actually see what is now called Wrangell Island was Kellett, who called it Plover Island, and made a sketch of it from a long distance away, of which I have a copy, and which is stated to be characteristic by Capt. Hooper. The high land, with extensive peaks, described by Kellett, like the Pelly Mountains of the arctic coast, described by Dease and Simpson, was simply one of those peculiar atmospheric effects which occasionally deceive the most experienced arctic travellers. The conclusion is, that no report of new arctic land is worth any thing until it has at least been very closely approached. — (*Isvestia imp. geogr. soc.*, May.) W. H. D. [559

Settlements on the Siberian coast. — Karzin gives a most valuable list of the settlements, summer fishing-stations, camps of ivory-hunters, and other places, where human beings are to be found at any season of the year on the coast of north-eastern Siberia. The chronicles of the Jeannette expedition might have been less gloomy, had the commander possessed himself of some such directory before proceeding on that unlucky voyage. — (*Isvestia imp. geogr. soc.*, May.) W. H. D. [560

(*Africa.*)

Sierra Leone. — According to recent consular reports, the population of this colony comprises sixty thousand five hundred souls, nearly all blacks, who speak among them more than sixty different dialects. Freetown, the capital, has a population of twenty-two thousand, chiefly of the Aku, Ebo, Timen, Susu, Maulang, Sherbru, and Krumen tribes. The Aku and Ebo people are extremely keen traders: the three following tribes furnish middlemen, who intervene between the caravan merchants and the purchasers. The last mentioned are freighters and boatmen, employed largely in loading and discharging vessels. The trade amounts to about three million dollars annually, less than half of which are exports. The soil is poor and not arable; farming is hardly practicable; and the real importance of the colony lies in its geographical position, and easy communication with the rich interior region. Taxes and customs-duties are very high, and have injured trade by driving it elsewhere. The exports are kola, palm and peanuts, palm-oil, gum-copal, rubber, ginger, and hides. — (*Bull. soc. Belg. géogr.*, ii. 1883.) W. H. D. [561

Portuguese Guinea. — Barros contributes a memoir on Portuguese Guinea, with notes on the customs and manners of the natives and on their language, especially of the Mandingo, Biafada, and Balanta tribes, containing little absolutely new except some songs. The article forms an interesting summary of facts. — (*Bol. soc. geog. Lisboa*, no. 12, 1882.) W. H. D. [562

BOTANY.

Cryptogams.

The oospores of the grape-mould. — Prillieux states that he has received from M. Fréchou of Nérac germinating oospores of Peronospora viticola. The germinating oospores produce at once a mycelial tube similar to that known in other species of Peronospora, in which the germination of the oospores has been seen. This is an important step in our knowledge of the grape-mildew, since, inasmuch as the conidia produce zoospores, it had been supposed by some that the oospores would also produce zoospores, as is the case in the related genus Cystopus. — (*Bull. soc. botan.*) W. G. F. [563

Swedish Algae. — Dr. C. Lagerheim describes a number of species new to Sweden, including several genera and species new to science. The species are from fresh water, as well as marine, and are illustrated by a plate. Of the genera treated most in detail may be mentioned Merismopedium. — (*Öfvers. svensk. akad.*) W. G. F. [564

Monograph of Ulvaceae. — The sixth part of Agardh's *Till algernes systematik* is devoted to the Ulvaceae. The author includes here the genera Bangia and Porphyra, as well as the green species generally placed in this order. The subject is elaborately prepared, and is illustrated by four colored plates giving the microscopic structure. Ulva and Enteromorpha are kept distinct, and E. erecta is credited to New York on the authority of J. Hooper. Monostroma pulchrum the writer suspects to be a form of M. lactuca, a boreal species of both hemispheres. — (*Acta univ. Lund.*, xix.) W. G. F. [565

Phanerogams.

Spines of Aurantiaceae. — Dr. Urban describes and figures specimens which show that the spines situated just above the leaf-axis of a number of members of this family, and hitherto considered as metamorphosed axillary branches, are in reality formed by the transformation of one or two of the lowest leaves belonging to the primary axillary shoot. — (*Ber. der deutschen bot. gesellsch.*, June 27.) W. T. [566

Orchis mascula. — Mr. Malair believes that the visits of bees to this species are for propolis, which is yielded by the papillae of the nectary. Flies also visit the flowers, which are described at length, but not very clearly nor accurately. — (*Science gossip*, March, April.) W. T. [567

Sterility of the Ficaria. — Mr. Neve notices that in England the plant seldom seeds, although its flowers appear well formed, and bees visit them. — (*Science gossip*, June.) W. T. [568

Pollination of willow. — Mr. Hamson states, that while amentiferous plants, dependent entirely upon the wind for fertilization. have pendulous catkins, "in the willow the catkins are upright and elastic. The bumble-bee is a heavy insect, and it almost invariably mounts to the summit of the catkin, which is borne down by its weight. On the bee taking flight, the catkin springs suddenly to its original position, and thus shakes out the pollen in the male, and further distributes that which may have lodged in the scales of the female catkin." Bees were noticed to confine their visits almost exclusively to the staminate plants. — (*Science gossip*, July.) W. T. [569

ZOÖLOGY.

Protozoa.

Division of the nucleus in protozoa. — It is known that in many protozoa the number of nuclei increases with the growth of the animal; but whether the additional nuclei arise by free new formation, or by division of older nuclei, was uncertain, although Zeller had shown that the multiplication in Opalina was due to division. Gruber, in a valuable article, now shows that in Actinospaerium and Amoeba division of the nuclei occurs, having obtained examples after very long search. In the former the young nuclei are small, and have a single large nucleolus with a clear space around it. As the nucleus enlarges, the clear margin disappears, and the nucleolus breaks up into smaller granules (nucleoli). In one specimen various stages of division were found. Their natural succession is probably as follows: the nucleoli arrange themselves in two parallel rows across the nucleus; they then unite so as to form a homogeneous band out of each row; the rest of the nuclear substance accumulates between the two bands, which then move asunder, and meanwhile threads appear running from band to band; a line of division (partition-wall?) appears between the bands. In Amoeba proteus the nucleus contains a peripheral layer of granules, and a large central mass to be regarded as the nucleolus. One specimen was found with nuclei in various stages of division. It appears that the nucleolus separates into two parts, between which, across the equator of the nucleus, appears a partition. Similar processes were observed in another Amoeba (sp.?). In these cases we have a form of nuclear division somewhat different from any hitherto observed; in that the nucleolus divides first, and the partition between is formed without the participation of the nuclear membrane.

Bütschli has asserted that in Amoeba proteus (princeps B.) the nuclei are either small and numerous, or large and few. Gruber has found them always of about the same size, and very variable in number and relative proportion to the bulk of the individual. — (*Zeitschr. wiss. zool.*, xxxviii. 372.) C. S. M. [570

Coelenterates.

The nervous system of the Siphonophores. — According to Korotneff, who has studied the minute anatomy and histology of the Siphonophores, the Diphyidae are the least modified, and present the most primitive or ancestral structure. In them the ectoderm is a simple muscle-epithelium with well-developed muscle-fibrillae, which lie upon *muscle-septa*, or outgrowths from the supporting layer.

A more highly differentiated organization is found in the Apolemiadae. The epithelial cells are nearly separated from the muscle-fibrillae, to which they are united only by fine protoplasmic threads. Between the muscle-septa the epithelial cells are folded over to form an open furrow, which is floored with cells a little larger than those over the general surface of the body.

In the Agalmidae the cells in this furrow are entirely covered up by the ordinary surface-epithelium. They are very large, are united by processes to the muscles, and they constitute a true central nervous system formed by involution of the ectoderm. The muscle-fibres of the Agalmidae are entirely separated from the epithelial cells, and the latter are flattened. Korotneff has traced the origin of the nervous system in the embryo. In a Forskalia larva there is no trace of nerve-cells; and the epithelio-muscular layer, the muscle-septa, and the endoderm are like the corresponding structures of Diphyes.

As the animal grows, these ectoderm-cells, which lie between the muscle-septa, grow larger, sink down, and become covered up by the ordinary surface ectoderm-cells. They then throw off processes to the muscle-fibres, and thus become converted into the nervous system. The nerve-cells are therefore, so far as their origin is concerned, epithelio-muscular cells, and they so far lend support to Kleinenberg's neuro-muscle theory.

Korotneff describes sensory cells in the region of the nervous system of the Agalmidae, and also in the air-bladder. These sensory cells are muscle-cells which still retain their primitive position on the surface; and they are furnished with sensory hairs, and are joined by processes to the muscle-fibrillae.

In the Physophora the ectoderm has been specialized in two ways. On the stem the cells have the morphological characteristics of nerve-cells and the position and arrangement which characterize muscle-cells: they are neuro-epithelio-muscular cells. There are also many sensory cells arranged in longitudinal rows among the ordinary cells; but there is no infolded nervous system upon the stem, as there is in the Agalmidae. This is to be found, however, upon the air-bladder, which is thickly covered with nerve-cells. On the upper surface of the bladder these are directly united to the surface-epithelium, while upon the lower surface they are directly united to the muscles. He says that there are physiological reasons (which are not stated) for believing that the upper nerve-cells are sensory, and those on the lower surface motor.

He speaks very briefly of the diffused nervous system of Porpita; and his observations apparently agree with those recently published more at length (see SCIENCE, ii. 396) by Conn and Beyer. — (*Zool. anz.*, 148.) W. K. B. [571

Worms.

Systematic papers on worms. — Dr. R. v. Drasche has taken advantage of the preservation of all Diesing's and many of Molin's original specimens of nematods in the Vienna museum to draw up fresh and more accurate diagnoses of the species described by these authors, and also to give a good many new figures. This labor is calculated to avoid much confusion which might otherwise arise from the very imperfect character of the original descriptions. — (*Verh. zool-bot. ges. Wien*, xxxii. 117.)

The same author also describes some new ascarids collected in Brazil by Natterer, and adds some notes on Ascaris ovis and A. rigida. — (*Idem*, 139.)

G. M. R. Levinsen has published the first part of a valuable revision of northern Annulata, Gephyrea, Chaetognathi, and Balanoglossi. He attempts chiefly to describe the species, elucidate their history in scientific writings, and their geographical distribution. The essay contains full synoptic tables. The work was undertaken at the request of Prof. Steenstrup and Dr. Lütken. — (*Vidensk. meddel. naturh. foren. Kjöbenhavn*, 1882, 160.) C. S. M. [572

Pentastomum from an Alligator lucius. — J. Chatin has found Pentastomum, probably P. oxycephalum, in the liver of a caiman. This is a new locality for the parasite. He gives an excessively prolix general account of the anatomy of the animal, but contributes little that is new. The booklets around the mouth have a stalk, and three movable claws thereon, — two at the sides near the end, the third terminal. The author denies the cellular character of the epidermis: it is 'formed merely by a mass of protoplasm in which are scattered numerous nuclei.' (It can hardly be questioned that this is a mistake due to superficial observation. The author gravely adds his doubts as to the cellular constitution of the epidermis in arthropods generally. In this he is singularly unfortunate; as there is hardly any fact in insect histology more easily verified, even by inexperienced students, than the existence of epidermal — so-called hypodermal — cells. The error of describing an epithelium as a sheet of protoplasm with scattered nuclei has been committed over and over again by persons not trained in histology.) The description of the course of the nerves rectifies previous accounts. — (*Ann. sc. nat. zoöl.*, xiv. art. 2.) C. S. M. [573

Crustaceans.

Isopoda of the Blake dredginga. — In a report on the Isopoda dredged on the east coast of the United States in 1880, by the U. S. coast-survey steamer Blake, under the direction of Alexander Agassiz, Oscar Harger says that the collection, although small, is remarkable for the large proportion of interesting forms; since nearly all the species are either new, or not hitherto known upon our coast, or known only from single specimens. Nine species, all belonging to Cirolanidae and Aegidae, are enumerated, and most of them fully described and figured on four excellent photo-lithographic plates from the author's drawings. — (*Bull. mus. comp. zoöl.*, xi., no. 4, Sept., 1883.) S. I. S. [574

Development of Panopeus. — E. A. Birge describes and figures the post-embryonal and some of the later embryonal stages of Panopeus Sayi and the second zoea stage of P. depressus. He describes four distinct zoea stages after the casting of the embryonic cuticle (or 'larval skin,' as Prof. Birge calls it) and a 'first megalops stage,' and discusses the metamorphoses undergone by the body and appendages in the change from each stage to the next. After describing the 'first megalops stage,' Prof. Birge says, "Subsequent changes in the megalops affect the proportions of the carapax, which becomes broader proportionally, and that of the abdomen, which becomes smaller, and is permanently flexed under the sternum. The appendages undergo many changes, gradually approximating them to the adult form. The last stage is reached after several — at least four — moultings." Unfortunately none of these remarkable later megalops stages are described or figured, as they certainly deserve to be if actually observed. During several seasons' observations the writer has found no evidence of more than one megalops stage in this or allied species; and, with the exception of Bate's doubtful observations on Carcinus, there are apparently no well authenticated cases of several megalops stages in any species of Brachyura. The numerous figures illustrating the paper are rude and inaccurate. — (*Stud. biol. lab. Johns Hopk. univ.*, ii., no. 4, July, 1883.) S. I. S. [575

Insects.

