Vol. I.—No. 1.] SATURDAY, MARCH 23, 1889. [Price One Penny.

A CABINET IN FRET-CUTTING.

An Art-Work for Skilful Workers.

BY J. W. GLEESON-WHITE.

There are, it is sad to remember, some amateurs in fret-cutting whose method (or lack of it) is to trace their pattern within one-sixteenth of an inch of its outline or thereabouts, and then paste the design upon a rough piece of wood from a cigar-box, cut it vaguely within another one-sixteenth of an inch of the tracing (this only gives an eighth of an inch away from the line, really a very fair result, as they take it sometimes in excess, sometimes less, so it comes all right in the end), then, having pulled off the tracing with the help of a moist finger and a blunt pocket-knife, proceed to make it up, with one white tin tack, one blue one, and a good big crack across the fretwork itself, and stand enraptured at the result—a bracket, say, that only cost one shilling for pattern, saws, and wood, and is worth less than the least valuable thing in the universe.

To such as these I speak not, nor even to the patient schoolboy who spends untold energy and turns out most creditable fretwork, yet contents himself with such rudimentary joinery that, however excellent the actual sawing of his design when his work is done, it is merely "fretwork." This design must be finished by a good joiner, whether by the amateur himself or passed over to a professional matters not, so long as it is well done, for this cabinet is distinctly *not* worth doing badly—few things are for the matter of that; and unless the would-be maker is willing to devote skill and care beyond the usual run, he had better select another of the many patterns available, and, saying, "That thing! why, it is not worth cutting; look at all the small holes the idiot has put in it!" or some such graceful word, bid it depart from his sight, for he will have none of it.

Yet, though the work involved is not to be rapidly done, the gossip about it may be short. It is intended that the fretwork be worked in duplicate in very thin ebony, or in wood stained black after cutting, and mounted afterwards on holly or other white wood; both being polished before being glued together, of course. The fretwork may be cut two pieces at a time; this reduces the sawing by half, and yields facsimile replicas of the pattern. The rest of the framework to be of ebonised wood polished, with appropriate mouldings of fine, neat design. If the four smaller panels can be worked to drawer fronts it will be much better; but, in lieu of that, cupboards will suffice.

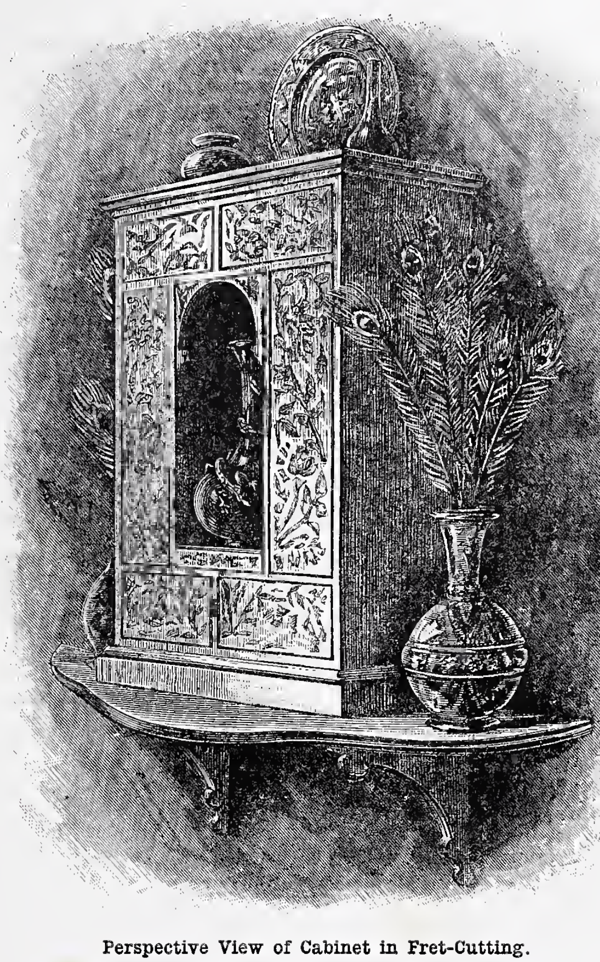
For inlay—and by that I mean the usual plan of replacing the cut pieces of wood in the holes from which they came—an alternative half of the design is shown much modified in its details. For since in this case the necessary perforations drilled in each cut-out piece to admit the saw can hardly be arranged so deftly—always at the point of an angle—that when each piece is replaced they are no blemish to the work, it will be better to reverse this arrangement of the wood. That is, to work as usual the whole design in white wood, staining the cut-out pieces with Stephens' ebony stain. These should be carefully replaced, and the holes stopped with a mixture of sawdust and glue before polishing, the whole surface being glued to a thin backing of hard wood. If the one who suggests it may say so, I do not think this plan would be so effective, although more genuine in some respects.

As a practical hint, I would suggest lining the wood with newspaper and replacing the pieces from the back, when the puzzle—for such it is—will be greatly simplified by the clue afforded in the printed matter. For the first method, knowing how easily white wood darkens with age, whether polished or plain, it may be that a coat of fine white enamel paint would be better for the under part. It is possible that if the cut and polished wood were laid over the varnish paint when wet, and left under a heavy pressure, that the junction would be as firm as glue. It would certainly avoid the danger of the glue oozing beyond its place and staining the visible parts of the design.

The framework of the cabinet being pure joinery, I need not speak of it here; more skilful cooks attend to the joints in our *menu*; my business is to provide the *entrées* and sweets only, and, as too many of the former is a proverbial danger, it is safest to leave the others to explain the serious part of the programme, as they are so well able to do.

It may be best to repeat the advice of absolutely perfect finish, so far as in this imperfect life such a thing is obtainable. For very many ornamental objects, whether carved or painted, a certain roughness and irregularity of handling gives a real artistic value, lost in merely "niggling" precision and absolute accuracy of detail. But for a cabinet on so small a scale, and in the style of symmetrical design chosen, an almost mechanical rigidity of correctness and unstinted labour to attain the very best result practicable must be exacted; then the amateur may put his work beside that of the skilled artisan with no fear of the contrast, since, in an art so mechanical as fretwork, the individual temperament of the artist that tells so largely in wood carving is practically unfelt.

In the illustration given in this page is shown a perspective view of the cabinet when completed and placed on a moulded shelf specially prepared for its reception.



Perspective View of Cabinet in Fret-Cutting.

(For Full-Size Working Drawing of Front, see Pattern Sheet presented with this Number.)

WORK.

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

TO OUR READERS.

"Read you, and let us to our WORK."
2 King Henry VI., i. 4.

ALTHOUGH no apology may be needed for the appearance of WORK, an explanation of its Why and its Wherefore—its *raison d'être*, as our friends across the Channel would put it—is certainly desirable, and a little space in this, its first Number, may be usefully taken up in showing the causes that have led up to its introduction; the persons to whom it chiefly appeals; the objects at which it aims; the special features by which it will be marked; and the field of operation that it seeks to cover.

First, then, let it be shown *why* and *wherefore* WORK has been called, and has come, into existence. What, let us inquire, is the great demand of the time; for what are most men chiefly asking and seeking in the present day? To this question the right reply is by no means difficult to find. It is, and must be—"Better and fuller means of Technical and Practical Education."

Never, indeed, it may be said, was the demand for technical education greater than it is at the present time! Never was it heard more loudly than it is now among workmen of British nationality! And why? Simply and solely because of late years it has become painfully apparent that by means of increased facilities for obtaining technical knowledge the foreign workmen have been stealing a march upon them. Never, forsooth, at any time has the necessity for sound technical education for the workman been so thoroughly impressed upon the minds of men as now; and never has it been so eagerly desired and demanded by all grades and classes of the people. At the present moment there lies in the pigeon-holes of the British Government a Bill for the Promotion, Extension, and Elaboration of Technical Education in the United Kingdom, which will be discussed and moulded into law at the earliest opportunity. Our Universities and great Public Schools are awakening to the necessity of teaching the hands to work as well as the brain to think. In every large town, and in London itself—the head as well as heart of the Empire—a craving is springing up for the establishment of technical institutes and workshops, in which any and every man, whatever may be his social station in life, may obtain improved knowledge of the leading handicrafts that are practised by men, or even to learn their very rudiments, if he so require. In these amateur workmen are already assembling, that they may better know through practice under trained teachers how to carry out the work they may have adopted as a hobby; and professional workmen that they may become better conversant with the theory that underlies the work they do; and by this, and a quickening of their taste and perception of the beautiful in form and perfection in execution, gain greatly in skill, and capacity for carrying out the work by which they have to live. And all grades of workmen are alike led to seek self-improvement, because they have realised the truth of the grand old saying —*Knowledge is Power*.

To meet, then, at a most critical period of our national existence, the needs of workmen belonging to each and both of the two great classes into which workmen are naturally divided—professionals on the one hand, and amateurs on the other—WORK has been brought into being. That WORK will prove the most useful and most complete serial of its class that has yet been given to the world, there is every reason to believe; and, without doubt, it will be eagerly sought after, read, and followed by those for whose benefit it has been produced, as the first, the best, the most helpful, and the most reliable practical instructor of the times in which we live. Nay, more than this, it may be regarded as being verily unique in itself through the comprehensiveness of its scope, for, although efforts may have been made, prior to this, to help and instruct the amateur, never yet has any attempt been made to regard all workmen, whether workers for gain and daily bread or workers for amusement and recreation, as one great family possessed of common aims and actuated by common interests, who enter the lists of competition in friendly rivalry alone, to provoke one another to the execution of work of greater excellence than either the one or the other has as yet produced. Each class has much to learn of the other; each class can teach the other much. Time it is to be up and doing, and, with regard to those who write in the pages of WORK, it is to lead and help their fellow-men to better things that they are banded together. They, verily, are first afield to guide where guidance may be needed, and to give assistance and lend a helping hand wherever aid may be sought. And this they will ever do in the spirit of Solomon's mingled counsel and command—"*Whatsoever thy hand findeth to do, do it with thy might.*"

Mention has been made, well nigh in the same breath, of the amateur and the professional workman; but are they not more closely akin than superficial thinkers are disposed to allow? Are not all men amateurs alike? Are not all professionals? Verily, yes; each and every man in his own order. What, indeed, is the difference between workmen, amateur and professional, save that the latter practises his craft or calling for gain, and the former loves and cultivates an art for his amusement. The distinction is very much like that which has been drawn from time immemorial between those who live to eat and those who eat to live; and the comparison runs far more closely in parallel lines than may appear at first sight, for if the professional works to live, does not the amateur in an equal degree live to work? Even a professional workman is an amateur in everything else except the one particular handicraft by which he lives; so that, speaking fractionally, every man, if he be one-fourth professional, is very likely three-fourths amateur, and so may be regarded as being in point of fact more of an amateur after all than he is of the professional. Said a working man to the writer one day, "I look upon myself as an amateur in every man's trade except my own, and as I like to know something about all trades besides my own, I hail with pleasure every source from which I can derive some knowledge of them." Every man, indeed, has, or ought to have, his hobby whether he be professional or not, and therefore, in seeking to administer to the improvement of one class and to build up and augment the knowledge of its members, precisely the same thing is done in the interests of the other.

This has been said to show that the pages of WORK are intended for both groups of workmen alike, and to point out, on the good old principle that what is sauce for the goose is sauce for the gander, that that which is desirable and useful for one group to know is equally useful and desirable for the other. If there be any difference at all, it will be found to consist chiefly in this—that the professional workman requires and desires to gain in comprehension of theory, and the amateur, conversely, in practice, and thus each will be brought on *pari passu* to the same goal—perfection in execution.

We must now pass on to consider briefly the objects of WORK, and the subjects that are to receive treatment in its pages. On this it is only necessary to say that in the papers which will appear from week to week will be found a clear and practical exposition of the *modus operandi* to be followed in every art, craft, or science that bears, either directly or indirectly, on handiwork of a constructive or decorative character, the directions being supplied and comments made, either in short single papers, or in series of articles tersely and comprehensively written. If the reader presses for a more accurate definition of the nature of the articles that will be treated in WORK, let him attempt to sum up in his mind for a moment the handicraft trades that are most familiar to himself, and endeavour to realise that instruction will be given on, or notice taken of, every one of them sooner or later. To catalogue them would be simply to make a list of every kind of constructive and decorative work that is practised by man. Let us take this as done, and so avoid the waste of time, space, and power that would be involved in its preparation. Number 1 and Part 1 will sufficiently serve as samples of the whole. It is impossible, manifestly, to touch on everything at once, but everything, nevertheless, will be touched on in time.

In general character, WORK will be purely technical and instructive. Nothing that comes within the region of polemics will be touched on in its pages, and discussion will be permitted on such subjects only as are possessed of common interest for all readers.

With reference to the special features by which WORK will be marked, it may be said that every paper that requires it will be fully illustrated with sketches, diagrams, or working drawings to scale, as may be necessary, of the articles and processes described. This alone will tend to render WORK invaluable both to the workman himself and those at whose bidding and for whose benefit he may work.

New machinery, new tools, new appliances, new arts, new processes, new modes of treatment will always find exposition in its pages, and a special feature will be made of

OUR GUIDE TO GOOD THINGS,

in which notice will be taken of tools, machinery, technical works, etc., and all things useful and novel that manufacturers and inventors may produce in the interest of those who labour with the hands. Manufacturers and others are requested to send the Editor timely notice of any new tool, machine, or appliance that they are about to introduce as a new claimant for public favour.

It is open to question if there exists a single workman, professional or amateur, who has not, at some time or other, desired to seek information on points connected with his trade or hobby. For the satisfaction of these in subsequent numbers—when time and opportunity have been given to readers to mention subjects on which they need advice—a portion of each weekly issue will be set apart for replies to queries under the title of

SHOP: A CORNER FOR THOSE WHO WANT TO TALK IT.

Questions, however, must be strictly confined to matters connected with trades and handicrafts. Replies will be given in every case by practical men who know what they are about, and who thoroughly understand the subject on which they undertake to write. It will not be possible, however—and readers must ever bear this in mind—to give answers immediately to questions asked. It is commonly thought that a question asked one week can be easily answered in the next week's issue. This is impracticable, as those who give the replies reside in every part of the United Kingdom, far and near, and with magazines of a large circulation, it is necessary *to go to press*, as it is termed, or, in other words, to finish them, some days in advance of the date of publication.

Readers and contributors who are possessed of reliable recipes that they themselves have tried and tested are requested to forward them to the Editor for insertion in

MEANS, MODES, AND METHODS,

a department which, in time, will constitute a most valuable collection of formulas and processes. Senders of recipes will be held responsible for their accuracy and utility, and must give names and addresses—but not necessarily for publication. In all cases when recipes are copied from contemporary publications, their source should be indicated. Recipes copied from old books will be declined, as it would be easy to fill whole pages of the magazine from such sources without any possible benefit to the readers.

At intervals, large sheets will be issued, containing full-size Working Drawings to Scale, of Art Furniture, Decorative Work, Machinery, etc., that may be made and mounted in the workshop at home, and other subjects of general and special interest. The Cabinet in Fretwork, presented with Number 1 and Part 1, will serve as an example of these sheets.

The articles and papers that appear in WORK will be supplied by capable writers of experience and marked ability, who will spare no pains to render the Magazine, not only unrivalled, but beyond all rivalry as

THE LEADING TECHNICAL INSTRUCTOR OF THE AGE.

It only remains now to indicate the field of operation that it seeks to cover. It appeals to the interests of all workmen, professional and amateur, who are to be found in the United Kingdom, the Colonies, and Dependencies of the British Crown, the United States of America, and, in short, throughout the world wherever workmen who speak and read the English language are to be found. It is a wide area, it is true, but WORK will be known all over it and throughout it before 1889 is numbered among the years that are past and gone.

THE EDITOR.

THE BUNSEN BATTERY.

How to Make, Work, and Maintain It.

BY GEORGE EDWINSON BONNEY.

I.—INTRODUCTION—CHIEF CHARACTERISTIC OF BATTERY—CLASSIFICATION—INNER OR POROUS CELL—POROUS POTS—POSITIVE ELEMENT OF BATTERY—ANOTHER ARRANGEMENT—DAMPER—AMALGAMATION OF CYLINDERS—CARBON ROD—BINDING SCREWS AND CLAMPS—WIRES.

IF I were writing for any other paper except WORK, I should feel myself bound to apologise to its readers for introducing a subject on which so much has been written in other and older magazines. The youth of WORK, however, in relation to its contemporaries, together with the fact that it will appeal largely to young workmen—more largely, I expect, than any existing publication, whether in the Old World or in the New—has led me to select a Bunsen battery for treatment in this my first article. Some of us older workmen are apt to think that because we know all that can be said or written on any given subject, everybody else must have an equally good acquaintance with it. We are apt to forget the troubles of our younger days, when we picked up our stock of knowledge bit by bit and crumb by crumb from every source within our reach. So, when we take up our weekly newspaper, we hastily scan the titles of the articles, and as quickly run our eyes down the columns in search of a novelty. If we find something new, something that adds to our stock of knowledge, we read the article carefully; but if we fail to meet with some new thing, we turn aside contemptuously and condemn it as a thing of little worth. Perhaps this estimation is a good one as regards its value to ourselves, but a little consideration will lead us to the conclusion that we are but units among many thousands, and of these there may be many only too glad to have what we despise.

We stand as lights to the younger workmen around us. The future of this nation depends upon those young men. If they learn to despise knowledge now, they will live to find themselves common labourers to the skilled workmen of other nations. Much good or harm may be wrought in the mind of a young man by the example of older men, and therefore it behoves us to be careful in our manner towards the inquiries of our young men. The best of them will not stand still because we happen to be tired with the day's work. The time has passed, and is gone never to return again, when lads were silenced by a peremptory order such as "You do as I tell you, and ask no questions." Youths *will* ask questions, and will *expect* answers, and if we do not answer them truly they rightly lose confidence in us and seek their answer elsewhere.

Therefore I take the risk of being told by my older brethren that I am writing on a stale subject, because I know that what I have to say will be acceptable to others, and I shall always be pleased to answer their questions.

The Bunsen battery receives its name from Professor Bunsen, its inventor. As generally used in England, it may be regarded as a cheaper and modified form of a battery previously invented by Mr. Grove, and now known as the Grove battery. In the Bunsen battery a plate of carbon, or a block of this substance, replaces a thin plate of platinum used in the Grove battery. This is the only difference between them. The result of this difference in cost is that between the prices of carbon and platinum, amounting generally from 4s. to 5s. per cell in favour of carbon. The result in power obtained may be put down as ·08 volt. in favour of the platinum.

The Bunsen is classed as a double fluid cell because two fluids are used to excite its action. Each cell of a battery is composed of an outer or containing cell or pot, and an inner or porous pot or diaphragm. One such composite cell may be named a battery, whilst this may be composed of any number of cells connected together. The outer containing cell in general use is a cylindrical jar of stoneware, 6½ inches by 3¾ inches, or 6 inches by 4 inches, holding (when the porous cell is left out) about one quart of liquid. This is named a quart Bunsen, and costs 9d. each cell; smaller cells holding a pint of liquid are used sometimes, and larger cells, holding respectively half a gallon and a gallon of liquid, are used for large operations such as in electroplating. When the battery is required to fit in a box or similar rectangular-shaped space, the cells are made either square or rectangular to suit. Cells are also made in glass and in porcelain, in all sizes and shapes demanded.

The inner or porous cell is made of porous earthenware, and is intended to act as a partition between the two liquids employed in charging the cell, to keep them from mixing freely together. The pores allow the two liquids to just touch each other through the pores, and thus form a conducting path for the electricity generated in the cell. These porous cells are made in a cylindrical form for round pots, or in flat, rectangular forms for the square or rectangular pots. They are made in sizes to suit the outer containing pots, the size of which should always be given when ordering porous pots. As a general rule, the rim of the porous pot should stand from ½ an inch to ¾ of an inch above the rim of the containing pot, and there should be ¾ of an inch space around the porous pot between its sides and the inner sides of the containing pot. Too much space between the two cells tends to increase the internal resistance of the battery.

Porous pots are made in two kinds of ware—one red, the other white. The red ware is sometimes glazed around the rim to keep the salts formed in one cell from creeping into the other; but this does not present any advantage, for the salts creep up under the glaze and eventually peel it off, leaving an unsightly ragged rim. The white ware is most compact and more uniform in texture, so to speak, than the red ware. Cells differ a great deal in their degrees of porosity, and should be chosen as nearly alike as possible. The appearance of hardness serves as one guide to a choice, and this may be verified by filling all the chosen cells with clean water and setting them aside on a dry bench or table. Very porous cells will allow the water to come freely through their pores, and their porosity may be determined by the quantity of water coming through the pores in a given time. If cells are too porous they allow the nitric acid to pass into the other cell, and so spoil the solution contained therein; while, on the other hand, if they are not sufficiently porous, or too hard, they increase the internal resistance of the battery, and thus reduce the force available for work.

The positive element of this battery is made of zinc. This is the wearing part of the battery; it is the fuel intended to be consumed to furnish electric force. As in the furnace of a steam boiler we oxidise or burn coal to supply steam force, so in a battery we oxidise zinc to generate electric force. The zinc element of a Bunsen battery is generally made of $\frac{1}{8}$ inch best rolled Belgium zinc plate, bent in the form of a cylinder when intended for use in a round cell, or in the form of flat plates when used in square or rectangular cells. When very thin porous cells of the flat form are employed, the zinc plates are sometimes bent in the form of the letter **U**, and thus made to surround the cell, going down one side, under the bottom, and up the other side. By this arrangement a powerful cell can be got into a small space.

Another arrangement possessing similar advantages consists in coupling two zinc plates together at their tops, and immersing their lower edges in a layer of mercury at the bottom of the outer cell. The zinc cylinder used in the round cells should be just small enough to slip easily into the cells without leaving any appreciable space between their sides and the sides of the cells, as only the inner surface is acted upon with advantage. The upper rim of the cylinders should come just $\frac{1}{2}$ an inch above the rims of the cells, for convenience in attaching the binding screws to which the connecting wires are fastened.

If we immerse clean zinc in dilute sulphuric acid (the solution employed in charging the outer cells of this battery), it will rapidly oxidise and be converted by the free acid into zinc sulphate, whilst a quantity of hydrogen gas is sent from the solution into the air. Under such conditions as these, a large part of the energy so generated would be wasted in heating the solution and ejecting hydrogen from it, and only a small part be available in the form of electricity. We have, therefore, to check this rapid combustion and put a damper on, to ensure a more slow and useful oxidation of the zinc. The damper employed is mercury, known under the common name of quicksilver. Mercury possesses the property of being able to take to itself a portion of some other metals with which it is brought into contact, and form an alloy which is named an amalgam of mercury. It readily attaches itself to clean zinc, and forms with it an amalgam of zinc and mercury. This amalgam is not so readily attacked by dilute sulphuric acid as is pure zinc, and it possesses the merit of being only dissoluble in the acid when the circuit of the battery is closed, or, in other words, when it is set to work. We therefore cause the cylinders, or the plates of zinc (to be used in this battery), to receive a coat of mercury, when they become amalgamated with it, and protected from the attacks of the acid.

Some makers send out their zinc cylinders amalgamated ready for use. If they are not thus prepared, they must be amalgamated before they are used. Our first care is to clean the zinc. If this is greasy, the cylinders should be soaked in hot alkali—soda or potash water—and then rinsed in hot water. Meanwhile get a shallow dish, such as an earthenware baking dish; pour into it enough water to cover the lower side of a cylinder when placed in it sideways; then add one-third of this quantity of commercial sulphuric acid (oil of vitriol) slowly and carefully. When this is done, pour into the dish enough mercury to cover the bottom of it, or to be easily scooped into the interior of one of the zinc cylinders. The acid solution will be scalding hot, and into this place the cylinders one at a time, rolling each cylinder over and over in the mercury, passing this through the interior and well brushing the mercury over every part, inside and out, with an old plate brush, a mop of hemp, or a hare's foot, until every part has been covered. If some fine copper wires can be placed among the hemp, or in the brush, they will facilitate the spread of the mercury. As each cylinder is amalgamated, set it to drain in a stoneware pot to catch any mercury that may come off. If parts of the cylinders are left uncovered with mercury, the acid will attack the bare parts and pit the zinc.

The negative element of the Bunsen battery is a bar or rod of carbon, of square section, or a plate of carbon to suit the porous pot in which it is to be placed. The carbon bars used in this battery are made from fine coal and coke compressed in a mould with some binding medium, such as gas tar, and heated to give it the needed hardness. A substitute may be improvised out of the scurf from the roof of a gas retort, obtainable from gasworks. This is procurable in rough misshapen lumps, which have to be sawn to the required shape before they can be used in the battery. This is done by means of an old saw, or a piece of sheet iron notched like a saw, using plenty of water as a lubricant. It is a hard and dirty job, and not worth the candle, when we consider the low price of carbon blocks (one penny per square inch), obtainable from all vendors of electrical articles. Common gas coke, or even best oven coke, is not hard or compact enough in itself to form a substitute. Well moulded and baked carbon blocks are indestructible by nitric acid, and will last an indefinite time.

Connection is made between the carbon block of one complete cell and the zinc cylinder of another by means of copper wires, or strips of sheet copper, attached temporarily to the elements by brass binding screws and clamps. The wire is secured to the zinc cylinder by means of a binding screw. The cheapest forms of these are usually very defective, and after a little use they either spring apart and crack at the shoulders, or the very fine threads of the screws wear out, and so fail to hold. When buying these, see to it that the screws are properly cut with deep threads, the females with long bearings, and the shoulders strong. The wires are secured to the carbons by a kind of binding screw named a clamp. There are some two or three patterns of these clamps in use. One has a slot only to receive a strip of copper as a connector. This is inconvenient for wire connectors. The other patterns have holes pierced in a lug, either at one side or on top and in the centre of the clamp. The last form is preferable in actual use. In buying clamps, see to it that the jaws are wide enough to clasp the ends of the carbon blocks, that the screws are long enough, and the threads well cut. The heads of the screws should be flat, not milled, as the milling cuts one's fingers when connecting or disconnecting the screws. It is also best to have all the screws and clamps lacquered before they are used, as the lacquer protects the brass from the attacks of acid fumes. If binding screws and clamps are not lacquered they should be made as hot as can be borne to the hand, then dipped in hot melted paraffin; allow all the surplus paraffin to drain off whilst still hot, then clean all points of contact with emery cloth. The holes are best cleaned with a pointed stick dipped in flour emery.

The wires for connections should be slightly larger than the line wires employed; that is to say, if we employ a line of No. 16 B.W.G. copper wire from the battery to the work, we should have connecting wires of No. 14 B.W.G. copper well annealed.

A CHAT ABOUT FURNITURE.

Text—Two Fancy Tables.

BY D. ADAMSON.

The Old Loo Table—Chippendale's Designs—Quasi Art Critics—Requirements in Designing Furniture—Curved Outlines in Furniture—Change of Tops: its Utility—Suitable Sizes for Small Tables—Materials—Tops—Legs—Framing—Blocks—Fixing—Alternative Form of Table.

The old-fashioned centre or loo table is seldom seen in use nowadays. The style in furniture, not only as regards the articles themselves, but in decorative details, has rapidly changed during the past twenty years—is, indeed, now changing. The place of the massive-looking loo table, with its frequent over-elaboration of carving, its ponderous claws, in all its glory of burr walnut top, a glory of marking which, as a little bit of decoration planned and executed by the Great Architect of the universe, could not be utterly ignored even amid the uncouth and inartistic work of the middle of this century, is now occupied by the small, light occasional table—or say, rather, several of them. Old-fashioned things, are they? The old style coming up again? Indeed! Yes, I have heard all that before often and often, but reiteration of a mistaken notion does not prove the truth of an assertion.

It is a popular mistake to suppose that our modern furniture designers do nothing but copy old models, and that the beautiful productions of the artistic cabinet maker are nothing more than facsimiles of—Chippendale, you suggest. Well, well, let the poor old man rest. You may safely do so without scruple, for not from him, nor yet from his contemporaries, does the modern designer draw inspiration. Occasionally a piece of Chippendale may be reproduced, but not often, and then it is generally one of his quieter and simpler designs.

In all its horrible eccentricity of nondescript Gothic, worse Chinese, and inane rococo, combined though they be with the most exquisite workmanship and occasionally a quaint gracefulness, Chippendale's style is not in favour with those whose training enables them to discriminate between the true and the false in design.

In designing furniture—and I daresay anything else—one must first have some acquaintance with mechanical work. Without this it is impossible to decide how the material—in this case principally wood—can be used to the best advantage, without cumbersomeness on the one hand or fragility on the other. After this, convenience must be studied. Is the design suitable for its intended purpose? To take an extreme case for the sake of illustration, in designing a chair for ordinary use, would any one raise the seat three or four feet from the ground? To do so, of course, would be absurd, for such a height would, except for special purposes, not be pleasant. One could not sit at an ordinary table in such a chair nor put it to the intended use of a chair. Fashion, further, has much to do with design, for it must not be forgotten that those who cater for the public must do so according to popular demand. If one asks who creates fashion, what can the answer be? It is a species of evolution, but in its origin is so intangible that it cannot be grasped. It is like the fog—very undefined, but with a very unmistakable reality. Is, then, the fashion in furniture not influenced by the designer or the manufacturer? To a great extent it is, but he does little more than apply his skill in such a direction as may, in his opinion, best supply the demand. For the rest the designer must rely on his own resources and his general ideas of what constitutes a beautiful object. At the present time fashion seems to require that everything must be cheap as well as pretty, the latter being an unknown quantity.

My ideas may be that the two little tables illustrated are pretty; the reader's may be that they are the reverse. I hope not; but they are certainly inexpensive, which means that there is neither a superfluity of wood nor that the construction is complicated. For this reason, if for no other, they will commend themselves to the inexperienced maker, and if he is influenced by a desire to have fashionably designed furniture, let it be said that they, or others of similar character, may be seen by the dozen in our leading furniture shops.

Those who observe these will notice that a reaction seems to have set in against the severe, straight lines of the so-called Early English style, and that curves are introduced where a few years ago it would have been considered heresy to do so. These curves are generally supposed to distinguish the Queen Anne style, so those who wish may call these tables so. The fact is that curves, more or less graceful, are not confined to any particular style, and it is by recognising and applying whatever is beautiful in form and colour that the art renaissance of the present age is nourished.

Another thing which must be regarded in designing furniture, or, if you will, in adapting old designs to modern tastes, is this:

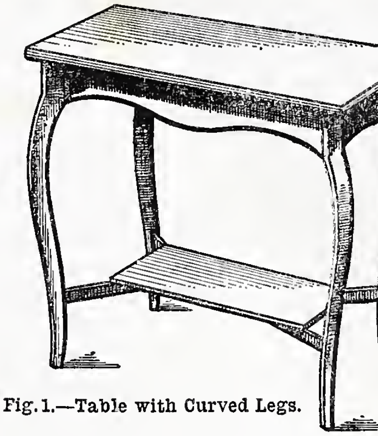

Fig. 1.—Table with Curved Legs.

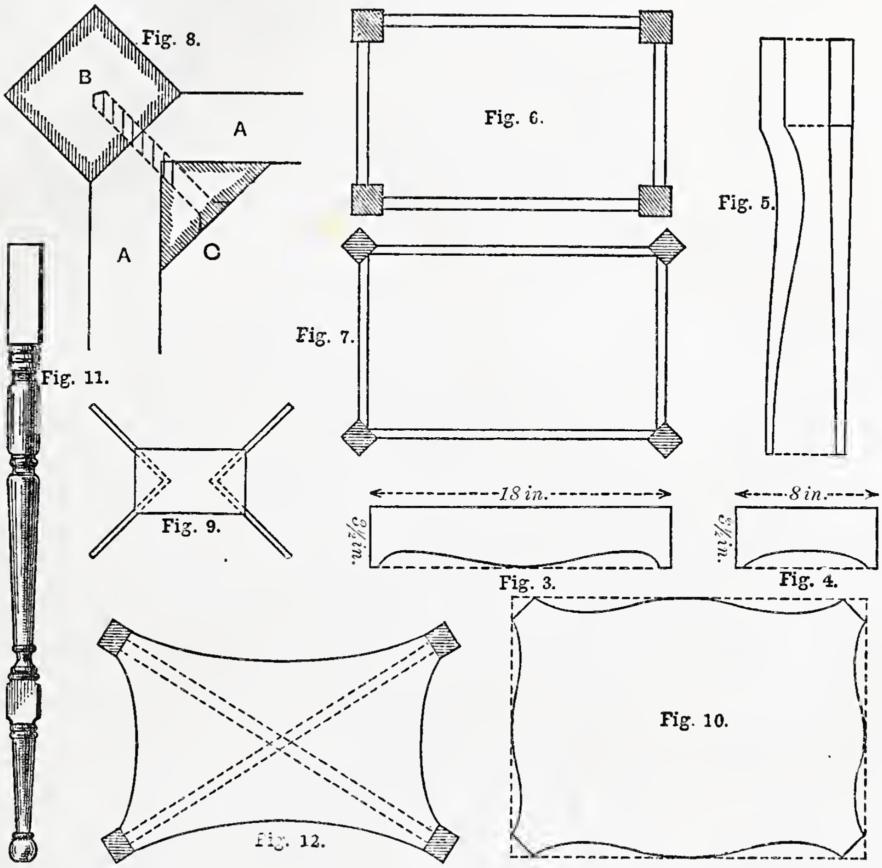

Fig. 3.—Long Rail of Framing. Fig. 4.—Short Ditto. Fig. 5.—Leg. Fig. 6.—Ordinary Framing. Fig. 7.—Alternative Ditto. Fig. 8.—Connection of Rails and Leg. Fig. 9.—Stretcher Board and Rails. Fig. 10.—Shaped Top. Fig. 11.—Turned Leg. Fig. 12.—Bottom Board and Stretcher for Fig. 2.

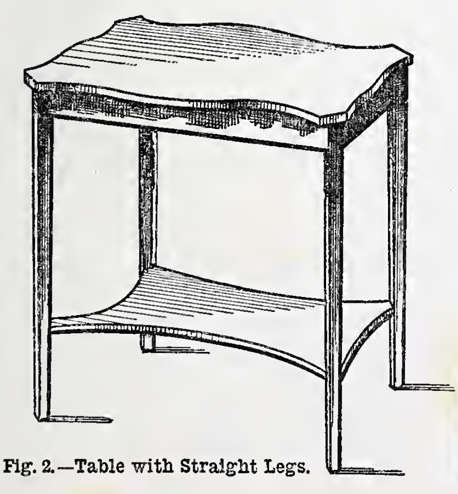

Fig. 2.—Table with Straight Legs.

as habits change, so does our furniture. In its way, the massive Elizabethan table with its bulbous legs is good—may have been best adapted to the period when it was supreme. Now, in our ordinary living-rooms it is out of harmony with the surroundings. We do not require such ponderous structures, in our drawing-rooms at any rate. Lighter things are more convenient, and if they are not so strong they are strong enough. We do not expect a small table to be knocked about in a reckless manner, nor yet that any great weight should be laid on it; hence, whatever some may say about the necessity for everything being made as strong as possible, let us qualify their dicta by saying as strong as service and utility demand. Now, for fancy drawing-room tables these are substantial enough, fragile though they may look and wrong in theory though the curved legs of one of them may be according to some people. For their comfort it may be admitted that were strength the only consideration, these curved legs are undoubtedly not the best form; but for the present let us adopt the Hogarthian idea and eschew straight lines.

Whether the "line of beauty" or the "Eastlake" style be the better need not be discussed. We want two tables with curves, and we will have them.

As a rule, curved outlines entail more work than straight, and it may almost be said that some forms of shaped construction are beyond the range of the amateur worker. These tables, however, are so simple that no one who can use a bow saw or a good fret machine need be afraid to tackle them. The general construction of both being the same, it will be unnecessary to give instructions separately for each. The drawings of the various parts will show sufficiently what is required to enable any one to make either, or, if he wish to exercise his ingenuity, to construct from the elements given tables which to a casual observer might seem new designs. Possibly this may be a new notion to some, and as all design is, broadly speaking, merely a new combination of forms or outlines already known and rendered with more or less ease and grace, let me just suggest as a very elementary lesson in furniture designing a few ideas that may be got from these tables.

Perhaps the first which will occur to most is merely the change of tops, and a very practicable one too. By transposing the tops we get already four different tables. Then there are the bottom boards; they may be changed in the same manner. The shaped rails may be substituted for the straight framing, or *vice versâ*. The tops, instead of being oblong, may be square. Alterations in outline will also occur to the student, and by-and-by he will find himself able to prepare his own designs instead of being, as is too frequently the case with amateur cabinet makers, compelled to merely copy a piece of furniture, whether in existence or only a drawing. When he is to some extent able to work alone, more pleasure, not to say utility, will be gained. There is a desire to see the ideas set forth in pencil embodied in solid form. The drawing but feebly represents the finished thing, in which the interest grows as the work proceeds. We have the ideal completed article in our mind's eye, and we are naturally wishful to see whether the actual approaches it. It never does; at least, I, for one, am always disappointed in some detail or other, and I imagine that is the experience of most of us, whatever our work may be.

But why should this be mentioned? Not needlessly, I hope, for it may save the novice, at any rate, some vexation to be aware beforehand that success is only comparative. If his work surpasses his ideal, possibly his work may be superlative, but—and a very big "but" it is—the chances are that the ideal has been a very poor one.

Is it an exception to find that as a man progresses in any art, so to himself does his ideal seem more and more difficult of attainment? Perhaps he gets more critical as increasing knowledge shows hitherto unsuspected weaknesses—just little, tiny, insignificant details which might be improved on. Ay, the ideal in furniture work is not more easily reached than it is in actual life; but shall we on that account sit down and not attempt anything? No; rather let us do the best we can, our motto being "Excelsior!"

The last few sentences are to me a strong confirmation of the ideal not approaching the reality. I would that I could have expressed myself in the glowing language of a Ruskin, but that is impossible; and I can but hope that the suggestions offered may be of some service to those for whom they are intended—viz., beginners—not so much in actual manipulation as in design. Of course, it cannot be expected that the novice, however well up in theory he may be, will be able to design furniture without practice and knowledge of facts, but there are many little things he might manage not only to make but to devise, without being dependent on any one for design. Having indicated the principles which may assist him, let us now leave the designer, or, rather, merge him in the artisan.

The size of such small tables is not bounded by any fixed rules, but suitable dimensions may be given as follows:—Top, 1 ft. 10 in. × 1 ft. 4 in., at a height of about 26 in. from the ground. For the tops $\frac{3}{4}$ in. stuff will do very well, and for the legs $1\frac{1}{4}$ in. The framing may be only $\frac{1}{2}$ in., but the same substance as the top will be better. In fact, with a supply of $1\frac{1}{4}$ in. and $\frac{3}{4}$ in. wood the tables may be made; and in speaking of these thicknesses it will be understood that they are those of the stuff in the plank, and consequently planing and cleaning up will reduce them. To begin with, they usually measure less than the nominal thickness, and by the time they are finished they will probably be little if any more than 1 in. and $\frac{1}{2}$ in. respectively. Those who prefer to use thicker stuff may of course do so, but with good sound timber the substance named is all that is necessary. In any wood the thickness for the top will be sufficient, but with a soft, weak wood—such as sequoia—it stands to reason that the curved legs may advantageously be thicker than if they are made of a strong, tough wood like ash. Ordinary baywood, walnut, pine, etc., will do if of the thickness stated.

The tops will have to be jointed, *i.e.*, the necessary width will have to be got by joining two pieces of board. Glue alone will be sufficient to join them, the edges in contact being planed as true as possible, and well worked together. The jointing should be done while the boards are in the rough, and before anything else is done full-sized drawings of the various parts should be made. For the shaped pieces, in order to ensure uniformity of outline, it will be better to form templates or moulds of thin cardboard or wood cut to shape. These can then be used as rules to set out the actual work by.

For the shaped leg table, besides the top, which is straight, and may be simply cut to size (22 in. × 16 in.), four pieces will be required for the framing. Two of them will be of the size and shape indicated by Fig. 3, and the others by Fig. 4. The legs must also be got out, as shown in Fig. 5, where it will be more clearly seen than in the illustration, Fig. 1, that they taper to the lower end, and that they are rectangular in section. They may be of the same thickness throughout, but they will not look so well, and the tapering, so far as the thickness is concerned, can easily be managed with the plane. The taper in width will of course be provided for when cutting the legs from the plank. We may suppose that the thickness of the leg at the top straight part is 1 in., or a little over, and at the bottom from $\frac{5}{8}$ in. to $\frac{3}{4}$ in. To ensure the right amount being taken off each side, the bottom end should be marked, and if this is done it will be unnecessary to take the trouble which would be involved by marking off the taper on the face of the wood. It will be observed that where the curve in the leg is most pronounced the wood is wider than lower down. The reason for this is to give extra strength where the bearing is across the grain, for a moment's reflection will show the veriest tyro that the wood can be more easily split or broken at this part than elsewhere.

It is now necessary for the reader to refer to Figs. 6 and 7, showing the plan of frame and legs fastened together. Fig. 6 shows the ordinary construction of framing, where the rails and legs are either fastened together by mortise and tenon or by dowels. Fig. 7 shows a construction which is very much simpler, and equally serviceable for light things. It will be observed that the legs are on the "cant," as it is often called, *i.e.*, not parallel with the framing as they generally are when the ordinary construction is followed. Now, understanding this, refer to Fig. 8, which shows, still in plan, the connection of the framing and the legs. A, A, represent the framing, B, the leg, and C, a block glued to A, A, which it connects, and by means of screws is fastened to the leg. To form and fit these connections proceed as follows:—Get four blocks of the section shown, and not longer than the width of the framing. See that two of the sides form a perfect right angle, easily ascertainable with the square, for if they do not it stands to reason that the framing will be "out." Fasten them into the corners of the framing with glue, and if there should be any doubt about the gluing being sufficiently well done to ensure durability, a small screw or two may be used through each block into the rail. No harm can result from the addition of screws, and if there is anything amiss either with the glue or its application they will prevent a collapse.

At this stage it is apparent that the framing will have square corners, which must be cut off so that the leg may be fitted. First of all get the thickness of the leg, and set it off on the top of the frame. Then with the gauge run lines down to the bottom of the frame. The lines give a reliable guide to cut off the corner to, and if they are accurately followed the square part of the leg must fit perpendicularly. To fasten the framing to the leg a couple of good stout screws are driven through the block into the leg, which may also be glued up, but, as it is next to end grain, too much reliance must not be placed on glue alone.

The top is fixed to the framing by blocks like those in the corners, glued both to the top and to the rails. Two or three blocks of, say, 3 in. long along each side, and one or two at each end, will be sufficient. They are of course fixed within the framing, not outside it under the overhang of the top, where they would show and be unsightly. In addition to the blocks, it will also be advisable to use screws, say one through each rail into the top. They should be driven in on the slant, and care be taken that they do not come through to the surface of the top.

The stretcher and bottom board shown in the illustration are not absolutely essential, but as they give rigidity it will be as well not to grudge the extra time required for them. For convenience of description they have been left till now, but in actual work it will of course be seen that they should be prepared before the table has progressed so far as described. The board, or shelf, may be taken as measuring about 13 in. × 8 in., but the size is really of no consequence; whatever it is, the construction will be the same. Four pieces, say, $\frac{3}{4}$ in. square, support it. The outer ends of these are to be cut to fit the legs, and the others screwed to the shelf from below, taking care that its corners are evenly placed above each rail. It will perhaps simplify matters for the beginner if these are fixed at right angles to each other, *i.e.*, the pair at each end of the table, as in the diagram Fig. 9. Were the legs stouter it would be better to sink the ends of the stretchers in them; and this might be done even as they are, but not to any great extent—not more than just sufficient to let the ends in, say, $\frac{1}{16}$ in. or so. In either case a screw ring or eye should be driven into each leg. The stretchers will rest on the eye, and a screw driven through it will hold firm enough.

Now for the other table, which is made in a precisely similar manner, the differences being that the top is shaped as shown in Fig. 10. The framing is straight (3 in. wide), the legs either straight tapered, or, as they may be, turned, and the bottom board larger, extending from leg to leg. As a suggestion for the turner, Fig. 11 is given. The square block allows plenty of substance for the shelf to be well sunk in it. The cut may be most easily made by sawing across and removing the surplus wood with a chisel, and the stretcher rails may be dispensed with altogether. It will, however, be better to have them, and in this case one can be carried right across to the opposite leg, the other being cut in the middle, as in Fig. 13. They will be screwed both to the shelf and the legs, as in the other table.

The maker's work is now brought to an end, and it only remains to finish the table by polishing, or, what is now very fashionable, painting them with one or other of the enamel preparations. Nothing need, however, be said at present about either of these processes, as our chat about furniture seems already to be rather lengthy, though I sincerely trust not unprofitable to any one. It has been my aim first to describe the form and construction of a good type of small table that will be found useful in any house in many places for a variety of purposes; and, secondly, by the designs that have been given by way of illustration, to enable any carpenter, whether professional or amateur, to make such tables either for his own use or for sale.

CIRCULAR-SAW RIGS FOR THE LATHE.

BY A FOREMAN PATTERN MAKER.

Circular Saw a desirable Adjunct to Lathe—Saw Spindles in Brass, Wood, and Steel—Iron Table to fit Headstock—Rough-and-ready Wood Attachment—Alternative Wood Attachment—Fences—Cutting Bevels, etc.—Bevel Sawing—Cutting Rebates, Tenons, Grooves, etc. — Canting Fence for Long Bevel Sawing.

Those who possess a lathe of not less than four-inch or five-inch centres might often save a good deal of the time spent in light sawing by attaching a circular saw thereto. A good deal of power is required to drive it, hence no heavy work of this kind can be done in a lathe. I should place the limit to the thickness which can be freely cut at from five-eighths of an inch to three-quarters of an inch. But workmen, and especially amateurs, often want to saw large quantities of *thin* stuff into strips alike, or nearly alike; and it is in such work as this that the saving is effected by the use of such a saw. When making small drawers, cabinets, boxes, etc., it is simply invaluable. There are several different ways of making the attachment, none of them very difficult, and the cost but slight. I propose, therefore, to show sundry ways in which it can be effected.

The saw itself is mounted on a spindle, shown in Fig. 1. If the headstock mandrel of the lathe has a good thread on the nose, and the spindle is screwed to make a good fit therewith, no other support will be necessary. But should the fit be imperfect, then the poppet centre must be run up, and centred in the free end to steady it while cutting. The spindle is preferably made of brass, cast from a pattern. After being screwed to the mandrel nose, it should be turned up in its place, care being particularly taken to have both the pin, and the shoulder against which the saw abuts, perfectly true. The dimensions are taken from a spindle of my own. I have found the friction of the washer, when pinched up by the nut, quite sufficient to keep the saw from slipping on its mandrel. But probably if a saw larger than five inches or six inches were used it might be necessary to make a projection, or steady pin, on the spindle to fit a corresponding notch in the saw, as is the practice with circulars of ordinary dimensions. But probably, in such a case, the interposition of a leather washer between the metal washer and saw plate would effectually prevent slipping under the heaviest cutting which could be done in a lathe.

Spindles of this kind can be made in hard wood, and will answer nearly, or quite, as well as metal ones. Fig. 2 gives an illustration of one of this character. A block of straight-grained hard wood, A, turned parallel, bonded with ferrules, and tapped like a wooden chuck to fit the mandrel nose, has a hole bored right through its body to take a half-inch bolt, B, whose square head is sunk in at C to prevent it from turning, a nut and washer at D tightening the saw in place.

Again, instead of designing the spindle to embrace the mandrel nose, it can be made, as in Fig. 3, of a piece of steel, being countersunk at both ends for the point centres of the lathe, and driven through a carrier. Or the left-hand end could be driven from a jaw chuck, or drill chuck; or, if filed square, could be driven from a square hole chuck.