Sucking-apparatus in butterflies. — P. Kirbach describes the structure of the maxillae and pharynx in the Lepidoptera precisely as described by Burgess in the *American naturalist* for May, 1880, and more at length in a memoir on the anatomy of the milk-weed butterfly in the *Anniv. memoirs Bost. soc. nat. hist.*, 1881. Kirbach makes no reference to either of these papers, though both were recorded in the very journal containing his article, as well as in Carus's *Zool. jahresbericht* by Bertkau, in the *Arch. f. naturgesch.*, and in the *Zoölogical record*. However, it is satisfactory to have observations independently confirmed; and Kirbach gives almost a verbal and pictorial repetition of the above-quoted papers. Thus the suspensory muscles of the pharynx receive the identical names given them by Burgess. Kirbach believes the proboscis is extended by muscular contraction, and rolled up by elasticity, but gives no proof of his view. This is the opposite of what the muscular arrangement *seemed* to Burgess to indicate; although he added that "it is more probable we fail to see, or to correctly interpret, some proper muscular mechanism for both movements of the proboscis." Unfortunately, Kirbach does not help us here.

Kirbach describes, for the first time, the syringe-like mechanism of the salivary duct, by which saliva is injected into the proboscis. This arrangement was overlooked by Burgess. — (*Zool. anz.*, vi. 553.) E. B. [576

Wheat-atem maggot or bulb-worm. — The larva of Meromyza americana Fitch has been very destructive this year to wheat and rye in Fulton county, Ill. Important additions to the published observations of Fitch, Riley, and Lintner, have been made by S. A. Forbes, who gives descriptions and figures of all stages of this insect. The egg is now figured for the first time, and a winter brood has been observed. — (*Prairie farmer*, Aug. 4.) J. H. C. [577

VERTEBRATES.

Histology of the nervous centres. — C. Golgi has investigated the morphology of ganglion-cells. His conclusions are in some respects very different from those of previous investigators, and, if confirmed, will mark an important advance in our knowledge of the subject. On this account we give a longer abstract than usual for special papers.

The origin of the nervous fibres depends on certain constant laws, uniform for the different centres, despite certain secondary differences in the morphology and distribution of the histological elements. The ganglion-cells may in general be distinguished from the other cells by their form, the appearance of their nuclei, and the mode of origin of their prolongations; but they are especially characterized by the presence of the *single* nervous (Deiter's) process, which *alone* enters into connection with the nerve-fibres to make part of, or constitute them. The protoplasmatic processes have nothing to do with the origin of the nerve-fibres, directly or indirectly: they are in relation with the connective-tissue corpuscles (exactly how is not shown, so this may be questioned). As each cell has only one Deiter's process, it follows that they are all really unipolar. The sensory and motor cells cannot be distinguished definitely by their form or size from one another; but, as regards Deiter's process, two forms are distinguished, — the first is supposed to go with the motor cells, the second with the sensory. The established view that the process is continued without branching into the axis-cylinder is discarded; for Golgi maintains that it gives off a more or less considerable number of filaments on its way. In the first form, the process, although giving off filaments, still maintains its individuality, and can be followed to the points where it enters the medullary sheath as the axis-cylinder. Corresponding nerve-fibres are found, which preserve their individuality, notwithstanding the filaments they give off from the axis-cylinder, which can be followed to the ganglion-cells. The structures are supposed to belong to the sensory system. In the motor system the individuality of the process or of the fibre is lost in the gray substance, completely breaking up into filaments which enter into the formation of a diffuse network. It would appear, then, that the motor process breaks up into filaments, forming a network, from which spring the other filaments, which unite to form the motor axis-cylinder. The network really receives filaments also from the sensory process and fibres; so that it may be regarded as a fundamental nervous plexus, both sensory and motor, by means of which each fibre communicates, not with a single cell, but with large groups. The tendency is towards extended, not restricted, communications; and there is no anatomical basis for the assumption of the isolated transmission of peripheral nervous impulses to hypothetical limited cellular individualities. This investigation, therefore, lends no support to the theory of cerebral localization. Deiter's process is characterized from its origin by its greater homogeneousness, its hyaline aspect and smooth surface, while the protoplasmatic processes are granular.

Golgi has also studied the histology of the *cortex cerebri*, especially to compare the anterior with the occipital convolutions. Meynert's plates, and division of the cortex into five layers, he thinks, do not agree with the reality. Golgi distinguishes three forms of ganglion-cells, — pyramidal, fusiform, and globular (or polygonal with rounded angles). He distinguishes three layers of about equal thickness. The superficial layer is formed almost exclusively by rather small pyramidal cells; the middle layer has, for the most part, larger pyramidal cells; while in the deep layer the fusiform cells prevail, and the globular cells, which occur throughout the cortex, are here most abundant. The largest pyramidal cells extend through the whole thickness of the cortex. Such is the organization of the *gyrus centralis anterior* (*frontalis ascendens*). The organization of the superior occipital convolution is similar, except that the deep layer contains the globular cells almost exclusively. There are no anatomical features to indicate that the anterior convolutions are motor, the occipital sensory, as Hitzig and others have maintained. "The specific functions of the different cerebral zones do not depend on the organization of these zones themselves, but on the specific character of the peripheral organs which are connected with the fibres entering or leaving the zones in question." — (*Arch. ital. biol.* iii. 285.) C. S. M. [578

Birds.

Development of the heart. — Assaky maintains, 1°, that the heart arises in the chick as a double tube, as may be seen before the differentiation of the third protovertebra; 2°, the myocardium is constituted from the first by a network of anastomosing cells; the muscular fibres arise by endocellular generation; 3°, the muscle-cells are derived from amoeboid cells [i.e., are mesenchymal]. — (*Comptes rendus*, xcvii. 183.) C. S. M. [579

Plumages of the stone-chat. — Messrs. Butler, Fielding, and Reid seem finally to have solved the variations in plumage of this interesting bird. According to them, there are nine different stages easily recognizable. We note with satisfaction that the theory of hybridization seems to be done away with. — (*Ibis*, 1883, 331.) J. A. J. [580

Mammals.

The influence of quinine upon heat-dissipation and heat-production. — In a late article by Wood and Reichert (*Journ. of physiol.*, iii. 321), the authors make the statement that quinine increases both heat-production and heat-dissipation, though, on the average, the percentage of increase of heat-dissipation largely exceeds that of heat-production. A desire to test the accuracy of these results has led Arntz to make a similar series of experiments. To measure the relative amount of heat-dissipation from the skin, he made use of a porous wooden cap, lined with felt, which could be applied to any part of the body. The temperature within the space thus enclosed was registered by a delicate thermometer. Any increase in the loss of heat through the skin would be shown, therefore, by the thermometer. Experiments were made upon men and rabbits in a normal healthy condition, the general results of which show that no increase in heat-dissipation follows the injection of quinine. To explain the contradiction existing between his own and Wood's results, he supposes that the doses used by the latter were too large for the animal (dog) experimented upon; and the increase in heat-dissipation was probably owing to the animal's struggles and attempts to vomit. Two experiments that he made upon dogs, using the same dose as that given by Wood, tend to support this explanation. To determine the effect of quinine upon heat-production, spirometric observations were made upon normal rabbits, and rabbits suffering from septic fever, the amount of oxygen absorbed being taken as an indication of the oxidations going on in the body. In normal rabbits, quinine was found to have no effect upon the amount of oxygen consumed; while, in febrile animals, it caused a diminution in the oxygen-consumption. The author's conclusion, with regard to the anti-pyretic action of quinine, is, that it acts in the first place indirectly by destroying the organisms which give rise to the fever, and, in the second place, directly diminishes the oxidations in the tissues of the body. — (*Pflüger's archiv*, xxxi. 531.) W. H. H. [581.

Action of carbon dioxide and oxygen upon the mammalian heart. — The present paper by Klug forms an extension of some previous work of the same nature on the frog's heart. His experiments were made upon dogs anaesthetized by means of morphia, and made to breathe in an atmosphere containing different percentages of carbon dioxide or oxygen. With regard to the action of carbon dioxide he finds, in accordance with previous observers, that it acts as a stimulus to the vaso-motor and cardio-inhibitory centres of the medulla; but, in opposition to the statements of Traube and Landois, he asserts that it disables the intrinsic motor centres of the heart. He grounds this statement on the fact, that, after section of the vagi and the cervical cord, the heart soon ceases to beat, when the animal breathes in an atmosphere containing from twenty to forty per cent of carbon dioxide. Breathing in an atmosphere of oxygen stimulates both the inhibitory and accelerator centres of the medulla: and the author repeats for the mammal a statement made with reference to the frog; viz., that oxygen acts as a constant stimulus for the heart-contractions. Want of oxygen, like carbon dioxide, stimulates the inhibitory and vaso-motor centres, and first stimulates, then depresses, the accelerator centres. — (*Arch. anat. physiol.*, 1883, 134.) W. H. H. [582

Maturation and impregnation of the mammalian ovum. — G. Rein has investigated these phenomena in rabbits and guinea-pigs. He describes minutely his manner of obtaining the desired material. In rabbits the tuba can be cut open, and examined with a lens: in guinea-pigs it is better to collect the eggs by pressing out the excised tuba with a blunt instrument. They may be examined fresh in the fluid from the oviduct, and even kept so for some time, if the cover-glass is surrounded by a rim of oil, and the slide placed in a warm box. To preserve the eggs, fix with (.1%–1%) osmic acid, place them for two or three days in Müller's fluid, and mount in glycerine.

The so-called corona radiata consists of the cells (changed to the spindle form) of the discus proligerus. It is most marked in the rabbit immediately before the bursting of the Graafian follicle, i.e., nine to eleven hours after copulation; by which time one polar globule has generally been formed. The cells of the corona present features most unusual in epithelia: they are elongated, spindle or star shaped, with processes which branch often and anastomose with one another; they are probably forced apart by the liquor folliculi, which accumulates, especially during the last hours before the bursting of the follicle; after that event they resume their original form. As the ovum matures, the nucleus is distended, and assumes an eccentric position and oval form. The nucleolus is replaced now by a cluster of granules, which then scatter themselves through the yolk, become smaller and ultimately indistinguishable. The nucleus comes to lie close against the zona pellucida, and there is flattened out. The next change is the expulsion of the first polar globule, which appears to be formed out of the germ-vesicle. No karyokinetic figures were observed in connection with the process. Rein suggests that possibly the mammalian polar globules are not complete homologues of those of the lower animals. The maturation is further marked by the contraction of the yolk, first, at the point where the polar globule is ejected; second, general, so that the yolk recedes, as in other mammalia, from the zona pellucida. In three cases active protuberances on the yolk were observed (cf. Kupffer, ante, i. **1132**). In the mature ovum also appear yolk-grains larger and much darker than the other granules. In four cases a second nucleus was observed more in the centre of the egg, probably the egg-nucleus (or female pronucleus).

Impregnation takes place in the middle third of the tuba thirteen to seventeen hours after copulation. Two pronuclei (male and female) are seen in the ovum: they travel towards one another, meet eccentrically, make amoeboid movements, and sometimes are quite near the surface. The radiating lines could not be seen in most cases around the pronuclei. At the time of impregnation the cells of the corona have partly fallen off. Numerous spermatozoa crowd around the egg, several pass the zona; but probably only *one* enters the yolk. The pronuclei pass to the centre of the ovum, the amoeboid movements continue; one pronucleus becomes crescent-shaped, and embraces the other: the two then probably unite. — (*Arch. mikros. anat.*, xxii. 233.) C. S. M. [583

Duration of systole and diastole of heart-beat. — From a series of experiments made upon the dog, Howell and Ely have come to the conclusion that variations of arterial pressure from fifty millimetres to a hundred and sixty millimetres of mercury have no direct effect whatever upon the duration of either systole or diastole. The experiments were carried out upon hearts completely isolated from every other organ of the body, except the lungs, after the method devised by Prof. Martin. The contractions of the heart were registered by means of a Fick spring manometer connected with the cavity of the right ventricle, and the time relations of the beat were determined by comparing this curve with the simultaneous tracing of a tuning-fork vibrating fifty times a second. — (*Stud. biol. lab. Johns Hopk. univ.*, ii. 453.) W. H. H. [584

ANTHROPOLOGY.

Tattooing among civilized people. — Last December Dr. Robert Fletcher read a paper on tattooing among civilized people, which he is now publishing. The custom presents itself from two points of view, — the medico-legal and the anthropological. Compared with the elaborate tattooing of many savage tribes, the designs which sailors, soldiers, and, above all, criminals, have imprinted on their persons, are trivial or offensive in subject, or clumsy in execution. In 1869 Berchon made several reports to the French government on tattooing among sailors and criminals, and published a work entitled 'Histoire médicale du tatouage.' At the meeting in Algiers in 1881, of the French association for the advancement of science, Magitat exhibited a chart showing the geographical distribution of tattooing, according to methods, as follows: 1. By pricking; 2. By simple incision; 3. By ulceration or burning; 4. Hypodermic tattooing; 5. Mixed tattooing. Among the distinguished observers of this practice are Cesar Lombroso of Turin, and Dr. A. Lacassagne of Lyons. Lombroso publishes a chapter on tattooing in his 'L'uomo deliquente,' and Lacassagne is the author of a volume entitled 'Les tatouages, étude anthropologique et médico-légale.' He gives a table showing the parts of the body operated upon in 378 subjects, and also one containing the details of 1,333 tracings obtained from the battalion d'Afrique, as follows: —

Patriotic and religious emblems	91
Professional emblems	98
Inscriptions	111
Military emblems	149
Metaphorical emblems	260
Amorous and erotic emblems	280
Fantastic, historical, and miscellaneous,	344
	1,333

The reader will find this one of the most entertaining and instructive anthropological papers which have appeared in a long time. — (*Trans. anthrop. soc. Washington*, ii. 40.) J. W. P. [585

The Mexican pulque. — "One of the first objects to claim the attention of the conquerors of Mexico," says Carl Beni, "was the maguey-plant (Agave americana; Mexican, *ncutlli*). Its manifold uses and products, considered in relation to the inhabitants of that region and to their manner of living, render interesting the study of this vegetable, which is justly called *pianta delle meraviglie*." De Candolle thinks that the plant is of Mexican origin; but the place where it was discovered to furnish a beverage is uncertain, for traditions concerning it are intimately connected with the history of the ancient peoples who occupied the central plateaus of South America. According to the Mexican traditions, Ixquitecatl was the first to invent the method of drawing the sweet juice from the maguey, and Titlacahuan used pulque to intoxicate Quelzalcoatl and to induce him to go into exile. Another legend says, that in 1045 the juice of the plant was introduced as a drink among the royal family. Signor Beni has collected from various sources the references to the uses of this celebrated plant, and in 1876, while in Mexico, made some observations on its cultivation and uses. The following is the analysis of the sap and of the fermented liquor: —

	Sap.	Pulque.
Albuminous substances	25.40	12.57
Sugar	95.53	8.23
Salts	7.26	2.20
Absolute alcohol	0 00	36.80
Water, gas, and waste	871.81	940 20
	1000.00	1000.00

— (*Archiv. per l'antrop.*, xiii. 13.) J. W. P. [586

The use of mollusks. — Dr. A. T. de Rochebrune has written a second memoir upon mollusks among ancient and modern peoples, this time treating of shells in the sepulchres of Ecuador and New Granada. The mounds of the United States furnish some beautiful specimens of aboriginal art in shell, and our archeologists have not been slow in taking advantage of the interest clustering about these objects. The relative rarity of mollusks utilized by the ancient inhabitants of the Peruvian coast is noticed by M. Rochebrune. The farther north we go, the more pronounced this poverty becomes. Indeed, the following five species are all that the author has found from that region: —

1. Spondylus limbatus Sow, statuettes and necklaces.
2. Venus multicostata Sow, spangles, necklaces.
3. Patella olla Brod., bangles, quippus(?) beads.
4. Oliva splendidula Sow, bangles, pendants.
5. Fasciolaria salmo Wood, pieces for clothing.

Two or three of the objects are carved with some elaborateness of design. — (*Rev. d'ethnog.*, ii. 311.) J. W. P. [587

INTELLIGENCE FROM AMERICAN SCIENTIFIC STATIONS.

GOVERNMENT ORGANIZATIONS.

Geological survey.

Comparative paleontology of the Devonian formation. — Prof. H. S. Williams has recently been devoting his attention especially to this formation in western New York, and, in a preliminary report to the director, makes known some interesting facts as a result of his study of the materials collected by him during the past summer.

In the black shales, which in New York lie between beds containing Hamilton faunas below and those bearing Portage faunas above, he has found Lingulas indistinguishable from those of the Cleveland shales; also conodont teeth identical in form with those described from the same Cleveland beds, and Sporangites and Palaeoniscus scales. Species, therefore, regarded by Ohio geologists as characteristic of the Cleveland shales (Waverly), occur together in a similar black shale in New York, which there is known to underlie the upper Devonian. Professor Williams says, however, that, although the identity of the two faunas can scarcely be disputed, he is not so sure that it is an indication of synchronous deposition. The various black shales of Ohio are more nearly continuous there than in New York; and he says it is pretty clear that the intercalated sandy deposits are of a more eastern origin. At the horizon of upper Devonian the sands are purer and of lighter color as we go westward and south-westward; and in some of the quarries of western New York, sandstones very similar to the Ohio Waverly stone are met with. In these sands distinct quartz pebbles have been found, nearly as low as the point where the first member of the typical Chemung fauna is obtained, leading Professor Williams to suspect that true conglomerates may, in some geographical area, have been contemporaneous with the early Chemung fauna. He says the evidences are accumulating in support of the hypothesis that the lower conglomerates are the geographical representatives of deposits of much finer character farther north, in which the Chemung faunas appear. He meets the argument for a high geological position of the conglomerates (based on an assumed regular dip towards the south-west in this region) by the supposition that conglomerates must express nearness to shore, and that, running along a line from shore into deep water, it is safe to assume that for any given length of time the thickness of the deposit will diminish with the distance from the shore; and hence, if the general relation of shore to deep water continued through the upper Devonian, the dip of the strata will diminish as we ascend in the series, and the tendency of one who depended upon a general rate of dip would be to reckon the more southern deposits too high. Professor Williams has good evidence that this has been done for the sands of Wyoming and Alleghany counties.

Professor Williams's observations lead him to the opinion (which may be modified by further facts), that the sandstones lying at the top of the series at Portage Falls, barren of fossils so far as reported, are, when taken as a mass, stratigraphically identical with the lower Chemung sandstones farther south and west, and that geographical conditions had more to do with the presence or absence of the Chemung fauna than had the geological time of the deposit, after once the Chemung fauna appeared in the sea.

The present stage of Professor Williams's investigations leads him to the following opinion as to the distribution of faunas at this mid-upper Devonian for the eastern area: —

1. A Hamilton fauna coming in from the east and north, and extending around the southern border of the old paleozoic continent into the interior sea, through Canada West, Michigan, etc., to Iowa, etc.

2. A black slate fauna, at first reaching quite to the eastern New York areas, but, with the advance of time, oscillating back and forth, each stage withdrawing farther and farther to the west and south.

3. A sparse Portage fauna, mainly small lamellibranchs and pteropods and cephalopods, rather pelagic in character, common over the New York area, but whose centre or origin he is unable to trace.

4. A Chemung fauna from the south and east, pushing northward with the withdrawal of the Hamilton fauna, mingling with it at first in eastern New York areas, but in western New York not appearing at all until the complete withdrawal of the Hamilton fauna.

There are also traces of a fifth fauna over this region; for, as the Chemung fauna is followed towards the western part of the state, species characteristic of the subcarboniferous of the interior begin to appear, both in the nature of the varietal modifications of the species and in the rare new forms mixed with the Chemung species, leading to the suspicion that the subcarboniferous faunas of the western interior may have been contemporaneous with the Chemung faunas of New York and Pennsylvania. He says, however, that the solution of this problem must be left until a more thorough study of the western interior deposits and their faunas is made, and that the problems involved are too complex to make hasty generalizations safe.

These investigations have been partly in the line of some remarks made by Professor James Hall in the 'Paleontology of New York' (vol. iv. part i., March, 1867, p. 257), where he speaks of the diminution of Devonian types and the augmentation of carboniferous types in the same beds in western New York, and also expresses the opinion that the mingling of Devonian and carboniferous aspects is due to geographical and physical conditions, and not to difference in age or chronological sequence of the beds which contain the fossils. Professor Williams is elaborating this idea, and is dissecting the faunas and tracing them to their centres of distribution.

NOTES AND NEWS.

PROFESSOR SYLVESTER, who has resigned the chair of mathematics at the Johns Hopkins university, and has been appointed to the Savilian professorship of geometry at the University of Oxford, sailed for Europe on Saturday last, Dec. 22. The night before his departure from Baltimore, a farewell assembly was held at the university in his honor. Mr. Matthew Arnold, who was present, made a brief speech. Resolutions were read on behalf of the board of trustees and of the teachers in the university, expressing their profound regret at the departure of Professor Sylvester, and the highest appreciation of his work and of the great stimulus his presence has given to mathematical research in this country. Professor Sylvester responded in a speech of characteristic warmth and *naïveté*, in which, along with most enthusiastic admiration and approval of the university he has helped to inaugurate, he took the opportunity of making some pointed suggestions. One of these was addressed to millionnaires, to whom he indicated several ways in which, while aiding the Johns Hopkins university, they might secure for themselves imperishable fame. Another pointed at the advisability of introducing a system of pensions or some equivalent provision for superannuated and disabled professors; and still another was a protest against the dismemberment of a university library by the establishment of specialized branches. Professor Sylvester's departure removes from the university not only the most distinguished scientific man, but the most interesting personality connected with it; and his absence will make a gap in the general life of the university no less than in his own department. It is hardly to our credit that no American college has conferred an honorary degree upon him during his residence in this country.

— In his recent address to the Royal society, President Huxley states that thirty-eight of the Challenger reports have been published, forming eight quarto volumes, with 4,195 pages of letter-press, 488 lithographic plates, and other illustrations. Thirty-four of these memoirs are on zoölogical, four on physical, subjects. Nine reports are now nearly all in type, and some of them partly printed. These will be published within three months, and will form three zoölogical volumes with 230 plates and many woodcuts, and one physical volume with many diagrams and maps: this latter volume will contain the report on the composition of ocean water, the specific gravity and temperature observations. A considerable part of the general narrative of the cruise is now in type, and nearly all the illustrations are prepared. The narrative will extend to two volumes; and it is expected they will be ready for issue in May or June, 1884. The work connected with the remaining forty-two special reports is in most instances progressing satisfactorily. Portions of the manuscript for three of the larger memoirs have been received and put in type, and the manuscript of many others is in a forward state. For these memoirs, 386 lithographic plates have been printed off and delivered to the binders, 404 others are now on stone, and the drawings for many more are being prepared. It is estimated that the whole work connected with the report will be completed in the summer of 1887.

— Professor Huxley also expresses a regret that the admirable energy of the government in taking measures to make the recent advances of medical science available during the late outbreak of cholera in Egypt was not extended beyond the purely practical side of the matter, or perhaps not so far as the practical side in the proper sense; for, until we know something about the causes of that terrible disease, our measures for prevention and for cure will be alike leaps in the dark.

Those, he says, who have looked into the literature of cholera may perhaps be disposed to think that a new search after its cause will add but another to the innumerable wild hypotheses which have been set afloat on that topic; and yet devastating epidemics, like the pebrine of the silkworm, so similar in their fatality and their apparently capricious spread that careful investigators have not hesitated to institute a detailed comparison of the phenomena of this disease with those of cholera, have been proved by Pasteur to be the work of microscopic organisms; and hardly less fatal epidemics, such as splenic fever, have been traced to similar agencies. In both these cases, knowledge of the causes, and of the conditions which limit the operation of the causes, has led to the invention of effectual methods of cure. And it is assuredly, in the present state of science, something more than a permissible hypothesis, that the cause of cholera may be an organic living materies morbi, and that the discovery of the proper curative and prophylactic measures will follow upon the determination of the nature and conditions of existence of these organisms.

If this reasoning is just, it is certainly to be regretted that the opportunity of the outbreak of cholera in Egypt was not utilized for the purposes of scientific investigation into the cause of the epidemic. There are able, zealous, and courageous young pathologists in England who would have been willing enough to undertake the labor and the risk; and it seems a pity that England should leave to Germany and to France an enterprise which requires no less daring than arctic or African exploration, but which, if successful, would be of a thousand times more value to mankind than the most complete knowledge of the barren ice-wastes of the pole or of the sweltering barbarism of the equator. It may be said that inquiries into the causation of cholera have been for some years conducted in India by the government without yielding any very definite result; but this is perhaps rather an argument in favor of, than against, setting fresh minds to work upon the problem.

— Professor George Davidson read papers at the meeting of the California academy of sciences, Nov. 5, on the solar eclipse of Oct. 30, 1883, and the appearance of Saturn as seen at the Dearborn observatory under very favorable conditions. He said of the latter, "The evening was clear and pleasant, and nearly calm. . . . The atmosphere was charged with aqueous vapor, and the dew ran down the observatory almost like rain. . . . But one of the best revealed features . . . was the undoubted difference in brightness of the gauzy ring at the two ansae. The preceding part was decidedly brighter than the following ansa. . . . I should mention, that, in my limited experience in examining Saturn, I have never seen the atmospheric conditions so nearly perfect as they were that night. . . . I saw more than is given in the beautiful Cambridge drawing."

Professor Davidson also spoke of a brilliant meteor as follows: "On the evening of Oct. 29, at eleven o'clock, a remarkably brilliant meteor passed vertically downwards very near to Eridani (3 mag.). It illuminated the street, and its light cast a strong shadow. The train, about five degrees long, was persistent for three or four seconds, with an intense, vivid brightness, then faded away to a white, vaporous-looking streak, which assumed a wavy motion for three or four seconds, and then vanished. The color was an intense white, tinged with a purplish hue; and the brightest part of the train which was left was not at the point of disappearance, but about the middle of its length."