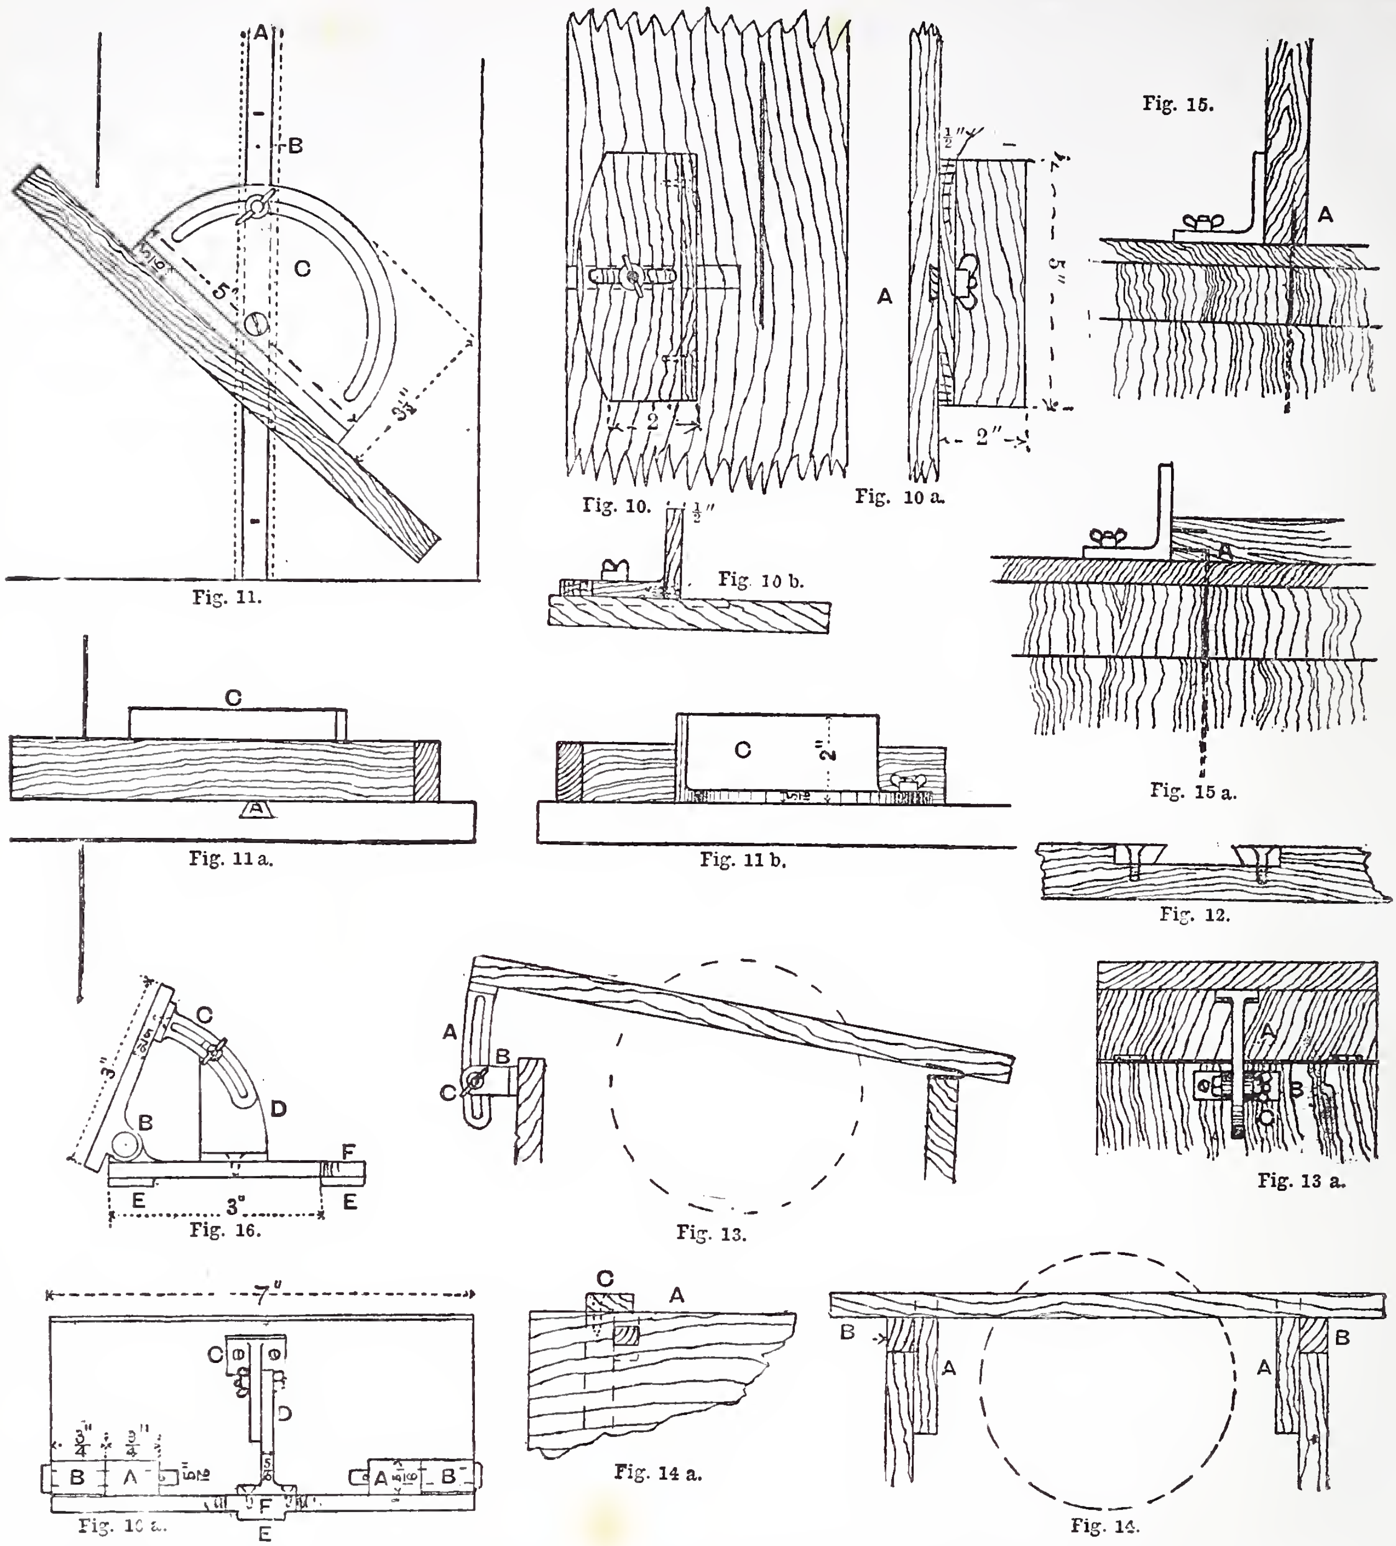
We have the choice of various tables. I will describe three. Fig. 4 represents one which I made for my own lathe, and which is a good and convenient type for headstocks having parallel edges on the front portion. It is made to fit the headstock by means of the grooves, A, A, sliding down the edges of the front upright. Two quarter-inch holes are drilled and tapped in the sides of the uprights, corresponding in position with the holes, B, in Fig. 4, and a couple of thumb screws passing through these hold the table at the correct height in relation to the saw, whose spindle passes close underneath the table without actually touching it.

The table is made of cast iron, for which a pattern is required. It is very light, only three-sixteenths of an inch thick in the plate, and stiffened with a flange running all round the bottom edge. At C is shown a small fence, also of cast iron, which is provided with a slot and bolt, so that it is traversed across the table. The strip seen at its front edge, by sliding along the front edge of the table, preserves the parallelism of the fence with the saw.

The top of the table may either be planed or simply filed, the latter answering sufficiently well. The slit for the saw should properly be cut, owing to the difficulty of casting it so narrow. A key-hole saw will, if sharpened with short triangular teeth of equilateral form, like those of a hack saw, cut through soft cast iron without much difficulty. A common hack saw will, of course, do the same, but it is not thick enough in the blade to cut a slot which would take the circular saw, since the latter must have a little clearance in order to avoid noise, and grinding of the teeth, when running. To start the cut, it is necessary to drill a couple of holes at the ends where the slit is to terminate, then remove the narrow separating film of metal with the point of a thin file and so gain an entry for the narrow end of the saw, which, once entered, will cut the slit with comparative ease. It will probably be a little irregular, and perhaps not quite wide enough. If so, widen and smooth the cut sides with a thin warding file. The holes drilled to start the cut answer the very useful purpose of giving clearance around the saw teeth, preventing risk of injurious rubbing of the same.

I have given the sizes of my own table, but these are not necessarily hard and fast dimensions. The measurement between the cheeks, A, A, is omitted, since this must be accommodated to individual lathes. In a large number of lathes, in which the front upright of the headstock is not parallel but curved in outline, the fitting and making of a table of this kind would be troublesome, hence I should in such cases adopt one of the forms to follow.

Fig. 5 shows a rough-and-ready table attachment, which, though handy for occasional use, is not so substantial as the other forms figured. It may be of wood, in which case a plate of metal must be let into the shank, to take the pinch of the set screw in the socket of the T rest. But preferably it should be of metal, in which case the plate and shank could be cast in one from a pattern, though a better method would be to get a piece of sheet iron or brass, about one-eighth of an inch thick, and screw it down on the top of a bit of iron bar, forming the shank. Fig. 6 shows an enlarged view of the union. A bit of solder may be run round the angle as shown, to stiffen the joint. Whether made in wood or metal, fences of some of the forms shown in the various figures can be fitted on the table with little trouble. Even where the most substantial tables are already fitted to a lathe, it is worth one's while to have one

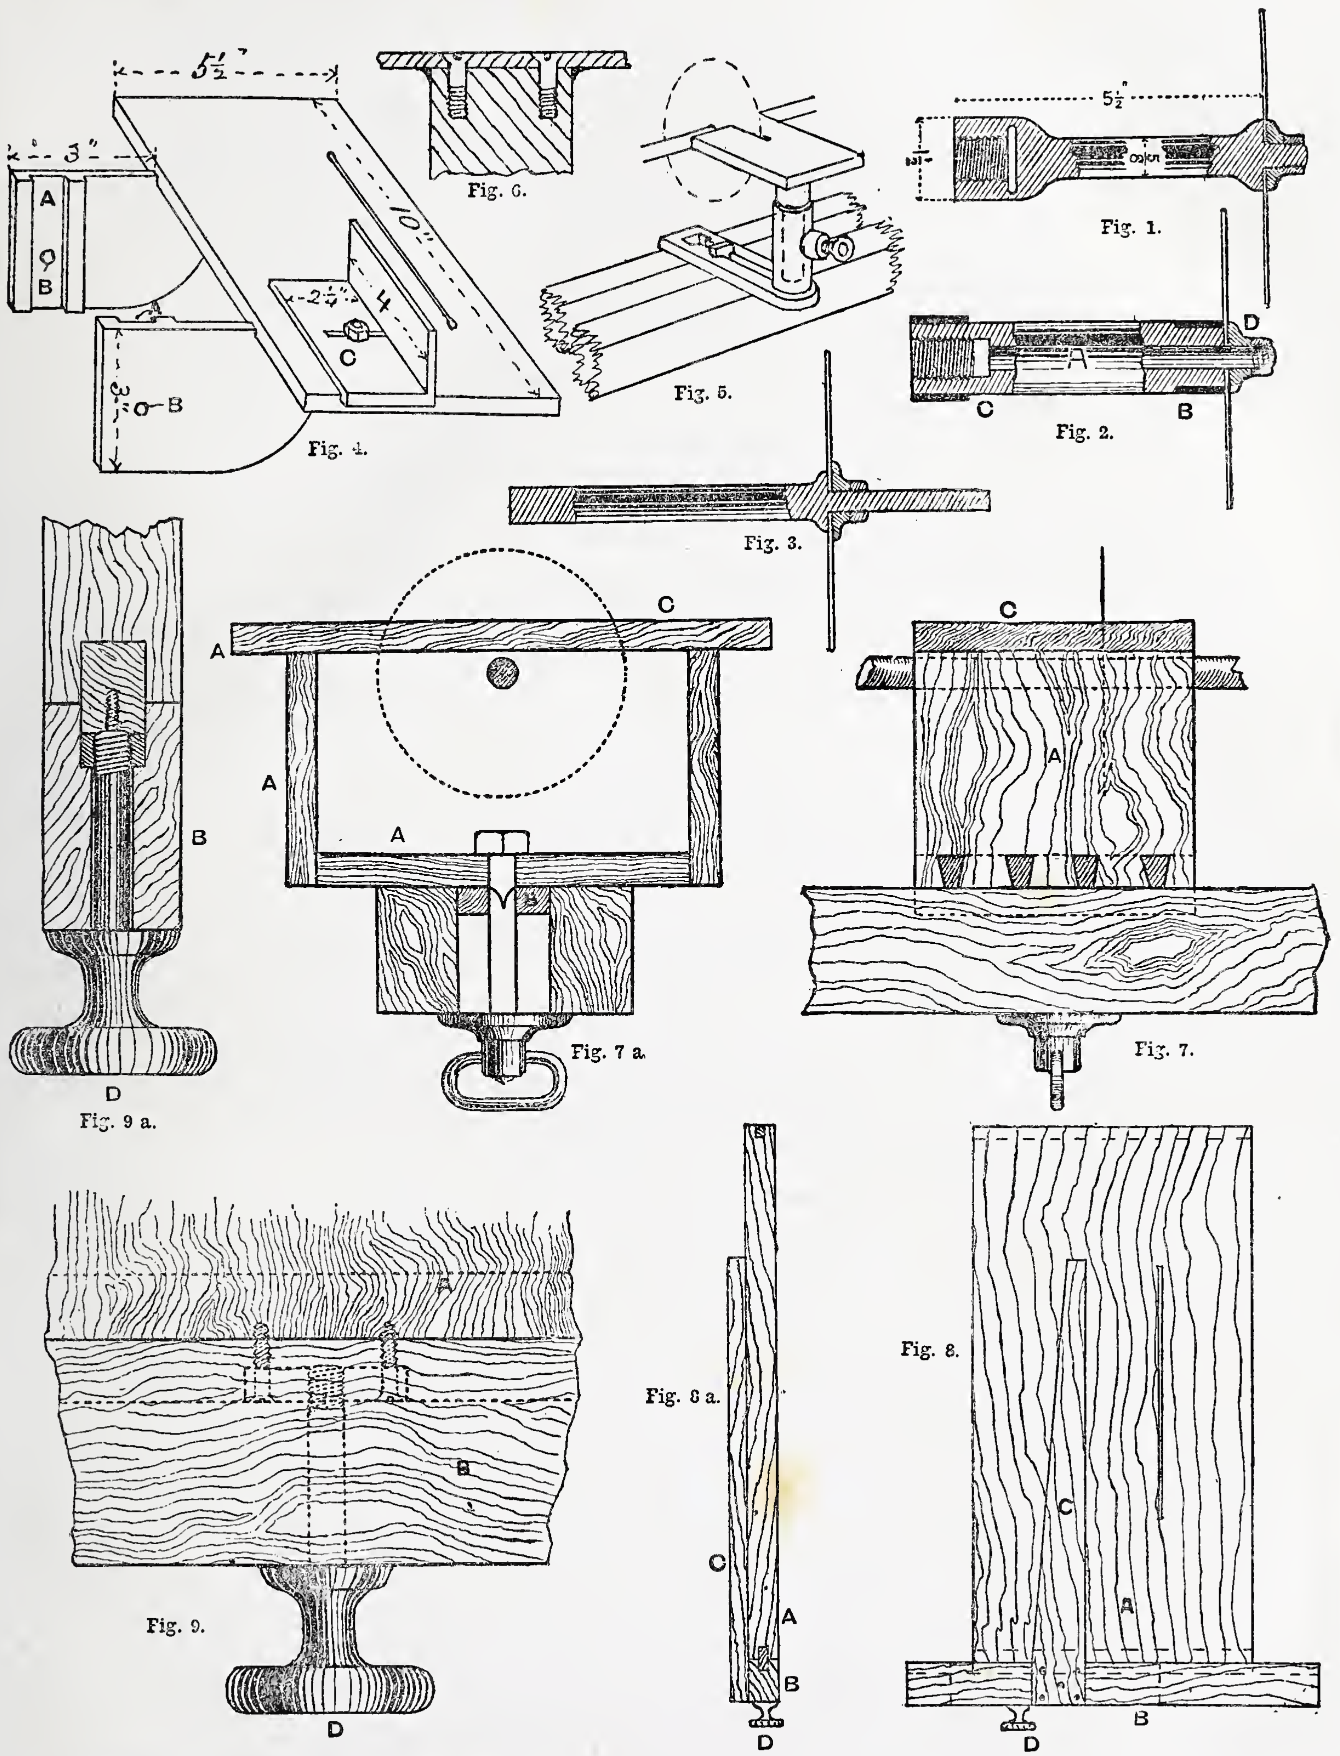


Circular-Saw Rigs for the Lathe. Fig. 10.—Plain Wooden Fence in Plan. Fig. 10 a.—Side View of Ditto. Fig. 10 b.—End View of Ditto. Fig. 11.—Fence for Bevel Sawing in Plan. Fig. 11 a.—Ditto: Front View. Fig. 11 b.—Ditto: Hind View. Fig. 12.—V Groove for Table. Fig. 13.—Hinged Table: Front View. Fig. 13 a.—Ditto: End View. Fig. 16.—Canting Fence for Long Bevel Sawing in Plan. Fig. 16 a.—Ditto: Side View.

like Fig. 5 for quick attachment and temporary use. Its slit is at once readily adjusted to the saw, and the T rest is then clamped to the bed in the position corresponding therewith.

Fig. 7 shows a very good and old-fashioned rig for a circular saw, and one which almost anybody who may not perhaps care to tackle iron work can construct with little difficulty, most of the work being in wood. A is a frame of hard or of soft wood, having a tongued piece, B, screwed to its under face to fit between the lathe bearers. C is the actual table hinged to the back of A, the throwing back of the table being necessary in order to bring the frame underneath the saw. Being thrown back, and the frame slid underneath, the table is then brought down over the saw, the latter passing up through its slit—the slit having been cut by the saw itself at the time of making the table. The tongue always fitting closely between the bearers, there can be no trouble due to want of adjustment. In this case no dimensions are given, but the diagram affords an idea of relative and suitable proportions, the sizes being properly adapted to a five-inch lathe.

The full advantage of these tables is to be obtained only by the addition of various fences for the guidance of stuff which is being sawn. Some of these attachments I will now describe. Fig. 8 shows a plain guide for parallel sawing, adapted to a



Circular-Saw Rigs for the Lathe. Fig. 1.—Brass Spindle for Circular Saw. Fig. 2.—Wooden Spindle for ditto. Fig. 3.—Steel Spindle for ditto for Point Centres. Fig. 4.—Iron Table and Fence. Fig. 8.—Wooden Fence in Plan.—Fig. 8 a.—Ditto: Side View. Fig. 9.—Pinching Screw shown in Fig. 8 on Enlarged Scale. Fig. 9 a.—Ditto in Section.

wooden table like Fig. 7. The table, A, is grooved along the front edge to receive the tongue of the sliding bar, B, to which the guide, C, is attached. This is clamped in any position by means of the set screw, D, which is tapped into a brass plate sunk and screwed into the tongue piece on A, a slot in the bar, B, allowing the latter to traverse freely over the screw. The screw attachment is shown enlarged in Fig. 9. This, if well fitted, forms an efficient guide.

Another fence is shown in Fig. 10, which may be fitted either to a wooden or to an iron bench, and which can very well be made of two pieces of any hard wood screwed together. The gluing and screwing of the dovetail slip, A, on the under side of the fence stiffens the base, which would otherwise be much weakened by the cutting through of the slot for the thumb screw. The dimensions given are proportionate and approximate only.

Perhaps the greatest advantage of the application of small circular saws to the lathe lies in their adaptability to the cutting of bevelled and polygonal faces. The lathe saw is essentially an amateur's tool, and the more it can be utilised the better. By devising suitable arrangements, much work which would otherwise have to be done with chisel and plane can be saved. Mitred and bevelled joints, rebates, grooving, tenons, and much beside, can be cut with rapidity and accuracy; and the very fine teeth of saws from three to seven inches in diameter will, if kept in order, leave the surfaces clean and smooth.

To do bevel sawing at right angles with the table, it is clear that the piece of wood being cut must not, when set at the angle required, be slid along the face of the fence, but that the fence and the wood must move together parallel with the saw. Hence the purpose of the arrangement in Fig. 11, where A is a V groove cut in the saw table, parallel with the slit, to receive the sliding piece, B, on which is pivoted the quadrant fence, C, capable of being slewed to any angle, and pinched with the thumb screw. The sliding strip may be of hard wood or of metal; but it must be very neatly fitted in either case. A metal strip is to be preferred, sliding between metal guides. If the table is made of wood, these can be fitted as shown in Fig. 12; and wrought iron or brass would be more suitable than cast iron. The quadrant, owing to the weakening effect of the slot, should be of metal; but it is quite easy to make, the pattern being simple, and the filing and fitting slight in amount. The slot can be cut out nearly to the size in the pattern, and finished in the casting by filing. It would not be a very troublesome task to divide out the circular edge of the quadrant into degrees, and, by bringing any division into correspondence with a centre line on the slide, to cut to any required angle without the trouble of tentative adjustment.

In order to cut rebates, tenons, grooves, and shouldered work generally, it is necessary either to use saws of various diameters, which is troublesome, costly, and not precise; or to place blocking, or thickness pieces, on the table, which, if deep, interfere with the fences; or to raise the table itself. The latter is the proper way, and it may be effected as follows :—Suppose the table is hinged, as in Fig. 7, it may be fitted with an attachment on the underside at the front of metal, Fig. 13, A being a slotted quadrant screwed to the table, and B, a piece screwed to the face of the box, into which the set screw, C, is tapped. This is a neat and exact mode of adjustment.

A rougher method is shown in Fig. 14. Here the table, instead of being hinged, is dropped in place simply by means of four pieces, A, fitting between the frame, the strips, C, being added to keep the table from shifting sideways. The pieces, A, are tenoned into the table, and by making them sufficiently long, there is room to permit of the parallel thickness pieces, B, B, being laid upon the top of the frame. A supply of strips of various thicknesses can be kept in readiness for use. The pieces, C, keep the table sideways.

To cut tenons and rebates it is only necessary to adjust the height of the table until the saw stands above it to the same distance as the depth of rebate required—to adjust the fence, and run the stuff along. (Fig. 15.) Then readjust the fence and table, and run the second cut along to meet the first, so removing the piece, A, at once. For doing work of this kind in quantity, the lathe saw is invaluable.

Lastly, the bevel sawing of long stuff is done by means of a canting fence. Fig. 16 shows a plain form made in metal, the construction of which is so easy that no amateur need be without it. In the absence of such a fence, blocks of wood cut to various definite angles would have to be made and placed against the rigid fence. In Fig. 16, two lugs, A, A, are cast on the base, and two, B, B, on the fence. These are united freely with pins. The quadrant piece, C, screwed to the fence, furnishes, with the set screw and the upright attachment, D, the means of adjustment for bevel. The guide strips, E, E, fit in the groove in the table, and a set or pinching screw (not shown) passing through the lug, F, holds the table down in any position.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

I.—INTRODUCTORY.

THERE can be no doubt but that the use of "signs," as a means of advertising, is of the most ancient origin; in fact, it is known that in old Rome the taverns had signs, and that the Greeks also made use of them, as is proved by the frequent allusions made by the old Greek writers on the subject.

In mediæval England, when most people could neither read nor write, a "sign," or "sign-board," was an absolute necessity to the tradesman, and in the reign of Henry VIII. almost every house in street, lane, and alley exposed a sign of some description. These signs were generally indicative of the trade carried on within. With the spread of education, however, these "signs" gradually fell into disuse, although many are in existence to the present day, as the three golden balls of the pawnbroker, and the gaily painted pole of the barber.

It is not, however, the historical side of the subject on which I intend to treat in the present paper, but on the practice of the modern art of lettering on signs, shop-fronts, walls, vehicles, etc. Therefore, *sign painting*, in the proper acceptance of the term, as an almost obsolete art will be left untouched, exception to this rule being made only in the case of the royal arms, arms of public companies, shields, and a few of the most general of hotel sign-boards. It is for this reason I have headed my articles "Sign Writing and Lettering" in contradistinction to "Sign Painting," which title, to say the least, is somewhat misleading. Indeed, the naming of this art—for art it is, although perhaps partly mechanical—has invariably been a sore point with all previous writers on the subject, but, for my own part, I unhesitatingly say that the correct description of the work, as practised at the present day, is to be found in the title of these articles.

There are very few men at the present day who undertake this class of work who could paint a subject on a sign-board; and this can hardly be wondered at, as the man who does such work must of necessity be a first-class artist. This reminds me that some of our most celebrated artists have, on occasions, not thought it beneath their dignity to paint a sign. A specimen of Hogarth's work is, I believe, still to be seen inside "The Mischief" in Oxford Street, near to Soho Square, and an engraving of it used to be exhibited in the window not very long ago, if not at the present day. This, the old sign of the house, is said to be Hogarth's handiwork, and is specified as such in the lease of the house. Catton, one of the original members of the Royal Academy, and Wade, its first professor of perspective, worked occasionally for the London innkeepers. The latter painted a full-length portrait of Shakespeare, five feet high, for a publican, whose house was at the north-west corner of Little Russell Street, Drury Lane. George Morland, I believe, painted more tavern signs than any other artist of note. David Cox, it will be remembered, painted a sign for "The Royal Oak Inn" at Bettws-y-Coed in Wales, which has since been the cause of litigation in the Law Courts, and only lately decided. At Wargrave-on-Thames, midway between Henley and Twyford, and hard by Sir Morell Mackenzie's country seat, is a quaint, old-fashioned inn, the "St. George and the Dragon," the sign of which was painted by two great artists; in fact, to be correct, that side of the sign-board on which St. George is charging the dragon was painted by Leslie, and the reverse side was painted not by Watts, as has been sometimes asserted, but by Hodgson.

By what I have said, therefore, it will be seen that there are three distinct classes of work and workers, viz., sign painters, sign writers, and the common letterers. The first is an artist pure and simple, capable also, as a rule, of doing any class of letter painting. The second is a clever man in his profession, capable of doing any class of writing and lettering, from church work to the outside of a West-end tradesman's shop, but stopping short at actual pictorial work. The last is the intelligent mechanic, who, in nine cases out of ten, accidentally discovers that he is gifted with being able to make exact formations of letters and figures, and which by a little practice he acquires to a nicety. These men are to be found in large wheelwrights' and carriage-builders' yards, and in the railway carriage and waggon works throughout the country. As a rule, they generally use block letters, with a simple shading, such as one sees on railway waggons and coal trucks. This work is simply "letter painting," and those who execute it seldom get beyond it. It has much sameness about it, and holds out no field for improvement in the way of spacing, style, and display. I have personally known many of these men on railways, and whenever they have made any attempt at sign writing it has proved a most signal failure; whereas had they received a little training from a practical man they would probably have soon been enabled to execute their work with credit. But I have knowledge also of two cases where men have possessed a remarkable "gift" for this work—one in general sign writing, the other in "lettering" waggons. The sign writer, a homeless, shoeless, drunken vagabond, is still alive. He cannot read nor write, yet he can paint a sign with ornamental borders and letter it in any style, without mis-spelling a word or making the slightest mistake. His charges are absurdly low; he is generally in a half-drunken condition, and his couch at night time is more often than not the floor of some out-house. This is one of the worst cases of a mis-spent and ill-directed life it has ever been my lot to witness. In the other man the aspect of the case was just reversed; he was a mechanic of the roughest order, a waggon repairer, but honest, frugal, and sober. Whenever occasion called for it, he would employ the sign writer just alluded to to re-letter a truck or waggon. Cheapness was no doubt his reason for getting his work done by such a man, who, moreover, frequently disappointed him. One day the waggon repairer—whom I had noticed frequently standing for hours watching me at work on a waggon—came up to me and asked, politely enough, how I had learnt the art of forming letters, or, as he put it, "Painting them 'ere letters on waggons?" I told him that I was self-taught, my only guide being a half-crown handbook on the subject. "Could I tell him where he could get the book?" "Oh, yes," was the reply, and I entered the office and gave him the publisher's address. It may scarcely be believed, but within a fortnight I saw that man lettering a railway waggon, and forming letters to such a degree of nicety as to put even myself and the drunken professional writer "in the shade."

These cases may help to illustrate the way in which a great majority of men drift into becoming sign writers. As in all other trades and professions, it is often a matter of chance. But these men can hardly ever hope to become clever and proficient in their chosen walks of life; they have not studied the rudimentary principles of the work, have not started at the bottom rung of the ladder, and do most of their work without knowing the why and the wherefore of each individual process.

It is not, however, this class of workman which we want in the coming generation—we must endeavour to make him something better; and now that he has found a fitting tutor and guide in WORK, he will have only himself to blame if he sinks in striking out for fame in the struggle of life.

In the succeeding chapters on Sign Writing it will be my earnest endeavour to take the student through each successive course in the easiest possible stages, commencing at the very root of the subject. It must not be inferred from what I have already said that it requires a gifted nature to properly acquire this art; on the other hand, with proper and methodical training it is within the reach of all. Indeed, towards the close of my subject I hope to show how the more simple styles of plain lettering may be carried out by almost mechanical means. These instructions, however, are principally intended for those who follow some trade in which a little lettering is sometimes required, but which the workman has not a chance to learn except by properly following up the course of instruction as laid down in these pages.

Having briefly surveyed the general aspect of the subject, I will, in my next, commence the practical part of our work.

(*To be continued.*)

THE KALEIDOSCOPE: ITS CONSTRUCTION AND APPLICATION.

BY THOMAS RICHARDSON.

I.—THE SIMPLE KALEIDOSCOPE.

THE "tube of ten thousand flames." Such was the title applied by the Chinese to the instrument which forms the subject of this paper; and certainly the title appears to be most appropriate and suggestive when we take into consideration the myriads of pictorial views it is capable of producing. The peculiar name bestowed upon it by its distinguished inventor, Sir David Brewster, is derived from three Greek words, signifying "beautiful," "a form," and "to see." When first introduced to the public, about the year 1818, it is recorded that the effects produced by its wonderful qualities created such an extraordinary sensation both in this country and abroad that immense numbers were hastily constructed, and cargoes of them sent to foreign and distant lands, copies having been met with in the most remote districts of Switzerland.

It is not my present purpose to enter into a disquisition on the principles of the kaleidoscope, but merely offer a short explanation to assist the reader in comprehending the nature of the various parts of the instrument, and then pass on to consider its construction in its simplest form and after a fashion which may be reasonably supposed to lie within the province of any intelligent amateur capable of using a soldering bit or wood-working tools, and wishful to provide a source of amusement for the younger, and, for the matter of that, the older portion of the family circle during the long winter evenings.

The kaleidoscope consists essentially of two pieces of glass, which may be oblong or tapering in form to suit the fancy of the maker. These are secured and supported at any angle which forms an *even*, aliquot part of a circle, in a suitable tube, at one end of which is a cell termed the object box, formed of two circles of glass, the inner one being clear, and the outer one of ground glass; these are kept apart about $\frac{1}{8}$ of an inch by means of a ring of brass or other suitable material so as to enclose between them a number of coloured and clear pieces of glass, etc. The opposite end of the tube is closed with a cap in which is a small aperture at which the eye is placed in order to view the pictures presented by the several reflections of the fragments of glass in the object box.

As wood workers undoubtedly predominate amongst the readers of WORK, I propose to treat the subject first from this standpoint as shown in Fig. 1. On inspecting the Fig., it is obvious that access to a lathe will materially assist the worker, or, if this is not possible, the cap and the flanged collar at the back of the object box may be obtained for a trifle from any turner.

To proceed, first turn or otherwise prepare a mandrel or cylinder of wood about a foot long and 2 inches diameter, on which to prepare a tube of paper; rub a little grease over 10 inches of its length as a precaution against the paper being glued to the wood. Cut out a strip of stout cartridge or brown paper, say 3 feet long and 9 inches wide, up to 3 inches from one end, where it should have a projection of an inch at each side, making 11 inches wide for the last 3 inches; set off 6 inches from this wide end, give the remaining portion of the strip a coat of thin, hot glue, fasten the projecting edges of the clean end square along the mandrel, and fold the strip tightly round it, pressing out with a cloth any excess of glue, so as to finish with a smooth surface. After standing aside for a day to dry, it will now require the ends cut true, and the best way to do this will be to fold a half sheet of note paper round the tube about $\frac{1}{2}$ an inch from the end and run a sharp knife neatly round close to the edge of the note paper; then treat the other end in the same manner, so as to leave the tube 8 inches long, and slip it off the mandrel.

We next require two circular pieces of mahogany $\frac{1}{4}$ of an inch thick to fit each end of the tube, having a portion removed as indicated in Figs. 2 and 3 to an angle of 60 degrees, which angle may be easily obtained by dividing the circumference of a circle into six equal parts.

The reflectors measure 8 inches in length, and are $1\frac{1}{2}$ inches wide at one end, and $1\frac{3}{16}$ inches at the other. They may be cut from mirror glass or from plain clear window glass, moderately thin, say 16 oz., and the backs prepared by giving them a coat of drop black mixed with varnish, and a little terebine to accelerate its drying, or even black varnish will do for the purpose. When dry, the reflectors are now ready to be placed in the tube and secured in position by a piece of stout card cut to fit round the curve and meet at the edges of the reflectors. Before placing the card in position, it should have a piece of dead black paper pasted on the inside or by giving it a wash with Indian ink.

The next step is to provide a cap for the eye, and this may be achieved in the lathe by hollowing one side to a depth of $\frac{3}{8}$ of an inch to fit outside the tube, with a clean cut aperture in the centre $\frac{3}{8}$ of an inch diameter, then to reverse the work by turning down a piece of wood on a chuck to fit the recess, and finish off the outside as shown in section, full size, in Fig. 4.

The object box may also be constructed of wood in the manner shown in section and elevation, Figs. 5 and 6. A piece of hard wood, preferably of mahogany, 4 inches square is trued up to $\frac{3}{16}$ of an inch thick, and an opening cut or bored in the centre $2\frac{1}{2}$ inches diameter; a recess $2\frac{3}{4}$ inches diameter and $\frac{1}{16}$ of an inch deep is further produced on one side in which to insert a circle of thin, clear glass; a cap is next turned with a flange and bored to fit outside the tube at the object end. Fix the glass in the recess by means of a red-hot wire applied to a few tiny pieces of marine glue laid round the edge, and secure the flanged cap centrally to this square piece with 4 screws, being careful not to split either in so doing. On the opposite face are also screwed two narrow strips $\frac{1}{2}$ an inch wide and $\frac{1}{4}$ of an inch thick, one piece along each edge and across the grain to prevent warping; between these two strips another piece 4 inches by 3 inches and $\frac{1}{4}$ of an inch thick is hinged, and provided with clips to keep it in position; this is also fitted with a piece of ground glass, as shown, on the inside, with the ground face of the glass outwards. The foregoing method of constructing the object box admits of the easy removal and change of the fragments of glass, etc.

To those who may prefer to take the alternative course, I may remark that the taper form is usually adopted when the tube is of tin plate. Still keeping to the same length and the same diameter at the object end, I propose to taper the tube to $1\frac{1}{2}$ inches at the eye end. The plate requires to be cut to the form seen in Fig. 7. First secure the plate by the corners with tacks to the bench or floor, and make a trammel to draw the large circles by driving a couple of wire nails through a lath 18 inches apart. Make the centre nail secure, and scribe a circle, A, B, on the plate as shown; now shift the outer nail 8 inches inwards and scribe a second circle, C, D. With a pair of compasses set to 1 inch mark six divisions along the line, A, B, and scribe lines through the first and last points towards the centre. Outside the figure thus formed, a space about $\frac{1}{4}$ of an inch wide must be set off to allow for the joint. Having cut the plate neatly to the lines, bend about $\frac{1}{8}$ of an inch along each edge slightly downwards over the edge of a block of hard wood, both edges one way; the underside will then form the inside of the tube, and the plate must now

Fig. 2.—Plan of Tube at Eye End, with Cap Removed (full size).

be gently bent or beaten with a smooth-faced wood mallet, round a mandrel having the same dimensions as the inside of the proposed tube. It now only remains to secure the plate on to the mandrel with a piece of wire twisted round in two or three places, solder the joint, and the tube is complete.

The reflectors for this form are $1\frac{1}{2}$ inches at the object end, and taper to $\frac{3}{4}$ of an inch at the eye end; for the third side I should still advocate the use of cardboard as in the cylindrical form, but it may consist of a similar piece of glass or a piece of thin wood blackened on the inner side. In order to bring the aperture in the cap at the eye end into a central position as regards the tube, it will still be necessary to raise the narrow end of the reflectors into the most suitable position for the eye, in its relation to the reflectors. This support is shown in elevation in Fig. 8, and may be formed of tin plate with the edges turned back where they come in contact with the glass. The same course must be taken with the object end, as in Fig. 3, securing each support with a drop or two of solder. It will be best to form the cap in wood, and perhaps the

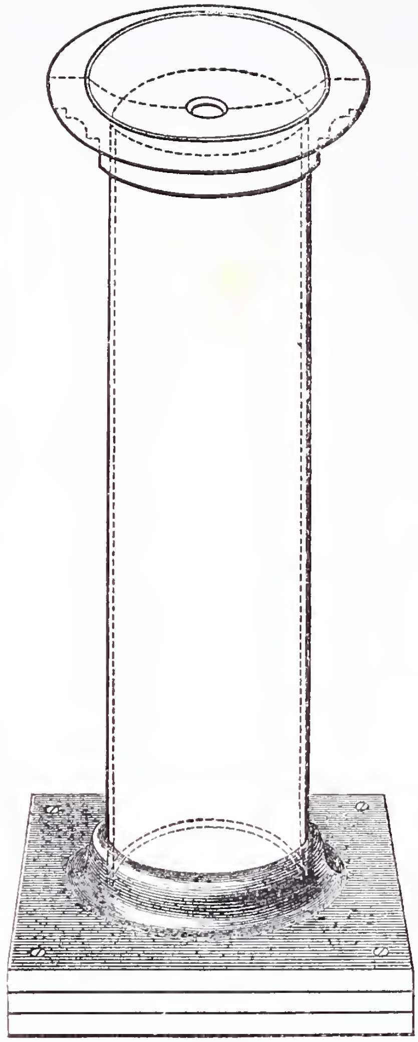


Fig. 1.—View of Simple Kaleidoscope, with Parallel Paper Tube (half full size).

same may be said of the object box; but if this is not desirable it may be made of a strip of tin plate $\frac{3}{4}$ of an inch wide, formed into a collar to fit outside the tube, and one edge turned over about $\frac{1}{16}$ of an inch all round to support a circle of ground glass cut to fit the interior; over this glass is placed a brass ring $\frac{1}{8}$ of an inch thick, neatly curved to the circle, and made to spring in somewhat tightly. The objects chosen are now introduced, and a circle of clear glass resting on the ring is laid over them; the box with its contents is then slipped on to its place, and by way of embellishing the tube and attaching the box to the same, a piece of wall paper of a small, neat pattern is selected and pasted over the whole length of the tube, the object box included. Now glue the cap to the paper cover and the instrument is complete.

Respecting the choice of colours, blue, green, and yellow will be found most suit-

Fig. 3.—Plan of Tube at Object End, with Object Box Removed (full size).

able, always selecting pale tints in preference to opaque objects. Colourless fragments may also be introduced, together with the coloured glass, with effect.

The symmetry and beauty of the picture or patterns produced, and consequently the pleasure derived from the contemplation of them, will depend principally on the degree of accuracy attained in adjusting the reflectors to the correct angle, which may be tested by having but one piece in the object box, large enough to occupy a considerable portion of the field, say one-third, when the observer will notice there are six views ranged round the angular point formed by the junction of the reflectors. Each section should then be apparently of the same size, and their adjacent edges coincide with each other. The images being reflected from the posterior surfaces of the reflectors, this interferes very considerably with the perfect form of the patterns, but this defect will be obviated in the instrument to be described in future chapters. This instrument, it may be said, is the invention of the writer, and will tend, it is hoped, to render the kaleidoscope of greater practical utility than heretofore.

OUR GUIDE TO GOOD THINGS.

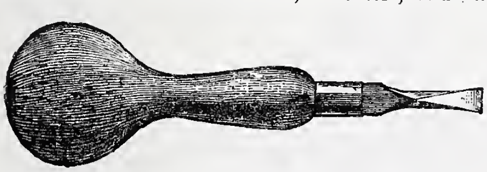
Introductory.

Many a workman, unfortunately, misses the chance of obtaining some special tool, machine, or appliance that may be of the utmost use to him in his particular calling, because he may not have seen it, or even heard of it, in the locality in which he lives. Show a man a new tool with which you have recently provided yourself, and it often happens that he will say, "Why, where did you get hold of this? It is the very thing I want, and just what I have been looking for I don't know how long!" And having learnt where the article on view may be had, off he goes, congratulating himself on his good fortune, and buys one at the earliest opportunity.

Now, it is in the spirit, and with the hope, of giving such useful and desirable information, week to week, to the readers of Work that "Our Guide to Good Things" has been set on foot—to make them acquainted, in fact, with the existence of new tools, machinery, appliances, technical works, etc., of which they might otherwise be still in ignorance: and, as it has been said elsewhere, to give timely notice of "all things useful and novel that manufacturers and inventors may produce in the interest of those who labour with the hands." That such notice may be beneficial to those whose productions and goods may be mentioned is obvious to all, but it must not be supposed for a moment that whatever may be advanced here is done in the interest of manufacturer or seller, with the view of directly recommending any particular article, and thus, perhaps, indirectly depreciating another. The names of makers, and of sellers too, must of necessity be mentioned, but in the case of the latter it will be rather to show who has been the first to give information respecting the tool or appliance described, than with any intention of bringing them prominently into notice as sellers of the goods described.

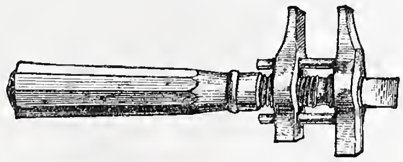
Further, in all notices of articles described in this part of the magazine, it will be sought rather to give a clear and accurate description of the tool, machine, or appliance under consideration, and to point out the purpose it is intended to serve, than to express any authoritative opinion respecting it, leaving it to each reader of Work to determine for himself whether or not it is the thing he needs, and if it be likely to prove of value to him.

Having thus cleared the way, as appears desirable, in order to avoid any misapprehension, let me ask all manufacturers, inventors, and



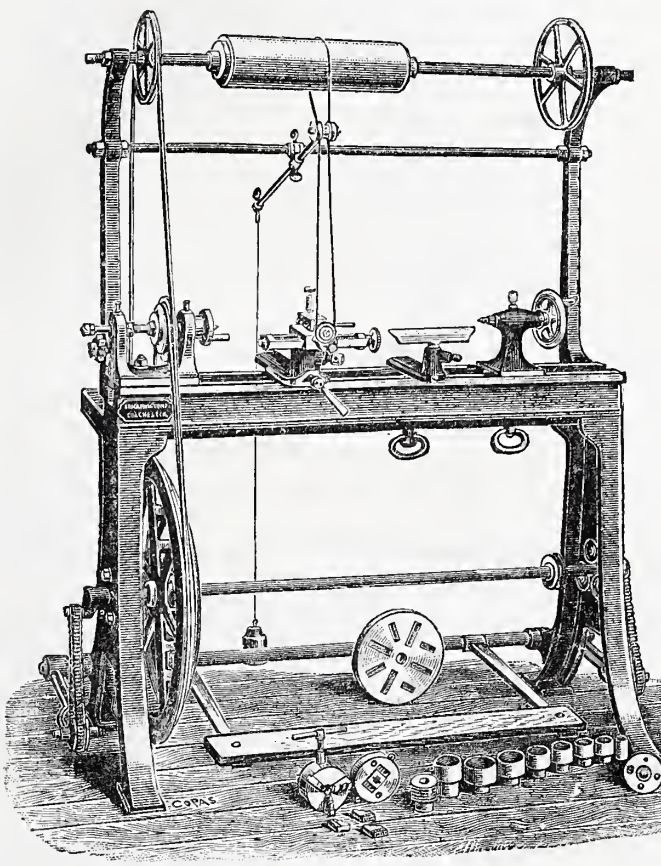
Handy Short Screwdriver.

patentees, under whose notice Work may come, to supply information with respect to their specialities, that they may receive early mention in these pages; and for the same end let me also ask all dealers, and readers of Work as well, to send information of any good thing with which they may become acquainted. In the case of small articles, which can be transmitted by parcel post, it is desirable that a specimen should be sent for inspection, as it is impossible to describe any tool clearly and accurately without seeing and handling it. With regard to machinery, lathes, etc., it is requisite that a full and complete description should be sent, or that arrangements should be made with the Editor for



Small Parallel-jawed Wrench.

its inspection, either by himself or by some competent person. In all cases it is of the utmost importance that an illustration of the article under notice should accompany the description.



The Britannia Company's New "Lukin" Lathe.

1.—The "Lukin" Lathe.

The first piece of machinery that offers itself for description in Work is the "Lukin" Lathe, a new and useful appliance for plain and ornamental turning, made from the design of the Rev. James Lukin, B.A., a gentleman who has long been known in the mechanical and engineering world as a reliable authority on lathes and everything connected with them. It is manufactured by the Britannia Company, Colchester, Essex, who will promptly answer any inquiries that may be made respecting it. The illustration given herewith affords a good representation of it, and from an inspection of this the reader may obtain a fair idea of its construction and general appearance. It is preferably made, however, either with crank and steel centres, or with improved roller bearings, so as to be readily accessible for cleaning and oiling.

It should also be noted that the lathe may be had constructed with inside cranks and hooks, with the axle upon hardened centres. These details, however, are altogether optional, and will be suited to the wishes of the purchaser.

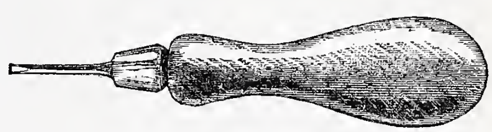
The lathe, as shown in the illustration, is said to be satisfactory in every respect. The beds are 4, $4\frac{1}{2}$, or 5 feet long, the length of bed being a variable quantity, so to speak; the centres are 5 inches high. The mandrel headstock is fitted with oil cups; the faces and edges are bright, and the rest japanned black. The mandrel is traversing, with the front neck 1 inch and the other $\frac{5}{8}$ inch, both working in collars of hard steel, or of phosphor bronze if preferred. Other dimensions are:—Width across face of bed, $4\frac{3}{8}$ inches; depth of bed, $4\frac{1}{2}$ inches; diameter of nose of mandrel, 1 inch; pitch of screw, 8 per inch; diameter of driving wheel, 27 inches. It will be understood from that which has been said above respecting the bed, that the lathe can be had in three sizes in this respect. It is also supplied with gap-bed if desired.

There are six formers, or guide screws, of steel, of the following pitches:—8, to fit the mandrel nose, 10, 12, 16, 24, and 30. These are fitted on in the usual manner, and work in a segment plate. By means of the traversing mandrel with the guide screws, threads may be cut upon telescope, microscope, and other similar fittings, in wood or metal, not exceeding the length of the guides.

The overhead is of the usual kind, with tension rod and pulleys, there being a hollow mahogany roller and a pair of cast-iron pulleys, that on the right being intended to gear with the small one on the crank axle, whereby a very slow motion may be obtained, which is sometimes desirable. The slide rest represented is of a very simple character, and, though good of its kind, is not intended to be taken as the best possible for the "Lukin" lathe, which can be fitted to order in this respect, according to the desire or the requirements of the purchaser.

The lathe was originally designed to meet the general purposes of amateurs who are fond of lathe work, and is therefore made of sufficient strength and substance to admit of rougher usage than usually falls to the lot of an "ornamental" lathe, properly so-called. Thus it will carry a 6 lb. jaw chuck or heavy 10 inch face plate, with large metal turning rest, and, at the same time, will execute fine eccentric work with the utmost accuracy. The range of its capabilities depends, of course, upon the chucks and fittings; but with a drill, eccentric, and vertical and horizontal cutter, an immense amount of beautiful work may be done.

For example, all kinds of plain turning in soft and hard wood can be done, such as boxes with or without screwed covers, tool handles, vases, egg cups, bread platters, butter dishes, needle cases,



Patent Brass-capped Bradawl.

spill pots, spice boxes, string boxes, ring stands, napkin rings, curtain rings, chair and table legs, pillars, plain or twisted, spindles for overmantels, brackets, etc., watch stands, chains cut out of the solid, metal spinning, etc. etc. All fittings can be screwed by aid of the traversing mandrel instead of being glued together, which is an advantage in many ways.

In ornamental turning, with an eccentric cutter alone, used with the division plate, all simple patterns of interlacing circles may be executed. With the vertical and horizontal cutter, basket and fluted work can be done. With the eccentric cutter alone, flat faces can be cut, as, for example, the flat sides of a hexagon or a cube, and also a perfect ball or sphere. With the drill, various perforated work of a highly decorative character can be cut, besides fluted work. By the addition of a spiral chuck and dome chuck to the lathe—appliances already mentioned—Elizabethan twist, spherical work, and such-like, may be included in the list of ornamental work done by means of this lathe.

In addition, any brass work, with screwed joints or otherwise, may be turned out, such as microscopes, telescopes, electric bells, the parts of model engines; and a variety of light work in iron and steel may be done, such as screws, nuts, and small bolts, and if castings are obtained the lathe will suffice for fitting up many pieces of mechanical apparatus, chucks, etc.

So much for the capabilities of the lathe, which it will be allowed are numerous and comprehensive. It only remains to afford a few particulars with regard to construction. The fittings of the fast headstock for ornamental turning have been already mentioned. A plain sleeve is provided, to be used in place of the screw former, when plain turning is to be done, or when screw cutting is only temporarily interrupted, a simple device being provided to avoid taking off and putting on screw guide and sleeve.

The cone pulley is made of gun metal with three or four speeds, and its front fitted with a division plate having three or more circles of holes of any selected numbers and a spring index point. A driver chuck and face plate are fitted.

The loose head or poppet is fitted with a steel tubular mandrel, coned at front end for centres and screwed at back end, and fitted with a left-hand square thread traversing screw, and bright turned hand wheel, and secured to the bed by a through bolt-and-bow nut and plate beneath. A plain hand rest, with T's for wood and metal, is fitted. The bed is of cast iron of strong section, without cross ribs to impede the free passage of poppet and rest from end to end, and with double flat face truly planed. It is mounted on strong cast-iron standards. The treadle is fitted with bright turned rocking shaft and cast-iron arms. The bright turned wheel shaft runs on friction rollers, and is coupled to the rocking shaft by chain and roller gearing. The heavy-rimmed driving wheel has three quick speeds and two smaller speeds for slow motion.

The lathe is fitted with a polished mahogany tool board at back. The ornamental overhead is constructed with strong rigid cast-iron vertical supports as shown, carrying the bright turned horizontal shafts. It has, as it has been said, a turned and polished mahogany drum or cylinder to slide along the upper grooved shaft, and driving wheels with tension rod and pulleys for adjusting the driving gut.

The price of the lathe alone, for plain turning, is £22 10s.; with ornamental overhead motion, £30. A plain slide rest in addition raises the price to £35, and an ornamental slide rest to £40 10s. These quotations are for the lathe with 4-feet bed; for longer beds or gap-bed a small additional charge is made.

2.—New Wire-thread Fret Saw.

I think the readers of WORK will be the first to hear anything about this New Wire-thread Fret Saw, which was shown me a few days ago by Messrs. Richard Melhuish & Sons, 85 and 87, Fetter Lane, London, E.C., and to which, for want of a specific title from the maker, we ventured to assign the above name. Literally this new fret saw is nothing more nor less than a piece of strong steel wire toothed on all sides at wide intervals between the teeth, and presenting the appearance of a piece of wire of extremely small diameter, barbed with small but exceedingly sharp points in every direction. Now the advantage of this peculiarity of construction is that the saw will cut in any direction, backwards, forwards, upwards, downwards, sideways, just as you will, *without any need of turning* the saw handle. Make a single hole with a drill, in the usual way, and insert the saw, and you may cut out the most intricate forms, going into as many points or curves as you will and back again without any palpable change of direction of the saw blade. It is a veritable novelty in fret-saw blades, and cannot fail, I think, to come speedily into favour with fret cutters. It is not possible to do more than make early mention of it here. The saw will, of course, be made in sizes like the generality of fret saws; but with regard to price, about which I particularly inquired, nothing definite is yet settled. Further notice will be given of this at the earliest opportunity.

3.—Small Parallel-jawed Wrench.

There must be few nowadays, it is fair to suppose, to whom a handy pocket wrench has not become a daily requirement, and especially for bicyclists and tricyclists. The Small Parallel-jawed Wrench figured in the preceding page is useful for a variety of purposes, and presents good points in its construction which are not to be found in others of its kind. In the first place, it is a composite tool, capable of acting as wrench, hammer, or screwdriver, as may be required, the projection at the upper end, above the wrench, serving as the last-named, and the upper jaw of the wrench, which, it will be noticed, projects slightly beyond the lower jaw, as the second. The jaws of the wrench are strengthened and kept in their relative positions by two stout bars fastened into the upper jaw, and passing through holes drilled in the lower jaw for their reception. The screw, which proceeds from the handle and passes through the jaws, is threaded in opposite directions, so that when turned one way it has the effect of drawing the jaws apart, and of bringing them together again when turned the other way. The jaws open to the extent of one inch when brought asunder to the utmost. The handle is of wood, and therefore more pleasant to handle on a cold day. The price of the wrench is 3s.

4.—Handy Short Screwdriver.

Without doubt many a workman has found the ordinary screwdriver very much in the way when he has been engaged in putting a lock on to the inside of the front of a drawer, and *vice versâ*—more particularly when doing the *vice versâ*, or taking the lock off, because this is generally done with the drawer in position—that is to say, in the table. The short screwdriver illustrated in the preceding page is well adapted for work of this description, and indeed for any kind of work in which it is necessary to insert screws with the blade of the screwdriver turned towards the workman. The handle being broad and flat is convenient to hold in the hand, and the blade is short and strong, and securely fixed in the handle by being deeply notched into the brass ferrule that is shown in the engraving, between the handle and the blade. This screwdriver is not mentioned as being absolutely new, for it has been in the market a year or more, but I do not think it is widely known, and possibly a knowledge of its existence may be useful to many.

5.—Patent Brass-capped Bradawl.