At a later meeting of the academy, Professor Davidson spoke of Trouvelot's red star, seen during the solar eclipse of May 6, and took the ground that δ Arietes was the star seen by Trouvelot.

Full accounts of all these papers were given in the *Mining and scientific press*, San Francisco.

— We take the following account of the awards of medals recently made by the council of the Royal society from Professor Huxley's presidential address: —

The number, the variety, and the importance of Sir William Thomson's contributions to mathematical and experimental physics are matters of common knowledge; and the fellows of the society will be more gratified than surprised to hear that the council have this year awarded him the Copley medal, — the highest honor which it is in their power to bestow. Sir William Thomson has taken a foremost place among those to whom the remarkable development of the theory of thermodynamics and of electricity in the last forty years is due. His share in the experimental treatment of these subjects has been no less considerable; while his constructive ability in applying science to practice is manifested by the number of instruments bearing his name which are at present in use in the physical laboratory and in the telegraph-office. Moreover, in propounding his views on the universal dissipation energy and on vortex motion and molecular vortices, Sir William Thomson has propounded conceptions which belong to the prima philosophia of physical science, and will assuredly lead the physicist of the future to attempt once more to grapple with those problems concerning the ultimate construction of the material world which Descartes and Leibnitz attempted to solve, but which have been sedulously ignored by most of their successors.

One Royal medal has been awarded to Dr. T. Archer Hirst, F.R.S., for his investigations in pure geometry, and more particularly for his researches into the correlation of two planes and into the complexes generated by them.

The other Royal medal has been awarded to Dr. J. S. Burdon Sanderson, F.R.S., for the eminent services which he has rendered to physiology and pathology, and especially for his researches on the electrical phenomena exhibited by plants, and for his investigations into the relation of minute organisms to disease. In making this award, the council desire not merely to recognize the merit of Dr. Burdon Sanderson's researches, especially those on the analogy between the electrical changes which take place in the contractile tissues of plants and those which occur in the like tissues of animals, but to mark their sense of the important influence which Dr. Sanderson has exerted upon the study of physiology and pathology in this country.

The Davy medal has this year been again awarded in duplicate; the recipients being M. Marcellin Berthelot, member of the Institute of France, and foreign member of the Royal society, and Professor Julius Thomsen of Copenhagen. The thermochemical researches of Berthelot and Thomsen have extended over many years, and have involved an immense amount of work, partly in the application of established methods to new cases, partly in devising new methods and applying them to cases in which the older methods were not applicable. Chemists had identified a vast variety of substances, and had determined the exact composition of nearly all of them; but of the forces which held together the elements of each compound they knew but little. It was known that certain elements combine with one another with great evolution of heat-forming products in which they are firmly united; while other elements combine but feebly, and with little evolution of heat. But the materials for forming any general theory of the forces of chemical combination were but scanty and imperfect. The labors of Messrs. Berthelot and Thomsen have done much towards supplying that want, and they will be of the utmost value for the advancement of chemical science.

— Dr. Charles W. Dabney, director of the North Carolina agricultural experiment-station, has issued a circular urging the necessity of a strictly scientific agricultural journal in this country, either a quarterly or monthly. Those interested should address Dr. Dabney at Raleigh, N.C. The station at Raleigh is reported to be in a prosperous condition.

— The next number of the *Journal of the Cincinnati society of natural history* will contain a biographical sketch and a steel-plate portrait of the late V. T. Chambers, the entomologist. Mr. Chambers was at one time president of the society, and at all times one of its most active members.

— The Ohio mechanics' institute of Cincinnati has inaugurated a series of popular scientific lectures on a plan pursued in former years. The lecturers and the topics for this series are as follows: Prof. T. C. Mendenhall, 'The electric light;' Prof. C. L. Mees, 'Molecular motion and crystallization;' Prof. F. W. Putnam, 'Ancient arts of North-American nations;' Dr. A. Springer, 'The cell and its functions;' Prof. E. S. Morse, 'Japan;' Prof. Thomas French, jun., 'Sound;' Prof. W. L. Dudley, 'Water;' Prof. T. H. Norton, 'Recent advances in chemical technology;' Prof. J. B. Porter, 'Mining and metallurgy.' The first two of these have already been given. The others will follow at intervals of about two weeks.

— The course of free popular scientific lectures just concluded by the Cincinnati society of natural history was a great success. Eight lectures were delivered on topics connected with zoölogy by members of the society. They were given every Friday evening from Oct. 19 to Dec. 7, and were attended by as large audiences as the lecture-room would accommodate. The lecture committee is arranging for another course, to begin on Jan. 4; and these lectures will treat of topics connected with geology and mineralogy. 'Gems,' 'Marbles and corals,' 'Physical geography of the United States,' and 'Fossil botany,' are some of the subjects. The officers of the society deserve credit for their efforts to make the institution of practical educational value.

— It is proposed to hold during the year 1884, says *Nature*, an international exhibition, which shall also illustrate certain branches of health and education, and which will occupy the buildings at South Kensington erected for the fisheries exhibition. The object of the exhibition will be to illustrate, as vividly and in as practical a manner as possible, food, dress, the dwelling, the school, and the workshop, as affecting the conditions of healthful life, and also to bring into public notice many of the most recent appliances for elementary school-teaching and instruction in applied science, art, and handicrafts. The influence of modern sanitary knowledge and intellectual progress upon the welfare of the people of all classes and all nations will thus be practically demonstrated, and an attempt will be made to display the most valuable and recent advances which have been attained in these important subjects. The exhibition will be divided into two main sections, — I. Health; II. Education,— and will be further subdivided into six principal groups. In the first group it is intended specially to illustrate the food-resources of the world, and the best and most economical methods of utilizing them. For the sake of comparison, not only will specimens of food from all countries be exhibited, but the various methods of preparing, cooking, and serving food will be practically shown. The numerous processes of manufacture connected with the preparation of articles of food and drink will thus be exemplified; and, so far as the perishable nature of the articles will admit, full illustrations will be given of the various descriptions of foods themselves. In the second group, dress, chiefly in its relation to health, will be displayed. Illustrations of the clothing of the principal peoples of the world may be expected; and a part of this exhibition, which, it is anticipated, will be held in the galleries of the Royal Albert Hall, will be devoted to the history of costume. In the third, fourth, and fifth groups will be comprised all that pertains to the healthful construction and fitting of the dwelling, the school, and the workshop, not only as respects the needful arrangements for sanitation, but also the fittings and furniture generally in their effect on the health of the inmates. The most improved methods of school construction will be shown; and the modes of combating and preventing the evils of unhealthy trades, occupations, and processes of manufacture, will form portions of the exhibition. The sixth group will comprise all that relates to primary, technical, and art education, and will include designs and models for school-buildings, apparatus and appliances for teaching, diagrams, text-books, etc. Special attention will be directed to technical and art education, to the results of industrial teaching, and to the introduction of manual and handicraft work into schools.

— The members of the polar meteorological station which Denmark maintained at Godthaab in Greenland have just returned to Copenhagen. According to *Nature*, the chief of the expedition, Lieut. A. Paulsen, reports, that, having left Copenhagen on May 18, 1882, in the sailing-ship Ceres, they arrived at Godthaab on June 14. On the voyage out, observations of the temperature of the sea and air were made every hour. On the arrival out, the expedition had to select the most suitable spot for the erection of the four wooden buildings brought with them, in which the magnetic and astronomical observations were to be made. A small mountain ridge near the church in the colony was chosen for this, as the preliminary researches in its neighborhood showed that the influence of iron strata on the magnetic current was here very small. The buildings were then erected, and the pillars raised on which the transit instrument, the great astronomical clock, and the eight different magnetical instruments, were mounted, and simultaneously the instruments for the meteorological observations were also placed; so that the weathercock and the anemometers, as well as the thermometer hut, were situated as free as possible. On Aug. 1 the meteorological observations could be commenced, but the magnetic ones were through an accident delayed until the 7th. From that date complete observations were made in exact accordance with the international programme, without interruption, every hour until Aug. 31 this year; and the expedition has thereby fully accomplished its object, viz., of obtaining a full year's magnetical and meteorological observations in this locality. A number of other scientific researches have also been pursued, of which those on the aurora borealis should particularly be mentioned. This phenomenon was frequently observed and studied during the winter, while some exceedingly valuable statistics were obtained as to the altitude of the aurora borealis above the earth's surface by measurements effected simultaneously in various places by light-signals. The measurements of atmospheric electricity have also led to valuable results. It is stated to have been the best equipped polar expedition ever despatched from Denmark.

— M. Laugier, at a meeting of the Académie des sciences held on Oct. 22, described a method of disinfecting plants for exportation, practised by himself and Dr. Koenig at Nice. Some branches of vine infected with phylloxera were treated with a solution of sulphocarbonate of ethyl, the eggs and phylloxera being completely destroyed. The plants submitted to the trial do not seem in general to have suffered from it. For the first trials in disinfecting leaves and twigs, gaseous hydrocyanic acid was used, as proposed by Dr. Koenig; and for the roots and surrounding earth, sulphocarbonate of potassium in weak solution. Their experiments, they believe, will be of great service to the flower-cultivators of the Riviera.

— The distinguished French geodesist, M. Antoine d'Abbadie, writes to the editor of *Nature*, regarding units of angular measure, as follows: —

"We probably owe our degrees either to the earlier supposed year of 360 days, or to the fact that this number has many divisors, although such divisors afford no practical advantage. When trigonometrical functions were subsequently discovered, it was found that the natural unit is not the circle, but the quadrant or right angle. Our system of numeration being decimal, it was then most convenient to divide the quadrant decimally; and the circle is thus considered as composed of four, forty, four hundred, etc., parts, according to the degree of exactness required. This was proposed by Briggs when preparing his logarithms, which are based on decimals; but unfortunately it was then set aside. Revived a long time after by Lagrange, it was acted upon by Laplace in his Mécanique celeste. Nowadays decimal divisions of the quadrant are the only ones used by French geodesists. . . . In Italy two geodesists were instructed to observe and calculate, in both the centesimal and the sexagesimal systems, the same large lot of angles. It was then found that the use of decimals gave a saving of two-sevenths of time, either in observation or in calculation. This result was unknown to Sir George Airy; but he judged rightly that the conversion of all sexagesimal angles into decimal ones would materially lighten his labors, and he actually did so when calculating all the lunar observations previously made at Greenwich."

— Prof. H. G. Van de Sande Bakhuyzen, the director of the observatory at Leiden, announces the completion of a new catalogue of star-places (began by Hoek, and continued by Dr. Kam, and contained in the first sixty-six volumes of the *Astronomische nachrichten*). The catalogue will contain nearly five thousand stars, reduced to the epoch 1855.0, with the data pertaining to the observations, and the usual elements for carrying forward the star positions.

— The last expedition of Lessar toward the Oxus was attended with severe hardships. He lost nearly all his animals; and to save his famished escort, almost destitute of water and provisions in the desert, he was obliged to seek assistance from the Khivans. Worn with three years painful and continual exploration, the explorer thinks of returning to Europe.

INDEX TO VOLUME II.

" 469, " 2, " 5, " " " "
" 471, " 2, " 8, for 'Mieham' read 'Mecham.'
" 483, " 2, 4th line from bottom, for '5 μ' read '.5 μ.'
" 523, " 2, last line, for 'Ifuagos' read 'Ifugayos.'
" 540, " 2, line 15 of second article, for 'Z. cavisortris' read 'Z. cavirostris.'
" 556, " 1, " 23, for '90°' read '45°.'
" 569, " 2, last line but one, for 'San Joan' read 'San Juan.'
" 570, " 1, line 18, for 'or Vancouver' read 'on Vancouver.'
" 607, " 2, " 9, for 'catalogue of mollusks' read 'catalogue of his collection of mollusks.'
" 701, " 2, note, for 'No. 42' read 'No. 41.'
" 722, " 2, " 38, for 'Hectariniinae' read 'Nectariniinae.'
" 735, in inscription of cut, for '1876' read '1870.'
" 802, col. 1, line 38, for 'Lanicera' read 'Lonicera.'
" 838, " 2, " 11, for 'Dearborn' read 'Davidson.'

SCIENCE

PUBLISHED WEEKLY AT CAMBRIDGE MASS. U.S.A · BY MOSES KING

COPYRIGHT IN 1883 BY THE SCIENCE COMPANY. Vol. 1. MARCH 23, 1883. No. 7. ENTERED AT BOSTON AS SECOND CLASS MATTER

THE PUBLISHER'S GREETING

TO THE

CONTRIBUTORS AND SUBSCRIBERS.

The following lists of contributors and subscribers are here printed in the hope of giving pleasure to the many contributors to SCIENCE *by showing them in detail the extensive and spontaneous reception which the public has awarded their efforts to establish a weekly scientific journal which should reflect creditably on Americans and American institutions, and then of giving permanent credit to the several hundred persons, who, by their prompt subscriptions, have shown their earnest good-will and sympathy with this laborious and responsible undertaking.*

The list of contributors will also show to subscribers that the projectors of the enterprise have exerted every effort to obtain from eminent authorities everywhere the news and articles which are appearing in the consecutive issues of SCIENCE.

It should be added, that other names ought to appear in the list of subscribers, — some because received too late, and others, who, by reason of absence or remote residence, and from other causes, have not yet had an opportunity of subscribing. And among the contributors might justly appear the names of many persons whose contributions the editors have accepted, and others who are actively engaged on articles soon to be published. In justice to both these classes, the publisher proposes later to issue a handsome volume containing names of all the contributors and subscribers, a copy of which will be sent to each one of them with the compliments of the publisher.

In looking over the successive numbers of SCIENCE, *one can readily see that a generous support has come from business men of numerous cities. The publisher trusts, therefore, that the readers of* SCIENCE *will always look through the advertising pages, and patronize these advertisers when possible; assuring them that he will make an investigation of any case where a patron seems to be unjustly treated, with a view of excluding that advertiser from future pages of* SCIENCE. *But there will probably be no difficulty; for the advertisers are, as a rule, well-known and thoroughly trustworthy firms; and in the volume above referred to there will be a classified list of advertisers in the earlier issues of* SCIENCE, *as being worthy of acknowledgment for their support.*

The publisher also desires to call particular attention to the fact that when SCIENCE *was projected, — notwithstanding it promised to be a pecuniary failure, — a company of scientific men and patrons of science was formed for its maintenance. To them, therefore, — although the enterprise now promises to become a pecuniary success, — is due all the credit for their philanthropic intentions. The directors of this Company are D. C. Gilman (president), the president of Johns Hopkins University: Alexander Graham Bell (vice-presi-*

dent), inventor of the Bell Telephone; Gardiner G. Hubbard; Othniel C. Marsh, professor at Yale College; Samuel H. Scudder (treasurer), president Boston Society of Natural History.

And to those who are and who may become subscribers, it may again be said that SCIENCE, *in its first two volumes, comprising one year, will furnish about fifteen hundred pages of text wholly apart from any kind of advertising, and will be provided with suitable titlepages and carefully-made indexes. It is the aim of The Science Company to publish such a periodical as will well be worth binding in permanent form, and one which will return for every subscription an ample* quid pro quo.

The annual subscription in the United States and Canadas is five dollars, and, in the countries of the International Postal Union, six dollars. Single copies, fifteen cents. No electrotype plates are made of the pages of text; and subscribers who fail regularly to receive their copies will please notify the publisher at once; for before long it will be impossible to supply back numbers.

For THE SCIENCE COMPANY,

MOSES KING, *Publisher*,

HARVARD SQUARE, CAMBRIDGE, MASS.

LIST OF CONTRIBUTORS.

INCLUDING ONLY THOSE WHOSE CONTRIBUTIONS HAVE ACTUALLY APPEARED IN THE FIRST SEVEN ISSUES OF "SCIENCE."

Dr. C. C. ABBOTT, Trenton, N.J.
Professor H. P. ARMSBY, Worcester, Mass.
Professor SPENCER F. BAIRD, Smithsonian Institution, Washington, D.C.
Professor GEORGE F. BARKER, University of Pennsylvania, Philadelphia, Penn.
Mr. H. W. BLAIR, Coast and Geodetic Survey Office, Washington, D.C.
Dr. WALTER K. BROOKS, Johns Hopkins University, Baltimore, Md.
Mr. EDWARD BURGESS, Natural History Society, Boston, Mass.
Professor F. W. CLARKE, University Cincinnati, Cincinnati, O.
Professor J. H. COMSTOCK, Cornell University, Ithaca, N.Y.
Mr. C. S. COOK, Dartmouth College, Hanover, N.H.
Dr. THOMAS CRAIG, Johns Hopkins University, Baltimore, Md.
Mr. W. O. CROSBY, Natural History Society, Boston, Mass.
Professor CHARLES R. CROSS, Massachusetts Institute of Technology, Boston, Mass.
Capt. WILLIAM H. DALL, United-States Coast Survey, Washington, D.C.
Mr. WILLIAM MORRIS DAVIS, Museum of Comparative Zoölogy, Cambridge, Mass.
Dr. J. W. DAWSON, McGill University, Montreal, Can.
Mr. CHARLES DEANE, Massachusetts Historical Society, Cambridge, Mass.
Dr. H. T. EDDY, University of Cincinnati, Cincinnati, O.
Mr S. F. EMMONS, Geological Survey, Washington, D.C.
Dr. W. G. Farlow, Harvard University, Cambridge, Mass.
Professor WALTER FAXON, Museum Comparative Zoölogy, Cambridge, Mass.
Professor S. A. FORBES, State Entomologist, Normal, Ill.
Mrs. C. L. Franklin, Baltimore, Md.
Dr. F. FRANKLIN, Johns Hopkins University, Baltimore, Md.
Professor EDGAR FRISBY, United-States Naval Observatory, Washington, D.C.
Mr. HENRY GANNETT, United-States Geological Survey, Washington, D.C.
Professor J. W. Gibbs, New Haven, Conn.
Mr. G. K. GILBERT, United-States Geological Survey, Washington, D.C.
Dr. THEODORE GILL, Smithsonian Institution, Washington, D.C.
Mr. G. BROWN GOODE, Curator U. S. National Museum, Washington, D.C.
Dr. GEORGE L. GOODALE, Botanic Garden, Cambridge, Mass.
Professor ASA GRAY, Botanic Garden, Cambridge, Mass.
Dr. EDWIN H. HALL, Harvard University, Cambridge, Mass.
Dr. G. STANLEY HALL, Johns Hopkins University, Baltimore, Md.
Dr. C. S. HASTINGS, Johns Hopkins University, Baltimore, Md.
Major DAVID P. HEAP, United-States Engineers, Washington, D.C.
Mr. F. H. HERRICK, Burlington, Vt.
Dr. JOSEPH E. HILGARD, Supt. U. S. Coast and Geodetic Survey, Washington, D.C
Mr. GEORGE ANTHONY HILL, Cambridge, Mass.
Professor E. S. HOLDEN, University of Wisconsin, Madison, Wis.
Dr. THOMAS STERRY HUNT, Montreal, Can.
Mr. SAMUEL HUSTON, Richmond, O.
Professor ALPHEUS HYATT, Natural History Society, Boston, Mass.
Mr. J. AMORY JEFFRIES, Harvard Medical School, Boston, Mass.
Mr. J. S. KINGSLEY, Boston, Mass.
Dr. SAMUEL KNEELAND, New-York City, N.Y.
Professor S. P. LANGLEY, Alleghany, Penn.
Dr. JOSEPH LEIDY, University of Pennsylvania, Philadelphia, Penn.
Professor LEO LESQUEREUX, Columbus, O.
Dr. H. CARVILL LEWIS, Academy Natural Sciences, Philadelphia, Penn.

Dr. D. G. Lyon, Harvard University, Cambridge, Mass.
Dr. Charles F. Mabery,
Harvard University, Cambridge, Mass.
Professor Jules Marcou, Cambridge, Mass.
Mr. J. B. Marcou, Cambridge, Mass.
Dr. H. Newell Martin,
Johns Hopkins University, Baltimore, Md.
Dr. Charles Sedgwick Minot,
Harvard Medical School, Boston, Mass.
Mr N Murray, Johns Hopkins University, Baltimore, Md.
Dr. John S. Newberry, Columbia College, New York.
Dr. E. J. Nolan,
Academy Natural Sciences, Philadelphia, Penn.
Mr. S. L. Penfield, Yale College, New Haven, Conn.
Mr. Charles B. Penrose, Philadelphia, Penn.
Mr. W. H. Pickering,
Massachusetts Institute of Technology, Boston, Mass.
Major J. W. Powell,
Director U. S. Geological Survey, Washington, D.C.
Mr. D. J. Pratt, Albany Institute, Albany, N.Y.
Mr. Frederick W. Putnam,
Peabody Museum, Cambridge, Mass.
Professor Ira Remsen,
Johns Hopkins University, Baltimore, Md.
Professor Robert H. Richards,
Massachusetts Institute of Technology, Boston, Mass.
Dr. Charles V. Riley,
Entomologist to Dept. of Agriculture, Washington, D.C.
Professor Miles Rock,
United-States Naval Observatory, Washington, D.C.
Mr. Denman W. Ross, Cambridge, Mass.
Dr. J. A. Ryder,
United-States Fish Commission, Washington, D.C.
Mr. F. G. Schaupp,
Brooklyn Entomological Society, Brooklyn, N.Y.
Dr. A. R. C. Selwyn,
Director Geological Survey of Canada, Ottawa, Can.
Professor Nathaniel S. Shaler,
Harvard University, Cambridge, Mass.
Professor Sidney I. Smith, Yale College, New Haven, Conn.
Professor Francis H. Storer,
Bussey Institution, Boston, Mass.
Professor David P. Todd, Amherst College, Amherst, Mass.
Mr. William Trelease,
University of Wisconsin, Madison, Wis.
Professor John Trowbridge,
Harvard University, Cambridge, Mass.
Mr. Frederick W. True,
United-States National Museum, Washington, D.C.
Mr. J. B. Tyrrell, Ottawa, Can.
Mr. Winslow Upton, Army Signal Office, Washington, D.C.
Professor George L. Vose,
Massachusetts Institute of Technology, Boston, Mass.
Dr. M. E. Wadsworth,
Museum Comparative Zoölogy, Cambridge, Mass.
Dr. Leonard Waldo,
Yale College Observatory, New Haven, Conn.
Mr. Lester F. Ward,
United-States National Museum, Washington, D.C.
Professor R. B. Warder,
Ohio Mechanics Institute, Cincinnati, O.
Mr. Sereno Watson, Botanic Garden, Cambridge, Mass.
Mr. Albert Williams, Jun.,
United-States Geological Survey, Washington, D.C
Professor Charles A. Young,
College of New Jersey, Princeton, N.J.

LIST OF SUBSCRIBERS.

MASSACHUSETTS.

Boston.

Oliver Wendell Holmes	Poet and Professor.
Robert Charles Winthrop	Orator, Author, and Statesman.
George Edward Ellis	Historian.
Elizur Wright	Mathematician and Author.
Charles James Sprague	Poet, Lecturer, and Author.
John D. Runkle	Ex-President Institute of Technology.
Thomas G. Appleton	Author and Capitalist.
Charles F. Choate	President Old Colony Railroad.
William H. Baldwin	Pres. Young Men's Christian Union.
Benjamin F. Stevens	Pres. New-England Mutual Life-Ins. Co.
William P. Hunt	President South Boston Iron-Works.
William L. Libbey	President New-England Glass-Works.
Franklin Haven	President Merchants' National Bank.
John Cummings	President Shawmut National Bank.
W. W. Kimball	President Fourth National Bank.
Chester Guild	Pres. Manufacturers' National Bank.
William Endicott, jun.	President New-England Trust Co.
Henry P. Kidder	Kidder, Peabody, & Co.
Nathaniel Thayer	Capitalist.
Spencer W. Richardson	Richardson, Hill, & Co.
William H. Hill, jun.	Richardson, Hill, & Co.
Edward W. Hooper	Treasurer Harvard University.
Thomas T. Bouvé	Treasurer Glendon Iron Co.
Elisha S. Converse	Treasurer Boston Rubber-Shoe Co.
Edmund Dwight	Treasurer Boston Manufacturing Co.
Alfred P. Rockwell	Treasurer Great-Falls Manuf. Co.
Francis A. Osborn	Treasurer Corbin Banking Co.
E. P. Cutler	Treasurer Tremont Foundry Co.
H. Weld Fuller	Treasurer Woodlawn Cemetery.
Edward P. Bond	Man. Boston Safe Deposit and Trust Co.
Wallis S. Chase	Asst. Cashier Nat'l Bank of Commerce.
Charles C. Smith	Secretary Boston Gaslight Co.
Mellen Chamberlain	Librarian Boston Public Library.
Charles B. Tillinghast	Librarian State Library.
Charles A. Cutter	Librarian Boston Athenæum.
Melvil Dui	Library and Metric Bureaus.

Charles W. Parker	Macullar, Parker, & Co.
Nathan D. Robinson	Macullar, Parker, & Co.
James L. Wesson	Macullar, Parker, & Co.
John W. Wolcott	Proprietor Hotel Vendome.
W. Tracy Eustis	Financier Hotel Vendome.
John W. Dunklee	Proprietor Hotel Brunswick.
Henry B. Rice	Proprietor American House.
Royal M. Pulsifer	Proprietor Boston Herald.
Edward P. Call	Publisher Boston Advertiser.
Charles W. Ernst	Editor Boston Advertiser.
Edwin M. Bacon	Editor Boston Advertiser.
Edward H. Clement	Editor Boston Transcript.
Bradford K. Peirce	Editor Zion's Herald.
Samuel J. Barrows	Editor Christian Register.
William J. Rolfe	Editor Journal of Chemistry.
Henry D. Dupee	Walpole Dye and Chemical Works.
George L. Damon	Safe Manufacturer.
Charles Henry Wise	Gen. Agt. Chicago & North-west'n R.R
Edward A. Taft	General Manager New-York and Boston Despatch Express Co.
John Cotton Paige	Paige's Insurance Agency.
William R. Gray	Paige's Insurance Agency.
Sidney M. Hedges	Gen. Agt. Mutual Benefit Life-Ins. Co
James B. Niver	Agent Equitable Life-Insurance Co.
Edward J. Smith	General Agent North-western Mutual Life-Insurance Co.
Henry McL. Harding	Insurance Agent.
Samuel W. Winslow	Real-Estate Dealer.
Alexander S. Porter	Real-Estate Broker.
James Freeman Clarke	Pastor Church of Disciples.
Joseph Cook	Clergyman and Lecturer.
Robert C. Waterston	Unitarian Clergyman.
Samuel H. Winkley	Clergyman.
William Burnet Wright	Pastor Berkeley-street Church.
Minot J. Savage	Pastor Church of the Unity.
A. A. Miner	Pastor Columbus-avenue Universalist Church.
Caleb Davis Bradlee	Pastor Harrison-sq. Unitarian Church.
Samuel K. Lothrop	Pastor Brattle-square Church.
Henry W. Foote	Pastor King's Chapel.