This is an improvement on the old form of bradawl, which only requires to be known to ensure its general adoption. In the old bradawl the tang of the blade was driven into the handle, and a semblance of strength was given to the tool by the ferrule, whether of brass or iron, with which the upper end of the handle was encircled; and frequently after a little use, when the bradawl has been thrust into a piece of wood somewhat harder than usual, handle and blade have parted company in a most aggravating way when it has been sought to draw it out again, the handle remaining in the operator's hand and the blade in the wood, from which it has been removed by other than the legitimate means. Such a catastrophe, however, may be averted by the use of the Patent Brass-capped Bradawl, in which the upper end of the handle is worked in such a manner into the brass cap that takes the place of the ferrule that the blade is secured in the handle so firmly that there is not the slightest possibility of any separation between the one and the other in the manner described above. Having used these bradawls myself, and found them far superior to the ordinary bradawl, I can recommend them.

THE EDITOR.

THE Society of Arts are offering prizes to Art workmen in the following classes:—I. POTTERY (INCLUDING PORCELAIN AND EARTHENWARE). 1. The Body, any material: *a.* Thrown, not shaved, first prize, £5; second prize, £2; *b.* Shaved or turned, first prize, £5; second prize, £2. 2. Decoration: *a.* Modelled and glazed, first prize, £10; second prize, £5; third prize, £3; *b.* Painted under glaze, first prize, £10; second prize, £5; third prize, £3; *c.* Enamel on the glaze, first prize, £10; second prize, £5; third prize, £3. 3. Stone salt-glazed ware: *a.* Plain; incised and glazed, first prize, £10; second prize, £3; third prize, £3; *b.* Coloured or otherwise decorated, first prize, £10; second prize, £3; third prize, £3. The Art workman must have designed the body of the pot as well as have executed the decoration. All the specimens of pottery sent in for competition must be dated on the clay. II. STONE CARVING. First prize, £25; second prize, £15; third prize, £10; fourth prize, £5. The capital of a column, with square, circular, or octagonal abacus, not to exceed twelve inches in width. III. WROUGHT-IRON GRILLES. First prize, £25; second prize, £15; third prize, £5. A grille measuring not less than three feet superficial, nor more than five feet superficial. The object for which the grille is intended must be stated—whether for a protective purpose, for the outside of a window, for a street-door panel, or for indoor use as a window screen, coil case, ventilator, etc. IV. GOLDSMITHS' AND SILVERSMITHS' WORK. [Prizes presented by the Goldsmiths' Company.] A cup or sugar basin of beaten silver, chased or otherwise, made within the year 1888, first prize, £20; second prize, £5. A pendant or brooch, or locket of gold without gems, first prize, £20; second prize, £5. All articles for competition must be sent in to the Society's House, John Street, Adelphi, on or before Tuesday, April 23rd, 1889. The conditions under which these prizes are offered can be obtained on application to the Secretary.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

POND'S EXTRACT

THE GREAT CURATIVE

Has no equal for allaying Inflammation and Hemorrhages, Rheumatism, Gout, Hemorrhoids, Wounds, Burns, Bruises, Cuts, &c. &c.

IN USE OVER FORTY YEARS!

***POND'S EXTRACT** is the only Proprietary Curative that is honoured with general Royal Patronage.*
We supply DIRECT the following Illustrious Personages:

HER MAJESTY THE QUEEN OF ROUMANIA.	Her Highness Princess of Nassau.
Her Royal Highness the Duchess of Cumberland.	Her Serene Highness Princess of Wied.
	His Serene Highness Prince Nicholas of Nassau.

PAMPHLET WITH MEDICAL TESTIMONIALS, &c., POST FREE ON APPLICATION.

Sold in Bottles only at 13½d., 2s. 3d., 4s. 6d., and 8s. 6d. Can be obtained of all Chemists, or of the SOLE PROPRIETORS:

POND'S EXTRACT COMPANY, LIMITED, 64, Great Russell Street, London, W.C.

CARVING TOOLS,

ARKANSAS SLIPS, &c.

We hold one of the Largest Stocks and most complete of any in London.

Rd. MELHUISH & SONS,

FETTER LANE, LONDON, E.C.

Prize Medal for excellence of

TAPS & DIES · VISES · TWIST DRILLS · CHUCKS · MACHINE SCREWS · LATHES · FILES · TOOLS · STEEL · S & S TOOL · STUBS

For all Workers in Metals, also Joiners, Wood Carvers, etc.

We hold the most complete Stock in this Country.

A PURE AND PERFECT ARTICLE FOR

TEETH, GUMS, & BREATH

PURILINE

Tooth-Polish.

"PURILINE" will Purify and Beautify the Teeth with a Pearly Whiteness; Polish the Enamel; Prevent Tartar; Destroy all living Germs; Harden and Invigorate the Gums and keep the Mouth in a delicious condition of Comfort, Health, Purity, and Fragrance. Non-gritty and Absolutely Pure and Harmless to use.

DIRECTIONS.—Rub the damp Tooth-brush freely across the "PURILINE." Use once a day or oftener. 1/- 1/-

PROPRIETOR, A. WILSON, 422, CLAPHAM ROAD, LONDON, S.W.

WHELPTON'S VEGETABLE PURIFYING PILLS

Are one of those pure Medicines which for their extraordinary properties have gained an almost **UNIVERSAL REPUTATION.** Recommended for Disorders of the **Head, Chest, Bowels, Liver** and **Kidneys**; also in **Rheumatism, Ulcers, Sores,** and all **Skin Diseases**—these Pills being **a direct purifier of the Blood.**

ESTABLISHED **1835.**

WHELPTON'S PILLS AND OINTMENT.

WHELPTON'S HEALING OINTMENT

Stands unrivalled for the Cure of **Cuts, Burns, Bruises, Ulcers, Sores,** and all kinds of **Skin Diseases.** A Specific for **Eczema.** *Burns, Scalds, Cuts, etc., happen when least expected—Be Prepared!*

Both Pills and Ointment are sold in Boxes, price **7½d., 1s 1½d.,** and **2s. 9d.,** by G. WHELPTON & SON, 3, Crane Court, Fleet Street, London, and all Medicine Vendors at home and abroad. Sent free by Post in the United Kingdom for 8, 14, or 33 stamps.

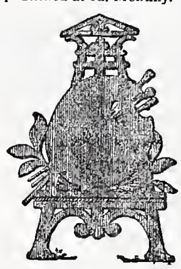
NOTICE!

"THE AMATEUR"

(ALL RIGHTS RESERVED).

Every Amateur and Professional Fretworker, Wood Carver, Painter, and Inlayer, who wishes to take a leading part in our Exhibitions and Prize Competitions, should not fail to subscribe to *The Amateur*, published at 6d. Monthly. Gold, silver, and bronze medals, diplomas of honour, certificates of merit, prizes, &c., for articles made from pattern sheets, published with *The Amateur*, and our German edition entitled *Der Dilettant*, have been awarded to many of our customers in all countries of the globe. Subscribers to *The Amateur* receive FULL explanation for putting the different articles together, which they will find most helpful, especially for the more difficult objects. The series of articles on fret, inlaid, carved, painted-work, and other similar domestic arts, appearing in *The Amateur*, are of a good, light, technical kind, concise, and to the point, and contain many new illustrations, hints, and much valuable information for lovers of our arts. Price of subscription, 6s. per annum, or 3s. half-yearly, post free to any part of the United Kingdom. May be obtained through all Booksellers. Specimen copy, 6d. free in English or Foreign postage stamps.



Mr. H. HOWES, Forest Gate, E., received a Bronze Medal at the Finsbury Polytechnic for a Picture Frame, published with *The Amateur* for 1888. Mr. EMIL LEDER, in Kukus, received a Silver Medal at the Agricultural Exhibition, held in 1887 in Német Palanka, Hungary. This is the second distinction conferred on our old friend and subscriber, having previously received a Gold Medal at an exhibition held at Kaaden, Bohemia, for articles made from pattern sheets published with *Der Dilettant*. Nos, 817 and 818, Easel, Photo-holder, Overmantel, and Handkerchief Box Fretwork designs, at 6d., post free. Catalogue 37 to 31, of Artistic Fretwork, Carving, Inlaying, and Wood-painting designs, Mouldings, Cabinet Fittings, Fancy Woods, Tools, Varnishes, Stains, Polishes, Machines, Clockworks, and every other requisite, with 900 engravings, 6d., free.

HENRY ZILLES & CO., Publishers of "The Amateur,"
24 and 26, WILSON STREET, FINSBURY, LONDON, E.C.

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

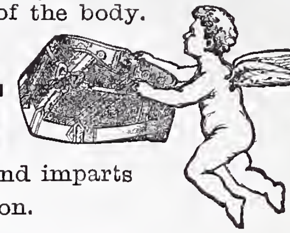
USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

NOTICE TO INVALIDS.

Men and women in search of Health, Strength, and Energy, should know that **HARNESS' ELECTROPATHIC BELT** will strengthen every nerve and muscle of the body. It is also unquestionably the best known Cure for **Rheumatic and Nervous Affections, Liver and Kidney Diseases, Ladies' Ailments,** &c.



HARNESS' ELECTROPATHIC BELT

Assists the Digestion, promotes the Circulation, stimulates the organic action, and imparts ***NEW LIFE and VIGOUR*** to the Debilitated Constitution.

BOOK of TESTIMONIALS, Descriptive Pamphlet, and Advice, free of charge on application to

The MEDICAL BATTERY CO., LTD., 52, Oxford St., London, W.

Guaranteed Genuine.

Our readers are invited to call and personally inspect the Belts before purchasing. NOTE ONLY ADDRESS AS ABOVE. *(Corner of Rathbone Place.)*

SPECIAL NOTICE.

WE ARE BONÂ-FIDE MAKERS OF 300 VARIETIES OF

LATHES, FRETSAWS, PLANERS, DRILLING MACHINES, VICES, &c. &c. &c.

Vol. I.—No. 2.] SATURDAY, MARCH 30, 1889. [Price One Penny.

A HOME-MADE DOG CHUCK.

BY OLLA PODRIDA.

Utility of Chuck—Materials—Cost—Proportionate Dimensions of Body—Mode of Making Chuck—Construction of Dogs.

The chuck about to be described will be found useful for almost every variety of work, and, as far as the needs of an average amateur go, it will compete successfully and compare favourably with its expensive descendant—the four-jawed expanding chuck. It is, in the form given herein, easily made—no patterns or special process being necessary—at home, and with a little practice will give entire satisfaction to the user.

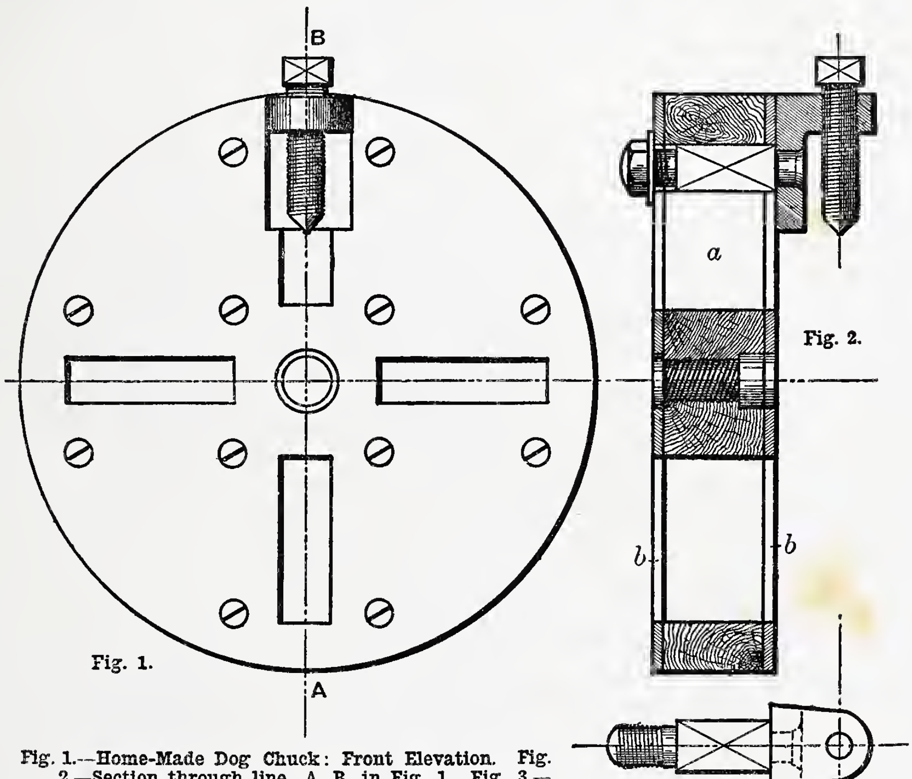

Fig. 1.—Home-Made Dog Chuck: Front Elevation. Fig. 2.—Section through line, A, B, in Fig. 1. Fig. 3.—Plan of Dog.

The materials required are within easy reach of every one, comprising a disc of hard wood for the body, some sheet iron for facing the front and back, and a few inches of square bar iron for the shanks of the dogs. The dogs may be made of angle iron or bent out of flat bar iron. The cost will, of course, depend on the size. For one about 8 or 9 inches in diameter the cost of materials would be about a shilling or eighteenpence.

Referring to the illustrations:—Fig. 1 is a front elevation showing the arrangement of the slots for receiving the dogs, which are four in number, one only being shown. Fig. 2 is a vertical section of the chuck through A, B, showing the construction more clearly. The thickness of this wooden part should not be less than $\frac{1}{6}$th of the diameter of the chuck; for example, a 9-in. chuck should have a body of wood at least $1\frac{1}{2}$ in. thick. The body or middle part, *a*, is of wood—box, beech, hornbeam, oak, mahogany, pitch pine, or other hard wood. This wooden part is faced on both sides with sheet iron, *b*, *b*, about $\frac{1}{16}$th or $\frac{1}{8}$th of an inch thick, secured by countersunk wood screws, as shown in Fig. 1. A plan of the dog is given in Fig. 3, but the construction will be better comprehended from Fig. 2, where it is also shown in section.

In making the chuck, first get a piece of wood of suitable size for the body, plane one side, and strike out the size with the compasses and rough out slightly larger to allow for turning. Bore and tap the centre to suit nose of mandrel; the thread, with care, can be formed by the mandrel nose itself if no suitable tap is at hand. By the way, every amateur lathesman should have a set of taps corresponding with the mandrel of his machine. Returning to the subject, the next thing is to prepare the sheet iron facing for the back by striking out a circular piece to the right size and marking out the slots, which must be cut before fixing on the wood. These slots must be drilled and filed out to suit the dog shanks; they must not be cut straight out with a chisel; by so doing the plate would be buckled beyond recognition. A hole must be drilled in the centre to clear nose of mandrel. The holes for screws must also be drilled and countersunk for stout screws; these screws to be rather less than half the thickness of chuck in length, so as to avoid fouling the others in front. The plate having been fixed, the chuck at this stage must be screwed on the mandrel and turned and faced truly. This done it must be removed and the slots cut through the wood by first boring holes through with a centre-bit, and shaping out the remainder with chisel, and rasp, or coarse file, care being taken that the slots, when finished, are square to the face. The plate may now be prepared for the front of chuck by cutting a piece to the size and marking the positions of the slots from the chuck by laying the latter upon the plate and tracing the outlines of the slots with a scriber, noting the position in which this is done so that the plate may readily be replaced in the position from which it was marked. The screw holes being drilled and countersunk the plate can be finally fixed, and in doing so the slots must be kept fair with each other. Trifling inequalities in these slots can be removed with a file after the whole has been put together. The periphery of the chuck can be turned up, and the clearing hole in centre of front plate bored in place. If convenient, a slight cut may be run over the face, but if the iron plate on the front has been well bedded this should be unnecessary. The chuck is now ready for the dogs.

These dogs are made of wrought iron. The shanks are formed out of bar iron $\frac{1}{2}$ in. square, rounded down to $\frac{3}{8}$ in. diameter at the back ends and screwed for nuts. The front ends are rounded to $\frac{7}{16}$ in. diameter, and the dog riveted on as shown in Fig. 2. Cold riveting will do, but hot is best, and a notch should be cut in one side of the hole so that when riveted on there shall be no tendency on the part of the dog to turn and become loose on the shank. In riveting, the shank must be held in a vice by the square part. The dog screws may be made from $\frac{7}{16}$ in. square bar iron, rounded down and screwed with conical points slightly flattened and case hardened, but the best job would be to make them of steel and lightly temper the points. The screws must be arranged so that they or the dogs may be reversed if required, and they must fit well in the holes. The dogs may be made by bending suitable pieces of flat iron, or they may be cut out of angle iron if the latter is obtainable. To avoid injury to work from the points of the screws, small pieces of iron, slightly curved for round work, and provided with a countersink on the convex side for the conical points of the dog screws, should be interposed. The dog screws should always be kept short, or project as little as possible between the dogs and the work, so as to avoid injury to them by bending.

Other uses might be suggested for this form of chuck, such as providing it with a few extra holes between the slots so that work might be bolted on to it or otherwise attached than by the dogs, which, of course, can at any time be removed; but, as space is limited, I leave such to the ingenuity of the worker, which, especially if sharpened on the grindstone of necessity, will readily adapt the circumstances to his needs.

LATHES AND TURNING APPLIANCES.

BY F. A. M.

I.—Introductory.—How to Choose a Lathe.

Man has been described as "a tool-making animal." He is probably the only animal with brains enough to enable him to see the value of tools, and with dexterity enough to make and apply them. If any one doubts the value of tools let him for a moment imagine what would be our condition without them, and he will very quickly be convinced that were we confined to our teeth and nails, and allowed to use no other implements than these, we should have to return to the existence of the most degraded savages. Gold, jewels, and rich robes, etc., may be precious, but far more precious still are tools. Look with respect, then, gentles, at the carpenter's bench and basket of tools, at the blacksmith's anvil and vice, for you could more easily dispense with your carriages and horses, your houses and parks, than you could do without these.

All work but the most mechanical is done with tools, therefore Work will be constantly occupied with them. A man may turn a crank without a tool, but this sort of work employs his muscles alone, his animal nature; and it is more and more left to animals and to the forces of nature.

Now of all tools the lathe is the king. Much as the steam engine has done for humanity, the lathe has done far more, and without it both the steam engine, and almost every other machine, would be impossible. Parents, do your boys trouble you in the holidays by knocking nails into the doors and carving their names on the gate? Perhaps you never considered they have an instinctive desire to use tools. Send them for an hour a day to a carpenter, get them some tools other than the pocket-knife, and set apart an outhouse, or a dressing-room, as a workshop for them; if they take to it, and work with perseverance, buy them a lathe.

I will here stop to confess that I am something of an enthusiast on the subject of the lathe, and I had better say so, lest my readers should fail to discover it. My own dear father gave me a lathe when I was fourteen years old; I climbed a high tree that looked along the road, and stayed there about three hours, watching for the cart which was to bring it from the station. It was a very suitable boy's lathe, costing £5; all iron, 3½ in. centres, and 3 ft. long. I have it now; it has been a great pleasure to me, and is so still; never were £5 better spent!

Before going into the general question of "How to Choose a Lathe," I may say here that, for a boy of fourteen, I do not advise an expensive lathe, lest the desire to turn should not prove permanent; besides this, a boy's small lathe will always be useful in after years, even when the turner has a more expensive one, a second and smaller lathe being a great convenience. As I intend to mention the names of several manufacturers in connection with the work in which I think they excel, I may say here that for a boy's lathe of the size here mentioned I should go to Charles Taylor, of Edmund Street, Birmingham, whose price is £4 15s. He supplies a small slide rest to suit for £2 18s., and a complete turning outfit, comprising 3½ in. centre lathe, slide rest, chucks, tools, and drills, for £11. With this outfit a boy might set to work at once upon small nicknacks, boxes, chess-men, etc. etc., in wood; and if in addition be added a 10s. 6d. parallel vice, and some files, taps and dies, rhymers, etc., he could fit up a model engine.

Let us now approach the question, "How to Choose a Lathe," from the grown-up amateur's, or mechanic's, point of view. It is a wide question, since the *kind* of lathe depends on the *kind* of work to be done with it, and the *quality*, or perfection of the lathe, on the depth of the purse. I can only hope, then, to offer such remarks as may enable my readers to choose for themselves according to their own requirements. Remembering, then, that we are dealing with foot lathes exclusively, we may say they can be broadly divided into two kinds, viz., those for turning wood, and those for turning metal; also some desire to combine the two.

Wood Lathes.—Suppose a carpenter, or cabinet maker, wishes to take up turning, he should look to three things—first, he will want high centres and a long bed, say 7 in. or 8 in. centres, and a bed that will take in work 4 ft. or 5 ft. long; second, he will want an easy-running lathe, therefore the mandrel must be of small diameter in the neck and run on a back-centre screw behind; third, he should have a mandrel of a good length, say 8 in. to 12 in. long, from collar to hinder end. A wood-turner's lathe must run fast, and if the bearing surfaces of the mandrel are large it will drive hard. You cannot tell whether a lathe runs easily by simply putting the foot on and driving it round, unless at the same time you notice how many times the mandrel turns to each turn of the crank, or, in other words, what is the speed ratio of the pulleys. A proper speed ratio for wood turning is 8 to 1, and at this speed the lathe should run easily or it is not fit for wood turning. This it will not do if the collar of the mandrel is more than 1¼ in. in diameter and ¾ in. long, or it may be 1 in. long by 1 in. diameter. The mandrel neck and collar should be perfectly hard so that no file will scratch them. I once bought such a lathe, for a workman friend, for £2; it was second-hand, and rough to look at, but very useful and light to turn; it is, no doubt, a bargain, but such lathes are to be met with for £3 or £4. A carpenter could make the frame of the lathe himself, and buy the headstocks, rest, wheel, and crank axle. This sort of lathe would be a workman's tool—for use, not for show. A wood turner may very likely wish to put his work together with screws, and to produce screws in the lathe he will probably require a traversing mandrel. Writing from Tunbridge Wells, where such things are used, I may say the turners here pay a high price for a traversing mandrel and collar, and these they mount themselves in a wooden headstock. The makers of ornamental turning apparatus make very beautiful lathes with traversing mandrels—quite works of art—but they are very expensive. I do not know that a good traversing mandrel can be obtained at a moderate price, but the Britannia Company have lately brought out a lathe with traversing mandrel and overhead motion, called the "Lukin Lathe," a notice of which, with an illustration, will be found in page 13 (No. 1) of this Magazine.

A good lathe for wood can be obtained from J. Buck, of 56, Holborn Viaduct: 5 in. centre, £11 15s. This would have no traversing mandrel; it would be of iron, and would not have the capacity of the wood lathe first described, but it would be better-looking. Buck's next quality "best lathe," with divided pulley and very well finished, costs £19 5s.; but if one requires a traversing mandrel and overhead motion the price rises to £65, and you get a fine tool, fit for ornamental turning when the requisite apparatus is added. These lathes could have slide rests fitted and be used for *small* metal work, though, as they are intended for wood, they have no back gear, and therefore could not well deal with iron of over one inch in diameter.

Metal-turning Lathes.—We will now turn to those lathes which are intended for turning metals. Now, metals require a much slower speed; also a slide rest (of no use for wood) becomes almost a necessity. These lathes, then, are fitted with back gear and slide rest. They will turn wood, but not conveniently, because they are made for slower speeds than wood requires. Metal-turning lathes are made in great quantities, and the price has been reduced, by competition and improved methods of manufacture, to what would have been deemed incredible some time ago. Moreover, in this direction our English manufacturers appear to hold their own. Supposing, as before, that a workman wished for an iron-turning lathe of about 5 in. centre with slide rest and back gear, he would find a great number of makers ready to supply him. Perhaps the first thing he had better do would be to obtain "The Metal-Turner's Handbook," by P. N. Hasluck; because there he will have in a small compass illustrations of the work of some of the best known English makers, with short descriptions and prices. If the lathe is to be a slide lathe with saddle and leading screw, then, if a *small* lathe be required of 3½ in. centre for model engine making, or electrical work, etc., there is nothing to beat the Britannia's Company's No. 14 lathe at £18 18s. For larger sizes, perhaps Milnes of Bradford may be preferred; his 5 in. slide lathe, with hardened collars, cut gears, and full set of 22 change wheels, is £26. It is possible to get such a lathe for £20, but it is not desirable, unless it were second-hand, for the work could not be properly done for that money. Such a lathe as that some years ago would have cost twice as much. Buck's price for a similar tool is £34 10s., whilst Whitworth's would be about £80, and would be more accurate—or should be; but these lathes of H. Milnes and the Britannia Company are fairly accurate, and suitable both for workmen and for amateur engineers.

We come now to consider the requirements of amateurs who like variety; they like to buy very beautifully finished and accurately made apparatus, and to be able to congratulate themselves on the wonderful and curious shapes and curves they *could* produce. Then, perhaps, the lathe room is wanted for something else, or the owner removes, and the lathe is sold for half its value, slightly rusty, perhaps, and the lacquer scratched, but with much of its apparatus still unused and destined to remain so even if it pass through twenty hands. Yet, though they often do not use the appliances they have, amateurs have a way of wanting still more and more combinations, more and more possibilities in their lathes. An ornamental turning lathe will only deal with small metal work, and a metal-turning lathe is not suitable for ornamental work. The best way out of the difficulty would be to have *two* lathes, each perfect for its particular purpose; and some adopt this plan. But some still wish to combine the two objects, and this can be done to some extent. An ornamental lathe, which means a lathe intended for ornamental or complex turning, is a very beautiful piece of work, and very expensive. There are only some five or six makers of this class of work, and it is not wise to order it from any ordinary maker who might think himself able to produce it. First comes the plain part of the lathe as the foundation; it has usually a wooden frame and an iron bed, and should have a traversing mandrel; this plain part alone costs about £60. Then comes the various apparatus: the slide rest £28, the overhead motion £10, the various expensive chucks and cutting frames, and the box full of beautiful little moulded turning tools, with goniostat for sharpening them, which soon brings the amount up to £100, about the lowest price at which a lathe and apparatus for ornamental turning can be obtained new. If the complete set of apparatus is required, the price goes up to £500 and more; in fact, there is no end to the curious and ingenious appliances that can be added to the lathe; a geometric chuck may cost £100 alone.

The old-established firm of Holtzapffel and Company, of 64, Charing Cross, were formerly without a rival in the business of making lathes and tools of the highest class, and some still put them first, as they are certainly the most expensive, numbering amongst their customers peers of the realm. J. H. Evans, of 159, Wardour Street, comes next, and some put him first; he has adopted some more modern methods, and his prices are a little lower. Then come Messrs. G. Birch and Company, of Salford, Messrs. Cooke and Sons, of York, and Messrs. G. Plant and Son, Nelson Street, Birmingham, who make good lathes, and the speciality of the latter is the geometric chuck which bears his name. Evans, Birch, Cooke, and Plant have made lathes in which both metal and ornamental work could be done. Birch makes the medallion machine invented by Mr. Jesse Lowe, by means of which very beautiful work can be done, and also a rose-engine arrangement by the same inventor. Quite lately, a new firm, The London Lathe and Tool Company, 37, Pomeroy Street, London, S.E., has been established, and are making very good lathes for scientific and ornamental purposes, of modern design and at somewhat lower prices than formerly prevailed.

My readers will find that if they go to the makers of metal-turning slide lathes, such as Milnes or the Britannia Company, they will get far more for their money than if they go to the regular makers of amateurs' lathes for wood or ornamental turning; but I warn them that however well such lathes may be suited for metal work, they are too heavy and hard to drive for wood. Perhaps, however, one way out of the difficulty would be to order a 5 in. slide lathe made with a small or light mandrel with shorter collars, so that it might run more easily and thus be more suitable for wood; but then it would be less fit for metal work. Also, in turning wood upon a slide lathe, the slide rest, etc., must be got out of the way, and the cogs of the back gear and other parts which are so useful in metal turning are apt to get filled with chips.

Having now gone through all that need be said about the *kind* of lathe, before passing on to advise my readers as to how they may test the *quality* of the workmanship of any lathe offered them, I wish to advise them to obtain one or two of the numerous books on turning, as this will greatly help them in coming to a decision.

First and foremost must be mentioned the best work of all, Messrs. Holtzapffel's "Turning and Mechanical Manipulation," in six volumes, five of which are published. The first three volumes are on: I. Materials; II. Cutting Tools; III. Grinding Processes; full of interesting and very clear descriptions of all kinds of mechanical manipulation. With Vol. IV. we enter upon turning proper, its subject being Plain Turning; its price is 25s. Vol. V. treats of Ornamental or Complex Turning; it is full of most beautiful plates, and its price is 30s. There is nothing equal to these books. I will mention some less expensive works in my next paper.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

II.—Preliminary Exercises.

For reasons which I shall state hereafter, in the chapter devoted to a review of the alphabet in its relation to sign writing and lettering, it is very essential that some practical knowledge should be obtained of freehand drawing and geometry. A little only is better than none at all; but the more the student learns the more will he be a master of his art. There is no necessity to dwell at length upon them here, so I shall confine myself to a few examples, in which it is absolutely necessary for the student to become proficient before he can hope to make correct formations of each individual letter of the alphabet.

In the first place, he must learn to draw in a bold, fearless style lines straight, horizontal, perpendicular, and oblique; and afterwards graceful curves. It must be understood that I am commencing with a short series of drawing lessons, so that the student should provide himself with a few sheets of common drawing paper, an HB. pencil, and a piece of indiarubber. The paper should be pinned to a drawing board, which may be purchased for about one shilling. The lines I have mentioned are the first exercises in freehand drawing, and, until these are thoroughly mastered, it is useless to attempt to proceed further.

To do good work at the outset of his career the draughtsman's pencil must be properly pointed—that being the first tool he will handle. This being accomplished, let him endeavour to draw a perpendicular straight line, A, in Fig. 1. This may be done the more easily by first marking it out as a dotted line, B, and afterwards filling it in with a firm, decided stroke from top to bottom. Horizontal and oblique lines are to be practised in the same way as shown in the examples C, D, E, in Fig. 1. Lines should also be drawn to meet each other at right, acute, and obtuse angles, as illustrated at A, B, C, in Fig. 2. The practice of drawing lines parallel to one another (Fig. 3) should also be persevered with. The student must next pay attention to curved lines, A, B, C, D, E (Fig. 4), and compound lines (Fig. 5), which may either be continuous or broken; and, following these, the circle and ellipse (Figs. 6 and 7) must be taken in hand.

Great patience, I am aware, is necessary in this, the initial and most uninteresting stage of our work; but this virtue, if persevered in, will be amply rewarded in the near future. In order to give more variety to the drawing lessons, the learner may presently proceed to copy, until perfect, such subjects as are shown in Figs. 8, 9, 10, all of which immediately concern the subject we have uppermost in our minds As they are merely given as copies for incessant practice, they need no further description. These should be followed on with the alphabet drawn within faint-lined squares.

It will be helpful here to give descriptive definitions of those geometrical terms which the sign writer has most cause to make use of in his daily work:—

1. A *point* is a position in space which may be indicated on a plane by a simple mark or dot, or the intersection of two lines, or the extremities of two lines.

2. A *line* is an indication of division, or boundary generated by the motion of a point, and has only the property of length. There are straight or right lines, curved lines, and compound lines—the latter composed of right and curved lines. Compound lines are "continuous" when the curve continues the right line; and "broken," when the right and curved parts of the line form an angle. (See Fig. 5.)

3. When two right lines meet in a point, they form an *angle*, which is an indication of a portion of the space round the point; this space is, for the purpose of measurement of angles, supposed to be divided into 360 equal parts, called degrees. The length of the lines forming the side of the angle has nothing to do with its measurement. When two lines cross in such a way as to form four equal angles, they are said to be at right angles, or perpendicular to each other; an angle of one-fourth of the space, or ninety degrees, being called a right angle. An angle that contains less than a right angle is called acute; and an angle that is greater than a right angle is called obtuse.

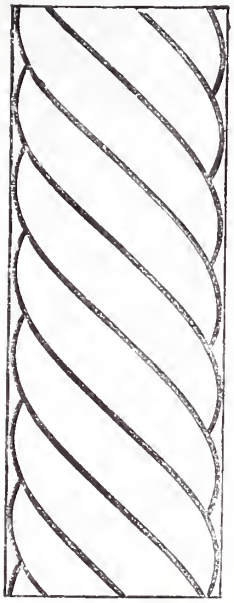
4. Lines that are at an unvarying distance from each other, and thus would never meet if continued in either direction, are said to be parallel to each other.

5. A line, or combination of lines enclosing space, constitutes a *figure*. *Figures* are either rectilinear—composed of right lines; or curvilinear—composed of curved lines.

6. Right-lined figures are divided into *triangles* or *trilaterals*, having three sides; *quadrangles* or *quadrilaterals*, having four sides; and *polygons* or *multilaterals*, having more than four sides.

7. An *ellipse* is a figure of one continuous curve generated by the motion of a point in a plane, the sum of whose distances from two fixed points is always the same; these fixed points are called the *foci*. A right line drawn through these foci, and produced to the curve at both ends, is the *major axis* of the ellipse; and a line through the middle of the transverse diameter, perpendicular to it and extended to the curve on either side, is the *minor axis*, or diameter conjugate to the transverse. The point of intersection of the axes is the centre of the ellipse; and

Fig. 8.—Example of Freehand Drawing—Coil Round Pole.



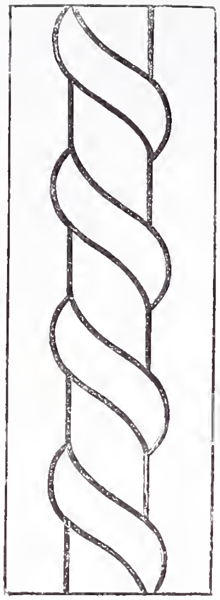


Fig. 9.—Example of Freehand Drawing—Twist as in Cable.

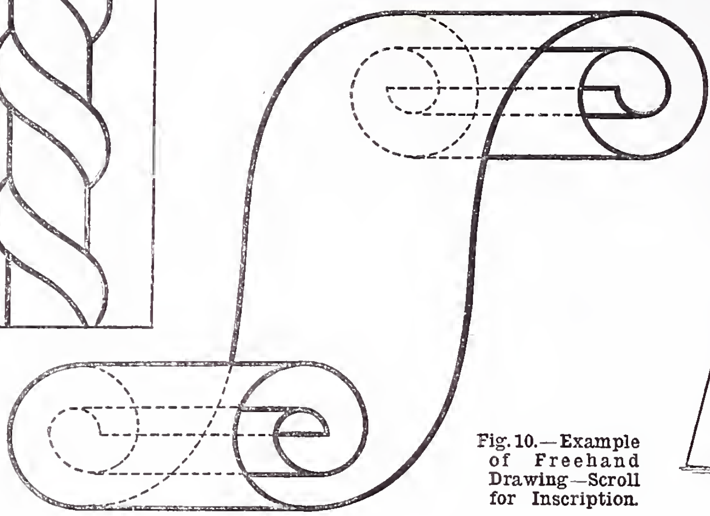

Fig. 10.—Example of Freehand Drawing—Scroll for Inscription.

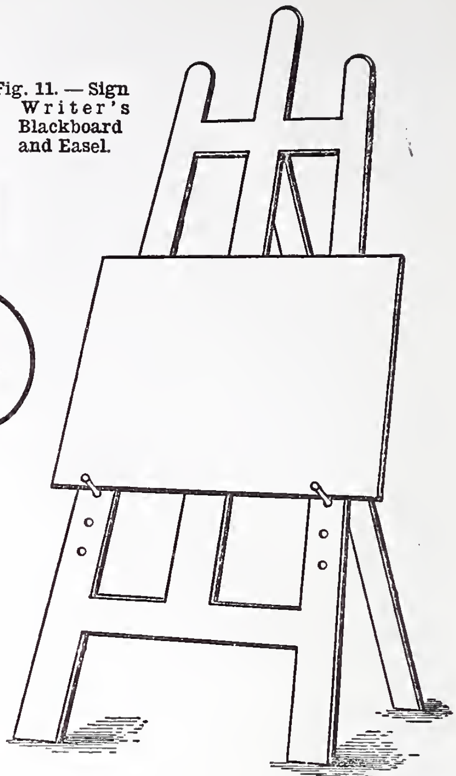
Fig. 11.—Sign Writer's Blackboard and Easel.



any right line drawn through the centre cuts the ellipse in two equal parts, and forms a diameter.

I have not the space here to give any geometrical problems; but it is advisable for the learner of the art of sign writing to obtain a good work on geometry, and carefully work out all those problems which are likely to prove most serviceable to him in his work. The elementary problems are those which he will find most useful.

As he will have occasion to make use of a blackboard for future lessons, I at once give directions for making one similar to the board shown in Fig. 11. Procure from the timber merchant's a good yellow deal board measuring 10 ft. long by 9 in. wide by $\frac{7}{8}$ in. thick, and thoroughly dry and well seasoned. Also another board of the same wood, 12 ft. by 9 in. by 1 in., for providing the legs and cross pieces of the stand, as shown in the illustration.

Take the first board, and, having squared both ends six inches from the outside, saw those off, and then saw the board into three equal lengths of 3 ft. each; these three lengths should then be tongued and grooved in a workmanlike manner, glued, and clamped up until dry.

The framework, consisting of the two legs, the centre piece, and the two cross pieces, should then be put together with mortise and tenon joints, and this finally well screwed on to the back of the boards, and the hind leg attached with an ordinary "butt" hinge. The board must now have several coats of paint, containing plenty of dryers, and must be allowed to rest and be well sand-papered between each coat. When thoroughly dry it is fit for use, and should be in constant demand throughout the painter's lifetime for freehand sketching, lettering, and working out original designs that may suggest themselves.

If preferred—and this arrangement, possibly, will be found to be more convenient—the frame may form an easel, as shown in Fig. 11, the board being supported on pegs inserted in holes in the framework.

WHY DOES A TOOL CUT?

BY J. H.

I.—Requisites in Cutting Tools—Strength and Support—Angle of Relief—Face—Practical Limit of Acuteness—Limiting Angle for Cutting Tools.

To some this may seem a stupid question, to which the obvious answer would be, "Because it is sharp." But that this is not a sufficient reply is apparent on a little consideration. Take a common wood-working chisel and try to cut a piece of iron or steel with it; the edge is turned over and spoiled directly. It fails to cut the iron or steel, not because it is not sharp enough, but because it is not *strong* enough; the form of the tool is such that it is too weak to do its work; in other words, the cutting edge lacks *support*.

It would, I imagine, be impossible in the absence of experience to predicate beforehand by a method of *à priori* reasoning what forms should be imparted to cutting tools in order to render them most suitably adapted for operating on materials of different kinds. A tentative method would have to be followed, and the tool-angles would have to be gradually increased until a happy mean was reached at which a reasonably permanent cutting edge should be secured. No such edge can be absolutely permanent, but in practice the tools used for metal working require, as a rule, regrinding and sharpening less frequently than those employed on the softer woods. This may appear paradoxical, but it is necessary, since it would be highly inconvenient when turning or boring work by slide rest which is required to be strictly parallel to have to remove the tool for grinding before the operation were finished.

When we have grasped the fact that *strength* is as important an element as keenness of edge, we may easily fall into error in the disposition of the necessary metal. We might so form our tools that they would be sufficiently strong, yet cease to act except by scraping. I will endeavour to render this matter clear by the aid of a few diagrams.

If we note the action of the chisel in Fig. 1, we see that the bevelled facet, A, is ground to make that angle with the lower face which happens to be best adapted for the removal of the largest quantity of material with the least expenditure of energy.

If the same chisel were presented to metal it would fail to operate. To make it cut metal, the angle of the facet would have to be increased in a tentative fashion (Fig. 2) until, say, for cast iron A would equal about 60°, and then, if thrust with sufficient force, it would cut after a fashion, because the cutting edge would be rendered sufficiently strong to withstand the stress imposed upon it. Actually, the tool used in practice would take the form of Fig. 3, in which the principle of Fig. 2 is embodied with certain necessary modifications. Let us look at this for a moment.

First, the absolute coincidence of the face of the tool with that of the work, which usually occurs in the wood-working chisel, would, when the contact of metal with metal is concerned, generate much friction and heat, with accompanying waste of power. The tool is therefore "relieved," or "backed-off," and the angle, B, in Fig. 3 is the "angle of relief," which is imparted to that extent which is necessary to prevent this injurious contact from taking place. By men ignorant of the principles of tool formation this angle is often unduly increased, and the consequence is that the cutting edge is much weakened by the unnecessary removal of the metal which is properly wanted to afford support to that edge. To take extreme cases, suppose the angle of relief were increased as in Fig. 4, it is obvious that the edge could not retain its permanence any better than that of the wood-working chisel when used on metal. Or, suppose the wood-working chisel to be thrown up at the angle indicated in Fig. 5, and thrust forcibly to its work by some strong coercive guidance—as the stock of a plane, for example—the edge would become blunted even on wood, and instead of chips or shavings being removed, fine dust only would be scraped off. We therefore find that we have not only to impart the angles

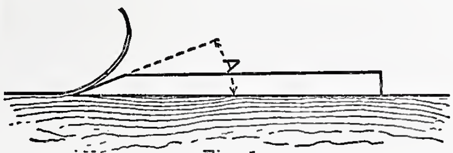

Fig. 1.

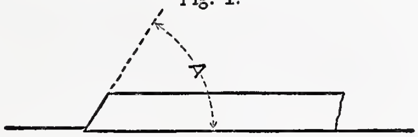

Fig. 2.

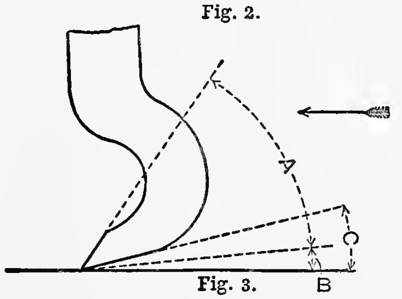

Fig. 3.

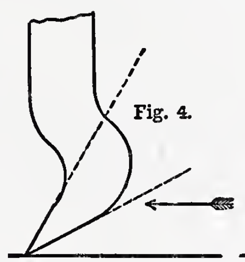

Fig. 4.

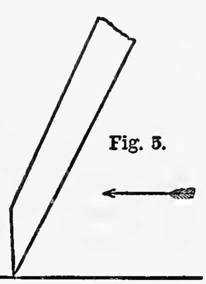

Fig. 5.

Fig. 1.—Wood-working Chisel. Fig. 2.—Angle necessary for Cutting Iron. Fig. 3.—Common Form of Tool for Planing or Turning Iron. Fig. 4.—Tool Badly Formed for Planing or Turning Iron. Fig. 5.—Diagram to Illustrate Improper Presentation of Chisel.

most suitable for cutting harder and softer materials respectively, but that we must, in order to diminish friction, have an angle of relief, whose amount, however, ought to be no more than sufficient to prevent rubbing of surfaces from taking place. The angle, C, in Fig. 3 is merely the angle at which the tool is roughly forged.

We may put this in another way, and say that the face of the tool ought always to approximate as nearly as possible, consistently with freedom from friction, with the face of the material which is being cut. After this, the settlement of the angle formed between the top and bottom faces is a matter to be determined by experience. But we may also say of this top face, too, that the nearer it can be made to coincide with the face of the material which is being operated on, the more perfect will be the action of the tool considered as a wedge. For all cutting tools, however uncanny their appearances, are in fact wedges, and operate by virtue of their wedge-like forms. The practical limit which determines the acuteness of the angles is the *permanence* of their edges. Hence, the harder the nature of the material, the more obtuse will be the angles of the tools. In the soft wood-working chisel, and spokeshave, and planes, the tool angles, A (Fig. 1), will vary from 15° to perhaps 25°. In the tools for turning the harder but fibrous wrought iron, the angle, A (Fig. 3), will be increased to about 50°. The tools for the still harder and more crystalline cast iron require to be ground to an angle of about 60°, while cast steel will often only yield to cutting tools whose angles are slightly more obtuse than this, or 65°.

We now approach the limiting angle for true cutting tools, namely, 90°. Yet there are materials, such as chilled iron and some kinds of steel which cannot even be cut with a tool, whose angle is as high as 65°; they, will only yield to a tool which is presented at an angle of 90° or thereabouts to them. But such a tool is no longer a wedge; it operates by scraping only.

To sum up, in order that a tool shall cut wedge-like action is necessary. But the degrees of acuteness of the wedges have to be widely modified for the operation of softer and harder materials, in order to afford sufficient permanence of cutting edge. The increase of metal imparted for this purpose must, for reasons of strength, be disposed as far as possible behind the cutting edge *in the line of action of the tool.* This cannot be absolutely the case, because of the amount of the angle of relief, which is necessary for clearance between the tool and the work; but this is the reason why the angle of relief should be kept as low as possible. These are axioms in tool formation, no matter how widely the shapes of the tools themselves vary. Practical conditions, however, often render such modifications necessary that the original idea or type becomes so disguised as not to be apparent at first sight.

Another matter, which has a marked influence on the action of a tool, is the frictional resistance of the shaving removed. Diminution of friction conduces to increased efficiency, and this is dependent partly on the nature of the material, partly on the angle of "top rake"—*i.e.*, of the upper face. Tools used for removing tough, fibrous material, such as wrought iron and mild steel, require a much greater amount of top rake than those employed on brittle cast iron, gun metal, and brass. In fact, in operating these alloys, whose shavings are highly crystalline, tools having no top rake at all—mere scrapes, whose faces stand perpendicularly to the work—are used. If such tools were employed on materials of the character first named, the continuity of the tough curling shavings would be very forcibly broken against the perpendicular face, and not only would a very wasteful excess of power be required to operate these tools, but it would be simply impossible to remove material in quantity. Giving ample top rake, however, the shavings curl down the top face, partly fractured, but with more or less of continuity remaining throughout their length.

In my next I will complete this subject by pointing out the application of these principles in the case of the common tools used for wood and metal working.

(To be continued.)

THE BUNSEN BATTERY.

Its Construction and Application.

BY GEORGE EDWINSON BONNEY.

II.—Acid—Solution for Outer Cell—Effect of Nitric Acid in Solution—Charging Battery—Chemical Action—Connection of Cells—Measurement of Power of Battery—Time of Running—Maintenance of Battery—Double Fluid Bichromate and Chromic Acid Batteries.

The acid employed in the porous cell of the Bunsen battery, with the block of carbon, is the strongest commercial nitric acid or aquafortis undiluted. This will cost from 6d. to 8d. per lb., if bought in large quantity.

The solution for the outer or containing cell of the battery, with the zinc, is made up of commercial sulphuric acid (oil of vitriol) diluted with water in the proportion of one part acid to 8, 10, 12, or 15 parts of water as may be desired. This acid will cost from 2¼d. to 2½d. per lb. In buying from a respectable dealer there is little danger of getting bad acid, but I may point out here some of the impurities likely to interfere with the working of a battery, and the means for their detection.

If the acid contains any nitric acid the zincs will be violently attacked, the amalgam undermined, and the plates or cylinders will be honeycombed. Filling the porous cell above the level of the outer solution, a flaw in the cell, jolting of the cells, and similar accidents will get nitric acid in the outer solution. If this is tested with a few drops of indigo sulphate solution, the presence of nitric acid will be shown by the colour of the indigo solution being changed from blue to red. If the sulphuric acid or its solution contains any copper, this metal will deposit itself on the zinc amalgam, form a galvanic pair, or short circuit with the zinc, and wear pits in the cylinder. The presence of copper is easily detected by immersing a piece of bright steel, such as the blade of a knife, in the acid or its solution, when a film of copper will show itself on the steel if copper be present. Zincs thus pitted are only cleaned and reamalgamated with difficulty.

In making up the outer solution, first put the requisite quantity of water into a stoneware pitcher, then measure out the acid, and pour this gently into the water. Never pour water *into* sulphuric acid, for it combines with water in such a violent manner as to cause great heat, and the boiling mixture is spurted about in all directions. It will cause painful blisters and sores if splashed on the skin, and will ruin any kind of clothing. Let the mixture get quite cold before using it to charge the battery.

All things being now ready we will charge the battery. First rinse the cells with water. Place the carbon block in the porous cell and the zinc cylinder in the outer cell. Fill the porous cell with strong nitric acid to a height equal to that intended for the outer solution; then place the cell and its contents in the outer cell. Fill the outer cell with the dilute sulphuric acid solution, pour a teaspoonful of mercury into each cell; then put on the binding screws and clamps.

As soon as the circuit of the battery is closed—that is, when the free zinc at one end is connected by a wire, or through the working line, with the free carbon at the other end—a chemical action and interchange of elements take place within the cells and set up a general movement in the whole circuit. The force thus generated is named electricity. The action going on in the cells is probably as follows:—Small particles of the zinc become oxidised, and the oxidised zinc is taken up by the sulphuric acid to form zinc sulphate. In this action a part of the hydrogen found in sulphuric acid is set free and is sent into the inner cell by the current. Here it would fix itself to the carbon and check further action if it could not be dissolved; but it is met in the porous cell by part of the oxygen present in the nitric acid, and unites with it to form water. In this way the nitric acid loses a part of its oxygen and becomes nitrous acid.

The cells may be connected up in one of two ways to form a battery. Connect the carbon in one complete cell with the zinc in the other cell by means of a short wire, and continue to connect up the whole in line one after another until they are all linked together, with one free zinc at one end of the line, and a free carbon at the other. This is termed connecting up in series, and is employed to get an intense current capable of overcoming high resistance, such as there would be in an electric lamp or an induction coil. By this arrangement the electro-motive force (generally expressed in print by the abbreviation E.M.F.) of one cell is added to that of the next, and so on through the whole series. For instance: Suppose we employ six quart Bunsens in series. We will put the E.M.F. of one cell at 1·86 volts. This, multiplied by 6, will give us 11·16 volts.—the E.M.F. of the whole battery. The other way of connecting the cells is known by the term connecting in multiple arc or in parallel. In this method we place the cells in two parallel rows of three cells in each row. The cells in each row are connected in series, and this leaves two free zincs at one end to be connected to one line wire, and two free carbons at the other end to be connected to the other line wire. The difference between the two methods may be graphically shown thus:—

Series: —o—o—o—o—o—o—

$$\text{Parallel:}\quad -<\begin{matrix}\text{o—o—o}\\\text{o—o—o}\end{matrix}>-$$

By this latter method we decrease the E.M.F., or pushing force of the battery, and increase the volume of electricity to be obtained from it, because we provide two conduits through which the current can flow. We therefore get a greater volume at a lower pressure.

The power of a battery, or any source of electricity, is capable of being accurately measured and determined according to a law called Ohm's law, discovered by a celebrated man bearing this name, several years ago. This law is expressed by the very simple formula, $C=\frac{E}{R}$, and is as simply interpreted thus:—The current of electricity equals the electro-motive force obtained from the generator divided by its internal resistance. Applying this law to the Bunsen battery, made up according to the two methods above indicated, we find the respective powers of the combinations to be as follows, the internal resistance of each cell being put approximately at ·08 volts:—

In series—

$$\frac{\text{E.M.F.}\quad 1{\cdot}86\times 6=11{\cdot}16\text{ volts.}}{\text{Resistance}\quad {\cdot}08\times 6=\ {\cdot}48\text{ Ohm.}}=23{\cdot}25\text{ Ampères.}$$

In parallel—

$$\frac{\text{E.M.F.}\quad 1{\cdot}86\times 3=5{\cdot}58\text{ volts.}}{\text{Resistance}\quad {\cdot}08\times 3=\ {\cdot}24\text{ Ohm.}}\times 2=46{\cdot}50\text{ Ampères.}$$

This large volume of current is available for the work of electro-depositing metals. As the pressure of the current is low, it is incapable of overcoming a high external resistance, so we must use thick conductors in the line wire to and from the work. In the parallel arrangement we have two batteries of three cells each, giving up their united currents together; and as this has to be carried by one line, we must increase its capacity.