D. P. Ilsley	D. P. Ilsley & Co.
William A. French	Abram French & Co.
Samuel N. Brown	Fairbanks, Brown, & Co.
Samuel B. Rindge	Parker, Wilder, & Co.
Benjamin Phipps	Parker, Wilder, & Co.
William H. Sherman	Parker, Wilder, & Co.
Henry D. Williams	Williams & Everett.
Joseph T. Brown	Apothecary.
Charles H. Bassett	Joseph T. Brown & Co.
William J. Knowlton	Natural-History Store.
C. J. Maynard	Naturalist.
William H. Bowker	President Bowker Fertilizer Co.
John W. Brackett	Piano-Forte Manufacturer.
Alonzo P. Howard	Benjamin Howard's Sons.
C. Allen Browne	Merchant.
John Hogg	Hogg, Brown, & Taylor.
Richard C. Greenleaf	C. F. Hovey & Co.
Samuel Johnson	C. F. Hovey & Co.
Abraham Avery	Rand, Avery, & Co.
Samuel Johnson	Rand, Avery, & Co.
John C. Rand	Rand, Avery, & Co.
Avery Lewis Rand	Rand, Avery, & Co.
Wright & Potter Printing Co.	State Printers.
Rockwell & Churchill	City Printers.
Daniel Lothrop	D. Lothrop & Co.
C. F. Jewett	James R. Osgood & Co.
A. Williams & Co.	Old Corner Bookstore.
S. E. Cassino	Publisher.
W. B. Clarke & Carruth	Booksellers.
Thomas Groom	Stationer and Manufacturer.
Albert C. Russell	Wood Engraver.
Rice, Kendall, & Co.	Paper Manufacturers.
Alexander H. Rice	Rice, Kendall, & Co.
C. F. Crehore	Press Paper Manufacturer.
William T. Barker	Paper Manufacturer.
Duncan D. Dexter	William T. Barker & Co.
William J. Wilson	Book and Pamphlet Binder.
Sylvester K. Abbott	Pamphlet and Periodical Binder.
William Claflin	William Claflin, Coburn, & Co.
James A. Woolson	William Claflin, Coburn, & Co.
Albert L. Coolidge	Houghton, Coolidge, & Co.
C. F. Quincy	Lewando's Dye House.
George D. Atkins	General Agent Nonotuck Silk Co.
Albert Metcalf	Dennison Manufacturing Co.
William H. Forbes	Forbes Lithograph Manufacturing Co.
Louis Prang	Prang Educational Co.
John S. Clark	Prang Educational Co.
Charles H. Ames	Prang Educational Co.
Henry C. Nash	General Agent D. Appleton & Co.
William H. Swift & Co.	Colors and Chemicals.
Frost & Adams	Artists' Materials.
Noyes Brothers	Men's Outfitters.
I. W. Moody	The Stationer.
Francis H. Storer	Dean of Bussey Institution.
Calvin Ellis	Dean of Harvard Medical School.
I. T. Talbot	Dean Boston Univ. Medical School.
James H. Whittemore	Res. Physician Mass. Gen. Hospital.
Frank W. Page	Supt. Adams Nervine Asylum.
C. Wesselhoeft	Physician.
John H. Dix	Physician.
James C. White	Physician.
Samuel G. Webber	Physician.
George Stedman	Physician.
George M. Garland	Physician.
Francis H. Williams	Physician.
Charles Sedgwick Minot	Physician.
Albert Day	Physician.
J. Foster Bush	Physician.
Frederick C. Shattuck	Physician.
Henry P. Quincy	Physician.
Henry O. Marcy	Physician.
F. H. Davenport	Physician.
Samuel L. Abbot	Physician.
James B. Ayer	Physician.
Edward P. Banning, jun.	Physician.
Henry H. A. Beach	Physician.
Samuel J. Mixter	Physician.
George F. Bigelow	Physician.
Clarence J. Blake	Physician.
Joseph W. Warren	Physician.
Charles E. Ware	Physician.
George Russell	Physician.
W. P. Willson	Physician.
William F. Whitney	Physician.
Edward Wigglesworth	Physician.
Richard Manning Hodges	Physician.
L. E. Sewall	Physician.
Alfred C. Garratt	Physician.
A. M. Sumner	Physician.
W. N. Bullard	Physician.
Thomas M. Dillingham	Physician.
Thomas Henderson Chandler	Dean of Harvard Dental School.
Luther Dimmock Shepard	Dentist.
George Frank Waters	Dentist.
David M. Parker	Dentist.
Eliot C. Clarke	Civil Engineer.
John C. Hoadley	Mechanical Engineer.
Samuel L. Minot	Civil Engineer.
George H. E. Trouvelot	Bell Telephone Co.
Edward Reed	42 West Newton Street.
William O. Grover	17 Arlington Street.

Henry Brooks	Forester.
George H. Barrus	Consulting Steam Engineer.
W. E. C. Eustis	Metallurgical Engineer.
Charles Tennant Lee	Chemist and Assayer.
Stephen P. Sharples	Consulting Chemist and State Assayer.
James F. Babcock	Chemist and State Assayer.
Frank A. Terry	Analytic Chemist.
H. Rathjens	Chemist.
Amory Austin	Analytic Chemist.
W. W. Jacques	Electrician.
Thomas W. Gleeson	Electrician.
Emile Berliner	Electrician.
C. Williams, jun.	Telegraph Instruments.
Frank W. Harrington	Telegraph Instruments.
David Dodge	Gold Plate.
William H. Brown	Electric Transfusing Batteries.
Frank Warren Smith	Tester.
Jacob Norton	Furrier.
Gilman W. Brown	Expert.
Charles Stodder	Microscopes and Scientific Apparatus.
Edward B. Pillsbury	Chief Am. Rapid Telegraph Co.
Francis B. Hayes	Attorney-at-Law.
Lemuel Shaw	Attorney-at-Law.
James A. L. Whittier	Attorney-at-Law.
Solomon Lincoln	Attorney-at-Law.
Godfrey Morse	Attorney-at Law.
Joshua H. Millett	Attorney-at-Law.
Francis Bartlett	Attorney-at-Law.
James E. Maynadier	Attorney-at-Law.
Samuel Wells	Attorney-at-Law.
Augustus E. Scott	Attorney-at-Law.
Thomas H. Russell	C. T. & T. H. Russell, Lawyers.
Marcus P. Norton	Judge.
Charles E. Pratt	Attorney Pope Manufacturing Co.
Charles A. Shaw	Solicitor of Patents.
Albert H. Spencer	Expert and Solicitor of Patents.
Robert Henry Eddy	Civil Engineer and Patent Solicitor.
Edward P. Lull	Captain U.S. Navy Yard.
W. O. Crosby	Boston Society of Natural History.
Edward Burgess	Boston Society of Natural History.
Caleb B. Frye	Boston School of Languages.
George Gannett	Boarding and Day School.
E. R. Humphreys	Classical Teacher.
William H. Ladd	Chauncy Hall School.
Robert W. Greenleaf	Student Medical School.
James W. Babcock	Student Medical School.
William C. Jennings	Student Harvard College.
John Amory Jeffries	Student Medical School.
Edward H. Goff	Vice-President American Electric Co.
Charles Whittier	President Whittier Machine Co.
Samuel M. Warren	Warren Chemical and Manuf'g Co.
Edward S. Philbrick	Civil Engineer.
Horatio S. Burdett	Burdett, Young, & Ingalls, Clothing.
B. Schlesinger	Naylor & Co., Iron and Steel.
Ferdinand A. Wyman	Leather Merchant.
George William Bond	Wool Broker.
Waldo O. Ross	Ross, Turner, & Co., Threads, Etc.
Robert W. Wood	Librarian, 19 Boylston Place.
L. Lincoln Thaxter	Book-keeper, 13 Tremont Street.
Isaac J. Osbun	Bernstein Electric Light Co.
W. S. Bryant	61 Beacon Street.
George H. Crosby	97 Oliver Street.
Andrew Robeson	18 Post-Office Square.
Thomas W. Lane	109 Court Street.
Miss Abby W. May	Education Lecturer.
Mrs. Sarah B. Jacobs	24 Bulfinch Street.
Miss Lucretia Crocker	40 Rutland Square.
Mrs. Charles Pickering	28 Beacon Street.
Miss E. D. Boardman	120 Beacon Street.
Miss Catharine I. Ireland	9 Louisburg Square.
Miss G. E. Atkins	37 Commonwealth Avenue.
Mrs. Henry P. Nichols.	
Miss M. L. Bacon	77 Pinckney Street.
Miss Harriet E. Freeman	37 Union Park.
Mrs. Mary Hemenway	40 Mount Vernon Street.
Mrs. R. C. Scudder	Hotel Pelham.
Miss E. S. Owen	315 Beacon Street.
Miss Mary R. Alling	Principal Whittemore School.
Mrs. Warren Hapgood	120 West Chester Park.
Miss Mary F. Littlehale	28 Chestnut Street.
F. C. Woodbury	1 Mount Vernon Street.
Charles W. Raymond	7 Somerset Street.
Charles B. Cory	8 Arlington Street.
J. Ingersoll Bowditch	28 State Street.
James M. Barnard	Hotel Vendome.
Henry W. Haynes	Writer, 239 Beacon Street.
Thomas Lee	44 State Street.
Thomas Gaffield	Retired Merchant.
Joseph S. Fay	88 Mount Vernon Street.
Philip Dexter	24 Mount Vernon Street.
John A. Higginson	260 Clarendon Street.
George Warren Hammond	10 Hotel Hamilton, Clarendon Street.
George H. Norman	343 Beacon Street.
James W. Converse	43 West Newton Street.
E. A. Buffum	35 Oliver Street.
Lewis W. Tappan, jun.	
Arthur A. West	Hotel Brunswick.
John B. Peirce	74 West Newton Street.
Charles A. French	334 Marlborough Street.
Henry P. Curtis	45 Mount Vernon Street.
James M. W. Hall	Lumber Merchant.

Charles T. White	213 Commonwealth Avenue.
Jeffries Wyman	16 Ashburton Place.
H. B. Carrington	32 Bromfield Street.
H. A. Hill	Hill, Clarke, & Co., Machinery.
Percival Lowell	60 State Street.

MASSACHUSETTS INSTITUTE OF TECHNOLOGY.

Francis A. Walker	Pres. of Mass. Inst. of Technology.
George A. Osborne	Professor of Mathematics.
Robert H. Richards	Professor of Mining Engineering.
William Ripley Nichols	Professor of General Chemistry.
Charles H. Wing	Professor of Analytical Chemistry.
William H. Niles	Professor of Geology and Geography.
Channing Whitaker	Professor of Mechanical Engineering.
Charles R. Cross	Professor of Physics.
Gaetano Lanza	Professor of Mechanics.
George L. Vose	Professor of Civil Engineering.
Eugene Letang	Assistant Professor of Architecture.
Silas W. Holman	Assistant Professor of Physics.
Henry K. Burrison	Instructor in School of Mechanic Art.
George F. Swain	Instructor in Civil Engineering.
Webster Wells	Instructor in Mathematics.
Herman Hollerith	Instructor in Mechanical Engineering.
Alfred E. Burton	Instr. in Topographical Engineering.
William H. Pickering	Assistant in Physics.
Walter S. Allen	Assistant in Quantitative Analysis.

BOSTON INSTITUTIONS.

New-England Mutual Life-Insurance Company.
Massachusetts' Institute of Technology.
Boston Public Library.
Boston Athenæum.
Massachusetts State Library.
Educational Society of Boston University.
Globe Chemical Company.
Cochrane Chemical Company.

Cambridge.

HARVARD UNIVERSITY.

Charles William Eliot	President.
Joseph Henry Thayer	Fellow.
Alexander Agassiz	Fellow.
Edward William Hooper	Treasurer.
Stephen Salisbury	Overseer.
James Elliot Cabot	Overseer.
Francis Minot Weld	Overseer.
Solomon Lincoln	Overseer.
Alexander McKenzie	Overseer.
Richard Manning Hodges	Overseer.
James Freeman Clarke	Overseer.
Amos Adams Lawrence	Overseer.
Edwin Pliny Seaver	Overseer.
John Osborne Sargent	Overseer.
Theodore Lyman	Overseer.
Henry Parkitt Kidder	Overseer.
Andrew Preston Peabody	Preacher to the University.
Oliver Wendell Holmes	Professor of Anatomy.
Asa Gray	Professor of Natural History.
Joseph Lovering	Professor of Natural Philosophy.
Hermann August Hagen	Professor of Entomology.
Henry Lawrence Eustis	Dean of the Scientific School.
Josiah Dwight Whitney	Professor of Geology.
Ezra Abbot	Professor of New-Testament Criticism.
Wolcott Gibbs	Professor of Science.
Calvin Ellis	Dean of Medical School.
Sereno Watson	Curator of the Herbarium.
Thomas Henderson Chandler	Dean of the Dental School.
Josiah Parsons Cooke	Director of the Chemical Laboratory.
Adams Sherman Hill	Professor of Rhetoric and Oratory.
James Mills Peirce	Professor of Mathematics.
James Clarke White	Professor of Dermatology.
Justin Winsor	Librarian.
Francis Humphreys Storer	Dean of the Bussey Institution.
George Lincoln Goodale	Director of the Botanic Garden.
Charles Herbert Moore	Instructor in Drawing.
Charles Sprague Sargent	Director of the Arnold Arboretum.
Nathaniel Southgate Shaler	Professor of Paleontology.
Edward Charles Pickering	Director of the Observatory.
John Trowbridge	Professor of Physics.
George Alonzo Bartlett	Assistant Professor of German.
William Gilson Farlow	Professor of Cryptogamic Botany.
Charles Loring Jackson	Professor of Chemistry.
William Morris Davis	Instructor in Geology.
Francis Greenwood Peabody	Professor of Theology.
William Elwood Byerly	Professor of Mathematics.
Walter Faxon	Assistant Professor of Zoölogy.
Charles Rockwell Lanman	Professor of Sanskrit.
Edward Laurens Mark	Instructor in Zoölogy.
William Fiske Whitney	Curator of the Anatomical Museum.
David Gordon Lyon	Professor of Divinity.
Edwin Herbert Hall	Instructor in Physics.
Benjamin Osgood Peirce	Instructor in Mathematics.
Francis Amasa Walker	Lecturer on the Tenure of Land.
Frank William Taussig	Instructor in Political Economy.
Charles Sedgwick Minot	Lecturer on Embryology.
Samuel Gilbert Webber	Instructor in Diseases of the Nervous System.
Clarence John Blake	Instructor in Otology.
Frederick Cheever Shattuck	Instructor in Auscultation.
Joseph Weatherhead Warren	Instructor in Anatomy.
Charles Edward Faxon	Instructor in Botany.
Edward Burgess	Instructor in Entomology.
Henry Parker Quincy	Assistant in Histology.
George Minot Garland	Assistant in Clinical Medicine.
Leonard Parker Kinnicutt	Assistant in Chemistry.
Charles Frederic Mabery	Assistant in Chemistry.
Samuel Jason Mixter	Assistant in Anatomy.
Harold Whiting	Assistant in Physics.
Robert C. Winthrop	Chairman Trustees Peabody Museum.
Henry Wheatland	Secretary Trustees Peabody Museum.
Samuel H. Scudder	Trustee Peabody Museum.
Frederick Ward Putnam	Curator Peabody Museum.
Lucien Carr	Ass't Curator Peabody Museum.
Joel A. Allen	Ornithologist Museum Comp. Zoöl.
Samuel Garman	Herpetologist Museum Comp. Zoöl.
M. Edward Wadsworth	Lithologist Museum Comp. Zoöl.
Jesse W. Fewkes	In charge of Radiates.
William C. Lane	Chief Cataloguer of Library.
Charles Moen Rice	Candidate for A.M.
William Trelease	Candidate for S.D.
Charles B. Penrose	Candidate for Ph.D.
Sumner Bass Pearmain	Student Senior Class.
Morris Loeb	Student Senior Class.
Wm. Wadsworth Wentworth	Student Senior Class.
Robert Berry Ennis	Student Senior Class.
William Henry Aspinwall	Student Senior Class.
Alfred Jerome Weston	Student Senior Class.
Henry Barton Jacobs	Student Senior Class.
Henry Francis Sears	Student Senior Class.
Howard Lilienthal	Student Senior Class.
William Charles Jennings	Student Senior Class.
Oscar Edward Perry	Student Senior Class.
William Orison Underwood	Student Junior Class.
Oscar Jonas Lowman	Student Junior Class.
Gerrit Elias Hambleton Weaver	Student Junior Class.
Silas Baynes Elliot	Student Junior Class.
John Adams Squire	Student Junior Class.
George Fauntleroy Davidson	Student Sophomore Class.
Everett Vergnies Abbot	Student Sophomore Class.
Frank Warren Smith	Student Freshman Class.
William Sanford Barnes	Student Freshman Class.
Edward Kellogg Dunham	Student in Medical School.
John Amory Jeffries	Student in Medical School.
James Woods Babcock	Student in Medical School.
Walter Greenough Chase	Student in Law School.
Frank Herbert Cunningham	Student in Law School.
Jared Slocum How	Student in Law School.
Charles Eliot	Student in Bussey Institution.
Charles Elliott St. John	Student in Divinity School.
Antoine de Reilhe McNair	Resident Graduate.
George Anthony Hill	Resident Graduate.
Albert Henry Tuttle	Student Scientific School.
Robert Tracy Jackson	Student Scientific School.
William Barnes	Student Scientific School.

IN GENERAL.

James A. Fox	Mayor of Cambridge.
James M. W. Hall	Ex-mayor of Cambridge.
Charles H. Saunders	Ex-mayor of Cambridge.
Lyman R. Williston	15 Berkeley Street.
John Holmes	5 Appian Way.
Charles E. Vaughan	Physician.
Walter Wesselhoeft	Physician.
John L. Hildreth	Physician.
Hiram L. Chase	Physician.

CHEAP FOOD FOR THE MILLION.

BY CHARLES S. BRAY, M.D.

[*From "The Century Magazine" for July.*]

I. INIQUITOUS ADULTERATION.

"There has been so much adulteration of food," said a New-York divine recently, "that it is an *amazement to me that there is a healthy man in America.* The great want of to-day is practical religion, — a religion that will correctly label goods, that will prevent a man telling you a watch was made in Geneva when it was made in Massachusetts, that will keep the ground glass and the sand out of the sugar, that will go into the grocery and pull out the plug of ale-adulterated sirup, that will dump in the ash-barrel the cassia-buds that are sold for cinnamon, that will sift out the Prussian-blue from the tea-leaves, that will keep out of flour the plaster of Paris and soapstone, that will separate the one quart of Ridgewood water from the one honest drop of cow's milk, that will throw out the live animalculae from the sugar. Heaven knows what they put in the spices, in the butter, or the drugs; but chemical analysis and the microscope have made wonderful discoveries."

"The Youth's Companion," in a recent article on the adulteration of food, says, —

> "A system of inspection is necessary to protect the public from the adulteration of food which is so common in this country, especially in the poorer quarters of our large cities, where the prices are low and the purchasers not fastidious. . . . Large quantities of unwholesome meat are sold to the poor, such as poultry which has been thrown out of the better class of markets, 'bob' veal, the meat of calves killed too soon after birth, and beef that comes from animals that have been unhealthy before slaughtering. . . . The health of a community can be seriously injured by the tricks of dishonest tradesmen, and people should be careful in buying food that is offered at unusually low prices."

These strictures may, perhaps, strike the average reader as foreshadowing a crusade against the compounders and venders of adulterated food; but this is not our prime object. The combined power of the pulpit and press is almost incalculable, and the batteries of the latter are being levelled against this "common enemy" along the whole line. That men, induced by the hope of gain, should adulterate the staples of life, and thus add crime, and, as often follows, murder, to their account on the "Great Ledger" of eternity, seems almost impossible of conception: and yet it is only too true. This criminal practice is as old as the hills; and its recent condemnation by the clergy and press is only another exemplification of the value of free speech and a free press, — two inestimable boons to Americans.

II. SPOILED FOOD.

It is a fact, lamentable enough in itself, that food has a natural tendency to decay, which men have heretofore unsuccessfully attempted to check. Especially is this true of animal food and its after-products, such as butter, cream, milk, cheese, lard, etc. The problem of pure, fresh, healthful, cheap food, in all climates and seasons, is a field broad enough to command the attention of all philanthropists. To the rich man all things seem possible; but to the laboring classes this problem of fresh and cheap food is, and ever has been, a veritable Gordian knot.

The laboring man looks forward to Sunday for a day of rest and a good dinner. The steak, oysters, chop, chicken, and such delicacies are procured on Saturday, and kept over for this sabbath meal. It goes without saying, that a lack of ice, a warm room, a muggy day, a poorly ventilated cellar, and a myriad of such every-day causes and circumstances, conspire to spoil these viands. Even slightly salted, they lose their fresh flavor; smoked, they are even less desirable; immersed in pickle, or corned, they become impregnated with the deadly saltpetre; placed in a refrigerator, they are practically frozen.

"All such food is injurious to health," says a learned Cincinnati judge; yet, left alone to the influences of climate, weather, and natural surroundings, they speedily spoil. What, then, shall rich or poor do to insure the coveted luxury of fresh, healthful food?

The problem has been a knotty one since the advent of man upon this terrestrial planet. The criminal cupidity of many dealers, on the one hand, and the hosts of natural causes of decay, and man's inability to find a reliable, safe, and cheap food-preservative, on the other, are obstacles which have always heretofore confounded the world.

III. FOOD-PRESERVATION.

One of the largest elements of risk in general farming and in dealing in food-products is the loss on perishable goods, both from decay and deterioration, as well as from the frequent necessity of forcing such goods upon an overstocked market at ruinously low prices. The world has long needed some substance, at once harmless and efficient, to maintain in their production that freshness and sweetness in provisions so essential to remunerative returns. Salted meats are distasteful to many, and repugnant and unhealthful to all, where a regular diet of such material is maintained. Once salted, a piece of beef is immediately lowered in value. Millions of dollars' worth of poultry, lamb, veal, and mutton are annually lost to the world through the lack of practical means of preservation. Milk and cream cannot be kept longer than a day or two, and tons of butter every year become rancid and are sold for grease. The want of a thing always directs scientific inquiry and inventive genius toward its discovery. It has been known for many months past, in commercial and scientific circles, that this important discovery had been made in a food-preservative by Prof. R. F. Humiston of Boston. A series of experiments was conducted to prove beyond a doubt the success of his invention, which resulted most satisfactorily to a number of leading capitalists and scientific men, who determined to bring it before the public in a large commercial way.

Professor Humiston must hereafter go down to posterity as an inventor or discoverer as great as Franklin, Morse, Fulton, or Sir Humphry Davy, and for the sufficient reason that he has, after long and patient years of study and research, with thousands of experiments, discovered and perfected a combination of antiseptics, harmless in their nature, which is a *perfect* substitute for ice, salt, sugar, smoke, heat, alcohol, sulphur, — all the agents, indeed, hitherto employed by man in attempting to save food. By the use of this preservative — which has been happily named "Rex Magnus" (for it is indeed the "great king" of preservatives) — all organic matter can be preserved from decay without the use of any of the agents above enumerated.

The process is cheap, simple, and perfect; and the results are certain, regardless of seasons or climates.

IV. THE NEW PROCESS.

In brief, the new process is based upon truly scientific principles, perfectly adapted to the preservation of a great variety of animal and vegetable products. The basis is a tasteless, innocuous white powder, which is dissolved in water, forming a solution in which the beef, or turkey, or mutton is immersed and treated, or which may be injected into the carotid artery of large animals as soon as the blood ceases flowing. By this simple and inexpensive process, the article thus treated may be hung up in ordinary temperature, remaining sweet and wholesome for an indefinite term. Upon the closest scrutiny and the most practical and exhaustive experiments, certain well-known business gentlemen of Boston and vicinity have associated themselves into a corporation, under the name of The Humiston Food-Preserving Company, choosing Mr. J. Willard Rice of Boston, of the well-known paper firm of Rice, Kendall, & Co., as their president, and Dr. R. C. Flower, secretary and treasurer. This company has established a large manufactory at Salem, Mass., with a daily capacity of five tons of Rex Magnus, and their headquarters at 72 Kilby Street, Mason Building, Boston, where may be seen and examined a most interesting exhibit of fish, fowl, game, beef, mutton, and like perishable articles of food, treated with Rex Magnus, and exposed to the atmosphere of a business office, and to the rays of the sun.

The public will naturally wish to know the means or the action by which this Humiston food-preservative performs its important work. In fact, the question is already asked, "Why is it that this preserves, perfectly sweet and pure, for an indefinite period, meats, fruits, vegetables, milk, butter, etc.?"