The time during which a Bunsen battery will maintain a constant current, varies with the load of work put upon it. If short circuited or placed on one of low resistance, it will warm to the work and give a powerful current for a short time, whilst giving off dense and pungent fumes of nitrous oxide from the inner cell. On electric light work it will usually run from six to eight hours without recharging, if put up in a proper manner. On electro-depositing work, with a weaker solution in the outer cells, it will run for ten hours and do good work in the last.

To maintain the battery in good working order, it should have care and attention at the end of the day's work. When its task is done, unscrew all the binding screws and clamps and put them in a little water to dissolve any salts that may be formed on the threads by the fumes from the acid. Take out the carbons, wash them in water, and set them on a shelf. Empty the contents of the porous pots into a jug or pitcher, and note the colour of the acid. If this is dark green and emits orange-coloured fumes it may be used again; but if a pale green, or without colour and fumeless, throw it away, and use fresh acid when the battery is again charged. Take out the zincs and examine them for signs of pitting. Well brush each in clean water, reamalgamate them if necessary, and set them aside to drain. Pour the outer solution into a pitcher for use again (and again until it becomes too much charged with zinc sulphate), unless spoilt with nitric acid. Rinse out the containing cells, fill the porous and outer cells with water, and let them stand, one in the other, till wanted again. Wipe the binding screws and clamps on an old rag and smear the threads of the screws with a little oil or vaseline. Cells put away in this careful manner are always ready for use and will work well.

All this labour is deemed troublesome by some persons; but I can assure them that it is as necessary to be done as the unharnessing and grooming of a horse at the end of his journey; and it does not seem to me to be more troublesome. Men do not expect to work a horse, or a steam engine, day after day without daily attention in feeding and cleaning, but they want an electric battery to run for months without both.

The Bunsen is a useful battery wherever a full, strong, and constant current of electricity is wanted. It has been in use with experimenters in the production of electric light, and has been a necessary adjunct to the laboratory of the chemist for many years. Its chief fault seems to be that it gives off noxious and destructive fumes whilst at work. This causes its banishment from workshops to boxes or small houses built outside, from which the line wires are led into the shop. It has been suggested that the best way to mitigate the nuisance is to enclose the battery in a box and keep it packed with wadding or blotting paper soaked in ammonia. If the porous cell is filled with sulphuric instead of nitric acid, the battery yields a mild current suitable to the requirements of electro gilders and platers working in a small way, as it then does not emit any fumes whilst at work.

As the same cells and the same elements

may be used in making up double fluid bichromate and chromic acid batteries, I will conclude with a few remarks on these. In making up a bichromate battery a solution of bichromate of potash replaces the nitric acid in the porous cell alone, the charge for the outer cell being the same as that for the Bunsen. The bichromate of potash solution is made as follows:—Dissolve four ounces of bichromate of potash in one pint of hot water, and add to it, when cold, three fluid ounces of sulphuric acid. When this is cold it is fit for use in the battery. When this solution becomes green it is worn out, and must then be renewed. The fumes are not generally considered to be so objectionable as those from the Bunsen; the E.M.F. is higher at starting, but falls off slightly in a short time, unless the solution is kept heated or agitated; but the battery recovers itself when the circuit is broken.

If chromic acid is used, instead of bichromate of potash, in making up the solution, it will give better results, and will not so readily crystallise on the carbons and in the pores of the cells.

(*To be continued.*)

ARTISTIC FURNITURE

EASILY MADE AND CHEAPLY PRODUCED.

BY DAVID ADAMSON.

Introduction—Utilisation of Packing Cases—Joints and Jointing—Pinned Joints—Nailed Joints—Screws in Door Making—Materials—Seasoning—Staining, etc.—Full-size Drawing—Dimensions—How to Make Overmantel—Ends on Uprights—Bottoms of Cupboards and Shelves—Recess for Frieze—Frieze—Fitting Frieze—Fixing Parts—Skew Nailing.

In the present series of articles I hope to describe the construction of various pieces of furniture, not as usually made, but specially adapted for the amateur cabinet maker, whose skill, means, or time is too limited to permit him to be a proficient in wood working. At the same time, while the things are to be of the simplest construction, and of the commonest material, they must not so far depart from ordinary domestic furniture in appearance as to proclaim the fact that they are anything out of the common. If you will permit me to do so, I will, as it were, take you at once into my confidence and explain the origin of the furniture to which I refer, just by way of introduction.

Some time ago I had in my possession some large packing cases which seemed too good to break up for firewood, but were very much in the way. Those packing cases became at last a kind of white elephant. No one would take them unless made into small firewood, so they remained lumbering up till one day, in an idle moment, I did some hard work—I thought—and this is something how my ideas ran. I should here state that I had long been contemplating getting an overmantel for my workroom or study, or, as it is disrespectfully called sometimes by friends, my "den." A costly affair was out of the question, and as a few rough shelves would answer my purpose just as well, I had almost decided on putting them up. However, being tolerably familiar with construction and other matters pertaining to furniture, it occurred to me that something more agreeable to look at than plain shelves might be put up with very little more trouble or cost. Could not the packing cases be used up somehow? The wood of which they were composed was sound enough, fairly clean, and about an inch thick. Some of the planks had rather more knots than might be desirable, but, on the whole, two or three cases represented a tolerably large quantity of workable material, costing, under the circumstances, nothing. But then the time; how could that be obtained from more important work? I had no fancy for having a piece of unfinished work lying about for an indefinite time. This necessitated something much simpler in construction than that generally found in furniture, and—in short, the overmantel shown in Fig. 1 was finally evolved, the first of a series of things designed on similar principles.

Possibly some may ask why these details of a personal character should have been given. Well, there's an old saying connected with sauce and a well-known feathered biped. Consider the circumstances in which the furniture originated as the sauce, and apply them personally. In other words, whatever the reasons may be, no doubt I am not the only one who has wanted to make simple furniture cheaply and expeditiously, and I trust the directions, founded on my own experience, may be of service to those who want to make such. By way of encouragement to those who are not adepts in carpentering work, I may here say that very little skill will enable any one to make up the various articles with a few ordinary tools. Difficult joints, or those that are so to the novice, are dispensed with wherever it has been practicable to do so. I refer, of course, to dovetails, mortises, and tenons, and other details which are so easy to read about, and look so easy when done by an expert, but which are so difficult to construct properly by those who have not "served their time." Instead of these ordinary workshop joints, nails, glue, blocks, and square cutting have been relied on.

Now, at this confession, my readers, don't turn away in disgust with the idea that some puerile contrivances are to be shown, or that the articles are shams—unenduring, flimsy things, not worthy of serious attention. Nothing of the kind; they may be as well put together, and as honestly made, as the most costly furniture, only there is not so much work in them. It has been said that good joinery should be firm without either nails or glue, and if these articles of furniture are to be judged by that standard, they will most assuredly be found wanting. This time-honoured statement, however, is, I venture to think, fallacious, and will hardly be seriously regarded by any who are not prejudiced against modern work, or rather modes of work and construction. Even those who have by practice become proficients in wood working—*i.e.*, cabinet making and joinery—whether as professionals or amateurs, may be disposed to look askance at any furniture made as this is described. Their scruples are entitled to respect; and, at the risk of being digressive, I venture to make a few remarks, for the consideration both of the artisan and the amateur, in justification of the simple construction of this easily-made furniture. I shall presume that I am addressing reasonable men, not those who regard age and goodness in wood work as synonymous, but men whose practical knowledge is sufficient to enable them to discriminate between good and bad workmanship, irrespective of its antiquity.

Apropos of this, it is strange that those who are never tired of belauding old work and decrying new, seldom know anything practically of the work. These antiquarian "cranks" carry their notions to extremes; but when any new method of work is proposed, are we not all more or less actuated by the same spirit of conservatism? They advocate the retention of "pinned" joints, such as were used so much in old wood work. We know this mode of fastening to be quite unnecessary with a well-made mortise and tenon, but coming to every-day usage, what are we to say about some of our constructive detail, the dovetail joint, for example? Are we to consider that this is necessary, while the former—the pinned tenon—is useless? Now, I have not a word to say against dovetails, or any other joint which experience has proved to be good and useful, but I maintain that we are sometimes rather inclined to be governed by tradition in our constructive details. A certain form has been regarded as the only permissible one, and we adhere to it as if it were absolute perfection, and that any departure from it would proclaim bad workmanship. Possibly it might, but by no means necessarily so. We must not forget that under altered conditions in the way of improved tools, together with improved accuracy in work, it is unreasonable to suppose that new forms of construction may not sometimes be desirable.

Among other matters, we overlook the fact that screw nails, and, indeed, all nails, as now produced, are of comparatively recent introduction; and without going so far as to say they ought to supersede the more customary forms of joints in cabinet work—for I am not prepared to go that length—I think we might make more use of nailed joints than we do, when time, and consequently cost of production, are important items. That a nailed joint will be better than a dovetail of course cannot be argued, but there can be no doubt that it is much more easily made, and there is no reason why it should not be equally strong. On this account I have no hesitation in recommending its use among amateurs in such simple furniture as I am about to describe. Everybody knows the holding power of screw nails, which are now brought to such perfection that they can be used with the utmost facility by the merest tyro; nor can they be considered in themselves as detracting from the appearance of any work in which they may be visible. It is not customary for them to be so, but it is very easy to conceive that sometime or other they may be regarded as ornamental rather than the reverse. Surely nothing can be urged against the appearance of a well-finished brass-headed screw. I am sometimes surprised that those who profess to admire the old-fashioned so-called honest work of our forefathers—a long way back—do not recognise that much of the detail is barbarously crude and uncouth, and that we moderns may turn out work equally good, and better finished, and more simply constructed, by taking full advantage of modern facilities. If any one cannot manage to make a tenoned door frame hold together, or, in other words, cannot work so accurately that the parts all fit so perfectly together that glue alone may be depended on, and requires to use nails of some sort, why should he make use of wooden pins? Surely screw nails are better in every way. Their only disadvantage is that they have not the merit of having been used some three centuries ago, and that is not a serious one. Probably the only reason for pins having been preferred then was because they were Hobson's choice, but as for us, why should we use them when we can get the altogether more satisfactory screw nail?

Reverting to the door framing, and going a step further, why, when screws can be used, should the mortise and tenon be considered

indispensable? Although I do not say it is not the best, surely it is not the only one, for if the ends of rails and styles are halved and screwed together, the desired object is attained. I would like to say more on this topic, but having shown, to some extent, the principles on which this easily-made furniture is designed, and, I trust, suggested, not only to the novice but to the professional worker, that it may be sometimes well to depart from inherited notions about construction, or, at any rate, that it is not altogether necessary to adhere to them, more need not be said at present. Those who differ from me in my advocacy of simpler, and what to them will seem "jerry," construction, will please remember that I am describing furniture for amateurs to make. I have no sympathy with slop work of any description, but I do most emphatically protest against the idea that only one method is permissible under any circumstances. At the same time I do not advocate that the tyro, either in theoretical knowledge or technical skill, should, without consideration and sufficient reason, depart from those details of construction which are generally employed, as they are the essence of generations of practical workers' experience, and it is seldom that any serious objection can be raised against them on the score of efficiency. Those who wish to make up any of the designs in a way more in accordance with the recognised cabinet-making construction will have no difficulty in doing so, if they are able to "set out" work, but I wish it distinctly understood that these chapters are intentionally of an elementary character, and complicated technicalities will as far as possible be avoided.

Reference has been made to packing cases as the source of the material. For those who are not acquainted with them, I may say, that those cases which have contained pianos or American organs, etc., are very suitable for the purpose. They are generally well made, and in many of them the boards being ploughed and tongued together dry, *i.e.*, without glue, a great amount of labour is saved in "jointing up" to obtain width. I have never experienced any difficulty in obtaining such cases at a price which renders them very economical material, and, as some idea to guide the purchaser, I may say that at 5s. or 6s. one will not find a good, clean case dear. They are, however, to be had lower than that occasionally. Perhaps other large cases would do as well, but I mention the kind I have, because I have used them satisfactorily. Of course, the people to purchase them from are importers of musical instruments, and I believe in the larger provincial towns, the cases can be more readily got than in London. Anyway, there is, beyond their cheapness, no special reason why they should be used in preference to new wood. This can be got anywhere, and as the wood of which the furniture is made is pine, it ought not to cost much. Mahogany or some of the choicer woods may be used instead, but for this particular furniture it will be seen as we proceed that they are not so suitable. The only caution I have to give the novice is to see that the pine is of the best quality. This will cost more in the first instance, but in the end will prove more economical than inferior descriptions, as there will be so much less waste from knots and other defects. Even with the best there will be some knots. If the furniture is to be painted, these will not be of so much consequence, but if it is to be finished by either varnishing or polishing, care should be exercised to use only pieces which are free from knots. In either case, the fewer there are of them the better, as no one who has done any carpentering will need to be reminded that it is much easier to work wood in which the grain is nice and even than to smooth a piece in which there are knots.

Perhaps I ought to say something about the necessity of the wood being thoroughly seasoned, and not only so, but thoroughly dry. For the first qualification, the timber merchant must be relied on; the second is more under the user's control, and as amateurs frequently complain of their stuff going—through what is almost invariably called the use of unseasoned wood—a few words of advice may with advantage be given. However well seasoned wood may be in the timber yard, it is rarely that it can safely be used up immediately without risk of its contracting, and of course splitting sooner or later—generally sooner. It stands to reason that, however well-seasoned in the open air, or even when under cover, wood may be, it can hardly be so free from moisture as to have shrunk to its smallest dimensions. If dried under those conditions, although to the touch or in working it may seem perfectly free from moisture, it will be found that if made up fresh it is sure to contract when placed in a warm, dry atmosphere, like that of an ordinary living-room with a fire in it. If the construction is such that the inevitable shrinkage has not been provided against, the almost certain result is a split; perhaps two of them, the second being with the timber dealer for having supplied unseasoned (!) wood. To prevent the wood shrinking, warping, or going wrong after it has been made up, give it a fair chance to do so beforehand. Keep it for a few days in a warm, dry place—if possible, in a room where there is a fire, especially in the winter time—before cutting it, or at any rate, before finishing it. If the wood has been well-seasoned there will not be much fear of it going or displaying any of these vagaries, generally attributed to the want of proper seasoning, and it must be confessed sometimes correctly so. Instead of pine, American whitewood will be a very good wood to use, but it is a little more expensive. For staining, it is, however, to be preferred. Nevertheless, there are now such an immense variety of the so-called enamel paints, that those who wish to do so can finish the furniture more easily with one or other of them than by staining and polishing.

We are, however, getting ahead to the final work before the overmantel is begun. The first thing will naturally be to make a full-sized drawing

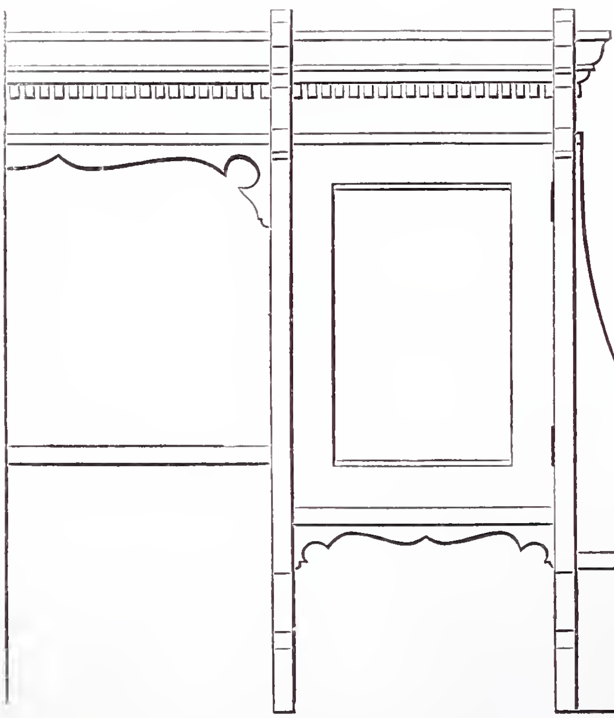

Fig. 2.—Half of Front Elevation of Overmantel.

Fig. 3.—End Elevation.

of the overmantel, as by its aid measurements of the various parts can be got much more correctly than without. The drawing need not be at all an elaborate affair; indeed, it will be far better not, for the simpler it is the less likelihood of any mistake being made, always provided of course that it shows sufficient to guide the worker. In such a thing as this it is not necessary to show joints. It will be quite enough if a front and end elevation are prepared, as shown in Figs. 2 and 3. For the sake of simplicity and to save space only one-half of the former is shown, the other half being exactly the same. As these drawings are made to ⅛ in. scale, there will be no difficulty in seeing that the size of the overmantel is as follows: Length, 4 ft. 8 in.; height, 2 ft. 5 in.; depth from back to front (on cornice), 8 in. These dimensions, of course, may be varied according to circumstances, for the veriest tyro need not be told that with a chimney breast only 4 ft. wide it would be absurd to make an overmantel as long as the one illustrated. It will be seen that the design is not one of the gorgeously reflective sort, but then it will be remembered the kind of room it was made for required something more useful than—I was going to say, ornamental, but I hope it is the latter as well. Utility, however, was of more importance than decoration alone, hence the small space available for looking glass. As a matter of fact, there is none of this latter in mine, but as an overmantel without glass might not suit every one, I shall, in due course, show how mirrors may easily be fitted without altering the construction. Possibly also some may prefer to have no shelf in the centre portion, and for the benefit of such I shall, in the proper place, explain the slight difference which its absence will render necessary or advisable.

In the meantime I shall show precisely and exactly how the overmantel as represented is made. The necessity—if the thing when made is to look well—of having the wood properly planed, and not only so, but perfectly smooth—no plane marks or flaws of that kind—is so self-evident that it need not be insisted on. To get the surfaces into this desirable condition first plane them, then scrape them to take out any trifling irregularities, and finally glass-paper. This latter, however, may be deferred till just before fitting together, particularly if the work is not to be painted. The edges of the wood must also be planed up as truly as possible, and of course every cross cut should be perfectly square. If it is not it will be hopeless to expect that the work can look well, however much pains may be taken with it otherwise. Roughness in finish may pass without offence; bad construction cannot be regarded with equanimity. The latter is the important part of the work; the former, the finish, is of secondary importance. Those who wish to excel will, of course, take the same pains with the one as with the other, for though our work may be cheap it need not be nasty. I saw somewhere lately—I think it was in "Every Man His Own Mechanic," though I am not able to verify the quotation—a sentence which puts the matter very neatly. It was as nearly as I remember in these words: "Though the work need not be well done it will be better if it is;" and whether they are exactly so or not that is their purport. I have insisted on these details because they are applicable not only to our present work but to all other of a similar kind; and having given these general instructions, I may now call attention to the various parts, their respective sizes, and the mode in which they are fitted together.

For the ends or uprights four pieces will be required, each 2 ft. 3 in. long and 6½ in. wide. By the way, as I have not mentioned it before, I may as well remind beginners that though wood 1 in. thick has been spoken of, it must not be supposed it will be of this thickness after having been planed. Even before this has been done it will not be fully 1 in. thick, unless it has been specially asked for, and paid for accordingly. Nominal "1 in. stuff" is what is supposed to be used, and this will measure, when "cleaned up"—*i.e.*, planed, etc.—little, if any, more than ¾ in. It will therefore be well to bear this in mind when setting out the work if, for any reason, exact dimensions, not only of this overmantel but of other furniture, are to be worked to. I may as well also state here that measurements are not given to within ⅛ in., as to do so would merely tend to error, and cramp the worker by imposing needless restrictions. Measurements will only be stated by

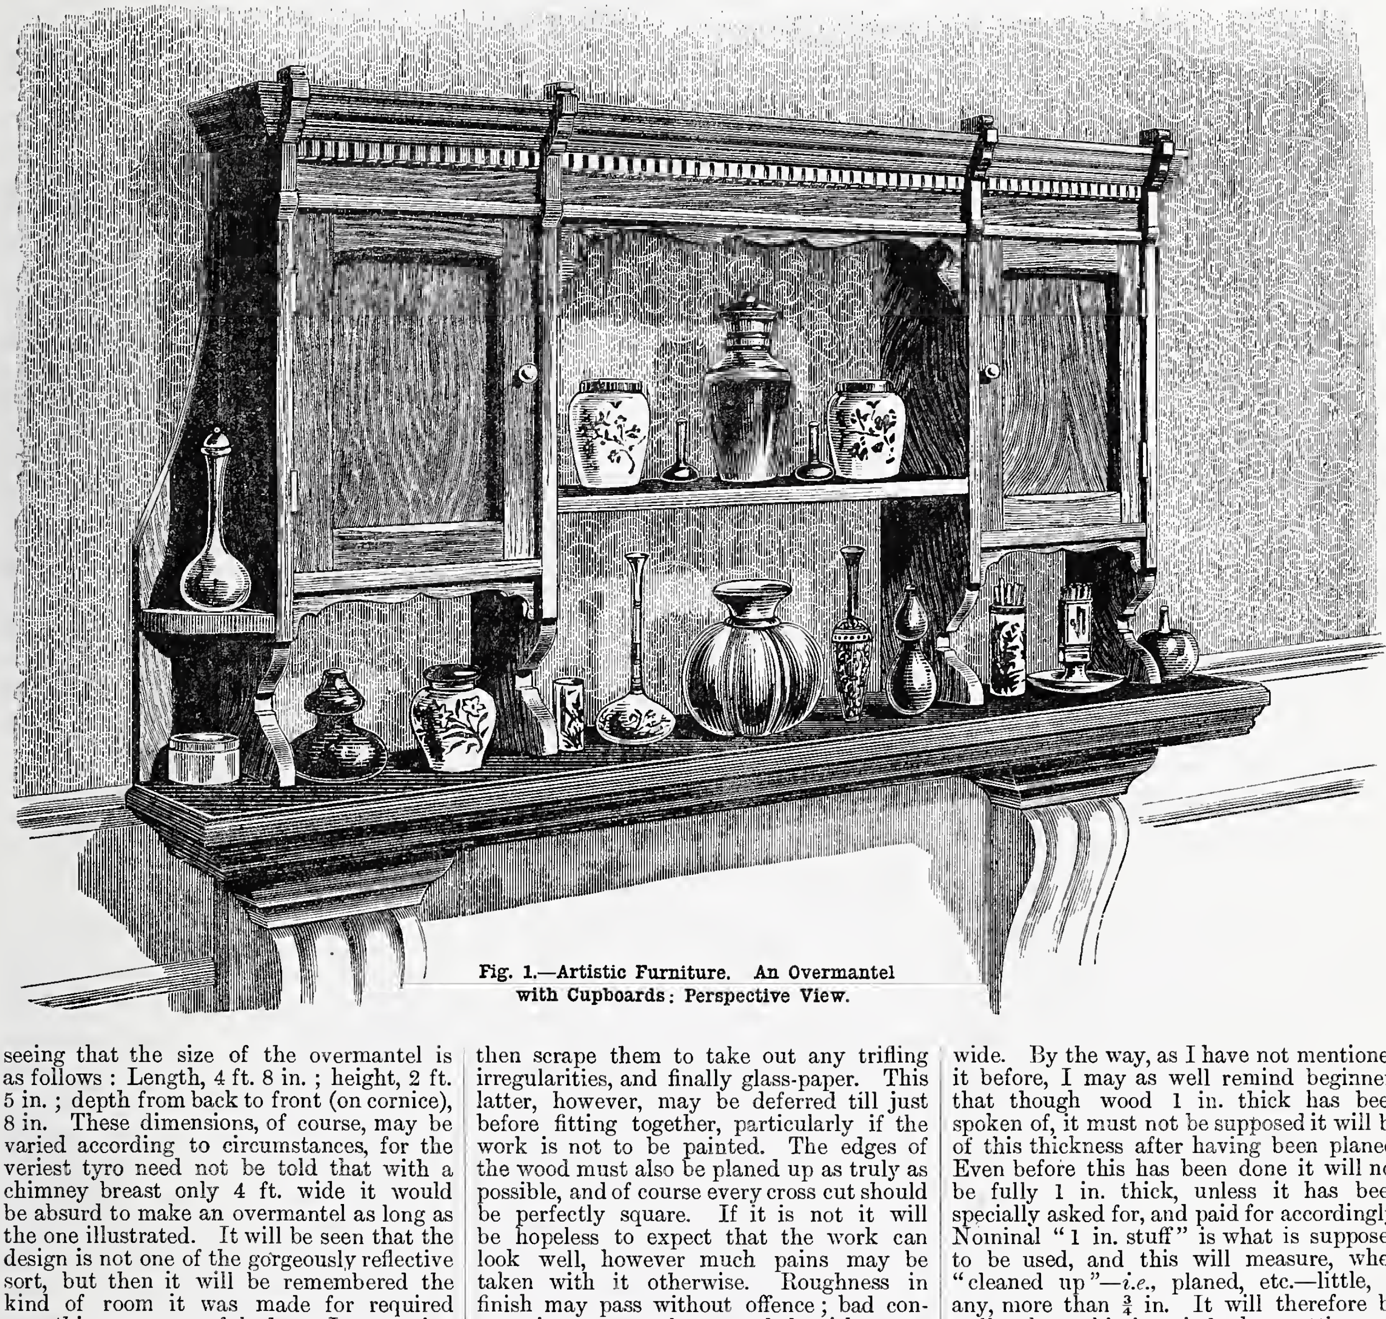

Fig. 1.—Artistic Furniture. An Overmantel with Cupboards: Perspective View.

the half-inch, which for explanatory purposes is quite sufficient, so that, in case of any dimensions not tallying exactly, it will be understood that parts less than half an inch are disregarded, except in the very few instances in which it will be necessary to mention them. Of course, in actual work the same disregard for fractions cannot be entertained, as they must be carefully noted.

Two pieces, each 11 in. long and the same width as the ends, will also be required for the bottoms of the cupboards, and two more of the same width, but longer than the bottoms by the thickness of the two ends. Thus, if these finish ¾ in. thick, the pair will make 1½ in., which, added to the length of the bottom of the cupboard's 11 in., gives us 12½ in. One piece the same width as the foregoing but 1 ft. 10 in. long will be wanted for the centre shelf, and another for the top of the same part of equal length, but ¾ in. narrower, to allow for the thickness of the next piece. This, which is 4 in. wide, and in length equal to the whole of the front less the thickness of the two outside uprights, will also have to be prepared before any of the fitting together can be done. To get at this length exactly, either measure from the working drawing or, what amounts to the same thing, add the length of the centre shelf (22 in.), the thickness of the two inner uprights (1½ in.), and the length of the two pieces for the bottoms of the cupboards (22 in.), giving a total of 3 ft. 9½ in. Now take the two inner end pieces, and from the top front corners of each cut a piece out exactly the width and thickness of the long piece, the frieze, just prepared.

To prevent any mistake as to how these spaces should be cut out, the diagram Fig. 4 is given. This represents the top of the inner end pieces, the part within the thick lines being that which is to be cut away. To mark these spaces out accurately, set the gauge—either the marking or the cutting variety being available for the purpose—to exact thickness of the frieze; then, with the block of the gauge against the front edge of the uprights, scribe for a length of at least four inches from the top. If the scribing is done on the top edge and on both sides of the wood the lines will furnish an aid to correct sawing, or to trimming up accurately afterwards with a chisel if necessary. This, of course, will not be requisite for those who are practised hands, but such adventitious aids are not to be despised by the unskilled worker, as by taking advantage of them he may turn out work as accurately made as that done by the most experienced. He will naturally require more time to get the same results, but these will well compensate for the extra pains taken. He must not hope to emulate the practised worker in speed, but he may reasonably expect to do so in accuracy—if he has the necessary patience.

The length of the piece to be cut away can most easily be ascertained by laying the frieze on the wood and marking off the width. When this is arrived at the square should be used to mark the lines, not only on the front but also on the sides, as far as those made by the gauge. Now it is evident that the cut made by the saw is of an appreciable width. It cannot be less than the thickness of the saw blade and set of the teeth, so that unless a very fine saw is used it will be found that if the wood is cut on the line, that is to say, if the saw passes through this, the space, when the waste piece is removed, will be found rather larger than necessary. In other words the frieze will not fill up the recess properly; it will not be a good fit. In this instance this would not be of much consequence, still it is better to form good habits of work at once. After what has been said, the natural inference will be that by cutting along the inner edge of the marked lines, *i.e.*, within the waste piece, so that a saw cut is formed in it, the space left will be just of the required dimensions. In any case if it is not big enough, a little paring with a chisel will soon effect all that is needful; for it is always easier to reduce wood than to add to its size when fitting; an axiom which the beginner will do well to remember.

When the frieze is fitted properly the pieces so far arranged may be fastened together if the shaping has been done on the lower parts of the ends, for this cannot be managed afterwards. Fig. 5 shows as clearly as possible, on a small scale, the outline of this shaping, all the principal measurements from which it can be set out being given in inches. The best way to get the outlines on the four pieces alike will be to form a template. As it may not be understood what this means, it may be explained as a piece of cardboard or thick paper cut with a knife or scissors to the exact outline. By laying this template, or mould, on the wood in position and drawing with a pencil along the shaped edge, all will be exactly the same. It will be noted that the upper curve is a counterpart of the lower, so that the drawing required for the outline is reduced to a minimum. The actual cutting may be done with a bow saw, but, of course, the work may be done with much greater facility with a good fret machine. I leave out of the question a band saw, as this is not often seen or required by amateurs. To prevent disappointment to those who are getting a fret machine, it may be said that I do not refer to makes which, though they may be good enough in their way, are too small to do such large work easily. With such a machine as the Britannia Company's No. 8, which for all-round purposes I consider the best in the market, there is, however, no difficulty in shaping such work as the present. The ordinary fret saws, however, even of the highest numbers, are hardly stout enough to be durable in cutting such thick stuff, and it may be news to some readers that, recognising this, the same Company have placed on the market some especially strong saws, which will be appreciated by sawyers who have once tried them.

Before fixing these parts together, mark with the square across the ends the exact positions of the shelves in order that these may be fixed truly and not sloping in all directions. The lines may be run across showing the thickness of the shelves, but it will only be absolutely necessary to make one for each shelf, indicating where either the top or bottom is to go. The first parts fixed together may as well be the centre shelf between the two ends. Its upper surface is 11 in. from the bottom of the overmantel, so the guide lines having been carefully marked on the inner sides of both the end pieces, mark with the square another line on the other side of each. These lines serve as a guide where to insert the nails, so that they should be drawn about half the thickness of the shelf nearer the lower ends, when if the nails are driven in straight they are bound to go well into the shelf. Screws may be used, but ordinary French nails will do well enough and hold just as securely if driven in as shown in the diagram Fig. 6. This represents the end in section with the shelf nailed to it. It will be seen that the end-nails instead of being driven in perpendicularly are inclined towards the centre of the shelf. Were they all to be straight like the middle nail, it is very evident that the pieces could easily be separated, but by inserting them at an angle they bind the pieces so firmly together that no stronger joint will be needed. The comparative strength of the two kinds of joint can easily be tested by experiment on a couple of waste pieces. To avoid repetition, it may as well be said, once for all, that, unless otherwise stated, it will be better in any of this nailed furniture to have one or two of the nails in a slanting direction, every precaution, of course, being taken to see that the slant is not towards the surface of a shelf. If preferred, the nails may be driven in straight, and in most instances would probably hold sufficiently, but as there is no more difficulty one way than with the other, it is just as well in case of doubt to choose that which seems the strongest. Three or four 2-in. nails, either French or of another kind, at each end of the shelf will hold it well enough. Drive the first nails in straight, and put the slanting ones in afterwards; and do not put more than one nail in any joint till it has been carefully noted that the pieces of wood are in their right position towards each other. To avoid accidents, of course, holes will be bored with a bradawl before the nails are hammered in. The holes need, however, only go through the first piece. The nails will easily make their own way into the end grain of the other, though just to guide them the bradawl may go a little way into this. These are very elementary details, but without some knowledge of them the beginner might fall into errors which could only lead to dissatisfaction with his work, so I trust those more advanced will not deem them needless.

(*To be continued.*)

"TIPS" FOR TYROS.

BY OPIFEX.

1.—Decorative Work for Panels.

Figures, flowers, etc., are very effective for decorative purposes when painted in oil colours upon a dull gold ground, and charming panels may be produced in this style. Cabinets, etc., with plain panels may be altogether transformed by placing other panels of tin, zinc, etc., thus treated, over them, cutting out the metal to fit exactly inside the moulding, then gold lacquering and painting, and, finally, securing by means of invisible pins.

Suppose we require a small panel 12 in. by 6 in. Cut a piece of common tin, or zinc, of the proper shape and dimensions; procure some gold size and best copal varnish, say half a pint of each, and mix together. Also a small packet of gold-bronze powder, costing about 1s. 6d. at any oilman's, and a camel's-hair brush—a gilder's "dabber" is best, and costs 6d.

Give the panel a thick, but even, coat of this mixture, or pour about a table-spoonful upon the centre of the panel, and let it run all over evenly—after the manner of photographers covering a plate with colodion—but this only in case of very small panels. This varnish will dry very rapidly, provided the ingredients are good and fresh, so must be carefully watched, as the gold powder must be applied before it is dry, and half an hour, or even less, will generally be sufficient time to wait.

Next dip the brush well into the gold powder, taking up as much as possible; dust it over the panel unstintingly, at the same time being careful not to touch the surface with the brush. This should be done several times until the panel is well covered with the gold powder. You may now venture, very gently and lightly, to apply the brush —and remember that you cannot have too much gold powder—and sweep it over the surface, hither and thither. The gold powder will protect the surface of the varnish from being abraded by the brush, and the result will be, if great care has been taken, that a perfectly smooth, gilt surface will be imparted to the panel. It may now be laid flat in a warm place until perfectly dry, when the surplus gold powder may be brushed off, and the surface rubbed lightly with a pad, formed by folding a piece of chamois leather several times.

The panel is now ready to be painted upon, after which, the whole should receive a coat of mastic varnish.

HOW TO MAKE A WOODEN COPYING PRESS.

BY DAVID DENNING.

THE press about to be described is essentially a home-made affair—one of those contrivances emanating from an amateur's brain, and capable of construction by hands almost unskilled in any handicraft. It is so simple that one feels almost that some apology is due for volunteering any instructions about it; but remembering that all amateurs are not adepts in contriving, any more than they are expert in making, the following hints may not be without value to some readers. The advantage of keeping copies of one's letters—at any rate, of those of a business character—is so generally recognised that nothing need be said about the desirability of doing so. The form of machine or press usually employed for the purpose is well known; but, if we except those of a portable character, they are entirely of iron, and quite unsuited for construction by amateur mechanics as a rule.

I had long intended getting a copying press for home use, but the cost had always been an obstacle. By degrees I began to consider if I could not make one which, even if not so neat in appearance, should be as effective as those sold for the purpose.

First question—Is it necessary that it should be iron throughout? Answer—No. Second question—Could not most or all of it be made of wood? Yes, certainly, except the screw. There came the stumbling block, for it seemed as if this must be of iron; or even if wood could be made to answer the same purpose, where could a suitable screw be got? On inquiring what one would cost, I found it was more than I cared to give, and it seemed a useless expenditure to buy a box and tap to make one, especially as there was no certainty that I should be able to succeed in working it. The matter remained in abeyance accordingly, till one day a discarded bench screw turned up among some rubbish. Why not make a trial with it? It was not wanted for any other purpose, and in the event of the press not being a success, no great loss would result. Anyhow, it seemed just the thing that was wanted, though, probably, if it had not been obtainable, some other arrangement whereby the requisite pressure might have been got could have been devised. Still, it was the ordinary screw press that appealed to my fancy, as no other form seemed so suitable. Perhaps, also, the knowledge that napkin presses, almost identical with copying presses, are made entirely of wood, first suggested the idea of making one. Certainly, compared with one made of iron, the wooden press is clumsy—even a makeshift, if you will; but are not practical "makeshifts," after all, the pride of the amateur? There is the satisfaction of having formed something useful out of what was probably little more than waste. Of course, it is very pleasant, no doubt, to be able to have the best and nicest thing of its kind; but, failing this, by a little consideration one may often be able to contrive a very fair substitute. That is all the wooden copying press pretends to be. It does not aspire to the dignity of a new invention; perhaps it is merely conceit that regards it as anything but a worn-out idea obtruding its insignificant self; if so, good readers, forgive it and pass on to a more congenial article. Allusion has been made to the press being constructed of waste material; and if pieces of an old packing case which had been put aside for breaking up into firewood can be called so, it is literally true. There is, however, no absolute necessity for getting a packing case for the purpose, as wood from the plank will do equally well—better, perhaps. The fact of my press having been made from an old case is merely mentioned to show beginners that they may make use of what may at first sight seem very unpromising materials.

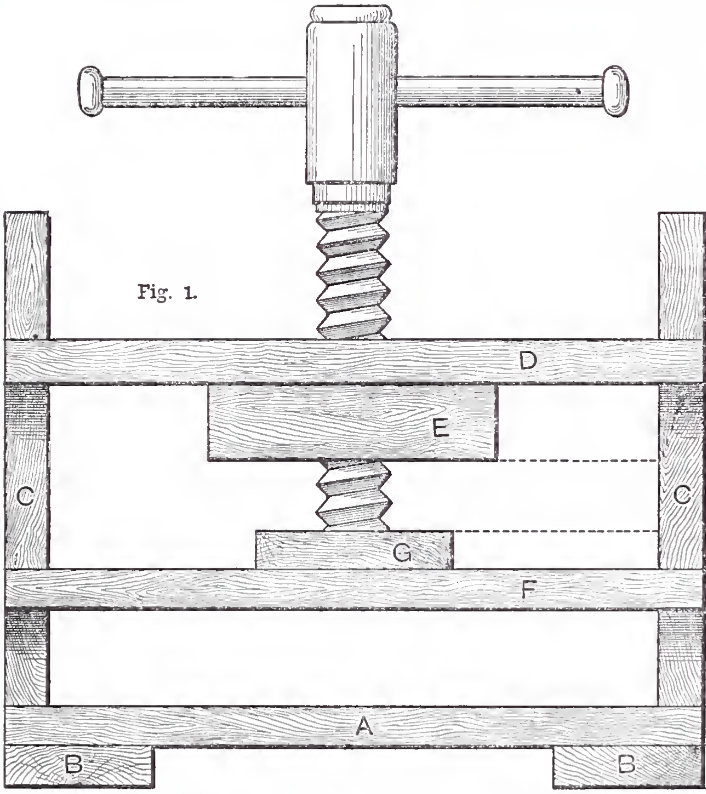
From what has just been said, it will readily be surmised that the press is made of pine, in the selection of which the only precaution taken was to get the pieces as free from knots as possible. The thickness was already determined for me, the case being entirely of 1-in. stuff, which, planed up, measures only a trifle over $\frac{3}{4}$ in. It does very well; but having got beyond the experimental stage, if I intended to make another press, a little more regard might be paid to appearance, in which case a harder wood might be used. Beech would answer well; while a really handsome press might be made by using mahogany or walnut, the cost of which is not great. However, enough has been said about material; and as for workmanship, I would merely caution the tyro against careless work under the erroneous impression that common wood deserves no better.

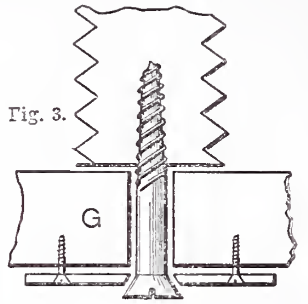
The general construction of the press may be gathered from Figs. 1 and 2, which give the front and end. The length is $14\frac{1}{2}$ in., and the width, 9 in., which allows of the ordinary quarto copying book being used. It will be seen that the only pretence at ornamental finish is in the rounded ends of the upright pieces, the remainder being "as plain as a pikestaff." The thing was made for use, not for show; and no unnecessary time was spent over it. Those who want to make something better looking will have no difficulty in making improvements, while following the same constructive details. For example, a moulding may be planted on the edges all round the bottom, and a small moulding may be worked on others. Chamfered edges would also be effective and not difficult; while various other details will doubtless occur to the worker. The bottom piece, A, or bed of the press, is $14\frac{1}{2}$ in. long by 9 in. wide. On the under side are screwed two pieces, B, one at each end, serving to give rigidity to the bottom. I am now inclined to think they might have been dispensed with, as the press is screwed to the top of the piece of furniture—a dwarf bookcase—on which it stands. This alone secures the stability of the press; but, as I was undecided where to place it, the cross pieces were used as an extra precaution against weakness. The two uprights, C, are 12 in. long by 3 in. wide, fitted to the bottom with a plain single dovetail joint. The transverse piece, D, 4 in. wide, and of course the same length as the bed, is $2\frac{1}{2}$ in. from the top of C, through each of which a couple of mortises are cut for corresponding stout tenons in D. Through this a hole is cut to allow the screw to pass freely, and on the underside the threaded block, E, in which the screw works, is fastened. I may here say that originally the block was placed above D, but on using the press for the first time this was found to be a fault, very little force—hardly, indeed, more than was required to copy a letter—being sufficient to pull the screw block away. Probably, had D been made of hard wood this would not have happened. Naturally, the tendency of the screw, when using the press for copying, is to force the block, E, upwards; so, to prevent further mishap, the alteration to the present position was made with very satisfactory results.

The movable board, F, is exactly the same size as the bed, which it resembles in every respect, except that at each end spaces are cut away to allow of the uprights fitting loosely into them; and that only one piece, G, instead of two, is fixed across. Now, all these parts might be fitted together, and the press would be effective so far as copying is concerned; but there is the objection that the loose board, F, would not rise with the motion of the screw, and I judged it would be awkward to lift it each time the book was put in the press. Some contrivance by which the action of the screw would raise as well as depress was wanted. Not being a mechanical genius this required consideration; but now that it is done the solution of the problem is as simple as that connected with the historical egg of Columbus. The end of the screw, as is generally the case, was tapered beyond the thread; and it did not seem as if this shape would conduce to effective action. I therefore cut the rounded portion off with a saw, leaving the bottom end of the screw perfectly flat. I then got a piece of zinc plate, about $\frac{1}{16}$ in. thick, and screwed it to the underside of the cross piece, G, about the centre. The size of this piece of metal is immaterial—all that is necessary being that it is large enough to allow of it being properly fastened with two or three screws, and to have a hole about $\frac{3}{16}$ in. bored through it. The shape also is of no consequence; and that of the piece I used may perhaps be best described by saying that it is irregular—very much so, indeed—for it was simply a scrap remaining from a plate out of which I had been cutting a piece of metal fret. In case it is supposed that only zinc would do, it may be said that the only reason for its having been employed was that it was lying handy, and that had a suitable-sized piece of brass presented itself it would probably have been used instead. Indeed, I am inclined to think that the metal might be dispensed with altogether without much, if any, disadvantage, especially if the piece, G, is of some hard wood. Still, I don't know; and the suggestion is only given for what it is worth to those who want to expend as little labour as possible on the press. It is seldom that one's first attempt at making anything is so good that it can't be improved upon, either by eliminating superfluous features of construction or by giving it an enhanced appearance—both considerations worthy of attention if they can be accomplished without detriment to utility. Therefore, it is to be hoped that these instructions will not be so far mistaken as to be regarded by any would-be press maker as admitting of no variation. They are merely given as a record of the way my press was made, and so far they are reliable. Whether the suggested alterations are improvements, or the reverse, must slightly exaggerated for the sake of clearness, for it will be understood that the more closely the parts fit without binding the better the work will be. In order that G may be screwed down closely to the piece F, the latter is slightly scooped out to receive the metal plate and screw head.

The parts are now ready for fixing together, and when done, the press as made is complete. Of course, I am supposing that each part is separate so far, and that any fitting together has been merely tentative. Perhaps it may be an assistance to beginners if they are told how to fit all the parts together.

Screw the two pieces, B, to A, though this has probably been done when cutting the sockets for the dovetails at the end of C. Pass the wooden screw through D and then through E. Fasten these (D and E) alluded to incidentally. These, though by no means generally met with nowadays, when we are apt to regard them as old-fashioned, are not to be despised as a convenient means of keeping such things as table-cloths, etc., nicely pressed. In some households they are still in constant use; and for the benefit of those who desire to make one, it may be said that the linen or napkin press very much resembles in construction that just described for copying. In size, however, it is considerably larger, but as the dimensions are governed by the articles to be kept in it, no specification can be necessary here. In construction the principal point of difference is that the handle of the napkin press, instead of being at the top, is usually found placed between the parts marked in the illustrations as D and F. In the copying press this would





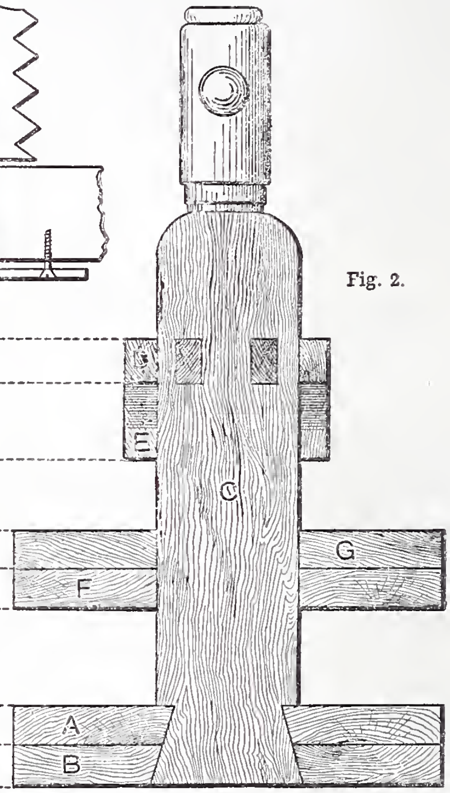


Fig. 1.—Front Elevation of Press. Fig. 2.—End or Side Elevation. Fig. 3.—Diagram Showing Mode of Attaching Wood Screw to G.

be left for each maker to decide for himself. For example, some may not have tools to bore the screw holes through the plate; and it would only discourage such at the outset to tell them they *must* use a metal plate. If I may offer a suggestion here, though one hardly directly concerning the subject, it is—that fellow-contributors, while telling us what ought to be done to produce the best results, might, when practicable, indicate "short cuts." But to make a "short cut" of this press: A hole was bored through the metal plate and G big enough to allow a large screw nail to revolve freely within it. This screw was then run through the hole and driven into the bottom of the wood screw, care being taken that while this and G were brought close together, the latter could be turned round easily on the screw nail as an axis. In order the better to explain this, Fig. 3 is given, showing in section the metal plate at the bottom, the wooden piece, G, above, with the nail passing through them into the screw. The spaces round the nail and between the bottom of the screw and G are together, taking care that the wooden screw does not jam in the hole through D, in which it should revolve freely. Then attach G to the end of the wooden screw. Next fix one of the end pieces, C, to the bottom, when F may be placed in position. The tenons at the end of D, corresponding with the mortises in the piece C, already fitted, may then be inserted; and finally the remaining upright, C, be fastened. Glue should be used at the mortise and tenon and dovetail joints; but it will be better to fasten the other parts together with ordinary screw nails. It now only remains to screw G to F, and the press is complete. Nothing has been said about the handle by which the screw is turned; but I presume it will be understood that this is the ordinary one supplied with it for bench purposes. Any tough stick would, however, do as well; and instead of leaving it loose, as it generally is in bench screws. I have found it convenient to fasten it in by a couple of brads—one on each side—so as to keep the handle immovable.

In the preceding page napkin presses were have been awkward, owing to the comparatively short space between the two uprights; but in the larger linen press this objection does not exist; and for practical reasons the lower position is generally chosen. There is, however, no actual necessity for this, so that those who want to make a linen press may, if they prefer to do so, make one in every respect like the press now described, merely altering the sizes to suit their own requirements.

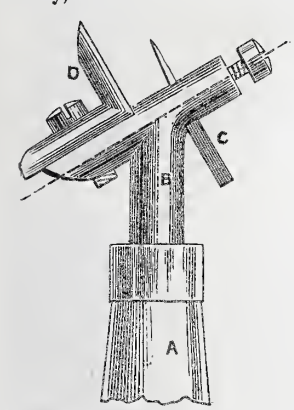
It will, no doubt, be perceived that such a press may be turned to a variety of uses, and that its utility is not confined to copying letters. For example, the amateur cabinet maker will find it handy in laying small veneers with a caul, the photographer in mounting and pressing his works of art, etc. etc.

So far, only the press as I have described it has been made; but, before long, it is probable that a stand will be contrived specially for it. If so, I shall have much pleasure in giving particulars in a subsequent article, and describing the methods that I may be led to adopt in making it.

OUR GUIDE TO GOOD THINGS.

6.—The Britannia Company's New Patent Saw.

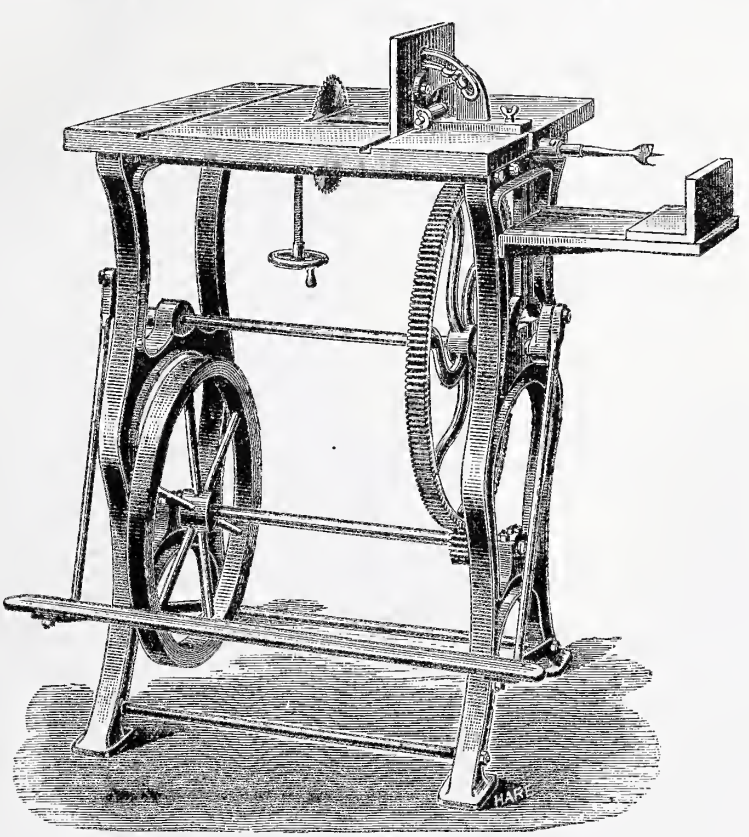
A circular saw is a tool which no workman who has once seen it at work would care to be without, for it is a labour-saving tool of the first importance, and enables its owner to do many things with an amount of ease, exactness, precision, and rapidity that cannot be attained with saws actuated by the hand and arm. When an amateur becomes the possessor of a lathe, one of the first things he will do is to have it fitted with a circular saw and the necessary appliances in the shape of table, fence, etc., to enable him to use it conveniently and with due effect. The professional workman, on the other hand, although he will not be without a circular saw to be worked on and by his lathe, wants something stronger and heavier that will save him the labour of using the rip saw, which has made many a man's arm and shoulder ache when the absence of suitable machinery in the workshop has compelled him to keep at this kind of work for many successive hours, perhaps, if not through the entire day; and every man who seeks to save time and labour, and therefore money, either for himself or for those in his employ, will, or ought to, take care to have a thoroughly efficient machine well suited to the requirements of his business in his workshop.



Adjustable Rebating Cutter.—A, Handle; B, Brass Casting; C, Cutter; D, Fence. Dotted lines show Angles of Inclination of Cross Piece to Axis of Handle.

I may say, with confidence, that I do not know a better all-round machine for general purposes than the New Patent Saw made by the Britannia Company, Colchester, Essex, of which the annexed engraving is an excellent illustration. It is a very powerful machine, well made and well put together, and suitable for workshops even of a small size, because it is compact in itself and does not take up much room. I have seen the saw in operation, and was astonished to note the "go" that is in it, if I may use the term, after the motive power has been removed from the treadle. When I saw the machine at work at the Company's London showrooms, 100, Houndsditch, where every machine and appliance made and sold by the Company may be seen and examined, the exhibitor set it running and then took his foot from the treadle. After some little time had elapsed, during which the machine continued in action just as if some invisible agency was keeping it going, I was asked to stand on the treadle. I stepped on it and stood there, but in spite of the dead weight that was then thrown on it, the machine went on as gaily as ever, and did not come to a full stop until some little time after I had stepped off the treadle and stood once more on the floor of the showroom. I regretted afterwards that I had not timed the duration of the running of the machine from the time the exhibitor ceased to actuate it until it stopped. I shall do so, however, the first opportunity I have of renewing my acquaintance with it, and then, through the medium of "Shop," I shall have much pleasure in answering the inquiries of an intending purchaser, or any one else who may be curious in the matter.

So much, then, in testimony of its power, which enables me to accept the assertion of its patentees and makers, that when the saw is worked by foot "4 ft. of 1 in. pine can be cut after the foot is taken off the treadle. It is claimed, moreover, for the saw that it will cut 10 feet of inch wood in a minute; and that with one man working at the treadle—for it may be worked by hand power as well—it will cut up to 4 in. square. This, in fact, bears valuable and incontrovertible witness to the worth of the saw as an economical machine, and goes far to make good the Company's claim that it will compare favourably in point of work done with any other treadle saw in existence, and that it will save its prime cost in the first twelvemonth of its use.



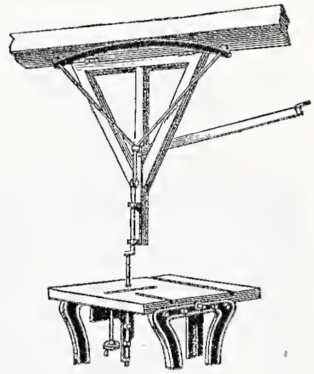
Britannia Company's New Patent Saw for Cabinet Makers, Joiners, etc.

The construction of the machine will be readily understood from an inspection of the accompanying illustration. The saw table is supported on a couple of standards, firmly connected and braced by bars, entering the standards a little above the feet on each side. Provision is made in the framing of the standards for the reception of two axles, the lower one carrying the heavy fly-wheel on one side, and on the other a pinion which gears into a large and heavy toothed-wheel, on the right side of the higher axle, to the ends of which are connected the bars that form the intermediate links between the treadle and the shaft that carries the large toothed-wheel. The end of the shaft to the left is so contrived that a handle can be fitted on to it, which may be used either as an auxiliary to, or instead of, the treadle. The large toothed-wheel gears again into a small toothed-wheel on the axle which carries the circular saw, which, when in motion, may be made to effect 1,500 revolutions per minute.

The table is fitted with the necessary appliances for the performance of various kinds of work in the form of fences, etc., and at the right side of the machine there is an adjustable table, on which dowelling is done, fitted with a special appliance for holding work and insuring uniformity. On this side is also a chuck for holding bits of various sizes for boring, which can be done with great rapidity and up to 2 in. in diameter.

In addition to dowelling and boring, grooving can be done at considerable speed, and mitre cutting is performed with such cleanness of cut and rapidity that the ordinary gilt mouldings used for picture frames can be cut without any shake, and will not require planing or finishing. For scroll cutting there is a separate appliance, of which the upper arm is suspended from the wall or ceiling, and only let down when wanted, thus leaving the table quite clear for work of any size. Timber, to the thickness of 4 in., may be cut with the vertical saw. The patentees and makers are about to add a moulding appliance to the machine, by which mouldings may be cut with a single cutter.

The adjustable table shown at the side in the illustration, for boring, can be removed at pleasure, and another table be substituted with suitable appliances for holding work for mortising. This operation is effected by using a fluted bit, which is placed in the same position as the centre bit shown in the illustration. The fluted bit, which cuts on the side, first drills a hole in the wood, and then completes the mortise by means of the screw movement. The price of the mortising appliance is £3 10s.



Vertical Arm for Suspension to Ceiling or from Wall, as Appendage to Patent Saw for Scroll Cutting by means of Vertical Saw.

The dimensions of the machine are as follows:—Height of upper surface of table from ground, 3 ft. 4 in.; length of table from back to front, 2 ft. 9 in.; width of table along front, as shown in illustration, 2 ft. 4 in. Area occupied by machine, or extent of base from outside to outside each way, including treadle, 2 ft. 9 in. by 2 ft. 9 in. In addition to what has been said above of the persistence of motion in the machine after the motive power has been removed or stayed, it may be said, in order to give a better idea of the momentum accumulated by the saw, that if six treads be first given you may then *stand upon the treadle*, and it will take you up bodily eighteen times. Generally speaking, treadle saws will cut no more than 6 in. by momentum of saw after motive power is removed, but the New Patent Saw will cut 48 in., or eight times as much as an ordinary saw.

The price of the machine in its simplest form and condition is £15, including a rip saw and a cross-cut saw, each 8 in. in diameter, and a 6 in. saw, with a pair of bevel washers for grooving. The fret arm for suspension from ceiling for fret cutting costs £2 10s. in addition, and 5s. more must be added to the price of the table if the purchaser desires to have a 12 in. cross-cut saw instead of the 8 in. saw usually supplied. An additional charge of 7s. 6d. is made for the crank handle to be used at the left end of the axle carrying the large-toothed driving wheel; and £1 2s. 6d. for the adjustable table at right hand side, and chuck for holding bits for boring. Centre bits suitable for the chuck are supplied at prices ranging from 8d. to 1s. 3d., according to size.

In conclusion it may be said that the Patent Saw Table is especially adapted to meet the requirements of cabinet makers, joiners, picture-frame makers, and pattern makers, and for the execution of circular work, grooving, dowelling, and drilling, as has been already pointed out. For amateurs who have room for such a machine, it is doubtful if anything more handy or more serviceable could be found.

7.—ADJUSTABLE REBATING CUTTER OR KNIFE.

This is one of many handy little tools that have been shown to me lately by Messrs. Richard Melhuish and Sons, 85 and 87, Fetter Lane, Holborn Circus, London, E.C. In the upper end of a nicely formed handle is set a round piece of brass about ¼ in. in diameter and ⅝ in. long. At the end of this piece of brass is set another piece, about 1 in. in length, obliquely, the two arms forming angles of 55° and 125° with the first piece on the opposite sides. The two pieces form a single casting, but I have described them as I have in order to make the construction of the tool as clear as possible to the readers of WORK. At all events we have a handle and a piece of brass at the end of it, inclined to the axis of the handle at the angles named. At right angles to the cross piece, at ¼ in. from its extremity, a cutter is inserted which is held in its place by a set screw in the end of the cross piece nearest to which the cutter is placed. Along the other end of the cross piece slides a guide or fence, also held in place by a set screw, which is adjustable, and can be moved a little more than ¼ in. from the cutter, which is ⅞ in. in length. For cutting small rebates not more than ¼ in. each way or for clearing the angle of a rebate already cut this tool will be found useful. It is, however, very limited in capacity, and would be far more useful if made in larger sizes. Its cost is only 1s. 3d., but any one who can manage to do a little brass casting can make one for himself on a somewhat larger scale. In order to give a little assistance to any would-be maker of a similar cutter I have given a sketch of the tool itself.

8.—FINE THREE-JAWED DRILL CHUCK.

This well-made little Three-jawed Drill Chuck, as its name implies, will be found of service by jewellers, and all who do small fine work, for holding drills in the lathe, to which the chuck itself must be fitted. It consists of a steel cylinder, into the upper end of which is fitted a tubular piece of iron, cut for the greater part of its length into three sections, the upper parts of which form the three jaws. A screw thread is cut along the upper part of the cylinder, on which a cap works, surrounded by a milled flange. This cap passes over the jaws of the chuck, and causes them by its pressure to grip tightly any small drill that may be placed within them. Its price is 6s. 6d.

9.—SHAPED WHETSTONES FOR WOOD-CARVING TOOLS.

Wood carvers, especially amateurs, often find a difficulty in obtaining, or even shaping, slips of a proper size and suitable form for giving a keen edge to wood-carving tools. A handy set of slips, four in number, has recently been introduced, which will obviate all difficulty in this direction in future. These slips are sold at 3s. 6d., enclosed in a box, in which they can be kept at hand, ready at any time for use when required. They are cut from the best Arkansas stone, and present in front and back every variety of form that can be required for carving tools, whatever may be their shape. They are about 2 in. long and ⅝ in. wide.

MEANS, MODES, AND METHODS.

*** *The Editor is not responsible for any statement made under this heading. Criticism and Suggestions are invited. Readers in possession of Tried and Approved Recipes, Formulas, and Processes, are requested to forward them for insertion in this column for the common good.*

PIANOS: HOW TO PRESERVE THEM.—It is remarkable how very oddly people proceed about taking care of their pianos—from sheer ignorance. It is a popular notion that pianos ought to be kept very dry. Nothing could be more fallacious. Pianos are not nearly affected so much by heat or cold as they are by dryness, but, reversely, also by dampness. It is not generally known that the sounding board—the life of a piano—is forced into the case, when it is made so tightly that it bulges up in the centre, or has a "belly," as it is called by pianoforte makers, on the same principle as a violin. The wood is supposed to be as dry as possible, but, of course, it contains some moisture, and gathers more on damp days and in handling. Now, when a piano is put into an over-heated, dry room, all this moisture is dried out, and the board loses its "belly," and gets flabby, and finally cracks. Even if it does not crack, the tone loses its resonance and grows thin and tinny, the felt cloth and leather used in the action dry up, and the whole machine rattles. Now how to prevent this. Nothing is easier. Keep a growing plant in your room, and so long as your plant thrives, your piano ought to, or else there is something wrong with it. It should be noted how much more water will have to be poured into the flower-pot in the room where the piano is than in any other room. In America it is the practice to keep a large vase or urn with a sopping-wet sponge in it near or under the piano, and keep it moistened. This is kept up all the time the fires are on.—*Iron.*

RUST JOINT.—For making a rust joint that will bear heat, cold, and rough usage, the following is said to be a good formula:—Iron Filings, 10 parts; Chloride of Lime, 3 parts; Water, sufficient to make the preceding ingredients into a paste. Put the mixture between the pieces to be joined, and bolt them together, leaving until dry.

SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

A Good Example.—C. R. (Glasgow) writes:—I have come across your prospectus of your new publication, WORK, and I think very much of it so far, and I believe it has a good chance. I shall be glad to act as your agent for this paper. I have a tool and cutlery business, and deal entirely with the working classes. Will you send me a quantity of your prospectuses (if possible, with my name and address), and also instructions, as this branch of business is a little new to me? I shall circulate your prospectus amongst my customers, and endeavour to get orders for WORK. Being a practical engineer, I also think I might at times send an article for publication.—[Your request for prospectuses has been complied with, and your communication holds the foremost place in "SHOP," as it is hoped it will be the means of stimulating many others in your position to follow the "good example" you have so aptly set in seeking to promote the circulation of WORK among workmen, for whose benefit and information it has been produced and published. Any letter or article from yourself or any other practical man will receive prompt attention.—ED.]

Picture Frames.—J. H. L. (Heywood).—An article on Picture-Frame Making, with illustrations of new forms of frames, will appear in an early number of WORK.

Ornamental Brass and Iron Work.—R. B. (Manchester).—Your suggestion is noted; and instructions for carrying out work of this description, with suitable designs, will be given in WORK as soon as arrangements can be made.

Working Models.—CHURCH.—Attention will be paid in due time to the construction of working models. It may be noted here that the particular model you require is that of a church, in which, when a penny is put in, the church bells will ring, and the figures of the ringers be seen to pull the ropes. Such a working model would be somewhat complicated in construction, and if you have never tried your hand at one before, it would be better for you to choose something easier and simpler for your first essay, before attempting anything of the kind described.

Trade Notes and Memoranda.

TOPICS OF THE HOUR.—Underground Railways in Paris.—Health and comfort in interiors.—Westminster Abbey additions.—Speculative building operations.—Oil for street lighting.—Portland cement and sea water.

SUGAR is suggested as a remedy for improving mortar.—In future none but certificated plumbers' work is to be permitted upon the Duke of Westminster's property.—£57,000 is asked to drain Margate, which needs drainage.—The fine parish church of Lyddington, Rutlandshire, is to be restored.—The Dean of Westminster has been asked to clear out some of the ugly monuments which now encumber the Abbey.—A temperance hotel is to be tried at the Devil's Dyke.—Electric headlights for trains have been successfully tried in America.—Another attempt is to be made to light the City of London by electricity.—Clacton-on-Sea has just started its much-needed sea-wall operations.

THE telephone is developing in Europe. There are now 33,000 telephone stations in Germany, 4,200 in Austria-Hungary, 4,647 in Belgium, 1,857 in Denmark, and 2,218 in Spain. France has 28 telephone systems, of which 2 are in Algeria, while Germany has 164. In 1888 the number of subscribers in France amounted to 9,847, and in Germany to 33,000. The United Kingdom had 122 systems with 20,426 subscribers; Italy 28 systems with 9,183 subscribers. Luxemburg has 15 lines with 483 subscribers; Norway 9 lines with 2,872 subscribers; Portugal only 2 lines, one of which is at Lisbon, and the other at Oporto, with 541 and 349 subscribers respectively. In Russia telephones have also been introduced. There are, in that country, 36 systems with 7,589 subscribers, of whom 1,500 are in St. Petersburg, 700 at Warsaw, 840 in Moscow, and 700 in Odessa. Sweden has 137 lines and 12,864 subscribers. Switzerland in 1888 had 71 telephone lines with 7,626 subscribers, of whom 1,533 are in Geneva, 1,066 in Zurich, 926 in Bâle, and 541 in Lausanne.

AT Pergamus a large sarcophagus has been found, near the Acropolis, determining the position of the necropolis of that city.

THE East Indian Art Manufacturing Company, situated at the foot of Cumballa Hill, near Bombay, has just laid down new machinery and sawmills, and has enlarged the workshops. About 170 workmen are employed, and some 225 tons of teak and blackwood are converted each year.

THE method of preparing the famous cæruleum or Egyptian blue has been discovered by a French chemist. The Egyptian blue is said to have been discovered by Vestorius, but it was not made after the fall of the Western Empire.

A COURSE of lectures on "Architecture," dealing with the practical side, illustrated by sketches, diagrams, and specimens of materials, are being delivered at the Central Institution of the City and Guilds' Institute, South Kensington, by Mr. Banister Fletcher, F.R.I.B.A., J.P., D.L., on Monday evenings, commencing 7.15.

A PARIS syndicate has purchased the tin mines of Villeder, which were about to fall into the hands of an English company. These mines are being erroneously represented as the only source of tin in France. But tin has been found in Bretagne from remote times. The tin mine at Montebras (Creuse) is still being worked.

A SERIES of examinations will be held under the auspices of the Carpenters' Company during the last week in June next, when gold, silver, and bronze medals (one of each), and certificates, will be awarded to successful candidates. The examination board includes Messrs. Banister Fletcher, T. Roger Smith, and W. Wilmer Pocock, and the presidents of the Institution of Civil Engineers, the R.I.B.A., the Architectural Association, the Builders' Institute, and the Clerk of Works' Association. Candidates must be between twenty-one and thirty years of age, and have passed at least in the ordinary grade of the examination in carpentry and joinery conducted by the City and Guilds' Institute.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS.** Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

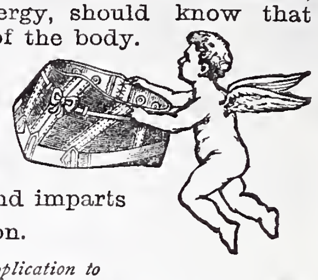
USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

NOTICE TO INVALIDS.

Men and women in search of Health, Strength, and Energy, should know that **HARNESS' ELECTROPATHIC BELT** will strengthen every nerve and muscle of the body. It is also unquestionably the best known Cure for **Rheumatic and Nervous Affections, Liver and Kidney Diseases, Ladies' Ailments,** &c.



HARNESS' ELECTROPATHIC BELT

Assists the Digestion, promotes the Circulation, stimulates the organic action, and imparts ***NEW LIFE and VIGOUR*** to the Debilitated Constitution.

BOOK of TESTIMONIALS, Descriptive Pamphlet, and Advice, free of charge on application to

PAPIER-MÂCHÉ.

How to Mould It and Ornament It.

BY SYLVANUS WARD.

I.—CONSTRUCTION IN PAPIER-MÂCHÉ—NAME AND ORIGIN OF MATERIAL—PULP—MOULDING ON MODEL—APPLIANCES REQUIRED—MOULDING ROUNDED FORMS—MAKING FLAT PANEL—MAKING VASES OF SIMPLE AND ORNATE FORMS.

PAPIER-MÂCHÉ, which, literally translated, means "chewed paper," is a term which we have been accustomed to hear applied to a great variety of products made by a pulping process, and some of which contain no paper whatever. If we look for the origin of the name we shall find that it was first applied to a coarse, unglazed paper reduced to a pulp, and then mixed with gum or glue paste, thus forming a substance plastic whilst wet, and when dry as hard, or harder than most woods, and unlike them not liable to crack. As the name would seem to indicate, the inventor, or reputed inventor, was a Frenchman—one Lefevre. About 1740 this person is said to have imparted his discovery to a German snuff-box maker named Martin, by whom it was found to be of commercial value in his trade. In or near the year 1745, John Baskerville, of Birmingham, the famous printer, took the matter up, and before long the manufacture of papier-mâché became an important industry in Birmingham and its district. Later on various fibres or fibrous materials, pulped and mixed with adhesive substances, have been known as papier-mâché; scrap leather, wood fibre imported from Sweden, potato peelings, and even sawdust, having, it is said, been made to take the place of paper; whilst in some preparations china clay, a substance apparently little suited for the purpose, has formed a large, if not an important, part of the admixture.

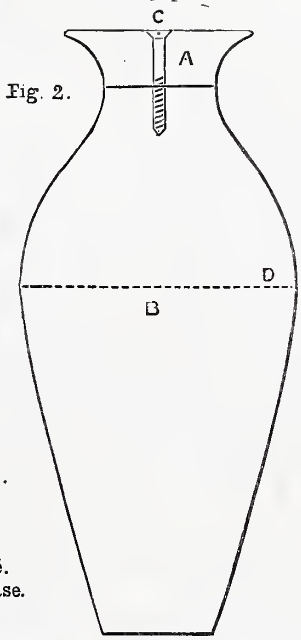

Fig. 2.

Fig. 1.—Plain Vase in Papier-Mâché.
Fig. 2.—Wooden Model for Plain Vase.
Fig. 3.—Taking out the Core.

In Baskerville's days there were reasons why an invention of the nature of papier-mâché should have been eagerly welcomed. The introduction of Oriental lacquered wares by the Dutch and English East India Companies in the latter part of the preceding century had created a fashion for such things, and roused a desire of imitation. Many of these imitations—the earliest efforts of the japanner's art in England—still remain. They are mostly clock cases, and the lids of corner cupboards, and are on wood, generally oak panel. Very curious some of them are; we call to mind one in which a shepherd and shepherdess, in the sham-pastoral taste of the day, are seated under a *bamboo* tree; the latter being, of course, borrowed from an Oriental original.

But wood, with its tendency to crack, and its rough grain, was not well suited to the japanner's art; and the advantages of papier-mâché were at once seen. It was plastic, and could be moulded to the required form; it would not crack, and, when dressed and covered with the black varnish of the japanner, it presented a level surface equal in uniformity to that of the lacquered wares of the East.

Yet this first papier-mâché did not prove to be altogether satisfactory. It is true that a fine surface was obtained, but that surface was not always to be relied upon as permanent; for if the article became overheated in any of the dryings to which it was subjected during decoration, it was apt to become wavy, or, in the technical language of the japanner, to go "curdled." Hence an improved material was a desideratum.

This was introduced in 1772, when Henry Clay, one of Baskerville's apprentices, took

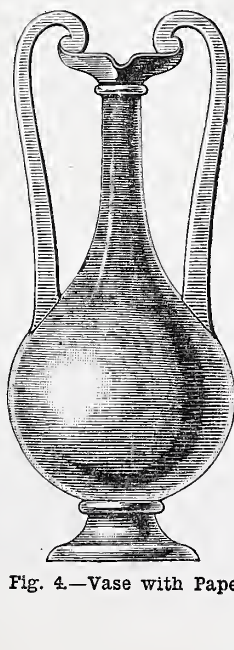

Fig. 4.—Vase with Paper Foot and Handles.

Fig. 5.—The "Lily" Vase.

out a patent for papier-mâché (though that name was no longer really appropriate), made by a new process. His plan was to form a solid mass of fibre by pasting sheets of paper together, and hardening it by saturation with oil. This gave a fine surface which, under proper management, was no longer liable to curdle. Thenceforward the pulped papier-mâché was used by japanners for inferior purposes only, their best articles being moulded by pasting.

In the process thus improved—and, it may be said, perfected, for a better substance in which to work, or a better ground on which to japan, could scarcely be desired—a rather thick, unglazed paper was used. The sheets of this were pasted together until (if a flat piece were wanted) a board or panel of some ¼ in. in thickness was formed; whilst rounded or ornamental forms were made by pasting the paper upon wooden models turned or worked into the shape which it was desired to reproduce in papier-mâché. By a combination of these moulded forms and panels it was found that any article within the range of the cabinet-maker's art could be produced, as well as others generally produced in plastic materials. The joiner could work in this paper substance precisely as in wood, except that carving was not attempted; but this was not wanted, its place being supplied by gold or colour decoration, or by pearl inlaying, or by a combination of two or all.

Of the strength of papier-mâché thus made an illustration may be afforded by the fact that when the writer was learning the business, he and his fellow-apprentices were accustomed to make cannons of it some 8 in. long, which would bear repeated firings, with fairly large charges of powder, without bursting.

For the worker in papier-mâché on a small scale, the pasting process has especial advantages. Instead of the moulds and presses wanted for pulp, he needs for this only a wooden model from which he can reproduce as many copies as he pleases.

Provided with this model, his requirements for making paper articles are:—

Rather thick unglazed paper in sufficient quantity.

Strong glue-paste, *i.e.*, paste in which some Russian glue has been boiled to give additional strength.

A brush and pasting board. The board should be somewhat larger than the sheets of paper which are to be laid upon it.

Grease or oil to anoint the models to make them leave; and a sufficient vessel of linseed oil to "bath" or soak the articles.

Also sand paper of various numbers, glue, and a few ordinary carpenter's tools; these are for treating the papier-mâché substance much in the same manner as wood. A tenon saw will in especial be necessary to saw the paper from the models; and rasps, it should be remembered, are more effective on this substance than files; whilst for planing it a toothed plane like that used for veneers is to be preferred.

Modelling.—Moulding a vase.—As a simple example of moulding on the model, let us take the plain vase (a well-known form in the trade), Fig. 1. For this the model must be in two pieces, as shown in Fig. 2, the top, A, being turned separately, and only attached to B by the screw at C. American birch has been the wood usually employed for such models, and before being used it must be thoroughly dried and repeatedly oiled with linseed oil till the surface ceases to be porous. The materials being provided, the operations of moulding are as follows:—

Rub oil or grease over the model, that the paper saturated with paste may leave it when required.

Cut up the paper into half or quarter sheets, or smaller if the size of the model demands it, and pile, say, half a dozen of these pieces on the pasting board.

With the brush dipped in hot paste, well saturate one side of the porous paper; then turn the piece over the sheet below, and treat the other side in the same manner. By thus doing the sheet below will be partially "satisfied," and surplus paste utilised.

Apply the saturated slip of paper to the model, covering as much of the surface as possible without leaving wrinkles, creases, or breaks. Continue this till the whole model is coated, pressing down the paper all over with the hand, and where needed with a smooth piece of wood, to squeeze out air bubbles. Note that the edges of the paper are to be turned down over the top and bottom of the model. At present these overlappings help to keep the coating in place, and they will be removed at the proper time.

The model having received its first coating, proceed to paste others above it to the number of four or five, taking care so to press each down as it is laid on as to squeeze out every air bubble, and to rub out wrinkles and creases as much as possible.

Place the model with its coverings in a stove or oven for the night. A gentle warmth is all that is required, the object being not to bake but only to dry. The domestic kitchen oven suffices for articles of moderate size. In the morning a hard shell of paper will be found to surround the wooden core.

Examine this to see if any blisters have arisen from the expansion of air bubbles, and if any are found cut them out. The holes so made must be stopped with a thick mixture of paste and paper dust—the latter being produced by sawing and rasping the papier-mâché, and of which waste, as the work goes on, there will soon be plenty on hand.

File off any inequalities, such as wrinkles, so as to get a fairly smooth surface to receive the next coat.

The wooden model or core may now be removed, and as a first step pare off the superfluous paper at top and bottom with a keen knife.

With a tenon saw cut through the paper along the dotted line at D, Fig. 2. The lower part of the vase will then slip off the model, as shown in Fig. 3. Remove the screw, C, and the two parts of the model becoming detached, one will slip upwards, the other downwards from the upper half of the paper vase.

The vase is now in two pieces, B and E, Fig. 3. These have to be glued together. The result is a thin, hollow, paper vase.

The glued joint having dried, the vase has to be covered with some four or five more coats of paper in the same manner as before. It has then to be again dried, air bubbles looked for and treated as before, and inequalities again filed down; these processes being repeated till the vase has reached the required thickness, which may, perhaps, be a quarter of an inch.

It should be borne in mind that it is better to build up the vase, or any other article, by several pastings of a few sheets at a time than to get the thickness by fewer and heavier pastings. The latter may appear to save time, but it would result in uncertain and inferior work. The exact number of sheets to be applied at one time must depend on the thickness of the paper, and as that may vary, it is impossible to speak on this point with precision.

Directions have been given for cutting the paper from the model after the first drying, but this must depend on circumstances. The thickness may not be sufficient for gluing, and in that case it will be better to put a second pasting of paper upon the first while the model remains within. Not only the glued joint, but the whole paper shell, needs to be strong enough to bear the rubbing it will receive in putting on the next coat.

The requisite thickness having been gained, it will be well to give the surface a rough dressing by filing and sand-papering—in a lathe by preference—in the case of a rounded object like the present. This preliminary dressing makes the paper absorb the oil better. The lower end has then to be smoothed off, and the bottom, which will be cut from a piece of paper panel, glued on.

The article is now ready to be laid to soak in a bath of linseed oil, in which it should remain for, say, two or three days. When taken out it will require to be dried in a warm, but not hot, stove or oven. The oil will be found to have penetrated every part of the mass, which will be hard enough to be turned in a lathe, or to be worked in any other way in the same manner as wood.

Mention has been made above of flat panel being required to form the bottom of the vase. Such panel will be required for many purposes, and making it is a very simple matter. The sheets of paper have merely to be pasted on a flat board (which will need to be cross-clamped to prevent warping), and the alternate pastings and dryings enumerated above will have to be gone through. If a panel becomes warped, as it may perhaps do, after being cut from the board, it may be straightened by being put in a cool place, as a cellar, under weights, and also weighted in the stove when drying.

As regards the paper to be used, it is no longer easy, or perhaps possible, to procure the thick, soft, unglazed paper manufactured for the trade in the palmy days of japanning; yet plenty of varieties are to be got well fitted for the purpose. It needs only that they should be thoroughly porous and pliable. With a thick paper the more rapid progress is made, but with a thinner one smoother and better work will, as is obvious, be secured, especially if the form be a difficult one.

Vases similar or approaching in form to Fig. 1 are frequently to be met with in old papier-mâché work fitted with brass feet and handles; but in Fig. 4, which is a vase somewhat more complicated and less easy to model, it will be observed that both foot and handles are made of paper. The handles are cut from a piece of flat panel and glued on. The core or model for this vase requires a separate piece of wood for the foot as well as for the lip.

Of a more ornate character is the vase shown in Fig. 5. This is a form sometimes to be found in old work, and was called the "Lily" vase. Its shape would seem to have been suggested by some favourite work in china. This vase is scarcely offered as an easy example for the beginner, but rather to show how the pasting process may be applied to designs of considerable intricacy. The rustic base and the stems which serve as handles are not like the vase itself, pasted, but are of pulp, built up a little at a time and stoved after each addition, the rasp being afterwards used to finish them.

(To be continued.)

ARTISTIC FURNITURE
EASILY MADE AND CHEAPLY PRODUCED.
BY DAVID ADAMSON.

An Overmantel with Cupboards
(continued).

Fitting Frieze — Bottom Boards — Moulding —Cutting Mitres—Mitre Box—Cutting Mouldings—Mitred Joints—Gluing—Ends of Cupboards—Dentils—Printers' Reglets as Dentils — Fixing Dentils — Doors — Framing for Doors—Rabbet or Rebate—Fastening up Frames—Panels—Fitting and Ornamenting Panels—Hinges and Lock—Shaped Pieces at Ends—Small Shelves—Painting and Finishing—Mantel Board—Fixing with Glass - Plates — Mirror for Overmantel.

When the shelf has been affixed to the two pieces, either the top or frieze may be fastened. Perhaps, as it will to some extent serve as a guide, the latter may as well be temporarily nailed into the recess made for it. Immediately behind it, and with the lower surface of the top flush with its lower edge, the frieze, the top piece or covering of the centre part must be nailed to the ends like the shelf. As it stands, if the frieze be taken away it is, in fact, another shelf precisely like the lower one, only set back ⅜ in. At this stage the job will consequently be as shown in Fig. 7.

Do not fix the frieze or top rail down yet permanently; better let it be removed altogether for the present, and continue the work by nailing up the two 11-in. boards. These are to be 8 in. from the bottom of the ends, and, it will be remembered, form the bottoms of the cupboards. The tops of the cupboards must also be fastened down, but, instead of them being within the ends, let them rest and be nailed *on* them. The job should now be as represented in Fig. 8, which is given to prevent any possibility of mistake as to the arrangement. One end, of course, only is shown. The frieze piece may next be finally placed and fastened down. See that it is quite long enough to fill up the whole of the space intended for it without leaving any unsightly gaps at the ends. Put one or two nails, or, in this instance preferably, screws through it into the inner ends of the cupboards, that is, those pieces in which the recesses were made; also a few, say, three or four, to hold it to the top of the centre part. Keep these latter as near the edge of the frieze as convenient, so that their heads may be covered by a strip of wood which will afterwards be placed there, and take particular care that all the screws are well sunk so that their heads do not project. A couple of screws should also be driven through the tops of the end cupboards into the frieze, when, if everything has been properly done, the whole structure should be perfectly rigid and firm. As the work proceeds, test it continually with the square. Do not be afraid of using this too frequently, and if it shows anything wrong do not pass the defects over without, at least, an attempt to correct them.

Now let us turn our attention to the moulding, which is such an important feature in the overmantel, and on which, with the shaped pieces at top of the centre opening and under the cupboards, almost the whole decorative effect may be said to depend. I do not advocate any beginner making his own mouldings, as they are not easy, and to form the various members properly not only implies skill but a stock of planes such as a novice is hardly likely to possess. Suitable machine-made mouldings are to be procured in any large town, and where the amateur cannot get the address of a maker or large dealer he may generally be able to obtain them through a builder, and many large cabinet-making firms will also be able to assist him. Still, as this may not be specific enough, it may be stated that in London machine mouldings may be obtained from Henry Smyth, 33, Wharf Road, City Road, N., who, as British agent for Ekman's Mechanical Joinery Company, of Stockholm, holds a large stock of them. The prices quoted are per 100 feet in lengths of about 12 feet. For mouldings of a finer character than those generally in request by builders, Mr. Samuel Elliott, Albert Mills, Newbury, Berks, may be recommended. In the overmantel the moulding is one of a very ordinary character, as will be seen by Fig. 9, where it is represented in section, full size. Of course, it by no means follows that others must adopt the same pattern, but the illustration gives a good idea of the size of what is suitable, and those who have the catalogues of either of the firms whose names have been given will have no difficulty in finding something appropriate. For example, among Smyth's architrave and panel mouldings there are over fifty designs, any one of which might be selected. I ought to say, to prevent disappointment in case of some choicer wood being used than that from packing cases or pine, that builders' mouldings are stocked almost exclusively in the latter wood only.

Whatever may be the pattern of the moulding, the only difficulty that it is possible there can be in adjusting it will be at the mitres or corners. If these are not accurately cut the members of the parts will not fit to each other, and no amount of "doctoring" can make them look right. Therefore, let every pains be taken to ensure a good mitre. It is not difficult with proper appliances, the simplest of which is perhaps that about to be described, and one which is as useful as any. It consists merely of three pieces of, say, 1-in. stuff, and of any convenient length—12 or 18 in. will be enough—fastened together as shown in Fig. 10. The sides must be parallel with each other and at right angles with the bottom. Saw cuts at an angle of 45 degrees (half a right angle) across the thickness of the sides must be cut perpendicularly through them from the top to the bottom, the position of the cuts being such that the saw will work through both sides, as in the plan, Fig. 11. The cuts form a guide for the saw, which it is evident will cut through any moulding held in the box, as shown in section, Fig. 12, at an angle of 45 degrees, and form a true mitre. By having cuts straight across, it will also be seen that this simple mitre box may be used as a guide in making rectangular cuts, as at the back ends of the mouldings. The manner of using this little appliance must, however, be so evident that it would be superfluous to make further remarks about it. A fine saw should be used in cutting the mitres, which I imagine there can be no doubt about; but in case any one should not understand, Fig. 13, showing a mitred joint, is given for his special benefit.

In cutting off pieces of mouldings for the ends, it will be as well for beginners to have them fully long. The surplus can easily be sawn off from the back afterwards. If preferred in this overmantel, mitred joints may be dispensed with altogether, and probably among experienced workers there would be considerable diversity of opinion whether it would not be preferable to shape the end to the moulding. After due consideration I am, however, bound to say that I do not fancy any but those skilled in such work would make so neat a job this way as by mitreing, nor would it have so workmanlike an appearance. Were we discussing this latter point, however, there is much that might be said on both sides, and it may fairly be left to professional technical journals to treat of. The moulding along the front may be cut of about the proper length, for as a break will have to be made at each of the four ends, any little irregularity can always be provided for when fixing up.

Before gluing any of the mouldings to the work it will be as well to make the mitred joint. To do so, cut the mitred end of the front piece, as shown in Fig. 14, where it will be seen that its length—if one may call it so—is just the same as the thickness of the end moulding. On fastening the two together it will be found that by this means the "return" of the moulding round the front end is effected. The result is, in fact, just what would have been got had the end of the moulding been cut as it was suggested above it might be, with the advantage, however, that there is no end-grain visible nor any unsightliness from the possibility or probability of the members not being evenly cut. Of course, both end mouldings must be treated in the same manner, the mitres being glued.

When the mouldings are ready for fixing they may be glued on to the ends of the overmantel, the upper surfaces of the mouldings being a little higher than the tops of the cupboards in case it should be thought afterwards that any blocking is necessary. This will be explained later on. A few brads may be used as auxiliary to the glue, but they should not be necessary, except, indeed, in hot, damp climates, where glue alone is not to be depended on. Without, however, giving here full instructions about the proper preparation and application of glue, both of which, especially the former, are of great importance, I may give the following hints:—See that the glue is hot; that both surfaces of the pieces to be attached are at least warm before gluing them; do not put the glue on too thickly; do not "dab" the moulding down, but slide it gently about to drive out air bubbles and superfluous glue; squeeze as much as possible of this out, and use cramps to hold the parts together tightly till the glue has set. Finally, those who do not understand the preparation of ordinary glue thoroughly will find it better to use Le Page's carriage glue. Why? Simply because this is always reliable, which even the best ordinary glue never is unless properly prepared.

The remainder of the moulding for the front must be cut into three lengths, one of them exactly the length of the centre opening, the other two the same as the cupboards. Perhaps before cutting them it will be as well to prepare the four small pieces of wood which are attached to the upper parts of the upright pieces or ends of the cupboards. These pieces, as will be seen in Figs. 2 and 3, rise above and project a little in front of the moulding, the shape of which they, to a certain extent, follow. The wood of which they are formed should be exactly the same thickness as that of the ends to which they are to be attached. Fig. 15 shows in full size the shape of these pieces with the relative positions of the moulding, etc. The work, of course, is done with the fret or bow saw, as already described. These pieces are merely glued on to uprights, though I have used a couple of fine brads as well, driven in through the thin flat part.

When the mouldings and these facing

parts are fixed as described above, the dentils under the former may be prepared and fastened as well as the small square strip just along the bottom edge of the frieze. The exact size of the dentils is not of much importance, but the same cannot be said of their uniformity, not only in size but in every other respect, such as thickness and spacing. The easiest way to prepare them is to get out slips of the required width and thickness. Place several of these pieces on top of each other, fastening them here and there with a small brad or screw nail so as to form a solid block. Mark off on the top piece the required width (or length) of each dentil, this being best done with a pair of compasses, and saw through the block at each mark. The box, as for mitres, but with cut straight across, may be used as a guide for the saw, but it need hardly be suggested that the fret machine affords a ready means of doing the sawing, especially as from the comparatively fine teeth of the fret saws the cuts will be so clean as to need little, if any, papering to smooth them down. I have used that excellent machine, the Britannia Company's No. 8, to make a number of dentils, and, by forming a kind of guide to work along and on the top of its straight-sided table, the sawing is bound to be even. If some contrivance of this kind is not used, it will be desirable to mark across the top piece of the dentil stuff with a square.

Those workmen who desire to reduce the preparation of the dentils to the smallest amount of trouble may be informed that printers' reglets come in very handy. They are pieces of wood about $\frac{5}{8}$ in. wide of various thicknesses, each of which is known by a special name, and is always true to gauge. The labour of cutting wood to the required size is thus done away with altogether by those who prefer buying a few reglets ; all that is then necessary being the cutting up into dentils. As some guide for the size of these it may be said that "pica" reglet is about the right thickness for such a piece of work as the present, and that $\frac{1}{2}$ in. is sufficient for the width of the dentils, etc. As all may not care about using reglet stuff, it may be said that $\frac{1}{8}$ to $\frac{3}{16}$ in. will do very well for the thickness of the stuff used for them.

Before gluing any of the dentils on to the frieze, mark this out for them in order to avoid irregularity in spacing. A dentil, not a space, should abut against each end, as shown in Fig. 2. In fixing them it will be just as well to use a needle point to each in addition to glue, which should be laid on as thinly as possible, for if any exude it will be found a tedious and troublesome job to remove it. The small piece along the lower edge of the frieze may be glued and bradded. Reglets, which, by the way, are sold at very low prices in lengths of 3 feet, will do very well for this, though perhaps the proportions shown on Fig. 15 present a more sightly appearance.

Now for the doors of the two cupboards. The construction of these will tax the novice's skill somewhat, though there is really nothing difficult about it. Naturally those who have acquired some facility in joinery will know that the top and bottom rails are attached to the upright pieces of the frames—or, as they are technically called, the styles, either with mortise and tenon joint or by dowelling. The tyro, however, may want something easier than either of these methods—or, if not easier, one more adapted to and likely to give better results in untrained hands. As has already been hinted, this may be managed by halving the pieces together. What this means will, I think, be understood without more words by Fig. 16, where the top rail is shown with half the thickness from the front, and the style with half the thickness from the back, cut away. On fitting these two together, it is evident that the front surfaces of both will be level.

Before showing how to manage this operation of halving in a systematic manner, let us see about the wood of which the door frames are to be made. From the directions already given, it goes without saying that the thickness is about $\frac{3}{4}$ in., though if they are more it is of no consequence. The width of the framing should be about $1\frac{3}{4}$ in. Four pieces will be required for each door—viz., two styles the exact length of the height, and two rails the width of the cupboard. These must be halved to fit each other, and, simple though the operation may be, it goes without saying that by method the work may be facilitated. In the present instance we will suppose that the different parts are to be literally halved, and the necessary rabbet in the frame for the panel to lie in to be cut afterwards. Not, perhaps, the most workmanlike way of proceeding, but the easiest for beginners. Skilled workers will know how to go about it otherwise ; and perhaps, by-and-by, other methods may be described in this series of papers, leading the novice from easy construction onwards. For the present, having got the four pieces for the frame of the door ready, proceed as follows :—Mark the width of the styles off from the end across the front of the rails. Do the same on the back of the rails, taking the width of the styles as a guide. Set the gauge to about half the thickness of the wood, and from the points mark off on top, bottom and ends. There are now guide lines for the saw to remove the pieces, and it will be well to saw within the lines, so that the space made by the saw is included in the waste to be removed. If not the spaces will be too large, and a good fit will not be obtained.

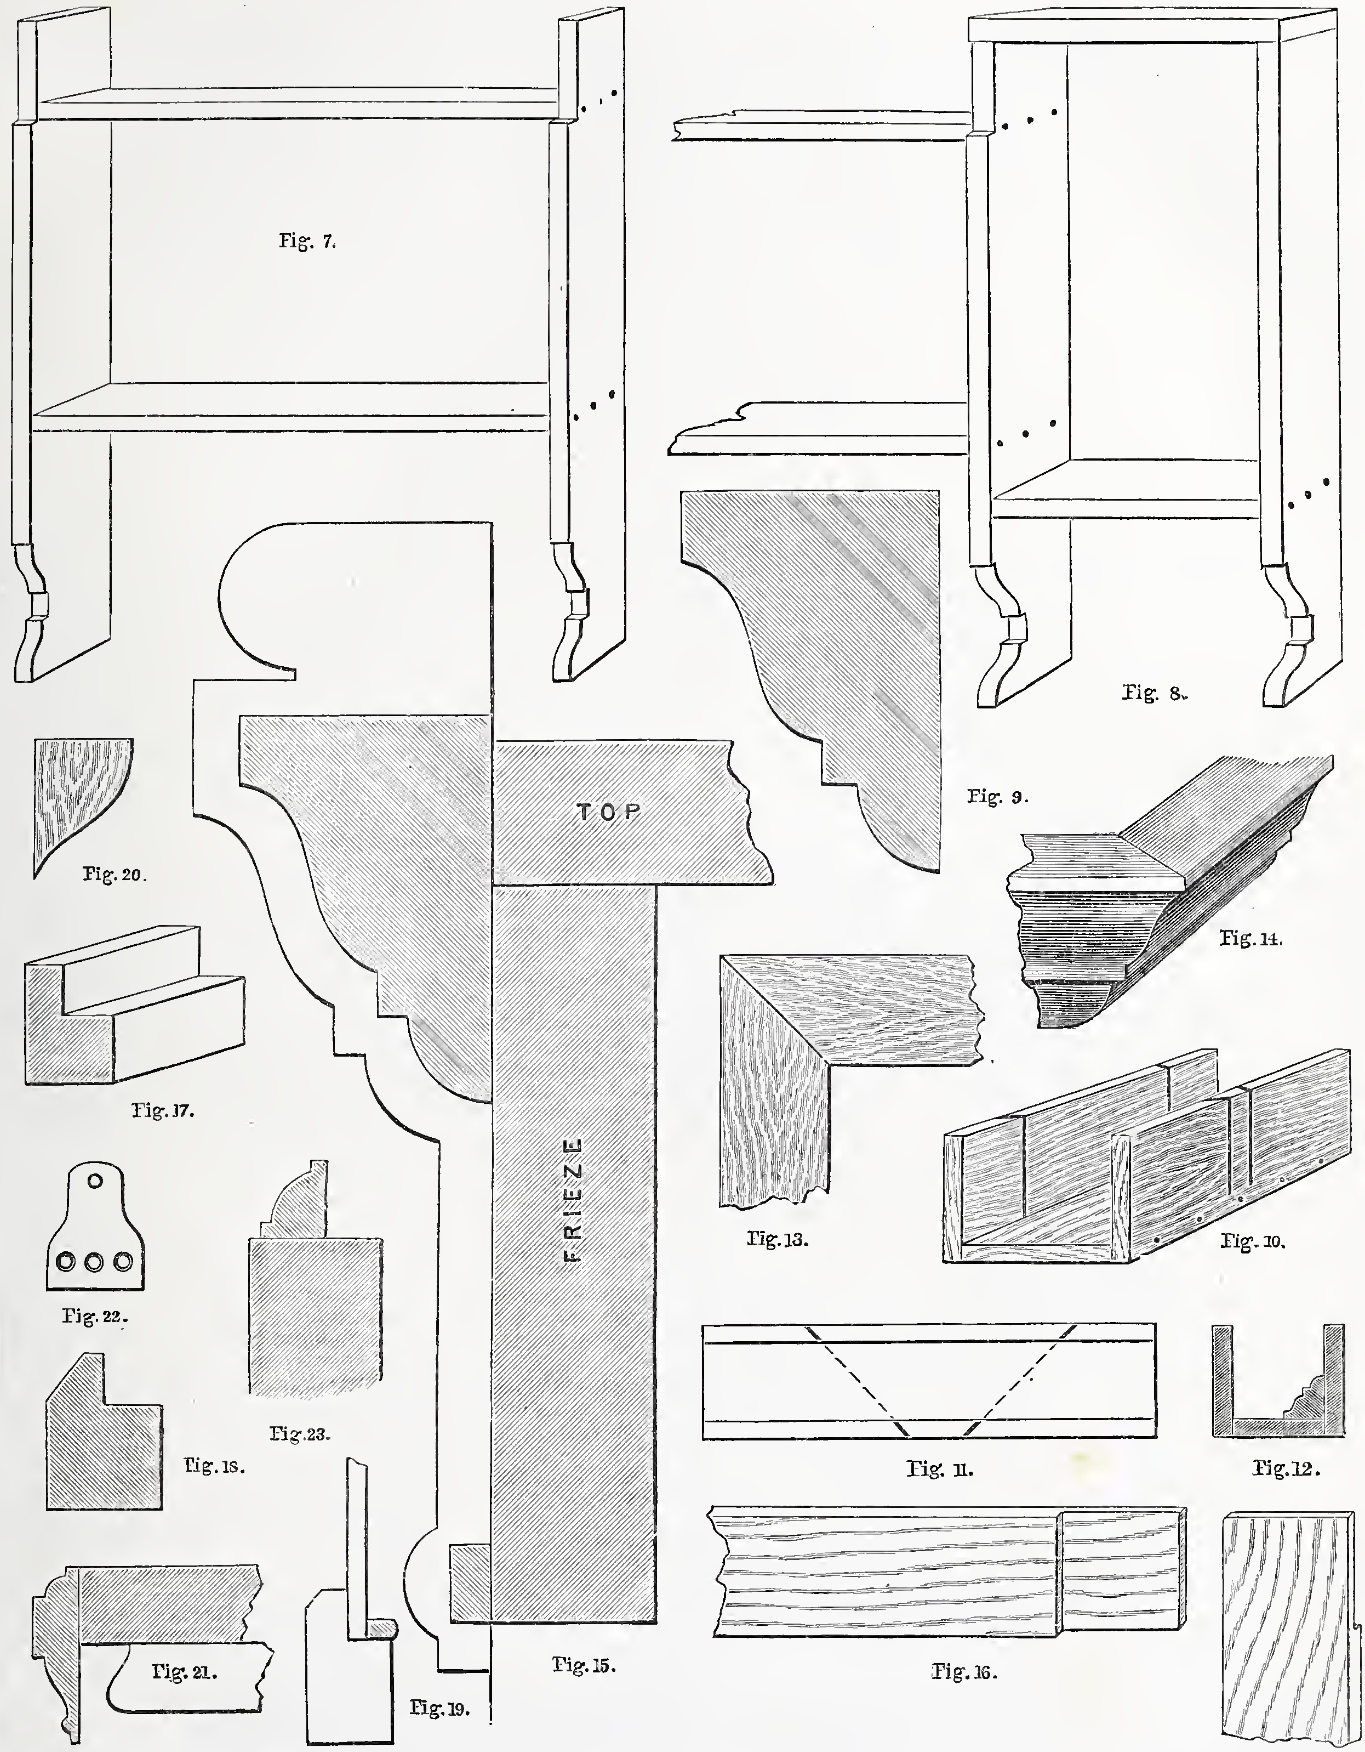
The rabbet or recess round frame has still to be cut, and to prevent any misunderstanding by the use of this technical expression a part of the rabbeted frame is shown in section by Fig. 17. The recess is the rabbet, or as it is sometimes written, and perhaps with greater regard to correctness, "rebate." The proper tool to do this with is the rabbet plane, but a gauge, preferably a cutting gauge on account of the deeper cut it makes, and an ordinary chisel may be made to do very well. The gauge should be set to mark about $\frac{3}{8}$ in., and a line scribed with it round the inner thickness of the frame, working from the front. The reason why the marking for this and for the halving should be done from the front is that, in the event of the thickness of rails and styles not being identical, any inaccuracy will be at the back of the door, where it will not be so conspicuous. The other dimension for the rabbet is not a matter of much consequence, provided it is sufficient to hold the panel in. The marking being done, the piece can easily be cut away with a chisel, especially if a cutting gauge with the blade set to cut a good depth has been used. It will be understood that the rabbet is only cut round the opening, and not extended to the ends of the frame pieces. The edges may be left square in front, but it will be neater to bevel off the rails, as shown in section, Fig. 18. This will be done by shaving off the sharp edge with a plane. The frames may be fastened up with glue alone, but perhaps it will be just as well to assist its adhesion by a couple of screws at each joint. As already suggested, brass screws driven from the front could hardly be regarded as objectionable, unless on the ground that they are not usually seen in furniture ; but there is no necessity for them being visible, except when the door is open, if they are driven in from the back. Care will, of course, in this case be taken not to bore the holes right through, nor to use screws as long as the thickness of the wood.

When the frames are ready the panels may be got out. They are only thin stuff, $\frac{1}{4}$ in. thickness being quite sufficient. In the illustration, Fig. 1, they are shown quite plain, but the intention is to cover them with lincrusta walton. As this may not be known, I may say that it is an embossed fabric somewhat resembling thin linoleum. It is principally used as a wall covering, but for decoration of a cheap kind it is admirable. The effect of a panel covered with it is very much like carving, and as the designs in which it is prepared are excellent it is superior in appearance to badly carved work. I shall, however, have more to say about lincrusta later on, but in the meantime I throw out the hint that it may be got through almost any high-class decorator.

The panels, whether plain or covered with lincrusta, should fit closely, and be fastened in with a few brads driven into the frame to prevent them falling out. Certainly a neater way would be to fix them in with small slips of beading, but this entails more labour, and so may not be judged necessary for such a piece of furniture. Still, for those who prefer this mode of fastening, Fig. 19, showing rail, bead, and panel in section, is given. The beading may be glued to the frame, but it will be better either to brad or screw it in case it should be necessary to remove the panel at any subsequent time for carving or other decoration. On no account, especially if the panel is not covered with lincrusta or something similar, glue it into the rabbet. If it is glued and the wood is not perfectly dry it will very likely split in shrinking. If unglued it will be able to "play" and contract without splitting.