It is the office of Rex Magnus to oppose and prevent putrefaction by the utter destruction, or holding at bay, of those parasites that prey upon organic matter. Meats, poultry, game, cream, milk, or oysters, preserved by this method may be carried across the continent, or shipped to Europe, retaining their freshness and purity without the use of ice or any refrigerating appliance, or they may be kept at home for days and weeks, even in the hottest weather, improving in taste, besides saving much expense in the cost of ice, and time and trouble in going to market. There is ample testimony that these are stubborn facts. It is infallible in its power to preserve, of great strength, and concentrated in form, tasteless and unobjectionable to the palate, harmless in its effect upon the human system, and, finally, capable of almost universal and simple application to such food-substances as are subject to speedy decay. The food treated with Rex Magnus carries no unusual or unnatural taste. Its use is so simple that a child may direct the operation of preserving food. The article to be preserved may be wrapped in cloths wet in the solution, and occasionally redampened, or it may be plunged into a tub or jar full of the solution, and allowed to remain for several hours. The powder may be worked into butter at the time of making, or the balls of butter may be placed in vessels filled with the solution, and allowed to remain for weeks and months. Dairymen have preserved butter with all the freshness and aroma of the June product for six months, and Professor Humiston has preserved eggs entirely fresh and sweet for fourteen months at a time.

V. THOROUGHLY INDORSED.

It has been subjected to the most severe and thorough tests, both by scientific, medical, and business men. Professor Samuel W. Johnson of Yale College, after testing it to his entire satisfaction, made a report, in which he says,—

"My tests of thirty-five days, in daily mean temperature of 70°, on meats, etc., bought in open market, have certainly been severe; and I am satisfied that the different brands of Rex Magnus, The Humiston Food-Preservative, with which I have experimented, *have accomplished all claimed for them.* So far as I have yet learned, *they are the only preparations that are effective and at the same time practicable* for domestic use. At the banquet on 'treated' meats at the New-Haven House, *I could not distinguish between those which had been sixteen days in my laboratory and those newly taken from the refrigerator of the hotel.* The oysters were perfectly palatable, and fresh to my taste, and better, as it happened, than those served at the same time, which were recently taken from the shell. The roast beef, steak, chicken, turkey, and quail *were all as good as I have ever eaten.* I should anticipate *no ill results* from its use, and consider it *no more harmful than common salt.*"

Rex Magnus is a valuable discovery, a boon to agriculturists, a legitimate business enterprise. It is not to be classed for a moment with the numerous humbugs of the past,—ozone, and a host of such, the impossible projects of scheming men or the visionary dreams of laboratory scientists. Professor Humiston has devoted many years to studying to assist the millions to get cheap food, and, as the great aid to this end, made intense application and active research in the matter of antiseptics alone. He perfected his process, he proved his theories, he demonstrated the feasibility of his methods, he enlisted his co-operators, he secured the necessary capital, the company was organized, who bought extensive works, and they commenced on a commercial basis before they took measures to inform the publc of this wonderful preservative.

VI. A BUSINESS BASIS.

This company is not seeking capital of the public: they simply propose to manufacture this preservative on a large scale, to offer it for sale eventually in every grocery and provision store in the land in large or small packages. All classes now have an opportunity of purchasing the preservative in small and inexpensive packages, and of testing, each for himself, its value in his own home and business. There is no opportunity or design for any misrepresentation or serious disappointment in a fair, open transaction like this. There are no territorial rights or patent licenses for sale, but every one may have equal and ample chance to use Rex Magnus. The company offer, however, to supply any one—in case his grocer, druggist, or general storekeeper hasn't it on hand—with any brand of Rex Magnus which he may desire, upon receipt of the price. They will prepay postage charges on *sample* packages, which cost but fifty cents per pound for meats, milk, and sea-food, while cream and other special brands cost one dollar per pound.

VII. PREVIOUS FAILURES.

The wretched failures by which the public has heretofore been deceived have pretended to preserve all kinds of food with the same compound,—an idea which is preposterous on the face of it. Meat is different in character and substance from sea-food, and this from milk, cream, and butter, these from eggs, and eggs from vegetable juices or fluid extracts Professor Humiston has treated the subject in a scientific way. Having thoroughly investigated the question of antiseptics, he found the properties and chemical analyses of the different kinds of food, and then, after thousands of experiments, having fully learned what antiseptics and what proportions were best adapted for each, he compounded his preparations intelligently, each to the purpose for which it is especially designed. Herein lies his success, and it is herein that all others have failed.

VIII. HIGH TESTIMONY.

The famous Miss Juliet Corson, in a recent article in "Harper's Bazar," on "Diet for Invalids," and treating especially of game and poultry, says, —

"While the general rule holds good, that fresh food is the most wholesome, and that actual decay in animal flesh used for food is apt to produce symptoms of irritant poisoning, game is often eaten in an advanced stage of decomposition without any perceptible injury to the epicure. Microscopic examination of meat which has been exposed to a medium summer temperature from 85° to 90° Fahrenheit, for three or four days, proves the development, at that stage, of a minute organism, termed by physiologists the death vibrio. This parasite seems to be present in other meats than pork, and, like trichinæ, is not destroyed by the process of salting and smoking meat, or of curing it in brine. There is no reason to suppose that the flesh of game is exempt from the presence of this natural product of decomposition. When meats containing it are imperfectly cooked, their consumption produces gastric disturbance, sometimes fatal in its result. As game is generally broiled or roasted, the action of intense heat may destroy the septic influence of the organism.

. . . .

"I have considered this rather unpleasant subject at length with the hope that when game is ordered for an invalid the caterer may be induced to supply it as fresh as possible. As a rule, the flesh of game is less dense and tough than that of domestic animals, so that there is not the same reason for keeping it, in order to let it become tender by the first action of decomposition. Game is also more digestible than butcher's meat, and for that reason may be eaten fresher. Its comparative freedom from fat makes it relatively more nutritious, while its intense flavor is tempting to the appetite. As the taste of the flesh and blood of game is nearly identical, the latter is generally carefully preserved in cooking."

It is in such cases as referred to by Miss Corson that Rex Magnus plays a most important part. It is of the utmost moment that the food of invalids, as well as of people in good health, should be tempting in quality and appearance, appetizing in flavor, and tender and easy of mastication; but at the same time, and above all, it must be perfectly sweet and fresh. Special care must also be taken that the living creature from which it is derived was in a perfect state of health, as otherwise germs of disease may be taken into the weak and enfeebled system, which perhaps would have no detrimental effect upon a state of health. Rex Magnus will, as we have already shown, enable invalids and others to keep meats, wild game, and other like delicacies, in a condition perfectly sweet and fresh for any reasonable time: sweet-breads have been kept four months, and cream nearly as long, and both sweet, and known as difficult to keep. Game can be treated with it when first killed, and then shipped to market; or, by taking care to purchase only that which is sound and good, it can be treated at home, and then kept until wanted, improving in quality, and growing more tender, digestible, and wholesome. It goes farther, and is of even greater value to the million as a preventive of disease and an aid to health. It not only arrests and prevents decay, and thereby obviates the danger of eating partially decomposed food, but it counteracts and destroys any hidden germs of disease, and renders all articles treated by it wholesome and harmless. In this respect it is a great boon to mankind.

Professor Humiston is a little over fifty years of age, is a native of that grand old town, Great Barrington, Mass. He received his M.A. at the Western Reserve College. He has the honor of being a Fellow of the Chemical Society of London, and also of the Geological Society, being elected after unusually severe examinations. President Huxley, of the latter society, said that "no American should boast of an election without a hard struggle." In evidence of this prejudice toward Americans, the fact that Professor Humiston was given two hundred and fifty questions — five times the usual number — may be cited. He is now superintendent of the company's works, which will insure the most careful product for this "mighty king" of food-preservatives. This company is meeting with great success, and deservedly.

THE ART OF BOOK-BINDING.

BY HENRI PÈNE DUBOIS.[1]

A VERY curious essay might be written on the history of book-binding, the fascinating department of the bibliomania which immortalized Grollier.

At the beginning, it was the art of goldsmiths and enamellers: and books were adorned with a silver cover, gilt, and precious stones. In Chaucer's time the fashionable binding was various-colored velvet, as in the Prologue to the "Canterbury Tales:" —

> "A twenty bokes, clothed in black or red,
> Of Aristotle."

And it was not until the close of the fifteenth century that the usual ornaments of silver, and massive clasps, and thick metalled corners, were discarded.

They were destined to render a book impervious to external injury; but in the wooden covers the worm was secretly engendered, and its ravages attest the defectiveness of ancient binding. Mr. Roscoe wrote eloquently in commendation of it, however, in his "Lorenzo de Medici:" "A taste for the exterior decoration of books has lately arisen in this country, in the gratification of which no small share of ingenuity has been displayed; but, if we are to judge of the present predilection for learning by the degree of expense thus incurred, we must consider it as greatly inferior to that of the Romans during the time of the first emperors, or of the Italians at the fifteenth century. And yet it is difficult to discover why a favorite book should not be as proper an object of elegant ornament as the head of a cane, the hilt of a sword, or the latchet of a shoe."

The prejudice in favor of ancient binding was displayed as recently as in the report of the international book-binding exhibition of 1857, wherein the judges, Merlin, Capé, and Bauzonnet, expressed the opinion advanced by Roscoe. They went farther than this in their extollation of the masters of the three preceding centuries, especially of those whom, as Dibdin would say, St. Jerome or St. Austin would have lashed for the gorgeous decorations of their volumes. But there was a feature in that exhibition of special interest to American bibliophiles.

Holland (once famous for its bindings of vellum), Germany (whose gilders had been constantly employed by the binders of France), Spain, and Italy exhibited nothing but copies of the declining French art.

The rivalry existed between France and England. France excelled in taste and finish, but at some sacrifice of flexibility; while in England the soft and coaxing manner in which, by the skill of Herring or Mackinlay, "leaf succeeds to leaf," was spoiled by the tarnishing of the once blazing gilt edges.

It became evident to an impartial observer that the decline of the art of book-binding was due to the apathy of the book-collectors.

It owed its existence to them, and to them only; and they, too, were responsible for its decadence. Therefore I presumed little in my estimation of the value of that exhibition to American bibliophiles: it inspired Bradstreets of New York with the thought that the art of book-binding was not to be restricted to one nation, or to one family, as tradition would have it in France, but that it would flourish

[1] This monograph on the art of book-binding is practically a partial reprint of a neat, small pamphlet issued by The Bradstreet Company. A copy of the pamphlet can be had free by addressing The Bradstreet Company at its main offices, No. 279 Broadway, New York, or any of its branch offices throughout the world.

wherever it would find a Mæcenas. Although the art of book-binding is not deteriorating in England or in France at present, — especially is this seen in the fact that in the interval of the past twenty-five years the book-collectors there have rallied to its support, — nevertheless, the American bibliophiles are so increasing in number and in strength, that a good portion of the most valuable books of the European auction-marts are finding their way to this country, many of which have been intrusted to Bradstreets to do the very class of work that bibliophiles were wont, in spite of the most vexatious delays, to send to English and French binders; and now, I should say, deservedly too, because there is a solidity, strength, and squareness of workmanship about the books of the Bradstreets' bindery, which baffle the closest scrutiny. Their gilding, too, is perfect, both in choice of ornament and in splendor of gold. There is no reason for their being of less potent renown than any of their predecessors.

The bibliophiles will appreciate this *de visu*.

The uninitiated should be aware of the qualities that constitute a good binding. It ought to unite solidity with elegance: the volume should open easily, and remain open at any page, the back flexible, and the leaves evenly cut. The gilding and other ornaments should be left to the artist; but the book-collector should supervise the inscription of the title as a precaution against the unfortunate experience of an ardent book-lover whose uncut scarce edition of the works of Brantôme, confided to an artistic but dreadfully provincial bookbinder, was returned to him with the leaves scrupulously cut, and the volumes inscribed as follows: —

Bran *Tome I.*
Bran *Tome II.*
Bran *Tome III.*

and so on to the ninth volume. And Dibdin relates, among anecdotes of barbarous titles applied to precious works, the discovery by a well educated bibliomaniac of the first and almost unknown edition of the "Decameron" of Boccaccio, in a volume entitled "Concilium Tridenti."

Those are primary considerations; but there are others which relate to the expression of the binding of a book. It should be sad or gay, sombre or brilliant, in accord with the tone of the work, its spirit, and its epoch. Didot even insisted upon a refinement in the matter of color, advising chromo-bibliotacts, as they are aptly styled by Uzanne, to clothe their works on theology in purple, astronomy in azure, and travels in marine blue, — presumably in accordance with the good and very appropriate metaphor of the inscription on a king of Egypt's bookcase, "Treasure of the Remedies of the Soul;" books being, like drugs, to be taken with discretion and in various doses, and their outward appearance to denote the nature of the remedy they contain in order that the poison be not mistaken for the antidote.

Thouvenin, as every bibliophile knows, was puffed by Nodier; but he failed to appreciate in his workmanship that evidence of the eternal fitness of things, wherefore his glory is gradually waning. A good point might be made of this in favor of American artists; for no man can put a varied-colored morocco coat upon the back of a book with greater care, taste, and success, than Bradstreets, who are, in fact, the American bibliopegists.

And I do not hesitate to commend their work to that eclectism of the veritable connoisseur, which is not to be affected by *camaraderie*, nor swayed by the dictates of the votaries of fashion.