When the door has been made it may be hinged, but as particulars of the whole of this part of the work will be fully treated in a separate paper it will be unnecessary to describe the operation in detail here. The size of the hinge is unimportant, but from $1\frac{1}{2}$ in. to 2 in. will be suitable, the "butt" variety being the proper kind. The door in mine has no fastening, as it is so hung that it keeps shut when closed, but of course a lock may be fitted if desired. "Cupboard" locks are the sort, one with "bolt shooting to left," and the other "to right;" but as lock fitting will come in in some other piece of furniture, description must be left for the present. To prevent the doors being forced too far in, a small block should be glued inside the cupboard. The block or stop will be more out of the way if fastened near the top, but if a lock is used perhaps the best place for it will be just behind the hole into which the bolt will shoot.

The shaped pieces placed at the ends of the overmantel and the small shelves have not been mentioned, but they require very little description. Like all the rest of the curved outlines, they were cut with a Britannia Company's No. 8 fret saw, and are of the same thickness as the ends. The only caution I would give is that the upright pieces should be long enough to fit closely



Artistic Furniture. An Overmantel with Cupboards: Details. Fig. 7.—Inner Ends with Shelf and Top. Fig. 8.—Ends of Overmantel showing Attachment of Shelves and Top. Fig. 9.—Section of Moulding. Fig. 10.—Mitre Box. Fig. 11.—Plan of ditto. Fig. 12.—Section of ditto with Moulding. Fig. 13.—Mitred Joint: Plan. Fig. 14.—Mitred Moulding. Fig. 15.—Facing Piece of End with Cornice. Fig. 16.—Construction of Halved Joint. Fig. 17.—Rebate or Rabbet. Fig. 18.—Bevelled Edge. Fig. 19.—Section of Rail, Panel, and Bead. Fig. 20.—Small Side Shelf. up to the piece at the lower edge of the frieze, and that they should be neatly tapered off to its thickness. The shelves are shaped as in Fig. 20. By screwing the shelves to the shaped uprights or side brackets, as they would probably be called by most cabinet makers, and then to the ends, it will only be necessary to drive a brad or two in through the upper part of the brackets to make the whole secure without any unnecessary display of nails. Of course, screws may be driven through the ends at the back of the cupboard into the brackets to any extent. The shaped pieces under the cupboards and at the top of the centre opening speak for themselves so far as outline is concerned. They may be of wood ¼ to ½ in. thick, but no object is gained by having them too stout. They are fastened by small blocks of wood glued to them and to the parts above them, as well as glued up themselves. A couple of brads are also driven through each where the wood is narrowest.

This operation completes the construction of the overmantel as it stands, the finishing having been given by painting with an enamel paint of a dark chocolate colour. That, however, is merely a matter of detail, as in the event of any one finishing the work with paint the surrounding colour should be taken into consideration, and it is almost unnecessary to point out that both bright and light-coloured painted furniture seems to hit the popular taste just now. A sufficient range of colours in enamel paints is to be had, so that the overmantel may be finished in almost any tint.

Leaving this, therefore, it will perhaps be more serviceable to describe how the back of the overmantel may be fitted either with glass, wood, or other panels. Perhaps before doing so it will be as well to advise that the overmantel instead of resting on the mantelshelf should rest on a board, which of course will cover the shelf. My own reason for using a board was that the shelf is shaped in front—serpentine, I believe, is the correct description. Now, however beautiful the curved line thus indicated may be to some, it certainly does not accord with such an overmantel as the present one. The wooden board, as it may really be called, covers the embodiment of the "line of beauty," which, however, I am afraid Hogarth would scarcely recognise as such. A moulding is planted on the front and ends of the wood, so that the original shelf is not seen. (See Fig. 21.) The moulding at the front corners is mitred, and is attached to the shelf with glue. Instead of a moulding I may suggest a fringe or mantel-frontal for those who, like dust accumulators, though many of these frontals are so beautiful that one ought hardly to object to their use. Much, however, must depend on the kind of room the overmantel is for. In a work-room excess of drapery is objectionable, in a drawing-room tolerable, for it is elegant—no, that's not the fashionable word nowadays; call it rather artistic or æsthetic. Any way, the reason I advocate a wooden shelf is that it gives a finish to the overmantel, and on some future occasion I hope to prepare a woodmantel to complete the fireplace, and as soon as the design is ready I shall be pleased to describe it in WORK.

In ordinary circumstances no fixing will be required for an overmantel such as the present. The shelf is laid on the mantelpiece, and above it the overmantel. If, however, it is necessary to fasten it to the wall it may easily be managed with one or two glass-plates. These are made of brass, shaped as shown in Fig. 22, and owe the perhaps rather misleading name by which they are generally known to the fact that they are much used for fixing chimney glasses to walls. They are obtainable at most furnishing ironmongers. To use them, screw the broad part of the plate to the back edge of some part of the article so that the smaller end is uncovered. The plate then lies flat against the wall, into which a nail is driven through the remaining hole in the plate. It is just as well to keep the plate or plates as near the top of any overmantel they are used to hold to the wall. In the present one the most suitable place seems to be at the back of the tops of the cupboards, one to each if two are used, or if only one then at the back of the top centre board. The plates will, of course, be fixed so that they are upright, projecting above the tops, as the nails into the wall can be more easily placed than if the plates hung downwards. Like many others, however, this is a detail which can only be generalised on, and enough has been said to enable any one to do what is necessary.

Lastly, let me say if glass is desired behind the overmantel, or, to put it more widely, if the wall behind the overmantel is to be covered, some sort of rebate must be made for the glass or wood panel to fit into. A frame, similar to that for the doors, may be made to fit into the spaces, and either glass or wood let into them. A simpler way, however, will be to get some small moulding, such as shown in Fig. 23, and glue it round the openings, leaving just such space behind as will form the necessary rabbets. It must be mitred at the corners, and besides forming a rabbet will have a suitably decorative effect. No backs will be required for the cupboards as the wall closes these behind. I trust I have now shown sufficiently and clearly how a useful piece of furniture may be simply made from such unpromising material as an old packing case, and if it may seem that the instructions are lengthy, let me say that as many of them are applicable to the construction of the remaining articles of the same kind which are projected, and will be described in following parts of WORK, it will not be necessary to repeat them. It will be taken for granted that those who wish to make any of the other things which will be described have read the present directions. This will prevent a lot of recapitulation, and allow succeeding articles to be briefly treated, only details of any operation not necessary in the overmantel being subsequently described. Possibly by the time we have done the novice now may find that he has gained a very fair idea of general construction as applied to wood work.

PHOTOGRAPHIC NEGATIVES:

Their Reproduction and Multiplication.

BY L. IVOR POOLE.

IN connection with my business, which, I may say, is not photographic, I find it convenient to resort to photography occasionally. As the prints are sometimes wanted in large quantities, that is to say, a few hundreds from the same negative, some speedier method than that of printing one at a time naturally soon suggested itself as desirable. In other words, I wanted to print several from the same negative—a negative which should be a reproduction of the original. As the pictures are mostly small, it occurred to me that, by reproducing the negative several times on the same plate, not only might the plates be economically used, but several prints might be got on the same piece of paper—*i.e.*, instead of arranging the printing frame for each picture, and so losing much time, a number of prints might be got at one operation. I may say that for my purpose it is not necessary that the prints shall be first-rate specimens of photography, or that they are all printed and toned equally. In fact, not to make any mystery about it, they are required for advertising purposes. What they show or advertise does not matter, but having explained what they are wanted for, any business man will readily understand that economy of production, both as regards time and money, is essential.

Well, seeing that the desirability of producing them quickly and cheaply was so great, I made various inquiries. Whether these were wrongly directed I do not know, but it is certain I could get no satisfactory explanation of any process that would suit. I was recommended to try the various quick printing processes, but none of them, either owing to difficulty or expense, came up to my requirements, and I could get no information how to reproduce negatives easily and quickly. The thing seemed to be a very simple matter, and doubtless would have proved so in the hands of an expert photographer. Even to me the work was very simple in theory, but in practice the failures were more than I care to contemplate, though why should it be so? If a certain road is paved with good intentions, the road to success is marked with failures which serve as finger-posts directing onwards. This was how I worked my theory out—not an original one, no doubt. If a positive could be printed from a negative, could a negative not be printed from a positive? Certainly. Could not such a reproduced negative be used to print other positives from? Again, certainly. Further, could not several negatives be made on the same plate, just showing what was required, and leaving the superfluous margin out? Yes; it seemed easy, but I was a long time before hitting on a satisfactory method.

At last, after many trials, I did so; and the result is that, instead of printing each photograph separately, when I want a number of any I reproduce a number of small negatives on one large plate. For example, just in front of me as I write is a "whole plate," containing fifteen facsimile negatives, not, perhaps, all quite so brilliant as the original from which they are reproduced, but sufficiently good. The consequence is that it is only necessary to put one piece of the sensitised paper in the frame and fifteen photographs are printed on it. These fifteen are afterwards easily separated with a pair of scissors.

Without going into the details of the various methods I have tried and discarded as being unsuitable from one cause or another, I may describe the process I adopt now, as it may not only be useful to others who are experimenting in the same direction, but may give them hints which will enable them to improve on it. If they do, perhaps they will give us the benefit of their experience in these pages, which no doubt will be open for any hints based on work actually tried. The notions may be crude, and the methods apparently self-evident, but some of us want a good deal of assistance even in such, and for the sake of us "duffers" I take the liberty of hoping that any particulars likely to be of use will not be withheld by our more skilful brethren. This will partly explain my presumption in explaining what, for want of a better title, is called the reproduction of negatives; and now I may remark that though I have said several of these are wanted on the same plate for my purposes, the same principle may be applied to the reproduction of a single negative.

This reproduction, it will be understood, may be useful occasionally when the original negative has been destroyed before a sufficient number of prints have been taken; and, as a matter of fact, I believe some such method is followed when it is not convenient to reproduce by a camera. I suggest this, as one evening lately, when I was preparing a quantity of negatives on the same plate, a friend who was with me happened to mention that he had destroyed a plate after having only got one print from it, although several were desired. My work gave him the necessary knowledge how with his own print he could reproduce any number. From my original negative, or rather from the part of which I want to print a number of copies quickly, I take a sufficient number of prints on the ordinary silver paper.

For instance, not to specify the things shown on my photographs, let us suppose that it is desired to reproduce one head only from a plate containing a group of several people. A piece of the sensitised paper is placed behind this head, and exposed in the regular way. The depth to which the printing is done must depend on circumstances, but, as a rule, better results are got from prints not quite so dark as those which are printed for toning. I aim at getting prints of much the same depth as if they were toned; that is to say, they are not printed darker than a finished photograph would be, no allowance having to be made for lightening by toning and fixing. These prints certainly may be toned and fixed in the usual manner, but these operations only needlessly complicate the work, for no one will need to be told that it is much more difficult to get a batch of photographs finished exactly to the same depth and shade than merely to print them equally.

Of course, when the prints thus produced are taken out of the frame they are kept in the dark till they are wanted, and light being kept from them, they retain their colour well enough to serve their purpose for some time. When a sufficient number of them are ready, their edges are cut and trimmed, each piece of paper being cut accurately so that they may fit well together. They are then stuck to a piece of glass, usually a spoiled negative, with the film washed off. This glass serves merely as backing to hold them flat during the printing of the negative. The prints need not be stuck down all over, as a small touch of some adhesive material—strong gum, or, what I generally use, glue—on each being sufficient. As the printed side must be uppermost, the plain side of the paper is stuck to the glass; and as the glue, or whatever is used, has the effect of increasing the density of the position, or, as it may now be called, the negative, *pro tem.*, at that particular place, it should be applied just behind the darkest part of the print. If this be done it will scarcely leave a trace on the subsequent negative.

When the prints are all fixed to the glass, this is placed in an ordinary printing frame, and the reproduced negative is taken from it. I proceed as follows, all this part of the work being done by gaslight, which not only allows me to utilise spare time in an evening, but is more reliable than daylight. The time for the exposure having been once ascertained with the artificial light, no guess work or calculation is required, as it would be with the variable shades of daylight. I always expose for these negatives with one particular light, so that making very slight allowance, according to the depth or thinness of the positive, the precise time for the exposure can be told to a nicety.

As some guide for others, I may say that I print under a common "pendulight," with a white shade over it. The frame during exposure lies on the table underneath, at a distance of, say, twelve inches from the flame. Time of exposure under these conditions is about thirty seconds, with a variation of five seconds, more or less, according to the density of the (positive) negative, for Eastman's negative paper and ordinary Ilford's. With the gas out, and by the aid of the ruby lamp, the plate or paper is arranged in the frame, which is then placed back upwards on the table till the gas is lighted, when the exposure is made as already described. The plate is developed afterwards in the ordinary way. It will then be seen that on the one plate the original negative has been reproduced, and by putting it in a frame with a sufficiently large piece of printing paper, the saving of time and trouble in producing prints must be manifest.

As a rule, I use whole plates for reproduction, but of course there is no limit to size. I do not separate each print at once, but tone and fix first, washing, etc., as usual. The backs of the sheets are then gummed over and left to dry, after which they are stored away, and the separate photographs cut off with a pair of scissors as may be required. There is then no more trouble in affixing them to their mounts than if they were so many postage stamps. Of course, gum could not be safely employed if the photos were intended to be durable, but for the purpose they are intended for it answers very well. The use of paper negatives has been alluded to. I use Eastman's, but no doubt any other kind would do, and I much prefer them to glass for this kind of work. For example, when an unusually large number of photographs is wanted in a hurry, several sheets of the paper negatives can be stuck on one piece of glass, if necessary as large as a full sheet of the silvered paper. The paper may seem to militate against speed in printing, and no doubt it is a trifle slower than glass negatives, unless these be rather dense. A well-prepared paper negative, free from stain, however, prints with a rapidity when its opacity is reduced by oiling, which may seem remarkable to those who have not tried them.

Perhaps something ought to be said about this oiling and sticking to the glass, though this latter is only necessary in the case of very large negatives, say when more than one sheet of the negative paper is used in the same frame. One negative sheet may be simply placed on the glass, to which it need not be stuck in any way. For the oiling, almost anything greasy may be used. There is a stuff, a preparation I believe of vaseline, called "translucine," which is recommended as specially applicable, but never having tried it, I cannot speak positively of its merit. Melted paraffin is not a bad substance, but I always use something more easy. To touch on everything that I have used would be to give a tolerably long list of oleaginous substances. I will content myself with mentioning two or three. Castor oil is—apart from its smell, and, I may add, its taste—a favourite. It penetrates the paper well, and is colourless, the one quality reducing the granulation which is often noticeable in prints from paper negatives, and the other not hindering rapid printing. Vaseline is also good, but its slightly yellow colour is not always convenient. Butter has been employed when nothing else has been handy, and I am not sure that it does not do as well as any of the others.

Whatever may be the oil or grease used the paper must be well saturated with it, and sufficient time given to allow it to soak in. By degrees, some of the oil evaporates, and the negative, instead of being clear all over, becomes patchy, some parts or spots being more opaque than others. The remedy, of course, is to re-oil. I give a liberal quantity of oil, and rub off superfluity with a soft rag, being specially careful that none remains on the film side of the negative, as, of course, this is next the silvered paper, which, if not spoiled, would not, at any rate, be improved by grease.

When the newly produced negatives require to be stuck to the glass, which, as I have said, is only necessary when several of them are used in one frame, I do not stick them down all over, but just sufficiently to keep them in position. Glue or paste, of course, does not adhere properly to the greasy negative. This generally can be arranged with a margin round it or on one side, and some strong adhesive material may be used, but I find it very much simpler to use pieces of postage-stamp margins, part being stuck to the glass and part to the negative. It sticks well to the gelatine film, and if necessary can be easily removed by damping. As, however, one or two small pieces only are required, the negative can simply be torn away from the glass, and fastened down with fresh stamp paper a good many times without any necessity for damping.

I should not omit to mention that instead of silver prints for the preparation of the reproduced negative, prints on the Eastman film may be taken, and the multiplied negatives taken from them. The other operations are identical, and though this rough-and-ready way of practising photography may not commend itself to the "artist" photographer, it will no doubt be of some use to those who, without requiring perfect reproductions, wish to have them quickly and in quantity without much expense.

A SIMPLE CEILING IN WOOD.

With Hints for Wall Panelling on the Same Plan.

BY HIRAM PRICE.

I.—Ceiling with Longitudinal Arrangement of Mouldings.

In common, I presume, with many to whom this periodical promises to be a boon, I am accustomed to do many things which people generally consider it necessary to pay other men to do. Wishing to have a house of my own, and one after my own mind, I have constructed a dwelling without employing either architect or builder. With a bricklayer and a carpenter acting under my own directions and supervision, I have raised a structure which thus far answers satisfactorily all the requirements of a home, and one, moreover, which embodies most of my own theories and views with regard to domestic architecture. Its fittings are mainly the work of my own hands. In a house so built, I make no question but that there must be many features which would have an interest for the readers of WORK. That feature, however, which just now I desire to bring under their notice is the peculiarity that throughout my dwelling no plaster whatever has been used. I object to plaster. It is in my opinion at the same time a costly and an unsatisfactory thing, as well as being a material in which an unprofessional workman like myself does not care to dabble.

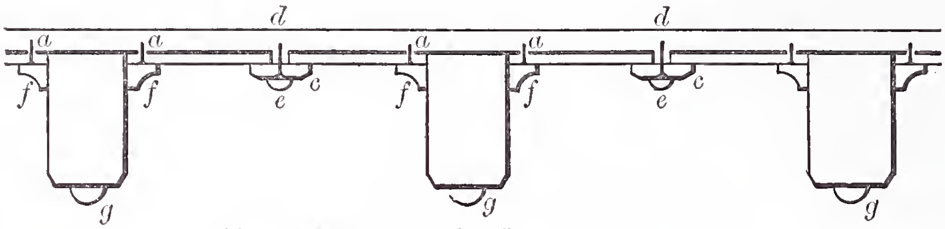

Fig. 1.—Wood Ceiling with Floor above, in Section.

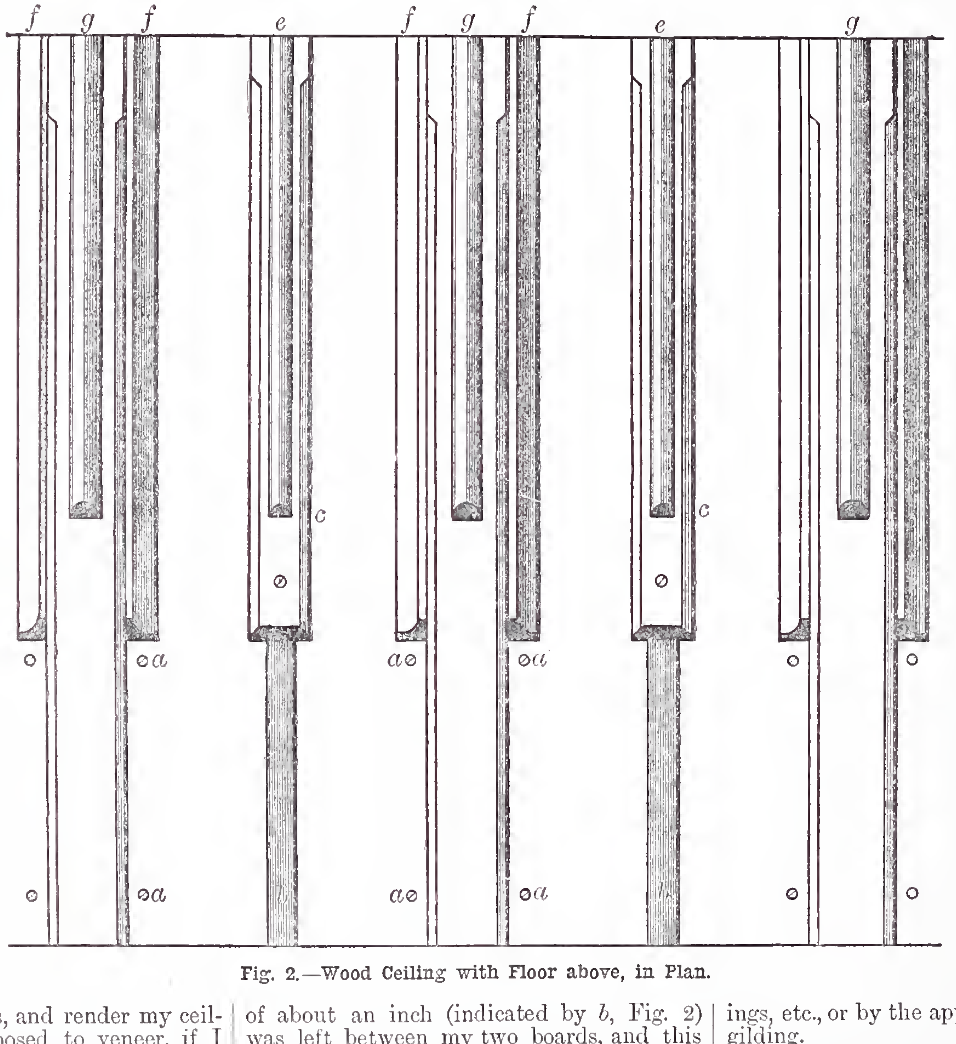

Fig. 2.—Wood Ceiling with Floor above, in Plan.

Now with walls there are abundant ways of dealing to the exclusion of plaster—you may batten and paper them, you may panel them, you may hang them with tapestry, or with pressed and moulded bricks laid carefully and neatly; you may, for certain purposes and situations, make the inside surface of your wall sufficiently pleasing to the eye to be left uncovered. There are such uncovered walls, relieved by ornamental brick mouldings, in my house. But, in the case of ceilings, one has fewer resources at one's command, and how I dealt with mine may be worth describing.

As I proposed to make an ornamental feature of my joists, I had them planed and stop-chamfered before being placed in position, and upon these the flooring boards were afterwards laid in the usual manner. My flooring boards were, as is customary, planed on the upper surface only, and left rough below; consequently, when nailed down by the carpenter, they presented anything but a pleasing sight to the spectator when seen from beneath. To do away with this unsightliness, and render my ceiling decorative, I proposed to veneer, if I may so use the term, between my joists with a second thickness of boarding which should be planed and finished.

In thus using thin board I knew that I should have a difficulty to contend with in the tendency common to all new timber used in a house, and which in thin board especially shows itself—that, namely, of shrinking whilst drying, and thereby causing the formation of ugly chinks; or, if so fixed as to be prevented from shrinking freely, of cracking and splitting. How I overcame this difficulty may be seen at a glance by reference to Fig. 1, in which is drawn a section of the floor and ceiling. The arrangement there shown has enabled me to avoid betraying any chinks, and to keep my wood from much danger of splitting.

The spaces from joist to joist which had to be covered were 15 in. wide. For each space I provided two 7 in. widths of planed ½ in. board; and laying them close to the joists, I secured them to the flooring above by screws driven 1 in. from the joists and a foot apart. These screws are shown in Figs. 1 and 2, and are marked *a*. A space of about an inch (indicated by *b*, Fig. 2) was left between my two boards, and this I covered by the strip of moulding marked *c* in the last-named figure, and also indicated by the same letter where seen in section in Fig. 1. This strip was 2 in. wide and an inch thick, and was fastened by screws to the flooring above. These screws, as shown in *d*, Fig. 1, were driven through its centre, and not, be it remembered, through its edges where they overlap the veneering boards. The object of this will be apparent—it is desired to *support* the edges of those boards without absolutely *fixing* them, that, thus being attached on one side only, they may have liberty freely to expand or contract with the alternations of damp and dryness, heat and cold. The most ordinary cause for the splitting of boards is thus avoided.

By this strip of moulding I hid the opening between the two boards, and I rendered the strip more ornamental, whilst at the same time I covered the screws which secured it by the piece of half-round beading (*e*, Fig. 1) which I fixed along its centre with needle points. The same beading is also shown under the same letter of reference in Fig. 2.

To cover the screws which fastened the veneering boards, and further to add to the enrichment of the ceiling, I then ran a strip of hollow moulding along the angle formed by the joist and the veneering board (*f*, Figs. 1 and 2), fastening it to the joist with needle points. Lastly, I gave a finish to the under surface of my joists by running a half-round moulding, similar to that before named, along their middles (*g*, Figs. 1 and 2), and fixing it in the same way.—N.B. Needle points are, for such purposes as this, far preferable to brads, as they can be broken off level with the surface of the moulding, and are practically invisible. Of course it is only for very light work that they are available.

For my own ceiling, I used only yellow pine and red deal, and these were merely stained and varnished. But I gained a certain amount of relief by staining some of my mouldings of a deeper shade than the general tone. I would, however, suggest that there are two ways in which a ceiling thus constructed might be made to give scope for considerable decorative taste: either by using woods of different and ornamental kinds in the veneering boards, mouldings, etc., or by the application of paint and gilding.

To a man handy with carpenter's tools, but not with the brush, the first method would no doubt chiefly recommend itself; and by a judicious selection of woods, in which colour and shade were well contrasted, a good effect might be produced. But the woods would be costly, and mouldings in such woods are not kept in stock by those who sell such things, and would have to be specially struck, which would cause additional expense.

To any one more at home with the paint brush, the second plan may seem the better:

it would cost less and be more effective. For such a purpose a good deal of bright and positive colour might be employed. On a ceiling brilliant colouring can be used more freely than on a wall. On the latter anything very pronounced looks crude and vulgar, because the eye is constantly resting upon and criticising it. But at a ceiling we rarely look directly; at most times we have but an indistinct sense of its existence; and to derive pleasure from any ornament upon it, our perceptions demand that that ornament should be pretty boldly made out. I am not, however, prepared to offer a scheme of colour for such a ceiling, and am now throwing out suggestions merely. My own wooden ceilings were merely stained and varnished.

In one respect I must admit that my work has not given me complete satisfaction: my ceilings transmit sound too freely. Now, this is a disagreeable, though, perhaps, scarcely to be called a serious, defect; for, without being a conspirator or murderer, one may have matters to talk over in one's house which it is not expedient to have heard by every person who may happen to be on the floor below, or the floor above, as the case may be. We like to feel sure of our privacy. Nor does any one feel at ease when he knows that every little sound he makes in moving about his bedroom—harmless as those sounds may be—is distinctly audible to those in the room beneath. Moreover, like thin partitions, floors which transmit every trifling noise are too much associated in our minds with cheap jerry-built houses to be ever altogether pleasing to us. I must own this defect to be a weak point. Yet I can now see how easily this inconvenience might have been avoided, and have a suggestion or two to offer on the subject for the benefit of any person who is inclined to ceil his rooms after my method. Sound might to a great extent be deadened by the simple and easy precaution of putting felt between the two layers of board; an inodorous felt of course to be used. Two or three thicknesses of the paper felt used for laying under carpets would, I imagine, be cleanly and effectual for the purpose. A felt in which the fibre is woollen is no doubt a more decided non-conductor of sound, as well as of heat, than one in which the fibre is vegetable, but it has disadvantages in other directions; and though I do not speak on this point from experience, I should say that a paper felt would be best for the present work.

Or, in case the worker prefers to cut off sound in a more thorough and substantial manner, he might adopt some such plan as that shown in Fig. 3: a space (h, h, h) might be arranged between the two layers, to be filled with some non-conducting substance, such as pugging or sawdust. Pugging—a rough mortar, that is—when thus used in Scotland is emphatically termed "deafening," and admirably answers the purpose of intercepting sound; it also goes far towards rendering the floor fireproof. It, however, weights the joists heavily. Sawdust, which is light, will to a great extent answer the purpose of a non-conductor of sound, and might, by putting a little powdered alum with it, be rendered fireproof. This would be adopting the plan employed in the packing of fireproof safes. Alum, it will be remembered, holds a large percentage of water in suspension, which, at a high temperature, it gives off in the shape of steam. Hence alum holds towards fire very much the attitude of a dog in the manger—it will neither burn itself nor let anything near it burn.

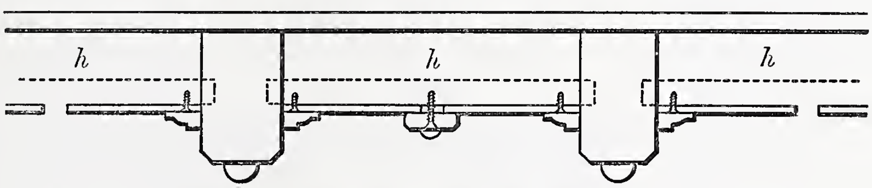

Fig. 3.—Wood Ceiling. Section, showing Space contrived under Floor for Packing.

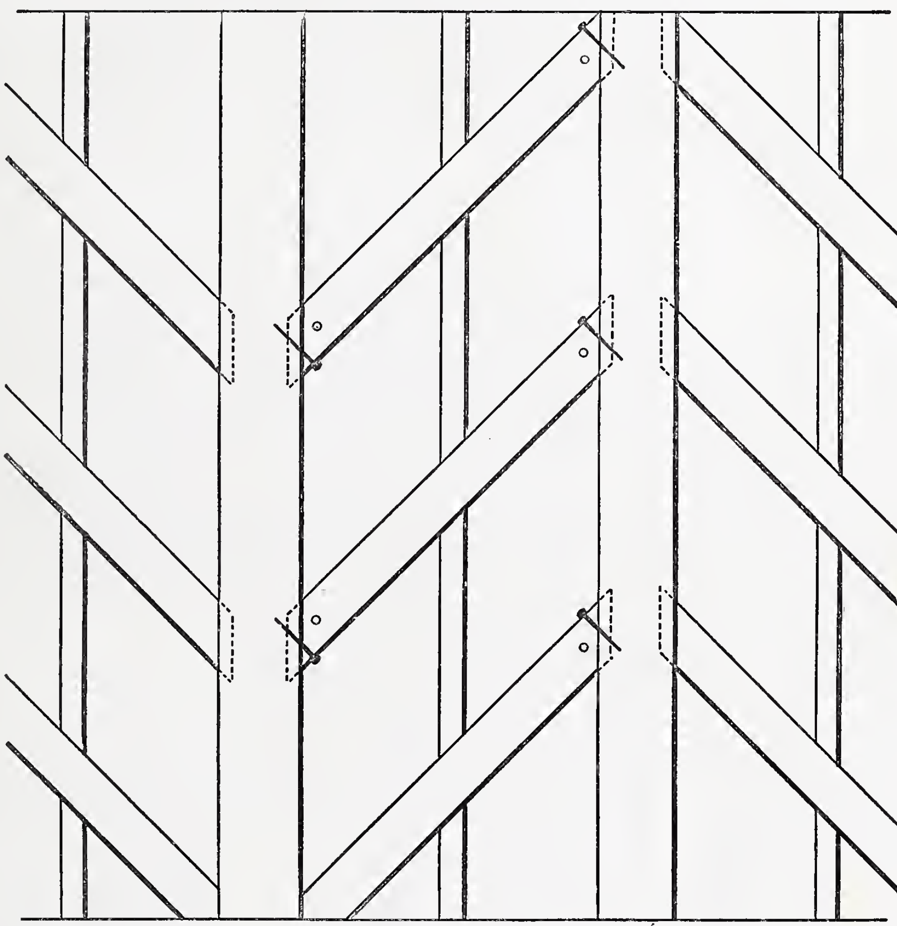

Fig. 4.—Wood Ceiling. Plan, showing Alternative Arrangement for Support of Veneering.

It is said that the discovery of this property in alum is due to a certain observant individual who was roasting a pinch of it in an iron spoon as a remedy for a gumboil from which he was suffering. Fortunately, his pains were not so acute as to prevent his remarking and speculating on the curious anomaly that this seemingly dry substance should, when heated, become moist, and exhibit all the characteristics of a moist substance. He reflected that if heat, which renders most things dry and inflammable, caused this to grow wet and to damp everything around it, it must needs be valuable as a fire resister. After experiments proved his conclusions to be correct: and alum has been used not only for admixture with sawdust in the packing of fireproof safes, but as a means of rendering fireproof a variety of inflammable materials, more especially the flimsy textile fabrics sometimes used for ladies' dresses. It is unroasted alum which has this property; by burning or roasting it all water is expelled, and it is thus rendered useless as a safeguard against fire.

This is a digression; but any means of guarding against fire are so important to all interested in building houses—and for that matter, to all interested in living in houses when built which includes a moderately large section of the public—that any apology for it can scarcely be needed.

Should the pugging or sawdust arrangement be adopted, the packing must of course be done before the flooring boards are laid, and the veneering boards and mouldings must be supported in some such manner as is shown in Fig. 4. Laths may be nailed diagonally at the proper height, from joist to joist, or, as there indicated, greater solidity may be attained by mortising them into the joists, and to these laths the veneering boards and mouldings are to be screwed.

In Fig. 4, an alternative arrangement for support of veneering, the ceiling is supposed to be seen from above before the flooring boards are laid down.

Thus far I have spoken of my simplest arrangement of wood work only; in the second part of my subject I shall deal with certain decorative arrangements which are somewhat more elaborate, with the application of the same kind of wood work to wall panelling, and some allied matters.

(To be continued.)

THE BUNSEN BATTERY.

Its Construction and Application.

BY GEORGE EDWINSON BONNEY.

III.—Constancy of the Battery.

The following table (from the *Electrical Review*) shows the constancy of the Bunsen battery. The experiments, which led to the results herein tabulated, were performed with one pint size cell of the Bunsen battery, or, rather, with two such cells, one of which was charged with nitric acid (specific gravity, 1·35) in the porous cell, and the other with the ordinary bichromate of potash solution in the porous cell. The outer cells of both were charged with a solution of dilute sulphuric acid (one part of acid to twelve parts of water) in each cell. Each cell was short-circuited through a wire connecting the zinc and carbon, the resistance of this circuit being 1·05 ohms. The cells were charged with their solutions one hour and three-quarters before the first test was made. The constancy of the Bunsen, when charged with nitric acid, should be noted and contrasted with the rapid failure of current when charged with the bichromate solution. During a working day of nine hours the first shows a vigour equal to its strength at the end of the first fifteen minutes, whilst the second shows only a fourth of the vigour exhibited at the end of its first five minutes.

Table, showing Constancy of Bunsen Battery, at Times as specified from Starting :—

After working	Nitric Acid.			Bichromate Solution.		
	E.M.F. in Volts.	Current in Ampères.	Internal Resistance.	E.M.F. in Volts.	Current in Ampères.	Internal Resistance.
			Ohm.			Ohm.
	1·71	1·21	·35	1·83	1·22	·45
5 minutes ...	1·70	1·21	·34	1·40	·90	·50

3 ,, ...	1·69	1·26	·28	·99	·67	·42
4 ,, ...	1·68	1·26	·27	·90	·60	·45
5 ,, ...	1·65	1·23	·28	·76	·49	·50
6 ,, ...	1·64	1·22	·28	·61	·37	·60
7 ,, ...	1·64	1·21	·29	·48	·29	·60
8 ,, ...	1·64	1·21	·29	·43	·25	·67
9 ,, ...	1·63	1·20	·29	·41	·23	·73
11 ,, ...	1·60	1·17	·30	·35	·20	·70
22 ,, ...	1·45	·91	·53	·31	·17	·77
23 ,, ...	1·36	·83	·46	·31	·17	·77
24 ,, ...	1·17	·73	·54	·31	·17	·77
25 ,, ...	1·02	·63	·56	·31	·17	·77
26 ,, ...	·90	·55	·57	·31	·17	·77
29 ,, ...	·43	·25	·66	·31	·17	·77
30 ,, ...	·42	·24	·69	·31	·17	·77
31 ,, ...	·41	·23	·72	·31	·17	·77

If larger cells had been used, the internal resistance would have been reduced, and, if a stronger solution of sulphuric acid had been used in the outer cells, the E.M.F. would have been higher in each case. This would have given a stronger current. The results are most satisfactory, and should be carefully studied by all who wish to employ a powerful and constant battery.

The author concludes his short article with the following words :—"The nitric acid cell is far superior to the chromic, as far as the work is concerned, and, if it were not for the disagreeable and unhealthy fumes it gives off, would be used in nearly every case."

The above table will, I think, be found to be a valuable appendage to the remarks I have made in the preceding papers on the construction and application of the Bunsen battery. The papers themselves have been written with the view of affording assistance alike to the young electrician who has not been at work long enough to gain the experience which time and observation alone can bring, and to the amateur who may be attempting to make and work a battery perhaps for the first time. Should any readers need advice or assistance, I shall at all times be ready and happy to give it them through the medium of "Shop."

CRYSTOLEUM PAINTING.

BY O. BECKERLEGGE.

I.—Introduction—Colours—Brushes—Glass—Choice of Photo—Removal from Card—Corn-Flour Paste—Treatment of Photo—Shifting—Removal of Specks—Thinning Photo.

There are but few arts that are almost purely mechanical which yield such artistic effects as the one now about to be described. Like many other tricks and notions it is not of English birth, yet it can be easily practised by any one with the smallest amount of art instinct. It is in no sense a fine art, yet at the same time by it really beautiful and artistic-looking work can be produced.

In the hand of the artist photography readily lends itself as a foundation both for oil and water colour painting, but to lay colour on the photograph to produce a good effect requires the skill of a trained hand and great judgment. During the last few years a modification of an old art has come to us from over the sea, which has been improved upon by successive individuals until now it is so simplified that any one with an appreciation of colours can almost rival in effect the beautiful ivory paintings of our grandmothers' days. Moreover, it is one which can be learned almost as easily from reading as it can by seeing it done, and this, I presume, is the reason of its popularity. I learned the art in this way, and although I have the advantage of a knowledge of mixing colours and using the brush, yet I was surprised at the simplicity and rapidity of the operation. And to those who have not an intimate knowledge of colours, I think I can give such explicit directions that their want of knowledge shall prove but little hindrance.

Before commencing work we must supply ourselves with sundry requisites as follows :—

Glasses, two for each picture.

Paint, oil in tubes.

Cobalt.	Carmine.
Vandyke Brown.	Rose Madder.
Burnt Sienna.	White.
Naples Yellow.	Black.
Indian Yellow.	Vermilion.

And any other colour that any particular subject, such as landscape or drapery, may require.

Poppy oil.

Two or three brushes. They need not be sable—though for oil painting these are best in a general way—but fine hog would perhaps be equal to our work.

And last, though not unimportant, the subject to be worked on. The glass must be selected according to the subject chosen. Glasses can be procured as follows :—

Locket size, 3d. per pair.
Brooch size, 6d. per pair.
Carte de Visite, 6d. per pair.
Cabinet, 9d. per pair.

Larger sizes up to 10½ and 8½ in. varying from 1s. to 3s.

Round 3½ in., 8d. per pair.
Round 4 in., 1s. per pair.

These and all other requisites can be obtained of Messrs. Reeves, 113, Cheapside, London. I have found him ever ready to oblige, and his materials are the best of their respective kinds. I mention this as for a while I did not know where the glasses could be obtained, and possibly there are others in the same condition of ignorance.

Some care should be taken in the choice of the photo. As a first experiment take a head—good size, strongly marked features, eyes well opened. There must be good half tone and modelling—that is to say, there must be good shadows, as they can only be supplied by the photo, and unless they are fairly intense the picture will appear flat and without character. Good and suitable photos can be obtained of Messrs. Reeves, varying in price from 6d. to 2s.

But we will suppose that we are about to use a carte de visite. In the first place give it a good licking—but perhaps you will not relish that ; if not, take a little benzole and wipe it over—this will remove any trace of grease. Place it in boiling water long enough to allow it to come off the card. It must not be pulled off until the cement is softened, as if in any way the photo is torn it is spoiled. Whilst your picture is soaking, boil a little corn flour. See that there is not a trace of lumpiness in it. It must be thoroughly mixed before the boiling water is poured on it. If there be any suspicion of lumps, you had better strain it through a piece of fine cloth.

Press the picture between blotting-paper. In the meanwhile thoroughly clean your glass and rub the concave side with your paste, also rub some on the right side of the picture. Now lay it on the glass, seeing it sets square. Place a piece of strong smooth paper on the picture, and with the thumb squeeze the paste out from between the picture and the glass, beginning at the centre and working towards the edges. A wooden presser or squeezer is recommended by some, but I have never used them, and never found the need of them. For a while there will be a danger of the picture shifting ; if it gets out of square it must be screwed around to its proper position.

Looking at your work in some lights you will find the picture covered with small silvery specks—these are caused by a want of contact between the picture and glass. These must be entirely removed. Perhaps you may find your work so dry that you will fail to remove them ; if so, place your work in a bath of warm water—not hot, else you may require a fresh glass. I have found a good soaking almost entirely remove the offending specks, and a few judiciously applied rubs with the thumb have completed this part of the operation. When everything up to this point is perfect, let it stand till next day, say, to get thoroughly dry.

We must now reduce the thickness of the paper, so as to secure transparency. Take No. 1 glass paper and gently rub away at the back of the photo, watching it very closely, as a scrub too many may destroy all the work. You will gradually see the picture growing more distinct, and on holding it up to the light will see where the thickness of the paper is uneven. Rub the thicker parts down so that there is an evenness all over the picture. When your judgment shows you that the paper is almost thin enough, take No. 00 glass paper and give it a few gentle rubs to take away the rough marks left by the coarser paper.

(*To be continued.*)

"TIPS" FOR TYROS.

BY OPIFEX.

2.—Imitation of Wood Carvings.

Old oak, or other carvings in low relief, may be very effectively and easily imitated, almost in facsimile, by the following process:—

Procure some "basil" leather, and wet it thoroughly in warm water, in which a small quantity of size or glue has been mixed; wipe it as dry as possible with a cloth, then cut a piece sufficiently large to cover the carving, and allow a small margin; lay it upon the carving, and press with the fingers all over, in order that the leather may take the shape of the carving as much as possible. Next, with a smooth-pointed tool made of bone—say the handle of a toothbrush, filed down till it assumes a blunt knife shape — go over the surface carefully, pressing the leather into all the interstices of the design, and smoothing the larger or bolder portions until you have succeeded in bringing out all details. Of course, this process can only be applied to carvings, etc., which are not undercut.

If the superfluous moisture has been removed from the leather in the first instance, it may now be easily taken from the carving without interfering with its shape, but if not, it must be left until partially dry.

When taken off, the leather should be placed in a warm place to dry thoroughly, when it will be found to be quite stiff, and may be coated thickly at the back with a layer of gutta percha; or with the following mixture: pitch, resin, plaster of Paris, equal parts; melt the pitch and resin together, and then stir in the plaster of Paris. If a small quantity of wax candle be added to the mixture, it will be rendered tougher.

The imitation may now be applied to the use for which it was intended, and if treated with dark distemper oak-stain, and oiled, will look wonderfully like genuine carved oak.

3.—Reproduction of Medallions.

Very handsome and highly artistic medallions, which are capable of being applied to many uses, can be produced from the paper replicas of relievo subjects, which are sold at about 1s. each, and which can be procured from most artists' colourmen, etc. Those used by the writer are manufactured by Monrocq Fres., Paris, and are chiefly facsimiles of famous classical heads — *e.g.*, Minerva, Achilles, etc. etc.

The reverse side of the paper medallion is used as a mould, placed face down upon a table, the edges resting upon four pieces of wood; the edges are then built up by a strip of gutta percha, etc., to a depth of about an inch. Now mix in water fresh plaster of Paris which has been well dried in an oven to the consistency of thick cream, using about a pint of water, or more than sufficient to fill the mould; see that it is kept well stirred until it is perfectly mixed, and then pour into the mould to a depth of about half an inch at the edges.

The plaster should be carefully and gradually, yet quickly, poured. to ensure its running into all crevices and to avoid air bubbles. It will "set" very rapidly, and in half an hour may be safely, but very cautiously, turned out, and left to dry; after, say, twelve hours, it should be placed in a moderately hot, ordinary kitchen oven for two or three hours, when it will be perfectly hard.

It may be found that some particles of paper have stuck to the plaster, and these should now be removed, and the edges trimmed with a sharp knife, to fit it for whatever purpose it is intended. Next dip the cast into skimmed milk several times, until it will imbibe no more, and then dry thoroughly in the sun. When dry, dust over freely with French chalk, and rub lightly all over with an old silk handkerchief, or other very soft cloth.

The cast will now present a highly polished surface, and will look more like ivory than plaster.

These medallions make most artistic ornaments when mounted in either ebony or ebonised frames.

4.—Bronzing.

An easy and successful method of bronzing articles, such as metal chimneypieces, ornamental metal work of any kind, plaster figures, etc., is to give the subject a coat of japan, in which a small quantity of Brunswick green has been mixed, just sufficient to neutralise the brown colour of the japan; and when almost dry, apply bronze powder, either gold, silver, etc., freely with a large round camel's-hair brush to the more prominent portions of the articles in hand, but very sparingly to the other portions; in fact, in the hollow and flat parts only a mere "suspicion." Care and some practice will be required to soften off the more highly bronzed portions, so as to avoid abruptness, and also that the brush may not take up any of the japan or paint; but if applied with a light hand and a very soft brush the bronze powder will prevent this.

Large earthenware jars, when first sized, and then treated in this way, are most effective for decorative purposes.

A thin, even coat of good varnish will ensure the bronze keeping its colour for a very long time.

PRICE'S "UNIVERSAL" LATHE.

A Lathe with Front and Vertical Slides.

BY F. A. M.

As long ago as 1883, there arose a discussion in the *English Mechanic* upon two points in lathe construction, and this discussion was continued a very long while, and it continues to reappear still from time to time. In fact, the subject appears to have excited very considerable interest. The object of the proposals which were brought forward was twofold: first, it was felt that however convenient was the usual construction of the slide lathe, with its leading screw, and its saddle sliding on the bed, for self-acting sliding, or for slide-rest work; yet, when a piece of hand work was to be done, and, still more, if a piece of wood was to be turned, it was necessary to get rid of the saddle by sliding it to the right hand end of the bed, and lifting the poppet over it. Those who clung to the old system had much to say in its favour; they contended that, for a bit of hand work, a rest for the hand tool can be made by fixing a slide-rest tool with the blunt end outwards, and using that blunt end as a rest, and that can often be done; or, better still, the slide rest, in a small lathe, can be made with a tenon pin to fit into a socket; then it can be taken out when required, and a T rest for hand-turning put in its place. Very true; but that plan is hardly suitable for large lathes, in which the slide rest requires a more solid support. Again, it was shown how the washer securing the poppet beneath the bed could be so made that, when the fixing screw was released, it could be lifted out with the poppet, coming up through the opening in the bed, and so it could be easily and quickly removed. This, too, is quite correct, and it is a method of construction which should be always adopted. Still, there were some who considered it an annoyance to have to clear the tools off the bed, and move the saddle out of the way of chips, etc., when the hand rest was needed; and these were inclined to favour a separate slide running along the front of the bed, on which the saddle should move, quite independently of the top of the bed, on which the headstocks, hand rest, etc., were placed; so that, if it were desired to remove the saddle and rest in the middle of a piece of work, it would not even be necessary to take the work from between the centres, nor to disturb the poppet at all; but only to rack or slide the saddle away past it, to the right, and place the hand rest on instead. If those who have not seen a front slide lathe will look at Fig. 1, they will understand how this can be done, and the section of the bed at Fig. 2 will explain still further.

And now, as in most improvements, it must be confessed that the advantage above mentioned is not obtained without cost. Instead of the weight and wear of the saddle falling as usual upon the broad, flat top of the bed, it comes upon the somewhat narrow, oblique edge, marked X in Fig. 2. It must, therefore, of necessity, be more liable to wear down than with the old way. To prevent this tendency, which is not of great importance in a small lathe, the front slide is made of considerable length; and, though it might look strange, since there is no obstacle at either end, it might be well to have it longer than it is. Where two plates of metal slide on each other, the shorter must in time wear the longer hollow; but if both are of the same length, there seems no reason why they should not keep straight indefinitely. It has, therefore, been suggested that it might be an improvement in this lathe if the front slide were lengthened, and the planed part of the bed on which it moves shortened, so as to make both, as nearly as may be, of the same length.

A far more important advantage offered by the lathe must now be mentioned. The slide rest is mounted on a *vertical slide*. Now, a vertical slide is the great want of the lathes of the present day; it is useful in so many different ways, it is hard to name them all; and many have been the attempts to supply the want, by additions or appliances of more or less unsteadiness, in the shape of vertical slide rests bolted upon the tool plate of the ordinary rest, or upon the seat where the quadrant plate of the rest usually goes; and these attachments, although so unsteady and troublesome to apply and remove, are very useful. How much more, then, must be a *permanent* vertical slide, *always ready*, and *never in the way?* This last point must be insisted upon. How many useful appliances might be, and are, added to foot lathes, which, however ingenious and well suited to the special work they are intended to do, are, nevertheless, a real trouble, and even a nuisance, when ordinary work is being done! Rarely, indeed, is it possible to add any special appliance to a lathe without in some way interfering with its general handiness. Here, however, we have a most useful addition, always ready for use, and yet its presence might pass almost unnoticed were it not for the hand wheel underneath the front slide, by means of which the vertical slide is moved up and down.

About two years after the discussion on the subject of front and vertical slide lathes, there appeared in the *English Mechanic* an illustration of a beautiful little American tool, in which the idea was well carried out, probably quite independently, by the Ballou Company; but, though one or two English makers undertook to make lathes with front slides, the far more useful vertical slide was not made in England until recently it was arranged by Mr. Price, and is now being manufactured by the Universal Lathe and Tool Company, of 131, Leadenhall Street. The 3½ in. centre size is shown in Fig. 1.

The following is the description of the lathe by the makers :—

"The *Bed* is 3×4½ in. deep, so made that a leading screw can be applied if wanted for screw cutting, and has webs every 12 in. of its length. The metal is distributed to give it lightness and strength combined.

"The *Head* and *Poppet* are made so that the line of centre will be parallel with the edge of the bed. The *Mandrel* and *Collar* are of the best cast steel, and carefully hardened. The mandrel is hollow, 2½ in. deep, $\frac{5}{16}$ in. diameter; nose ⅝ in., Whitworth's. The *Driver Chuck* is of gun metal, with steel centre; drill or cutter chuck is of ¼ in. bore. Cone pulley has four speeds.

"The *Poppet* has a steel cylinder mandrel, and it is so arranged that the hand wheel does not project beyond the barrel of the headstock, so that the front slide will pass the poppet without its being loosened.

"The *Front Slide* is fitted so that it will slide along the front of the bed, and can be locked instantly by a cam lever; the vertical slide is well fitted to saddle and arranged to rise and fall; has steel square-threaded screw and gun-metal nuts.

"The *Slide* is fitted to vertical slide bracket, and indexed to take any angle; the transverse slide is made and arranged with two T slots, and is 8 in. long and 3 in. wide. All the slides are carefully ground in, and are as firm as if they were of one piece of metal. The slide and tool holder can be placed on any part of the T slot table, and is supplied with two T rests and socket.

"The *Standards* are of the best form to give it stability and strength without being cumbersome; the *Crank* is of forged iron with steel ends for centres. The *Fly wheel* is accurately turned, and has three speeds. Treadle motion is light and strong. Approximate weight about 3½ cwt."

The makers desire it to be known that they have altered the square-looking tool-holder shown in the illustration for one which enables the tool to be set at any angle. They have arranged a backstay for turning long bars. The screw in the bed is for adjusting the position of the work when milling; there is a collar upon the screw with holes for a tommy. In turning, the upper part of the rest being in position, the longitudinal feed can be given by that, and the small screw in the bed is not needed.

The following are the various advantages over ordinary slide-rest lathes which are claimed for Price's "Universal" Lathe by the makers :—

"1. Whereas an ordinary slide-rest lathe can only be applied to turning, this lathe can be applied instantly to milling of every description, by simply putting the cutter between the centres of the lathe; and then bolting the work to the table, the cut can be adjusted to a nicety. This lathe can be applied instantly to the following work, and

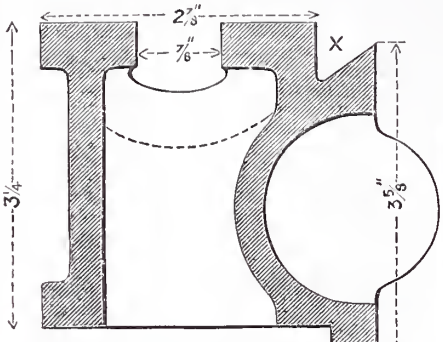

Fig. 2.—Section of Bed of Lathe (half size).

will save its cost in a few weeks in time and files. It is considered by the most scientific mechanics that it can be applied to any description of work, and that it will do the work of six different machines in one.

"2. The front slide has an enormous advantage; it can be put out of the way and replaced instantly, and is always at hand.

"3. Having a vertical slide fitted to saddle, the depth can be readjusted, and the tool can be raised and lowered according to the diameter of the work, and therefore does not require packing as in a slide-rest lathe.

"4. Poppet traverse screw is arranged out of the side of poppet, so that no chips will get into the screws, and the barrel is full length of the headstock, so that it will not spring when a heavy cut is taken."

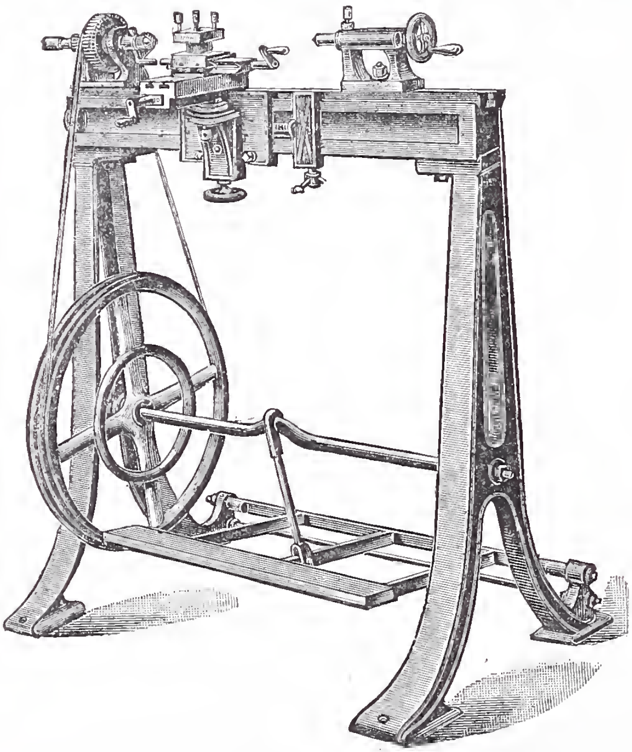

Fig. 1.—Price's "Universal" Lathe, with Front Slide and Canting Head.

The work that may be done by aid of this lathe may be summarised as follows :—

"(1) The vertical slide has a fall sufficient to cut gear wheels 3 in. diameter, and will cut them as small as ¼ in. diameter. (2) The lathe will turn and cut up its own cutters any form, according to shape required. (3) Most handy to mill up hexagon nuts and bolts to uniform sizes. (4) To mill up cams of any shape, face, or barrel. (5) For milling up key seatings in shafts. (6) Drilling and dividing hubs for tricycles and bicycles the same time. (7) Profiling steam ports of cylinders. (8) Profiling quadrant links of locomotives. (9) Milling the bearings. (10) Cutting slots in screws. (11) Shaping cranks. (12) Fluting taps and rimers. (13) Milling groves in dies. (14) Fluting drills that will cut equal to Morse. (15) Mill up slides for any machinery.

"Any one with ordinary skill can do all the work on this lathe without a vice or file, as it can be machined throughout."

Special attention has been bestowed on this lathe by the makers in order to render it one of the best universal machines that can be turned out. It is certainly most simple in construction, and its scope of work is wide, thus causing it to be a desirable machine for amateurs, electrical engineers, opticians, gunsmiths, and all other mechanicians.

The price of the "Universal" Lathe, with 2 ft. 6 in. bed, is £9 10s.; with 3 ft. bed, £10; with back gear, £12; if fitted for screw cutting, £20; dividing appliance, £2 10s.; vice for table, extra, 25s. It is made in larger sizes, with back gear from 3½ in. centre and 3 ft. bed, to 5 in. centre and 5 ft. bed. The prices for these sizes will be supplied by the makers to any applicant.

The writer of this notice took part in the discussion in the *English Mechanic*, and feels much pleased to see the ideas he there advocated so well carried out. The advantages of the lathe do not seem overstated, and one or two are not mentioned, perhaps because they would apply to rather larger lathes. For instance, if it were required to bore a small engine cylinder, the cylinder could be clamped upon the main transverse slide, and then by means of the screws of the slides be quickly adjusted, so that its bore would be true with the boring bar without any packing up.

Milling by circular cutters is coming into more and more extended use; but we cannot all afford to buy a milling machine. Now, only one thing is wanting to enable us to do milling in our lathes, and that thing is a vertical slide. If to that we add a bed, or table, to bolt the work down upon, as is done in this case, all we have to do, when we wish to go from turning to milling, is to remove the top slide of the rest, and we have a capital milling bed clear for the work, a mandrel to drive the cutters, and a back centre point to support and steady the end of the arbor that carries them. The lathe has become at once a very efficient little milling machine, and its powers as a tool are doubled.

OUR GUIDE TO GOOD THINGS.

10.—Self-Centering Simultaneous Grip Chuck.

Some handy and well-finished fittings for lathes and other machine tools have been recently introduced by the London Lathe and Tool Company, 97, Pomeroy Street, London, S.E.; and as they are mostly of novel design, it is desirable to call the attention of the readers of Work to them, and to describe and illustrate some of the most useful forms.

First among them is a Self-centering Simultaneous Grip Chuck, of which an illustration is given in Fig. 1. As may be seen from the engraving, from which the principle and action of the appliance will be readily recognised, this chuck is possessed of great strength, and yet is of simple construction. It is a very handy lathe chuck for general purposes, and the Company believe they are fully warranted in asserting that it is the best and strongest of existent self-centering chucks. It is made in eleven sizes, ranging from 4 in. to 42 in. in diameter, and in price from £4 10s. for the smallest size to £52 for the largest.

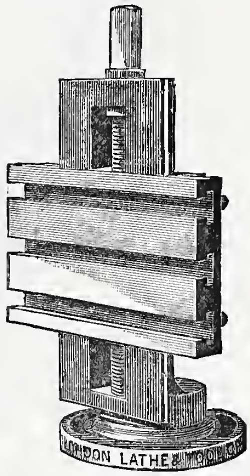

Fig. 5.

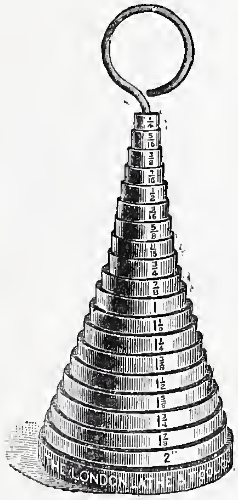

Fig. 3.

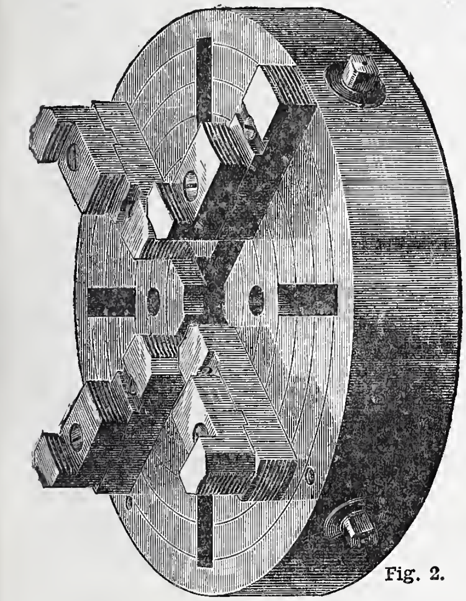

Fig. 2.

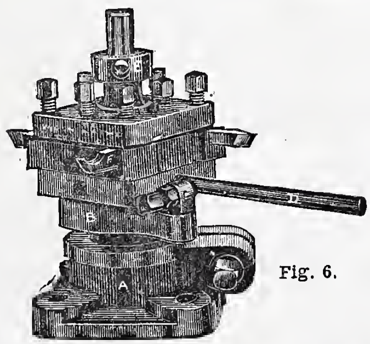

Fig. 6.

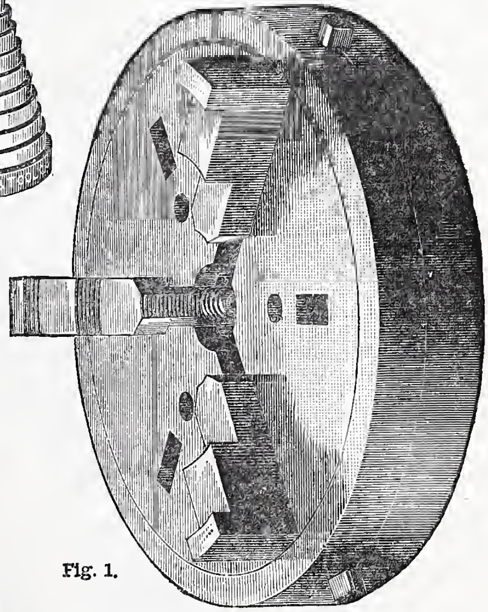

Fig. 1.

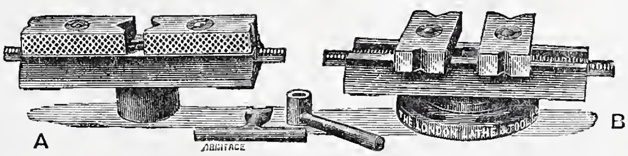

Fig. 4.

Some Specialities of the London Lathe and Tool Company. Fig. 1.—Self-Centering Simultaneous Grip Chuck. Fig. 2.—Independent Grip Chuck. Fig. 3.—Calliper Gauges. Fig. 4.—Useful Vice Chuck. Fig. 5.—Vertical Slide Rest. Fig. 6.—Revolving Slide Rest.

11.—Independent Grip Chuck.

Another well-made and beautifully-finished chuck is to be found in the Company's Independent Grip Chuck, which is effectively illustrated in Fig. 2. These chucks are furnished with four independent jaws, with changeable reversible grips, as may be seen by noticing the position of the jaws, as shown in the engraving, in which one is so placed as to show the reversed action. The screws used in this chuck are of steel, and the jaws of charcoal iron, case-hardened. They are made in ten sizes, ranging in diameter from 6 in. to 60 in., and in price from £4 10s. to £60. They are cheaper in first cost than the Simultaneous Grip Chucks, as will be manifest to any one who will take the trouble to compare sizes and relative prices.

12.—Calliper Gauges.

It is said that if half a dozen workmen take the same dimension from the same rule with callipers, and each man turn a shaft to such callipers, careful measurement will show that no two shafts are exactly the same, and that no one shaft will be of standard size, except by chance. To reduce the possibilities of such differences in work to a minimum, the Company have introduced a useful form of Calliper Gauge, which is illustrated in Fig. 3. The gauges are made in a variety of sizes, the divisions rising by eighths, tenths, sixteenths, twentieths, thirty-seconds, and hundredths of an inch, as may be required, or gauges to the metric system can be supplied to order. Callipers, as every one will readily see, can be set to these gauges in less time than to a rule, and the work, it is said, is nearly as accurate as when ring gauges are used. To give some idea of the price, a set of gauges rising from $\frac{1}{4}$ in. to 1 in. by eighths of an inch costs 5s., but one rising from $\frac{1}{4}$ in. to 1 in. by hundredths of an inch costs 50s. The Calliper Gauges, it should be said, are made up to 3 in. in diameter. Being really very cheap, and very useful, a set can be provided for each lathe. The Company also supply gauges of flat steel, carefully hardened, for both outside and inside measurements, and plug and ring gauges. These appliances range, in flat gauges, from $\frac{1}{4}$ in. to 4 in.; and in plug and ring gauges from $\frac{1}{8}$ in. to 4 in.

13.—Vice Chuck.

The London Lathe and Tool Company have also devised, and supply, a novel Vice Chuck, which is illustrated in Fig. 4. The chuck is made in two forms—the first to screw on to a lathe nose, as at A, and the second to bolt on to the receiving table of a lathe saddle drilling machine, or other tool, as at B. The jaws may be rotated or turned to take round or square articles at the V's, of which there are two sizes, as shown in the illustration, or to grip flat articles, or taper articles, when the jaws are brought into the position shown at B, in which their sides are opposed one to the other instead of the ends. Both jaws move together by turning the screw at either end. For light work it is believed that they will be found the handiest vice chucks that have yet been brought into the market. The price of either form for a 4-in. lathe is £2, rising to £4 for an 8-in. lathe.

14.—Vertical Slide Rest.

Vertical movements are very useful for many classes of work, and in Fig. 5 is shown a Vertical Slide Rest, specially designed by the London Lathe and Tool Company for the lathes manufactured by themselves, but which can be readily adapted so as to suit any other lathe. The receiving table may be placed at any angle, and as its slots are of the same size and pitch as those of the main table, any of the tools, sockets, or other apparatus usually fixed upon the main table may be fixed to the receiving table of the Vertical Slide Rest. The traverse screw is made with either 8 or 10 threads per inch, as may be preferred, and is finished with a micrometer collar. The constructive action and principle of the vertical slide rest may be seen from the illustration given in Fig. 5. The price of one suited to a 5-in. lathe is £3 10s., rising by £1 for each size for 6-in. and 8-in. lathes.

15.—Revolving Slide Rest.

A neat little Revolving Slide Rest to carry four tools is shown in Fig. 6. It is intended for the economical production of small screws and other articles required in large numbers and of identical shape and size; and for such a purpose as this it is clear that a revolving rest, such as the one shown in the illustration, is an absolute necessity. Hitherto capstan rests have been applied only to lathes specially constructed to take such rests, and unable, indeed, to take any other. This slide rest, however, may be used with any lathe or milling machine, and although simple in construction, it is as complete and as perfect and effective in its action as the most expensive rest in the market. It has been said that it carries four tools, such as may be necessary for the production of the article required; thus, supposing it desirable to cut some screws of a particular size and thread, the tools that are necessary are one for roughing a screw blank, a second for finishing the blank, a third for cutting the thread, and a fourth for cutting off the screw. Each tool may be separately adjusted, and the height and angle of the rest may also be adjusted, without disturbing the tools. The rest may further be fixed in a couple of seconds by tightening the central screw, and it may be removed from the lathe in half a minute should it be desired to make room for an ordinary slide rest.

There are many other appliances, fittings, and tools which the Company have lately introduced, and which, for simplicity, finish, and price, compare very favourably with similar articles in the market. It should be noted, however, that many of the appliances, etc., have been introduced now for the first time, and have been specially devised as labour-saving tools by the Company. I hope at some no very distant time to find space for the illustration and description of some of them in the pages of WORK.

16.—Wood-screw Cutters.

These new tools ingeniously contrived for cutting wood screws without the intervention of the lathe are a clever invention of Peugeot Brothers, a French firm of tool makers, whose name they bear. The specimen cutter that I have is numbered 12, from which it is to be inferred that the size is indicated by this number. From actual measurement I find that it will cut a screw thread about $\frac{1}{16}$ in. deep on a cylinder $\frac{5}{8}$ in. in diameter. These cutters are clearly made in graduated sizes, but I am not able to give at the present moment the limits of size in each direction. At the end of a handle, short in itself but of sufficient length, an iron casting is attached, in the centre of which is a circular tube-like hole cut on the interior with a thread, which is the exact pattern of the screw to be cut. This, of course, is of the kind technically known as a female screw. In a groove cut in the top of the iron is a V cutter, which is held in its place by a piece of iron projecting from a bar that passes vertically through the casting in a convenient position.

Another entirely distinct and separate casting fits on the top of the first casting, being placed in the bar already mentioned, and a pin projecting from the latter near the handle. This second casting forms a prolongation of the screw-cut tube and forms a convenient entrance for the end of the wood cylinder on which it is desired to cut a screw thread. The free casting is held firmly in its place when put in position by a nut working on the vertical bar which is threaded through its entire length. Its chief use is to admit of the easy withdrawal of the V-shaped cutter when it requires sharpening. The cutter, it should be said, is further fixed and held in place by a screw passing through the fixed casting and pressing against the cutter. All that is necessary when it is desired to cut a screw thread on a cylinder is to introduce the end of the cylinder into the upper end of the tube, the instrument being held in the left hand, and then work the wood round and round with the right hand against the cutter until a sufficient portion of the cylinder has been threaded. For cutting a wood female screw to receive the wood screw thus cut an iron borer or tap is used, which is introduced into a hole sufficiently large to admit of the entrance of the end of the tap that is not threaded, and which must be formed by a centre-bit or shell-bit. The top of the tap is square in form, so that a handle may be placed on it, and the tap actuated in precisely the same manner as a gimlet or auger.

The utility of these cutters will be obvious to all who consider how many kinds of wood work there are, and that it would be more desirable to put together, or fasten together, by dowels in which a screw thread has been cut instead of the ordinary means and modes that are usually applied. Wood clamps, too, for fret working and for other purposes can be made quickly and with the utmost ease by their aid.

These tools are of very recent introduction, and are scarcely yet on the English market as far as I am aware. As I have said, I do not at present know the sizes in which they are made, nor am I acquainted with the prices that are asked for them, but I can easily make inquiries on behalf of any one who desires further information on the subject, and give a reply through the medium of "Shop." THE EDITOR.

MEANS, MODES, AND METHODS.

*** *The Editor is not responsible for any statement made under this heading. Criticism and Suggestions are invited. Readers in possession of Tried and Approved Recipes, Formulas, and Processes, are requested to forward them for insertion in this column for the common good.*

A HINT FOR FRET-CUTTERS.—The song of the fret-saw makers might well begin:—"Break, break, break on the hard thick boards, oh, saw!" I would have put "don't" before the first break, only it would have spoiled the rhythm, but as I can't write poetry I will put in prose what I have to say, in the hope that it may be at least as intelligible as some poems. I refrain from mentioning names for obvious reasons. "It is only this," quoth the sawyer, "nothing more." Pieces of a broken band saw can easily be obtained. Bits to fit any good machine can be cut off as required. One that has been filed down till it is very narrow will do best. It will even then be much stronger than a large-size ordinary fret saw, these being all too thin and not increasing in thickness sufficiently with their width. Any ordinary work can be done with a bit of band saw more quickly and easily without such constant breakage as occurs with the usual saws. Try it, is the advice of one who knows.

SHOP:

A Corner for Those who Want to Talk It.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

Bicycle Making.—H. W. (Newton Heath).—To lower the position of crank tread of an ordinary bicycle, I would advise you to dispense with cog wheels. You would not meet with success by the application of such to a bicycle. The best means for attaining your desire would be to fit your machine with reciprocating levers, links, and cranks, similar to those fitted to the ordinary "Facile" bicycle manufactured by Ellis and Company, London.—[C. I.]

Polishing Pebbles.—T. M. BEAR, Wellesley House, Colchester, wants books which will give information as to polishing Pebbles, Stones, etc., and show all the various tools that are necessary for the work.

Writing-Desk.—P. J. B. (London, E.).—It is satisfactory to learn that you are pleased with No. 1 of WORK, and that in writing of it you can say "it is a very good book, suitable for my purpose." The Magazine is intended to be suitable, not only for your individual purpose, but for the purposes of every workman of British and American nationality at home and abroad. Try your hand at cabinet making by all means. I can say from experience that you will find it a most pleasurable and useful occupation. If you are a novice, as I think you are, let me advise you to try your hand on something less ambitious than a writing-desk at starting, for this requires very neat and nice work, which is the outcome of practice and experience. Try some of the useful and tasteful articles that are to be described in "Artistic Furniture," and more especially the "Screen Secretary," which will appear very shortly, and which, I think, will go far to meet your present want. Instructions for making a handsome and serviceable writing-desk will be given by-and-by, with the necessary explanatory diagrams and working drawings. It is not possible to touch on everything at once, a fact which you, as a sensible man, will readily acknowledge. Meanwhile, to you and all readers of WORK, I must say, after the manner of notices that one sometimes sees in the shops—If you do not see what you want, ask for it. I can assure you that no pains shall be spared to comply with any and every request, at least in time, if not directly.

Photo-Lithography.—PEN AND INK.—In reply to your query on this subject, I cannot do better than direct your attention to the latter portion of the preceding reply. Will you kindly write again and specify distinctly what your special need may be, and the purpose for which you wish to acquire a knowledge of the art? It may be that I may be able to offer some suggestions that will serve your purpose in the interval before papers can be given on the subject you name.

Photography.—R. A. R. B. (Oxford).—The photographers are buzzing round WORK like flies round honey, and early in the field as you may seem to be, I am bound to say that arrangements are in progress for articles on this most interesting subject by an old photographic hand. The road, however, is open for suggestions on all branches of photography, and all who like to send in papers on special points will meet with due consideration.

MR. OUSPENSKY, a Russian engineer sent to Central Asia on a special scientific mission, reports that the oil wells at Penjakend, near Samarcand, in the Zerafshan Valley, contain at least 9,000,000,000 lbs. of perfectly pure oil.

THE man with his barrow and his broom is to be brushed aside for ever. He is being crushed out of existence by machinery. There has been successfully tried in London a new machine which does all at once which the scavenger and his besom, and his shovel, and his scraper, and his barrow do, one after the other. It is a street-cleansing machine. Its horizontal brushes, fixed on a pair of endless chains revolving around spindles, sweep the mud into a receiver. From that receiver a series of buckets, fixed on endless chains, lifts the mud into a shoot, which delivers it into the mud cart. The travelling wheels on which the apparatus is mounted set the mechanism going.

VERY little is now wanted to complete the thousand feet of the Eiffel Tower. It is expected, therefore, that this modern Babel will be finished, as far as height goes, shortly. The lifts were to be in operation by April 1st. There is every appearance that all will be ready for the opening on the 1st of May.

A GENEVA firm have taken out a patent for a new alloy, to be used as a substitute for steel in the manufacture of certain parts of watches such as spiral springs and escapement wheels, which are at present liable to become magnetised. This alloy is composed of from 30 to 40 parts of gold, the same number of parts of palladium, 10 to 20 of copper, and small quantities of rhodium, silver, platina, and manganese. The copper and the manganese are first melted, and the other metals are subsequently added; or all the metals may be placed in a crucible at the same time, the manganese being at the bottom.

THE Edinburgh Lunacy Board are about spending £60,000 on new buildings on the Craighouse Estate.

HOME-MADE TOOLS.

BY J. H.

I.—AN IRON TRYING PLANE.

INTRODUCTION—PATTERN FOR STOCK—HOW TO MAKE PATTERN—CASTING—TRUEING UP SOLE AND SIDES—FILING—FITTING WOOD BLOCKING—PLANE IRON—FILING MOUTH—WEDGE—POLISHING—LEVER.

IN this series of papers I propose to describe the construction of many of those common tools which, though more or less costly to purchase, amateurs can very well contrive to construct for their own use. There are many such in our workshops — tools which workmen themselves seldom think of purchasing, and which require no very great amount of skill in their construction, but chiefly considerable patience, and much care. I think it well, in the absence of a very strict classification, to divide these tools into four main sections, as follows:—first, planes; second, tools used in measurement; third, miscellaneous tools; fourth, general shop tools. This will be sufficient for our purpose, and in carrying out my plan, as indicated above, I shall keep this arrangement in view and follow it.

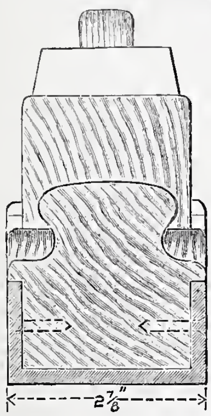

Fig. 2.

Let our first example be an iron trying plane, a tool which no wood worker who aspires to do the very best class of work can well afford to be without. Such a plane costs about thirty shillings in the shops, but it can be made for five shillings.

First, we want a pattern for the stock. This should be made of mahogany, planed very true and free from winding to a thickness of $\frac{3}{16}$ in. bare, say $\frac{1}{64}$ in. bare. But keep the bottom of plane *full* $\frac{3}{16}$ in., to have sufficient metal in case of possible curvature of the casting in cooling.

The shape of the pattern is seen in Figs. 1 and 2. The sides will be nailed on the bottom, perfectly square therewith, and the merest trifle of taper should be given to their inside faces, so that their thickness at the upper edge shall show slack by the callipers, when by comparison they are tight at the bottom edge. This taper is for clean delivery in moulding.

A strip, A, is glued across the inside face of the bottom, just behind the mouth, to form a good bedding for the iron, and also as a shoulder for the abutment of the hinder piece of blocking; and two pieces, B, C, at back and front, to terminate and stiffen the ends, and to act as abutments for the blocking. Two pieces, D, are fitted against the sides to take the resistance of the tightening wedge, if a wedge is used. If a lever is employed no such pieces will be required. These will not be fastened into the pattern, since they would then prevent delivery by pulling up the overlying sand in the mould. They must each be fitted with a vertical sliding dovetail, so that they will be left behind in the mould on the withdrawal of the main pattern. They are taken out subsequently sideways from the mould. Clean the pattern off with fine glass paper, varnish, and rub down.

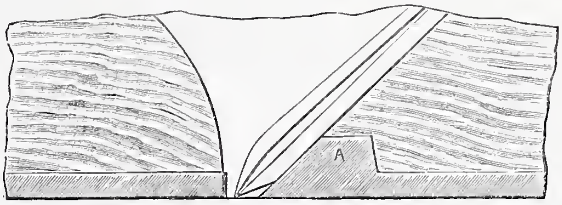

Fig. 3.

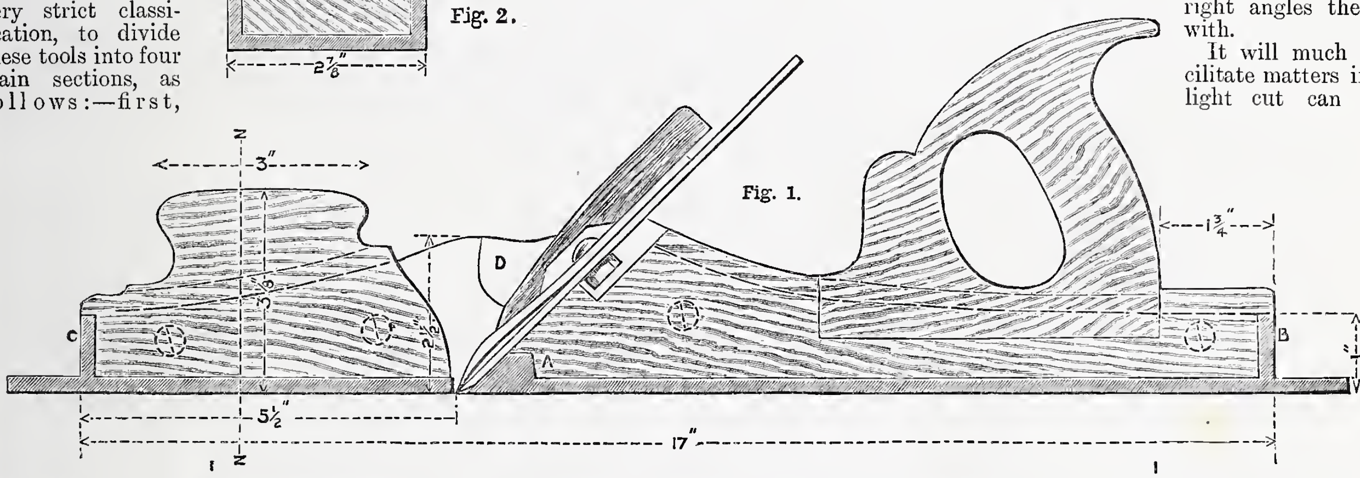
Be careful to take the pattern to a foundry where soft and clean castings are made. A hard, rough casting will be quite useless for the purpose. Stipulate that if the surfaces show blowholes when filed or planed, that the casting shall be replaced free of cost. This precaution is necessary in order to guard against any loss that might otherwise be brought about through the occurrence of a defect of this kind which will sometimes happen in the process of casting.

The most difficult task now follows—that of trueing up the sole and sides of the casting. These, especially the sole, must be straight and free from winding. For use on the shooting board it is also necessary that the sides be truly at right angles therewith.

It will much facilitate matters if a light cut can be taken off all over in the planing machine. But to pay for planing would run up the cost of the plane by about ten shillings. Hence, in most instances, the amateur or cabinet maker will have to true the stock by filing only—not a very severe task after all, provided he is fairly skilful in the use of the file.

Briefly, then, remove the outside hard skin either by grinding, or with an old, nearly worn-out file. Having done so, take a bastard file and go all over the surfaces carefully until they are very approximately level. Their accuracy would be best tested on a fitter's surface plate, supposing the use of one can be obtained. But if not, then a



Home-Made Tools. Fig. 1.—Iron Trying Plane: Longitudinal Section. Fig. 2.—Ditto: Transverse Section. Fig. 3.—Ditto: Enlarged Section of Mouth.

steel straightedge of sufficient length will answer the purpose, trying the plane lengthways, crossways, and diagonally; the latter for winding. It is quite possible to use a very true mahogany straightedge for this purpose if a steel one is not available. As the later stages of filing are approached, the coincidence of the surfaces of the plane and of the surface plate, or straightedge, is carefully tested by smearing a thin film of red lead and oil made to the consistence of thin paste over the plate or straightedge, and observing the extent of its transference to the faces of the plane. Finer files will afterwards be used, finishing with a dead smooth file. Scraping is hardly necessary.

The most troublesome portion of the work is now accomplished. The next task is the fitting of the wood blocking. This blocking may be conveniently made of rosewood, beech, oak, or hard Honduras mahogany. Whatever wood is used it must be perfectly dry. It ought to have lain in the shop under the bench for two or three years at least. Then, being once fitted, there is no reasonable likelihood of shrinkage and splitting occurring.

The pieces may be fitted flush with the inside faces of the sides of the casting, or they may preferably be shouldered over the edges and made flush with the outside faces. The latter plan is shown in Figs. 1 and 2. The fitting of the blocks into the interior and over the edges should be quite finished before the upper outlines are cut. No hard driving must be done, else the iron will probably become broken. Gentle tapping only must be given, and red lead or chalk may be rubbed over the iron to indicate where contact of the blocking occurs. When fitted, drill and countersink four holes in each side to secure the blocks in place permanently with wood screws. The hinder block will have a handle fitted into a mortise recessed therein, and the end which comes next the mouth will be bevelled to an angle of 45° for the bedding of the iron. This bedding face must be very free from winding, else the iron will rock, and so cause the shavings to choke the mouth of the plane. The end of the front block will be bevelled back as shown for the clearance of the shavings.

At this stage it will be desirable to procure the iron, which should properly be a "gauged" or parallel iron, because, unlike the common or tapered iron, its wearing backwards by regrinding does not cause that enlargement of the mouth of the plane which occurs with the tapered iron.

The filing of the mouth, about which I have said nothing, will be undertaken now that we suppose we have the iron bedded on its block, and both front and back blocks screwed in place, as shown. It must be filed, at both back and front edges, perfectly square with the edges of the plane, and with reference to its own iron and wedge, in such a manner that the slightest possible clearance opening for the shavings shall be permitted. See Fig. 3, showing a section of the mouth enlarged. The wedge is fitted at about the same time, the strips, D, being filed underneath to make good contact.

With this, the essential work of the plane is completed, and the cleaning up with glass paper and the polishing only remains. If the wood is of a light colour, staining will improve its appearance. The polishing not only adds to the beauty of the appearance of the tool, but also protects the wood to some extent from atmospheric influence.

The main points, then, to be regarded in the making of this plane are accuracy in the pattern, a soft, clean casting, free from blowholes, the selection of dry, hard wood for the blocking pieces, good fitting of the same, without such severe driving as would tend to break the casting, good bedding of the iron and wedge on its seat, and the most scrupulous nicety in the width of the mouth.

If we elect to use a lever instead of a wedge, the pieces, D, in Fig. 1 are omitted, and the wedge is made of brass, cast from a pattern. It is pivoted, and tightened on the iron by means of a screw of coarse pitch and large, coarsely milled lead.

This method is preferable to the wedge, but involves more work and slightly more expense. In the next article, however, I will describe a smoothing plane fitted in this manner, and therefore give no details of such fitting here.

(*To be continued.*)

LATHES AND TURNING APPLIANCES.

BY F. A. M.

II.—Introductory (*continued*).—How to Test a Lathe.

There is an enormous difference in the price of lathes of apparently similar design, so that the supposed purchaser I hope to help by these directions is by no means delivered from his perplexities when he has fixed upon the kind or design of lathe he wishes to possess. Why, for instance, should he pay three times as much to one maker as is asked by another? Ask the expensive maker and he will answer, scornfully, he does not wish to enter into competition with such work as that you have mentioned, and that if his men got such a thing in their shop they would quickly "throw it on the scrap heap." Ask the cheap manufacturer wherein the work of the dearer maker surpasses his, and he will descant on the worthlessness of polish and lacquer, and hint at the enormous profits made by some people, till the prospective customer becomes bewildered. Having passed through all these troubles and perplexities I should like, if possible, to help those who are still suffering.

First, then, let me say that, while there is certainly a great deal of real rubbish in the market, you may avoid that if you go to a reputable maker and attend to the following directions. Secondly, it is probable that amongst respectable makers, whether cheap or dear, you will get your money's worth. The profit is not very different with the one or the other, except that if you buy a lathe of which a great many have been made, it will cost a good deal less than if only a few of that kind had been produced, so that it is no doubt true that makers of cheap lathes are contented with less profit than makers of expensive amateurs' lathes, of which only a few are required. Perhaps the reason for the great discrepancy in the price of lathes will appear from the following little story:—An American applied to Henry Maudslay, some years ago, for an accurate screw some three feet long, expressing himself, naturally, with great emphasis on the high degree of perfection required. The screw was made, but what was the horror of the American when he found the cost was to be £100! He refused to pay, and a commission of experts was appointed to report upon the matter, and decide the true value of the screw. To them Maudslay explained the process of manufacture, the precautions taken to ensure accuracy, and the several methods for correction employed, when they decided that the charge was not excessive and the whole amount must be paid. Let us hope the American was consoled by the thought he could at any rate say he had a screw that would "lick creation." Now suppose that screw had been cut up in a tapping machine (as I am told the leading screws of some of the cheapest slide lathes are treated), and what would have been its value? Five shillings, perhaps! This story is given from memory, not as history, but because I hope it may explain wherein lies the difference between an expensive lathe by one of our best makers and a cheap one. Lay the five shilling screw beside the £100 one and, except for a little extra finish, you might not be able to tell them apart; but, if tested by the microscope or measuring machine, the thread of the good screw would be found to advance regularly by an equal distance each turn, not varying by the one-thousandth part of an inch, and it would be the parent of other screws almost equally correct, whilst the cheap screw would be afflicted with drunkenness; the thread would advance too fast or too slowly, and every screw cut by its means would partake of the same faults. An expensive lathe surpasses a cheap one in *finish*. True, but that is of small consequence. It surpasses it in *exactness of fitting* of the slides and other parts—this is important. It surpasses it in *durability*, which is most desirable; but chiefest of all it surpasses it in *accuracy of adjustment*. The true value of a lathe cannot be estimated until, besides its design and general arrangement, all these four qualities have been considered.

Before proceeding to show what kind of accuracy is required and how a lathe may be tested, it may help if I give a piece of experience with that same boy's lathe referred to at the beginning of this paper. It had certain serious faults of design and construction which will serve as examples in introducing the subject. These faults did not become apparent at first, but when the boy turner grew older he became somewhat disgusted with what had at first seemed absolute perfection. The first fault to be discovered was that when a long piece of work had to be hollowed out, such as a deep cup, and had been chucked by one end on the "taper-screw" chuck, the back-centre point could not be brought up to support the end while the outside was turned. If this was attempted, the point, instead of entering the little central hole made for it with the corner of a chisel, would scratch a circle round that hole of about ¼-in. in diameter. By degrees it dawned upon the mind that this was not a necessity but a fault of construction; the centre line of the mandrel did not point straight down the bed, but only met the point of the back-centre when this was brought close up to the "live" or "running" centre. Here then is an important point in lathe construction: the holes through the two headstocks must be in one straight line, and that straight line must be parallel with the bed, so that, if these holes were of the same size, the headstocks might be clamped upon the bed in any position, and a bar fitting the holes might be passed through both.

My readers will now understand more easily how they may test a lathe and try its accuracy. Take the *plain lathe* first, and begin with the moving headstock. Loosen the holding-down bolt and slide it on the bed, from end to end, to see that it moves freely—it is pretty sure to do so; now try whether it is at all loose; put both hands on it, front and back, and pull and push alternately, listening for a little knock that would prove the tenon underneath did not perfectly fill the space between the bed; slide it along to another place and try again. If there is a decided knock at any part of the bed, so that you can see the point of the back-centre makes a little movement across the bed, the lathe may do for wood turning, or, if fitted with slide rest and the knock is not much, it will do for metal; but it would not do for accurate work as a slide lathe because its centre line does not preserve any certain direction. Suppose, however, that you are satisfied with the fit of the moving headstock, you should next make sure that the cylinder of the headstock that holds the back-centre point fits, and slides in and out without shake; screw it half-way out, push forward the headstock and fix the holding-down bolt so that the point of the back-centre almost touches that of the running-centre; take the back-centre point in your fingers and, without having fixed the pinching screw of the cylinder, try to displace its point. If the cylinder fits the headstock and the centre-point the cylinder, it will feel quite firm, but if it is loose its proximity to the other centre-point will show how much it moves. The next thing to ascertain, since the cylinder of the poppet or headstock has a fixed direction, is whether that is the correct one? Screw out the back-centre point until it begins to feel loose, fix it with the pinching screw, and slide up the headstock till the centres meet. Now observe very carefully whether they come together exactly, looking at them from above and then from the side; if they do so, screw in the cylinder as far as it will go, move up the points to touch, fix the pinching screw, and look again. If they still correspond, the moving headstock is true, but it requires a trained eye to detect slight divergencies.

We may now turn our attention to the fixed headstock; its accuracy is even more important than that of the movable one. Usually there is a hole in the front end of the mandrel into which the running-centre fits, but in small lathes this centre forms part of a chuck which screws upon the mandrel. Now this hole is usually turned out, by a tool fixed in the slide rest, to a cone, each side of which is about 1°, so that the two sides of the cone would form with each other an angle of 2°. It appears to be almost impossible to get this hole perfectly true. To test it, wipe it out carefully; wipe the centre and press it firmly in; now turn the lathe rapidly and bring the point of a tool very carefully forward to touch the end of the revolving centre, when it is almost certain to be found slightly out of truth; turn the centre round to several positions in the mandrel and try again till you find the position in which it seems to run truly. Mark both it and the mandrel so that you can put it in always the same way, then turn the centre half round in the mandrel—*i.e.*, to its worst position—and observe how far from truth it is. You can measure this error approximately by bringing up the corner of the hand rest till it just touches the end of the revolving centre; then turn it half round from the touching point, when the distance between the two will be the greatest. Try first to slip in a piece of newspaper; if that will go, double it and try again. The *Times* paper is about $\frac{4}{1000}$ of an inch thick, say $\frac{1}{200}$, so that if you can get in two thicknesses, as is very probable, the point of the running-centre, instead of running truly, is describing a circle having a radius of $\frac{1}{50}$ of an inch. In such a case as this the hole should be very carefully rebored. Next proceed to take out the mandrel and examine the rubbing surfaces, both inside and outside, to see that they are perfectly hard, smooth, and evenly polished, showing that they touch all over. If the mandrel be fitted with a back-centre, it should pass through a plain, not a screwed, hole, which hole should point straight to the centre of the collar. To ascertain whether it does so, take out the back-centre, turn up a roller of wood to fit the hole, and, passing it through the back-centre hole from the left as far as the hole in the collar, look whether it takes up a position in the middle of that hole. If this were not the case, advancing the back-centre point to take up any wear of the wearing surfaces would throw the mandrel out of line with the lathe bed and cause it to jam in its collar. The last and most important point to examine, is, whether the centre line of the mandrel is in one straight line with the centre line of the moving headstock, and parallel with the bed. Begin, as with the moving headstock, by releasing the holding-down bolt and trying whether you can twist it sideways on the bed; if it prove loose, it may come true if pressed against one or other side of the opening in the bed, but this would be a bad fault. Supposing it is tight, and remembering that you have already satisfied yourself that the point of the running-centre corresponds with that of the fixed or "dead" centre, therefore *one* point of the centre line of the mandrel is right; but we must also ascertain that a *second* point in this central line is true before we shall know that the heads are in line. To ascertain this, prolong the mandrel by fixing a roller of wood in a chuck; let the wood be about 12 or 18 in. long, and melt a little wax on the end of it. Now, while the wood is revolving in the lathe, bring up the point of the back-centre to touch the wax; if the lathe is true it will make a dot; if it is tolerably true, a circle which will be small—say $\frac{1}{32}$ in. in diameter; but if the circle be $\frac{1}{4}$ in. or more, the lathe is not fit for boring, nor for accurate work, unless it can be adjusted. This last test is easily applied, and is more likely than any other to show whether the lathe has been conscientiously made. Now, since it is only a plain lathe we are testing, you can conclude by putting on the band, so as to give eight turns of the mandrel to one of the crank, and, after oiling all the centres and bearings, run the lathe by the foot, to try whether at that speed it goes easily and continues turning some little time after you take off your foot.

We come now to the *slide* lathe fitted with a long leading screw and a saddle to carry the slide rest. All the foregoing tests must be tried for this class of lathe, and that with additional care; besides these, we must test whether the lathe is true enough to turn up a face-plate quite flat, and to slide up a shaft parallel. Take the largest face-plate supplied with the lathe and try, with a straightedge laid across, whether it is perfectly flat; then screw it on, after carefully wiping the screw threads and faces of the chuck and mandrel. Put a point tool in the rest and bring it up carefully to the revolving plate, to try whether it is perfectly true. Let the tool be so fixed in the rest that, when the cross-slide of the saddle is fully drawn back, the tool will point to the face of the plate close to the outer edge. Adjust its distance from the plate till you can just get a card or a bit of paper in between the two; then screw the slide forward till the tool point is opposite the inner edge of the plate near the hole where the end of the mandrel nose appears, and try with the card or paper again. The last test is the one for parallel turning. Wipe the holes for the centres and put them in, taking care that the running-centre is true. Then take a bar about an inch in diameter, as long, or nearly as long, as the lathe will take in; centre it, and, putting it in the lathe, turn up about an inch at one end; then, after adjusting the tool point till it just touches the turned part, take off the handles of the slide rest, take the bar out from between the centres, rack the saddle to the left till the tool point comes opposite the running-centre, turn the bar end for end, and put it between the centres again. Now gently rack the saddle to the right to bring the tool point on to the turned end, and see whether it touches it just as it did at the other end. If you can get a bit of paper between, it would not be very bad, as the test is a severe one, but every thickness of paper you can get in detracts from the value of the lathe.

There are usually screws put through the tenon of the fixed headstock of an engineer's slide lathe, which screws afford means of adjustment; but it must be remembered that it will not do to move these screws to suit any *one* of these tests, since by so doing the adjustment would be thrown out in other directions.

I trust my readers will not have been puzzled by the foregoing attempt at explaining how lathes can be tested. If they will follow out my directions in testing their own, or a friend's lathe, they will, I think, obtain a considerable insight into the principles of lathe work which will be useful to them afterwards, and they will at any rate perceive that the value of a lathe lies not in its appearance but in its accuracy; also that if they buy a cheap lathe it may content them pretty well, for a time, till they become better workmen, and then they are sure to become dissatisfied, so that the quality of lathe they buy might well be made to depend upon the perfection of workmanship to which they mean to attain.

I will now redeem my promise to name some books on Turning, smaller and cheaper than Holtzappfel's voluminous work.

Mr. J. H. Evans has written and published a book on "Ornamental Turning" only, at 21s., which is very good.

Next to this comes "Lathes and Turning," by W. H. Northcott, of the London Lathe and Tool Company; it costs 18s., and covers the whole ground of plain and complex turning. I recommend my readers to buy that book, and to inspect the lathes and tools made at Pomeroy Street.

"The Lathe and its Uses," by the Rev. J. Lukin, costs 10s. 6d.; it contains matter not comprised in other books, but is rather marred by some bad engravings.

After these come a number of smaller books, such as "Lathe Work," by P. N. Hasluck, price 5s., and "Turning for Amateurs," an elementary work well suited for beginners, by the Rev. J. Lukin, 3s.

(*To be continued.*)

A SIMPLE CEILING IN WOOD.

With Hints for Wall Panelling on the Same Plan.

BY HIRAM PRICE.

II.—Panelled Ceilings and Walls.

In my former part I confined myself to speaking only of simple longitudinal arrangements of mouldings which followed the direction of the joists. By such means what may be called a handsome ceiling can be formed with little labour. But far greater decorative results are to be obtained by the additional employment of transverse or even of diagonal mouldings. I have myself attempted something in this direction in the small entrance hall—or, rather, the vestibule to the hall—of my house. The arrangement there carried out is shown in Fig. 5. The lines of the real joists, A, A, are crossed by imitation joists, B, B, which latter are for effect only, and form no part of the construction. The real joists rest on a projecting ornamental brick moulding of the walls, C, C—the walls themselves in this vestibule being, as was hinted in Chapter I., of uncovered but carefully finished brickwork. In this ceiling the four compartments are of course alike, but in the illustration I have (for economy of space, that I may furnish as many suggestions as possible) shown how four different patterns may be formed by the addition of some little moulding or turned work.

By using mouldings crossing diagonally, we may attain truly elaborate effects, nearly approaching in richness to the "artesonado" ceilings of Spain. Some partial idea of the appearance of these may be gained from Fig. 6, which shows one repeating compartment of a ceiling of the kind, sketched by myself, at the Café del Comercio, Murcia, the house having formerly been the mansion of a "Condé." Rich ceilings are an important feature in Spanish domestic architecture. One learns there to expect them, and to feel some disgust when remembering the poverty of our own ceilings at home. It was during a residence in Eastern Spain that I conceived the idea of trying something of the sort myself whenever I should build in England.

The joists used by Spanish builders are much thicker than those commonly used in this country. Those seen in the illustration (Fig. 6) are probably cut half through at their intersections, and still have sufficient strength left to carry the heavy quarry floor above them.

From what has already been said, it will be seen that any one with but a limited knowledge of the joiner's craft could put up a wooden ceiling like mine. No very accurate workmanship is required—a mere dabbler in carpentry could do it. And for that reason I would suggest that any person who may wish to panel a room with his own hands, and who has not the skill or tools to carry out the work in the orthodox fashion, should proceed on somewhat similar lines.

Had I the panelling of a room before me, this would be my way of setting to work. I should first surround my room with two horizontal bands of lath, one at the top and the other at the bottom of the walls; and between these, at proper intervals, I should fix upright laths, which might be said to represent the joists in a panelled ceiling. That the laths might be perfectly firm, it would be well to drive wooden plugs into the walls to which to nail them; the uprights must be in plumb and fixed at equal distances apart, those distances to depend on the width of the veneering boards employed.

My next proceeding would be to screw veneering boards to the vertical laths—two boards to each alternate lath, back to back. They would be fixed by one edge only, the other edge merely lying loose on the intermediate lath. Space would be left between each two boards to give room for expansion, as it was in the ceiling; these spaces to be afterwards hidden, as then, by mouldings laid over them. In Fig. 7 I have drawn a section of panelling thus arranged. The line, A, A, shows the surface of the wall; B, B, B, are the upright laths; C, C, C, are the veneering boards, which for wall panelling should be somewhat stouter than for ceiling work, say ¾ in. instead of ½ in.; and D, D, D, are the mouldings.

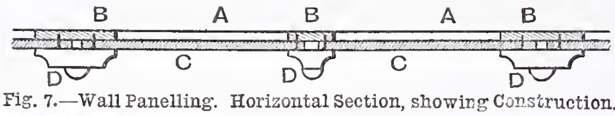


Fig. 7.—Wall Panelling. Horizontal Section, showing Construction.

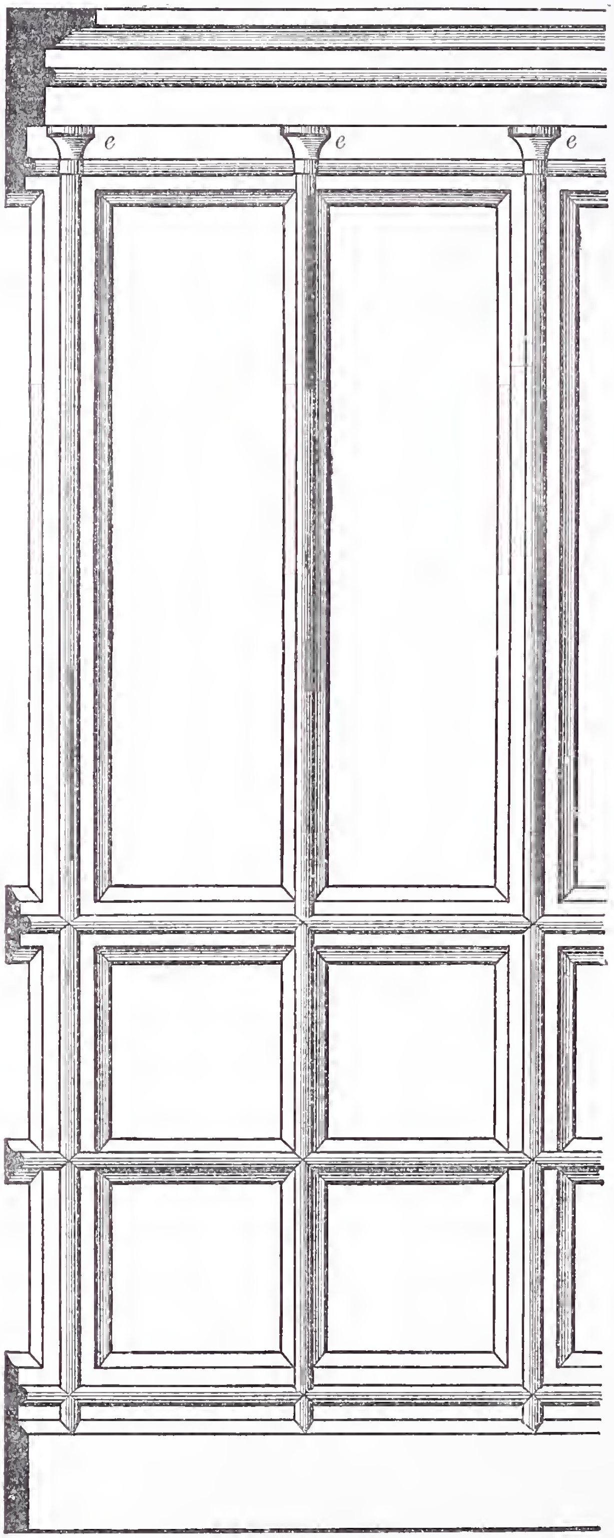

Fig. 8.—A Simple Method of Wall Panelling.

In Fig. 8 I have shown some of this panelling in a completed state. It will be seen that it is finished above by a cornice, which is supposed to be composed entirely of wood mouldings. The small capitals at *e*, *e*, *e*, are turned and then sawn in half; but a worker who has no lathe, but who can carve, might make a richer cornice with carved caps. In the lower part of the panelling I have indicated an arrangement of cross pieces which form a kind of dado, and not an unsightly one.

When panelling walls on this system, it will, I think, be found desirable, for the sake of effect, to keep the longitudinal divisions wider apart than in panelling ceilings. Were I dealing with a room to which I had made a ceiling of this kind, I should, if possible, get my veneering boards 13 in. wide, so that I might arrange to bring one of my larger upright mouldings under each alternate joist only, and one of my smaller uprights under the intermediate joists; for, taken with the ribbed ceiling, the walls would otherwise look too much cut up and crowded. If, however, I were panelling a room with an ordinary plaster ceiling, I should fear no such danger, and make my veneering boards — or panels, if you will—of the more usual 11 in. stuff.

Not much bench work is called for in the construction of these ceilings and wall panellings. Cutting to length, fitting, and fixing up, is nearly all that has to be done. All the stuff can be bought ready prepared. The veneering boards will be bought ready planed on one side; and steam-struck mouldings, which can be bought far more cheaply than such mouldings could be worked at home, will of course be used. The principal firms who sell such things issue price lists which show full-sized sections of a sufficient variety of mouldings, and these may be had at prices ranging from a couple of shillings to as many pounds for the hundred feet run. The wood in which they seem to be usually kept in stock is yellow pine. Such a moulding as that needed for the large upright in Figs. 7 and 8 (width, 2 in.; projection, ¾ of an inch) would cost about 7s. 6d. That required for the smaller uprights would be proportionately less. For wall panelling a *separate* circular bead down the centre of the moulding is not recommended. Needle points would scarcely be strong enough to hold it in place in such a situation; it would be better to have the moulding all in one piece. It will be necessary to screw through the centre, but the holes can be countersunk so as to let the heads well in, and they can be puttied over and coloured like the surrounding wood work. But for where such round beadings are wanted in ceilings (as at *e*, Figs. 1 and 2), they may be had of various diameters, from $\frac{3}{8}$ of an in. to 2 in., at prices from about 3s. to 16s. The top of the cornice, Fig. 7, will need a heavier and bolder moulding. I purchased one that is very effective for such a purpose, which shows a projection of nearly 3 in., for about 25s.

I may mention that I got my mouldings from Messrs. Joseph Sandel and Co., Waterloo Bridge Road, Lambeth, S.E., London. I found them quite satisfactory: good material and little waste.

Whilst speaking of these mouldings I may suggest another way in which they may be made serviceable in home-made house fittings. One of my friends bought an old-fashioned house in which none of the rooms had any cornices beneath the ceilings. My friend was of a mechanical turn like myself, and proposed to decorate his house with his own hands—and a little help from me. We all know how mean and unfinished a room looks with no cornice, and to remedy the defect we got some of these steam-struck pine mouldings, of three or four different patterns. We ebonised them with decoction of logwood and solution of iron, and polished them with beeswax and turpentine. This is quickly done with mere narrow strips of moulding, and after we had papered the walls we nailed up these mouldings in place of cornices. They look very well; the black line between wall and ceiling has a good effect, more especialy if the prevailing colour of the wall paper is green or red.

But in two rooms we did something more than this. In one—the dining-room—we used a large moulding of some $2\frac{1}{2}$ in. in depth and projection, which had a deep rounded hollow running along its centre. We cut from pine board a quantity of square ornaments, something like the "dog's tooth" at *d*, Fig. 5, gilded them, and fitted them into this hollow at intervals of about a foot. This had a very handsome effect. In the other room we used *two* bands of moulding, one ($1\frac{1}{2}$ in. wide) against the ceiling, and a second ($\frac{3}{4}$ of an in. wide) a foot below, thus forming a frieze round the room. The paper of the lower walls was green, that between the mouldings crimson and maroon. This, too, was successful.

This was not very costly work apart from the trouble, for a hundred feet of moulding go a long way (they will cornice a room 25 feet square), and some of the moulding which we used did not cost

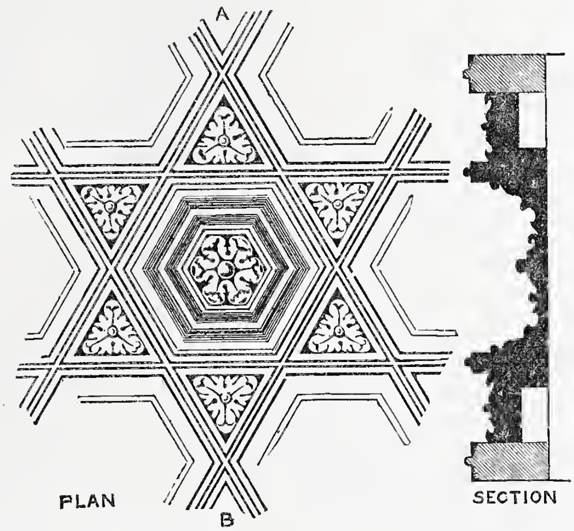

Fig. 6.—Single Compartment in Plan, and Section along A, B, in Plan. Café del Comercio, Murcia, Spain.

more than 3s. 6d. a hundred. To return to my wooden ceiling. I would mention one especial advantage which I find it to possess over a ceiling of plaster—it does not require the periodical nuisance of white-washing.

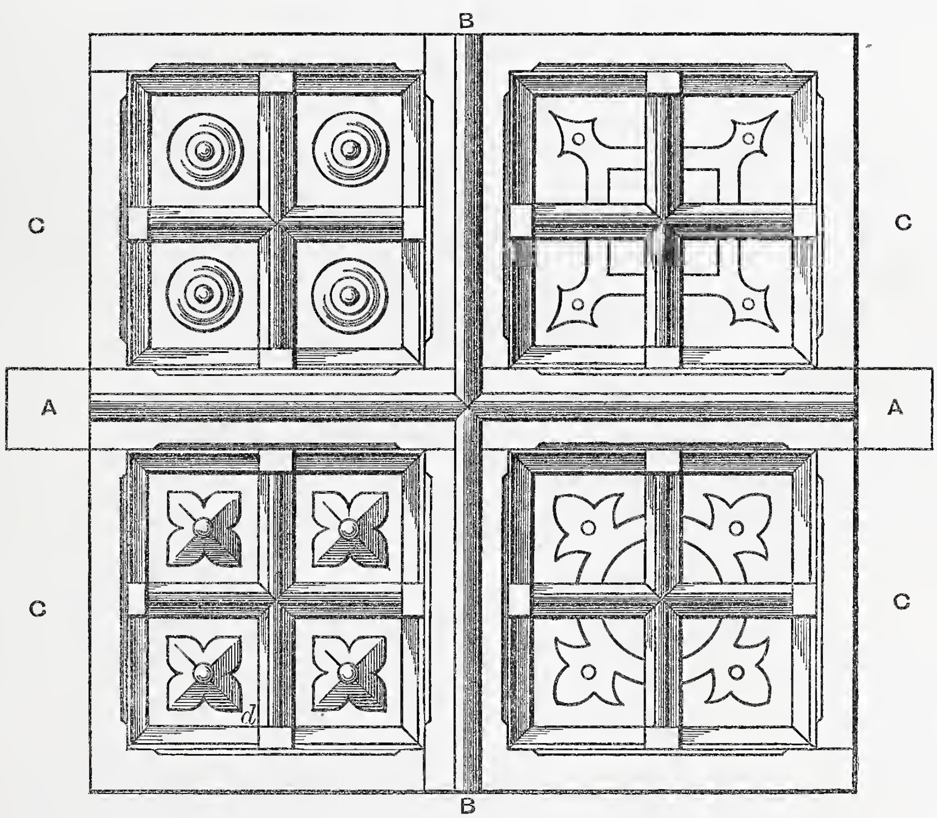

Fig. 5.—Wood Ceiling of Hall, with Four Alternative Designs for Panels.

On looking over the above, it appears to me desirable that in the matter of ebonising some more particular directions should be given; for not only is that process applicable, as above remarked, to cornice mouldings, but it might well be employed both in our ceilings and panellings upon projecting central beadings, etc., if an attempt were made to produce a decorative effect by staining the wood work of different shades.

The process of ebonising is of such simplicity, that any one with moderate care can do it successfully. My plan is to boil the logwood chips in an earthen pipkin, till I have a decoction sufficiently strong to show of a deep orange-red colour, wherever it is laid on the pine wood. This I brush over the wood whilst quite hot, and I go over it twice in order that no part may be missed. In a few minutes the wood is fit to receive the solution of iron, which I also brush on hot and apply twice over. I make my solution by dissolving any odd scraps of iron in vinegar, and dilute it before using with about half water. The wood when touched by the iron at once turns to a deep black, but with rather a purple tinge; this tinge, however, disappears with polishing. Before the polish is applied, the wood should remain for a night to get thoroughly dry, and thin boards, or anything liable to warp, should be weighted. The polishing, as mentioned above, is done with beeswax and turpentine. Pouring some turpentine into a saucer, I scrape into it as much wax as it will moisten freely, and then place the saucer near enough to the fire to melt the wax; but this needs care, as the mixture is highly inflammable. The polish thus made should be of the consistency of cream. It has to be applied with a hard brush and hard brushing; a little of the mixture and a liberal amount of brisk rubbing is the way to get a brilliant polish.

It is, however, rather for cabinet work that great brilliancy becomes a desideratum. For the purpose that we have before us—the ebonising for mere mouldings for our cornices, ceilings, or wall panellings—no higher polish is needed than is to be attained with a very moderate amount of rubbing.

I trust that the hints I have thrown out in this and the preceding paper on the treatment of ceilings will be found useful by many, and such as they may adopt with advantage. Generally speaking, the ceiling in rooms in English houses offers a wide expanse of whitened surface to the view utterly devoid of ornamentation. The only excuse for the invariable whiteness lies in the additional light that is gained by reflection from the ceiling. This would not be materially lessened by the adoption of a warmer tint or stencilled bordering.

FRIENDLY HINTS TO AMATEUR WOOD WORKERS.

BY DAVID DENNING.

I.—Difficulties of Amateurs—Matters often Overlooked—Unseasoned Wood—How to Season it—Warping or Casting—Why Wood should be Turned when Drying—Casting of Dry Wood—How to Distinguish Seasoned Wood—Sources of Supply—Making Glue—Appearance of Good Glue—Fracture of Glue a Test of Quality—Soaking Glue—The Glue-Pot—Melting Glue—Gluing up—How to Use Glue.

Few who have paid any attention to amateur workers' productions can have failed to notice the difference between them and those of the professional; and without any desire to disparage the former, it can seldom be said that they surpass the latter in those points by which superiority is determined. Even where they are not actually faulty either from carelessness or want of knowledge in some constructive detail, there is, if one may so call it, a want of breadth, a niggling kind of work, which proclaims the more or less unskilful artisan. It is, of course, not to be expected that the amateur can have acquired the same facility in working with the tools of any craft as the professional worker who spends a great portion of his life in handling them. In any special pursuit the latter has undoubted advantages not only by seeing how others work, but from constant opportunity of acquiring the manual dexterity which can only be the outcome of practice. The amateur seldom has opportunity of watching skilled craftsmen at work, but must to a great extent depend on what he can pick up by reading, with, perhaps, an ocular demonstration now and again by some friendly expert. True, the sources of his information are now much more accessible, so far as books are concerned, than they were a few years ago, but for all that he must rely to a great extent on his own versatility and ingenuity as well as on his power to "read between the lines" of any technical book or article he may be studying; for, speaking for myself—and I imagine the experience of other technical writers is not dissimilar—it is impossible to convey often what one feels must be necessary information to the novice in any particular branch of work. One may do one's best with pen and ink, both verbally and with illustration, but nothing can equal practical demonstration; and it is much to the credit of those who, without special opportunities of acquiring skill and knowledge of modes of working, have worked so assiduously that they can produce anything worth looking at.

Now, with this little preamble, which, it is hoped, no amateur will take amiss, or regard in any way as intending to discourage him or decry his efforts, I should like to mention a few matters in connection with amateur joinery or cabinet work, merely premising that though I am not an amateur at this, I am in other mechanical pursuits, so that the difficulties to be encountered by the amateur in it may fairly be taken as understood by analogy by the writer. Let me then point out to you, my amateur wood-working readers, a few little matters the neglect of which is often a source of blemish or weakness in your productions. I do so in all friendliness, and I trust that none will object to the remarks. I do not intend to perplex you with complicated technicology, or the insistence of hard-and-fast lines of working, but rather to reiterate those principles which, though well known and perhaps obvious, are apt to be overlooked in actual practice by those who are not continually putting them into operation.

First of all may be taken into consideration the material—wood—not so much with regard to kind of timber or quality of figure and those other features which give to the various sorts their value, as to wood that is fit for working. Now, I suppose every one knows that wood ought to be thoroughly seasoned before it can be prudently made up. If it is not, there is little chance of anything made from it being satisfactory; but it must not be forgotten that even thoroughly seasoned wood may not be dry enough for use. It is too often thought that if wood is seasoned nothing more is necessary, hence the complaints one so frequently hears of the difficulty in obtaining seasoned stuff. As a rule, however, there is no difficulty in obtaining well-seasoned boards of the ordinary kind of timber in any of the larger towns, but *dryness* is another matter altogether. How can it be expected that timber which has been exposed to all weathers, or at the most has only been covered on top, can in our climate be thoroughly dry? Well, when you get wood from the yard do not work it up at once, but let it stand awhile—it may be for days or weeks or only hours—in some warm, dry place before using it. There will then be fewer complaints of "unseasoned" wood having been supplied. Unless wood is thoroughly dry it is bound to shrink when made up, and unless due allowance has been made for this shrinkage it will certainly split.

Again, it is useful to note during the drying process, even while in the rough, boards are apt to cast or twist, or, in untechnical words, to become uneven, some woods being much more prone to this bad habit than others. As a rule, those with straight, even grain, like American walnut or Honduras mahogany, are more reliable than those with finely-marked, elaborate figuring, such as pollard oak, which is a timber that requires the utmost care if used in the solid. It twists and casts in a manner which would surprise any one unaccustomed to its vagaries. Whatever the wood is, planks should be turned occasionally when drying, unless there is an equal air space on each side, for if they are laid on the floor, or leaning against a wall, it will very likely be found that they become rounded, or convex on one side and correspondingly concave on the other. This is owing to the wood becoming either dryer on the concave side or absorbing moisture on the other.

As an effective illustration of this, take a piece of thin board—any will do for the purpose—and leave it in some damp place for a few days, or wet it well on both sides, allowing the water to soak in. If both sides be equally wet, the wood will remain level, but if damper on one side than the other, it will swell on that side. When the moisture has soaked in, hold one side to the fire and just watch how the wood curls. Hold the other side to the fire, and the board curls over in the opposite direction. If while the wood is wet—*i.e.*, after the water has soaked in thoroughly—it be nailed to a dry piece the grain of which runs transversely, in order that the experiment may be better tried, and then held to the fire, the wood, instead of bending, which it will be unable to do, owing to the rigidity of the board to which it is fastened, will, as it dries, naturally contract, and the chances are, will split. Of course, in nailing it down the nails must be put in near the edges, for were it just fastened by one or two in the centre, it would merely contract from the edges to this. Now, the heat of the fire merely accelerates the natural process, the movements in the boards being the same, whether the drying process takes months or minutes, so we see pretty well what course must be adopted if we wish to have good workable stuff free from "shakes"—*i.e.*, without cracks, and flat.

Sometimes the wood worker will find, whatever precautions are taken, that the wood will cast, and if it is really dry and the defect is only slight, it may be rectified by laying the board, hollow side downwards, on a cold floor, and leaving it for a time, or by exposing the convex side to the heat of a fire. In either case watchfulness is necessary to prevent the curve forming the reverse way. Very thin wood may often be flattened by simply placing it under weights, but this process is not altogether to be depended on. When boards are very badly cast and twisted, the only reliable way to level them, with any degree of certainty that they will remain so, is to plane them down. Please note, nothing has been said about unseasoned wood being dried, for it is assumed that every precaution will be taken to use only that which is seasoned; but to sum up, take equal precaution to see that it is *dry*. If this be attended to, most of the defects commonly—and no doubt often correctly—attributed to unseasoned wood will be found non-existent.

Perhaps it may be thought by some of my readers that something should be said about distinguishing when wood is seasoned or not. Much might be written about this, but after all it would simply amount to saying that experience is the best and almost the only guide. A fair idea may often be gathered by noticing the weather stains, but as these depend to a great extent on where and how the timber has been stored, unless the buyer is well acquainted with the material they are not to be regarded as "a fixed quantity," but rather as the unknown X of algebraists. It is true that to the experienced eye weather stains often indicate much, and where they are very marked the wood will generally be at least fairly seasoned—not necessarily dry, mind—but it will frequently be found that thoroughly seasoned wood has little or no stain. Hence the difficulty of giving reliable data on this score.

As a sound and indisputable general rule for the amateur to follow, the best advice that can be given him is to buy from reliable dealers only, and to put confidence in their judgment. As for the sources whence the amateur can draw his supply, it may be said that timber merchants' yards seem the most natural, especially for the coarser kinds of woods, but it stands to reason that many of them will not cut planks nor allow their stock to be turned over for selection when the purchase is only a small one. When there is any difficulty in getting suitable stuff in small quantities from timber yards, cabinet makers who actually make furniture—many of them do not—can generally be applied to with success; only as the bulk of the wood they use is selected for the purpose of furniture making, and therefore often above the average quality of that found in a builder's timber-yard, prices are proportionately higher. Speaking roughly, wood at very low prices generally means wood of inferior quality. Amateurs have been known to complain of one-inch thick mahogany at one shilling per foot being dear, but what would such say to mahogany in veneers at three to four shillings per foot? Yet possibly any of these figures might indicate better value than some mahogany at only sixpence per foot.

With this the remarks on timber must be concluded for the present, and a little may be said about another matter of almost equal importance to the wood worker—viz., glue and its application.

The mixing, or in colloquial language the "making," of glue is one of those little matters which the amateur sometimes seems to think will take care of themselves. No more serious mistake could be made, for glue must not only be good before it is made, but it must be made properly, neither too thick nor too thin, and when this has been satisfactorily arranged, it must be properly used. Any one can stick two pieces of wood together with glue, but whether the joint will be clumsy or neat, durable or only of a temporary character, depends almost entirely on the care and ability with which it has been made. Given good glue rightly mixed and used, the joint, say between two boards, may be so strong that it will be easier to break the wood than to separate the pieces where they are joined.

To begin with the raw material, the glue in the cake as sold in the shops, a few hints may be given which will be of service to the novice, to whom, however, it would be useless to give those finer distinctions and tests by which an expert in glue may fairly estimate its quality. The slightest observation will have shown any one who knows what glue is that there are very marked differences in colour in different makes. Some are almost black except when viewed by transmitted light, while some are almost like amber or gelatine in colour and transparency. Neither extreme is good where strength of joint is a primary object. The black, opaque, unclean-looking stuff proclaims its quality sufficiently even if retail prices do not indicate to the buyer that he can hardly expect much at considerably less than the best qualities are sold for in bulk. The very light-coloured glue is often fairly good and of medium price, but the bleaching to which it is subjected in order to obtain the captivating, and at the same time unnatural, transparency and light colour sometimes impairs its tenacity. For some purposes, such as gluing down thin, light-coloured veneers, it is very good, simply because it does not darken the tone of the wood, as some consider the darker glue does. This, however, may as a moot point be almost considered as beyond the amateur's ken. It is very seldom such extremely delicate veneer is used as to necessitate colourless glue, much of which, if not all, is of continental origin by the way. Those who are familiar with many Teutonic and Gallic productions will understand that they are often excellent imitations of English productions of the same type, but that after all there is something not quite right about them. So it is with glue. I have at various times tested, or had tested, many samples of continental glues which were nice to look at and offered at tempting prices by plausible German bagmen, but I never met with a sample which could be compared with the best British glue for strength and economy in use. I say *British* advisedly, for the best glue for general purposes is Scotch, and it is worthy of every care and attention that the worker can bestow. In colour it is a clear, wholesome, ruddy brown, not a muddy-looking compound, nor yet refined to gelatine.

The manner in which glue breaks when struck, or rather the appearance of the fractured edges, is often a good indication, as is likewise the feel when it is held or rubbed between a moistened finger and thumb; but to go fully into these details would give a quite too technical character to these hints. It will be more within their scope to give a few directions for mixing now that a few leading qualifications of good glue have been indicated, and in doing so it will be seen that there are other points to be observed.

The first thing in making glue is to break the cakes into pieces of moderate size. If the glue shivers easily like a piece of glass would do it may be looked on as too brittle to be perfect, and *per contra* it should not be tough and leathery. Any way, the pieces must be covered with cold water and allowed to remain in soak till they are soft. Mind, good glue should not dissolve in cold water; it should merely swell up and soften. If the water dissolves it as it soaks in and does not seem to penetrate to more than a slight depth there is something wrong. The quantity of water which glue will absorb is a fairly correct estimate of its value being arrived at. Roughly speaking, a glue which will absorb more water than another is the preferable of the two.

When the glue is thoroughly softened by soaking in water it must be liquefied by heat in an ordinary glue-pot, the general features of which are too well known to call for any remark. With regard to size, however, it may be said that a large pot does not require heating so frequently as a small one, which naturally chills more quickly. This leads me on to say that glue should always be used as hot as possible, merely warm enough to be sticky will not do, it must be as hot as it can be made. With the outer pot kept well supplied with water it is not possible to burn the glue, and it is to prevent this that a double pot is required. In its absence a very good substitute may be found in an ordinary jam-pot or similar jar and a small saucepan, the water in the latter, the glue in the former. Never attempt to heat glue in a single pot, or the contents will assuredly be spoiled.

With reference to gluing, while the glue is being rubbed on the wood, especially if a large surface has to be covered, of course it has a tendency to harden by cooling. To counteract this and to make the glue adhere it is generally advisable to warm the work to which it is applied, but in doing this bear in mind what has been said about heat bending boards. Occasionally both the surfaces to be joined should be glued before they are put together, which they should be while the glue is still hot on them. Do not wait till it congeals. If one may so express it, the glue is first stuck to each surface, and then the glue coalesces when they are brought in contact. When practicable—and it generally is so except in the case of large veneers—the glued pieces should be worked against each other with gradually increasing pressure, not only to expel any air between them, but to squeeze out as much of the glue as can be got rid of. On the extent to which this is managed much of the stability of the joint will depend. The thinner the film of glue between the pieces the more firmly will they adhere; nothing is gained by leaving a thick layer of glue. Indeed, the reverse is the case, and it is hardly too much to say that the effort should be to press out all the glue. Of course, to do this is not possible, but what remains will be so small in quantity—if the contiguous surfaces are true and bear uniformly on each other—that were it not for the thin hair line which marks the joint, and the different figurings on the pieces, it would be next to impossible to detect the presence of glue. To prevent the joint from opening, and to keep the surfaces in contact till the glue has set and can dispense with any auxiliary support, it is necessary to keep pressure on the parts. With large thin pieces such as veneers, joined superficially, not by the edges, the pressure is applied by means of a hot caul, which partially liquefies the glue in the joint and forces most of it out at the edges.

From all this it will be gathered that no benefit is gained by too lavish a use of the glue when rubbing it on the surfaces to be joined—unless it be by the glue vendors profiting by the waste. The consistency of the glue when made has not been mentioned yet, though it is an important matter. I mean, of course, its consistency when hot. The expert will adapt the thickness or consistency to the work he has in hand; but for the novice to do so would imply so much knowledge that he might fairly claim to rank as a skilled worker. It must therefore suffice to state that the glue should run from the brush like thick oil, not paraffin oil, but colza or olive oil, or to use other comparisons, which may perhaps be better understood, like melted butter or thin golden syrup. This may not seem very definite, but after all it is only an idea which can be given. A drop of suitably prepared glue if placed on a cold surface should quickly become a jelly. If too thin it will be some time in hardening sufficiently to be handled, and if it is so thick as to harden almost directly and be unworkable with the brush, it is obvious that more water is required. Another important factor in forming a strong joint is to use only freshly-made glue. The tenacity of glue is diminished every time it is heated up. In practice it is not necessary to make glue every time it is used, but certainly no one who knows anything about the way in which the strength deteriorates would think of constantly reheating the same lot. In the practical workshop this tendency to diminish in strength is of little moment, comparatively, as the glue-pot is in constant requisition; but with the amateur who, perhaps, uses it only at long intervals and in small quantities it should not be overlooked. Therefore no larger quantity should be mixed at a time than is likely to require heating up more than a few times. It is owing to neglect or ignorance of this quality in glue, as well as the mistaken notion that the more the better in a joint, that domestic gluing up is so often a failure.

(To be continued.)

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

III.—Freehand Drawing—Outlining Ornaments and Devices—Blackboard Practice.

I TRUST the student has been closely following the directions laid down in the last chapter, for as "lettering" is nothing less than a special class of drawing, more or less advanced, according to the proficiency attained by the pupil in the higher orders of ornamental lettering, a good deal of practice, after the plan laid down in these preliminary lessons, is an absolute necessity.

Before I leave the subject of freehand drawing, I would like to give one little hint for obtaining facility in describing the circle, one of the best examples of free-hand drawing the pupil in lettering could have placed before him for practice. Of course, a perfectly true circle is quickest done with the aid of compasses, and these are always used in actual work, but it is, nevertheless, possible to produce one just as accurate with the hand, guided by the eye alone. This entails a close application to practice, repeated

Fig. 25.

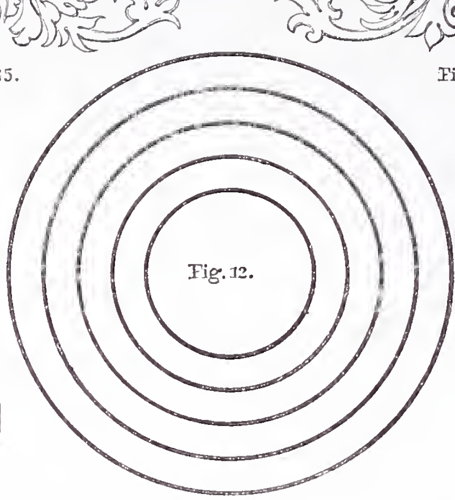

Fig. 12.

Fig. 26.

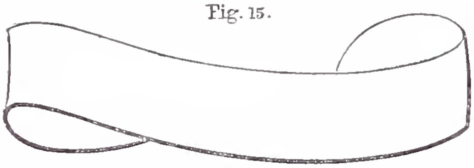

Fig. 15.

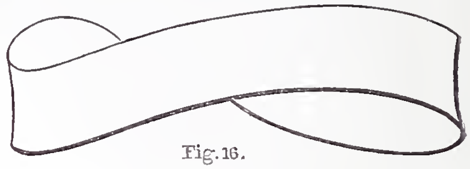

Fig. 16.

and repeated again: but in course of time success is an ensured certainty, and the man or boy who can, off-hand, draw a circle in this way, is competent to undertake any branch of work that may be placed before him. In fact, I do not know of any better method of educating the hand and the eye, and of enabling the former to obey the dictates of the latter, than repeated practice in drawing the circle in all sizes, and without any extraneous aid.

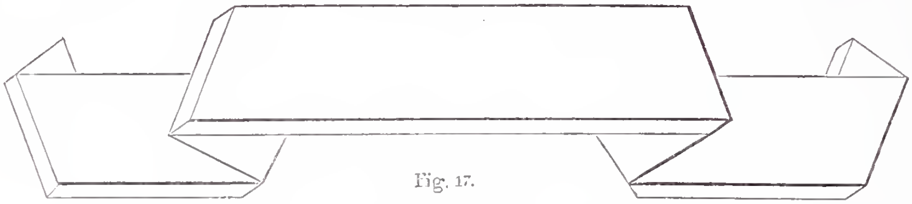

Fig. 17.

In order to make my method of study in the first few chapters more clear to the reader, and so enable him to pursue his studies as I would suggest, I had perhaps better explain how I am endeavouring to train him for accomplishing the work I hope to expound later on.

Now, the true essence of proficiency in the sign writer's art lies, firstly, in training the eye to that degree of perfection that it can instantly detect the perfect from imperfect, the truthful from the untruthful in form, and is capable of at once judging the result of any work it rests upon. The workman must, in fact, always be able to carry, "in his mind's eye," as it were, the accurate formation of all lines, curves, and objects incidentally portrayed in the usual routine of his work. And secondly, having advanced so far, he must next attain a perfect freedom and command over the hand, so that it is capable of giving a truthful rendering of the eye's invisible, but—let us hope—artistic will. Thus, to explain still further, we have before us a blank signboard, on which is to be written the name "JONES," and the usual lines being "mapped" upon it, we face it, and in our "mind's eye" we see the letters on the board, and at once proceed to put in a chalk or pencil mark around them—transforming the invisible into the visible, seen by all.

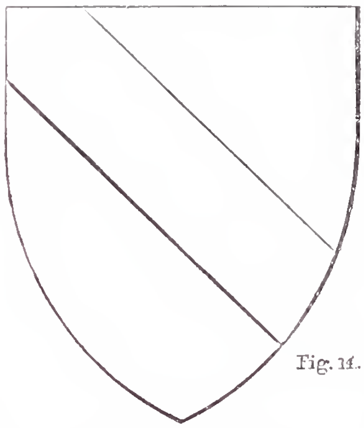

Fig. 14.

This is my own individual method of procedure, but I, of course, do not say it is followed by others, or, in fact, by anybody; but I do insist that, before a man proceeds to "chalk in" his work, he must, to a certain degree, picture to himself the size, shape, and construction of the letters, and the hand obeys the eye accordingly. And, regarding myself, I go even further, for I actually see the letters there before I draw them, so that the work resolves itself into a species of tracing. But this is theory, and open to contention, so I will say no more on the subject.

I have, I think, now explained the object of these opening chapters, viz., the proper and methodical training of

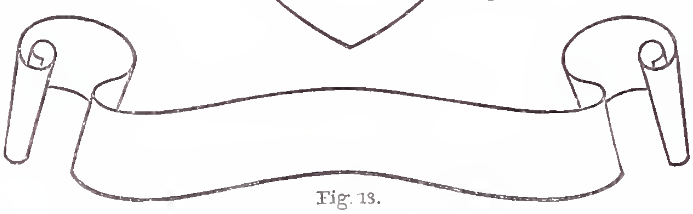

Fig. 18.

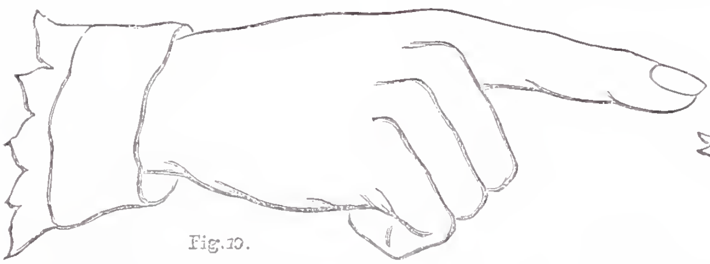

Fig. 19.

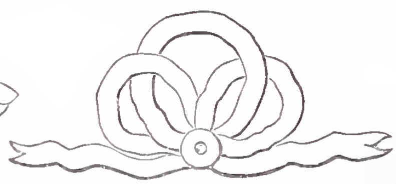

Fig. 24.

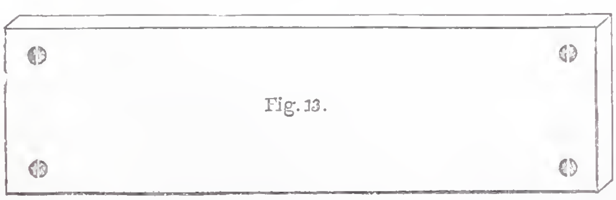

Fig. 13.

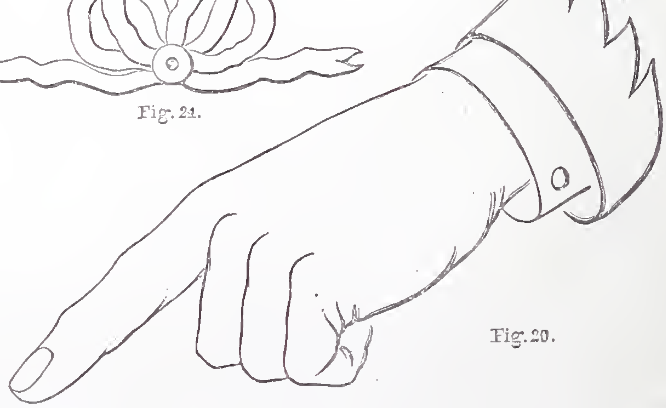

Fig. 20.

Fig. 12.—Concentric Circles. Fig. 13.—Plain Board with Screw Heads at Corners. Fig. 14.—Shield. Figs. 15, 16, 17, 18.—Scrolls. Figs. 19, 20.—Index Hands. Fig. 24.—Centre Ribbon Ornament. Figs. 25, 26.—Scroll Work Corner Pieces.

the hand and eye, and we trust the student will follow us with due appreciation, as it is a matter most other writers on the subject have entirely overlooked.

The illustrated examples of freehand drawing and outline subjects which I give have been selected, to the best of my ability, for the special purpose we have in view, but as I have so urgently advised the novice to diligently practise the circle, I had better make some remarks on the best method of proceeding to work in this direction.

It is, of course, much easier to draw a small circle than a large one. The beginner should therefore make a start by describing a circle three inches in diameter, persevering until he is able to draw it, time after time, tolerably correct. This is best done on a large slate with slate pencil, but the slate should not be allowed to lay down upon the table. On the other hand, it should be held in a nearly upright position, propped up with books, held by the left hand, or, better still, placed on a small home-made easel, which is easily constructed.

Having made satisfactory progress with the small circles, proceed as follows:—

Describe a circle three inches in diameter, and then continue to construct larger ones outside this, and all at a given distance from each other, until the whole surface of the slate is covered. (See Fig. 12.) Practice in larger circles may afterwards be transferred to the blackboard with both chalk and brush, but the student must by no means bore himself with this or any one class of work, but should change about from one subject to another, so as to infuse variety and interest into his work.

We will next turn our attention to a few subjects which the sign writer is frequently called upon to paint, and this being so it is, of course, necessary he should know how to draw them with accuracy. I give some examples with this chapter, a series of outline drawings only, as copies for repeated practice.

Fig. 23.—Crown.

Fig. 21.—The Royal Arms.

Fig. 22.—Prince of Wales's Plume.

In commencing practice use drawing paper tightly pinned upon the drawing board, and one of Rowney's twopenny HB. pencils, which is the best for beginners, as it gives a good bold stroke, and the lead is thick and very easy to work with. In drawing these examples compasses and rule are now permissible. Nevertheless, I would still recommend that they be drawn in freehand for a time—in fact, in order to set a good example, I have myself done some of these drawings with the unaided hand, and with the pen I am writing with, merely using Rowney's liquid Indian ink instead of ordinary writing ink; and, be it known, it is much more difficult to execute freehand drawing with a pen than it is with a pencil. It is good practice, however, to follow the pencil lines over with Indian ink, and as a suitable pen I use Gillott's school pen No. 351 F., and Cassell's series of drawing books.

Having tired of pencil and paper, the student must next bring his blackboard into requisition, a description of which has already been given. He will also require a box of Rowney's white demonstration chalks—this is a tapered chalk four inches long, and is more expensive than the ordinary blackboard chalk, which, however, would be of no use for our purpose — a camel-hair writer, a thin piece of "planed" board to act as a palette, and some white (zinc) paint thinned out to the proper consistency with a little *sweet* oil, and some old dusters or bits of rags.

We now commence at the beginning again, and proceed to draw the straight lines, curves, circles, etc., with the chalk, but on a larger scale. This last remark reminds me that I have omitted to say—as I should have done in the first chapter—that it is not necessary for the student to continue to draw his copies exactly the same size as they are given in these pages, although for the purpose of the eye training, as just laid down, he should for some time endeavour to draw them to the same scale, and ascertain by measurement how far he is out when his drawing is completed. After that it is also necessary to become proficient in both reducing and enlarging, and we would therefore advise that the student should, after awhile, make each succeeding drawing larger than the preceding one, and taking this last as his copy for the next one. He can thus go on until he reaches the limits of a full-sized sheet of drawing paper, so that when he comes to practise upon the blackboard he will gradually have worked up to the enlargements almost without being aware of it. He should keep all these intermediate drawings as copies to practise from on his blackboard, and it will be a good plan to work backwards until at last he actually makes an enlarged drawing on the blackboard from the drawings in these pages; but in doing this he should put his other drawings out of sight.

I will now suppose that the pupil has been practising for some hours on the blackboard with chalk, and has redrawn each subject several times over. He should now take his camel-hair writer, and having worked a little white paint on to his extemporised palette, and having thoroughly cleaned the chalk marks from his board, he should proceed to draw all the freehand subjects with his brush and paint, commencing with straight lines and curves. His first object is, of course, to be able to make a line, with his camel-hair writer, of the same thickness throughout. He may now use a mahl stick to rest his wrist upon, or may rest his right hand on the left wrist, the left hand being placed against the board. If his hand is steady and firm enough, however, he had better dispense with either in all his preliminary work, as he will then be the better able to appreciate the help of a mahl stick when it comes to the "grim reality." Here again I may say I have never had one, although, possibly, better work would have been the result if I had. It, however, shows they are not absolute necessities for a young man with a steady hand and of sober habits.

The workman should make his lines, as far as possible, with the point of the brush and not with the side. He must work with a bold, unhesitating hand, if he wishes to give a firm and finished appearance to his work. Any timidity or hesitancy on his part will only end in a very dubious result, and at once betray the hand of the novice. The white paint should be of just such a consistency as to flow freely and evenly from the pencil, and at the same time giving sufficient covering power on the board. The brush is held in much the same way as a pen in ordinary writing; it should not, however, be grasped too tight, as the strain on the sinews of the hand tends to cramp it, which very soon tires it and so renders it unsteady.

As soon as the board is covered all over with paint marks, it must immediately be wiped clean with a piece of rag, which has previously been steeped in a little common turpentine. It is as well to have the paint in a tin dipper, which will be described hereafter.

Coming next to the series of outline subjects given with this chapter, I would impress upon the student the desirability of practising these on the blackboard until he is absolutely perfect, and able to turn out a passable specimen of each one. Fig. 13 is a plain board with a screw head at each corner; Fig 14 a plain shield; and Figs. 15, 16, 17, 18, a series of four scrolls. Next we have a pair of hands (Figs. 19 and 20), one pointing in a horizontal direction and the other downwards. The Royal Arms (Fig. 21) will, no doubt, prove the most difficult subject to tackle, but as the sign writer is so frequently called upon to paint it, he must take it very seriously in hand, and, after he has gained some little experience in the manipulation of his brush, he will find it not so difficult as it at first appears, and he will soon be able to draw it in proper proportions with the greatest facility. He should firstly draw the subject on the board with chalk in a somewhat sketchy manner, allowing his hand a roving freedom, and relying more on his pencil brush for afterwards putting in the lines in a firm, masterly way. This subject is only treated here purely as an outline example; the method of shading will be described, and the colours to be used given, in a later chapter. The Prince of Wales' Feathers (Fig. 22), being a much easier subject, had better perhaps be attempted first. The Crown (Fig. 23) is more difficult, and a little practice will be necessary to draw it to the correct shape. Fig. 24 is a centre ribbon ornament, and Figs. 25 and 26 two scroll work corner pieces. The student should not confine himself entirely to the examples given here, but should draw anything that comes in his way, if it is likely to be of use to him. He will find plenty of other subjects in books and illustrated advertisements, and even on the poster hoardings in the street. He should also go round, sketch-book in hand, and jot down any little bits of good work which he may take a fancy to over the shop fronts and other places of business. He may afterwards make finished drawings of them at home for future use and practice. Making use of his brains in this way will prove of great assistance to the student in his course of self-tuition.

(*To be continued.*)

CRYSTOLEUM PAINTING.

BY O. BECKERLEGGE.

II. — How to Render Photo Transparent—Painting — Suitable Colouring for Portrait — Treatment of Details — Second Painting—Draperies and Background—Finishing and Mounting — Landscapes — Colouring Foliage, Clouds, etc. — Conclusion.

Our next business will be to make the picture transparent. To secure this end several modes are adopted. There is a crystoleum wax sold. This has to be melted in a bath, and the picture soaked in it until the transparency is obtained. I have no doubt this is a good plan, but I have not adopted it, as it necessitates bath, lamp, etc., and there is the danger of overheating the wax, when it is said to turn yellow. I have a shrewd guess that the so-called prepared wax is nothing more or less than paraffin wax. The plan I adopt is one which dispenses with the bath, etc., and saves the expense of wax. Take a little of the poppy oil and pour it on the picture. When it has stood an hour or two the picture will be beautifully clear. Drain off all the oil and it will be ready for painting. I have also tried copal varnish, using it as the oil, but I have the most confidence in the former. Some recommend sweet oil, by which I presume olive is intended, but of that I have no practical knowledge. It seems to me that almost any clear oil or varnish that will dry would answer the purpose.

Well, having got our work up to this point let us proceed to the painting. I will suppose it is your own portrait. According to your complexion, hair, etc., so must be your colours.

Presuming I am giving instructions to one quite unused to paint, let me mix the paint for you.

Eyes. — *Blue*, cobalt; *black*, vandyke brown; *grey*, cobalt and black; *brown*, burnt sienna.

Hair.—*Very light*, Naples and Indian yellow; *medium light*, burnt sienna; *dark*, burnt sienna and vandyke brown.

Cheek and Lips. — Carmine and vermilion.

Complexion. — *Light*, white, carmine, and Naples yellow; *dark*, white, Indian yellow, vandyke brown.

Silver. — White and black. Gold.—Naples and Indian yellow, burnt sienna. Of course, it will be understood that a variety of tints can be produced by the paints named. We must, therefore, use our judgment as to the quantities—as, for example, two persons may be dark, but the colour may be very different; in one case the yellow may prevail, in another the brown—so for hair. We must, of course, bring our judgment and taste to bear on these matters. I will make a few remarks on landscape painting further on.

Let us now proceed to details. With a very fine pointed brush put a point of light in the eye—any picture, even an engraving, will suggest where it should be placed. This representing the reflected light in the eye, gives brilliancy and character. Then the iris, blue or brown, as it may be necessary; the white of the eye, white and a tinge of Naples yellow. Next work on the lips and cheeks; the latter, carmine only, using judgment as to depth of tone. As Opie said once, "mix your colours with your brains." Then put in the hair, using only transparent colours, as I have indicated. Linen, lace, etc., white with just a trace of blue to take off the rawness; jewellery, as before indicated, whether it be silver or gold. Flowers and foliage, as per nature. All this to be painted on the transparent photo. There must be no attempt at shading, either now or at the subsequent stage. The photo, if it is a good one, will provide all that, and if it is not a good one you cannot improve it. All your various studies can be brought up to this point, supposing you have several on hand. They must now stand over till they are hard, which will be by the next day.

We must now proceed to the second painting. When the first paint is dry, remove any dust that may have settled on the glass. Take the second glass and rub it so that there may be no dust, fluff, or grease on it. Provide a strip of gummed paper—the margin off stamps will do admirably—let them be, say ⅜ of an inch wide, place the second glass on the first, and fasten them together on the edge by the gummed paper. Now take your colour for the face and hands, mixing it with a little poppy oil; it will be understood that the paint in every instance is brought into a fit consistency for work by mixing it with this medium. Pass the colour over face and hands, simply taking care to keep to the outline. By turning it over during the operation you can easily see whether you have come too far, or not far enough. Any alteration can easily be made —the entire paint removed, if needs be— without doing any injury to the picture.

Draperies must be painted in the same way, our judgment guiding us in the tint. The background will now claim our attention. The tint will, of course, depend to a great extent on the main subject. A nice effect will be produced if the several colours, blue, yellow, and red, be placed in patches on the glass, and then mixed all up together. A soft prismatic effect will be the result, one tint gradually fading away into another.

When the work is done as near to your satisfaction as possible, cut out a piece of cardboard the size of the glass, and with strips of gummed paper bind the edges all around to keep out dust, etc. It may then be mounted in a plush frame, or, if preferred, a narrow gilt frame will look exceedingly nice if a narrow fold of plush is glued in the rebate of the frame so as to project, say, ⅜ of an in. in the place of the usual flat. This narrow beading of plush will cover the strips of paper which bind the picture together. If in the progress of our work we find the details painted on the first glass are either too hard or not distinct enough, it can easily be remedied by cutting down the gummed paper on one side and opening the glasses, and retouching or softening the first colours as may be desired. Do not cut down the two edges, as you may find some little difficulty in bringing the two glasses in exact correspondence. By leaving one side secure the glasses will find their true position.

Should we purpose painting a landscape, then let the foreground with its details be painted on the first glass; middle distance, clouds, sky, etc., on the second glass. I can only indicate, of course, in a general way what colours to use, as every subject must be treated according to its nature.

A dry open road, Naples yellow, white, and tinge of red. Foliage, with a glint of sunshine on it, soft greens, yellow predominating; sombre greens, blue, burnt sienna; sky, cobalt, and white with a tinge of either red or yellow towards the horizon. Instead of putting on these in distinct washes, as would be done in a water-colour drawing, a dab of the colour should be put on the horizon, and then mixed together on the glass; this will give soft mysterious blendings of colour, the soft light melting into the blue above it. Very distant hills, blue and red; prominent spurs should be lit up with the colour of the horizon, but just a shade lower in tone. Water must take its tone from the sky. Clouds, various shades of grey made with white, blue, and red in different proportion, with a little Naples yellow. In all these cases the shadows in clouds, mountains, etc., must be put on first, the lighter tints behind them.

Any one following these instructions will be able to produce work which will give satisfaction. From briefer notes than these I acquired the art, and I know that persons have been able to turn their knowledge of the art to commercial advantage who have acquired that knowledge simply by reading instructions even briefer than those I have given. Should any little difficulty arise, I shall be happy to answer a question. On reading what I have written, I find I have omitted to mention that the eye-brow and nostrils must be painted on the first glass. For the eye-brow use colour as per hair; soften it towards the eye with a dry brush, stroking downwards.

NOTES FOR ELECTRO-PLATERS.

BY GEORGE EDWINSON BONNEY.

I.—Introduction—Acid—Acetic Acid—Acetate of Copper—Acetate of Lead—Acetate of Silver—Acetate of Zinc—Acetate of Iron—Acetate of Mercury—Acetate of Alumina—Acetate of Cobalt—Acetate of Nickel.

The following notes have been collected from various sources of information, and have proved of some use to me in my work. I now offer to share the benefits I have received from them with my fellow-workers. They are here arranged nearly in alphabetical order for easy reference, and may thus be regarded as an Electro-plater's Dictionary.

Acid.—The acids in general use among electro-platers are: acetic acid, hydrochloric acid, nitric acid, nitrous acid, sulphuric acid, and sulphurous acid, all described under their respective headings. "Most of the acids are soluble in water; they possess an acid taste, and have the property of turning blue litmus solution red. All acids contain hydrogen, combined either with an element, or with a group of elements, which almost always contains oxygen, and in this case the substances are termed *oxi*-acids." (Roscoe.)

Acetic Acid.—French: *Acide Acétique.* Chemical formula, $C_2 H_4 O_2$. Common vinegar is dilute acetic acid prepared by the acetous fermentation of alcoholic liquids. Crude acetic acid (named also pyroligneous acid) is prepared on a large scale by the dry distillation of wood. Glacial acetic acid is obtained by heating acetate of soda with strong sulphuric acid. This acid is a colourless liquid, with a peculiar, sharp, pungent odour, and strong acid flavour. It will mix with alcohol, ether, or water in any proportion. When concentrated by distillation, it boils at 118° C., and solidifies at 17° C. to an icelike mass, hence its name. It will blister the skin, and dissolve camphor and several resins. It forms with bases some important acetates, described under their respective names.

Acetate of Copper.—French: *Acétate de Cuivre.* There are two substances commonly named acetate of copper. One of these—ordinary verdigris—is only a sub-acetate of copper obtained by spreading the marc of grapes (vintage refuse) on copper plates exposed to the air during several weeks. This forms a bluish-green salt, not entirely soluble in water. The true acetate of copper (sometimes known by the names: crystals of Venus, crystallised verdigris, and distilled verdigris) is made by dissolving common verdigris in hot acetic acid, and setting aside the filtered solution to cool. The salt forms beautiful dark-green crystals, which are soluble in water in the proportion of one part of the salt to fourteen parts of water. Mr. Smee says: "A solution of acetate of copper is difficult to decompose, requiring the intensity of several cells." Acetate of copper is used in making up brassing solutions. It is very poisonous.

Acetate of Lead.—French: *Acétate de Plomb.* Described as plombic acetate, Saturn's sugar, and sugar of lead. This salt of lead is made in large quantities for commercial purposes by dissolving litharge in strong acetic acid. It is generally met with in the shape of heavy white crystals, or a mass of them, resembling loaf sugar; this, coupled with its sweetish flavour, has ensured for it the name of sugar of lead. Sugar of lead is poisonous. It is soluble in one and a half parts of water, and in alcohol. "In a solution of acetate of lead, zinc is the only metal that receives a coating of lead by simple immersion." (G. Gore.) This property has led to the performance of a beautiful and simple experiment illustrating the arborescent formation of metallic crystals. A small piece of zinc is suspended by a fine brass wire from the bung of a pickle bottle nearly filled with a solution of lead acetate in distilled water. As the zinc dissolves, crystals of lead take the place of the dissolved zinc, and arrange themselves around the wires in the form of vegetation, and is then named a lead tree. This salt is also used in making up solutions for the electro-deposition of lead. (See *Lead, Electro-deposition of.*)

Acetate of Silver.—French: *Acétate d'Argent.* Mr. Gore has tried a solution of this salt, and says: "For depositing purposes, a solution composed of water twenty parts, cyanide of potassium four parts, and acetate of silver one part, conducts very freely, and yields a fine white deposit of silver." The salt may be made either by adding a solution of acetate of potash or of soda to a solution of nitrate of silver as long as a precipitate occurs, decanting the liquid, and washing the salt in the usual way, or by digesting the oxide or the carbonate of silver in hot and strong acetic acid.

Acetate of Zinc.—French: *Acétate de Zinc.* This salt may be made, either by dissolving zinc in strong acetic acid to saturation, or by adding a solution of lead acetate to a solution of zinc sulphate, as long as it produces a precipitate; filter, evaporate the liquid, and set aside to crystallise. This salt is sometimes mentioned in some formulæ for brassing solutions.

Acetate of Iron.—This has been recommended as an antidote to poisoning by cyanide solutions. There are two acetates of iron—an acetate of the protoxide of iron (crystals of small greenish-white needles), and acetate of sesquioxide of iron, "a dark-brownish-red, uncrystallisable liquid, of powerful astringent taste." (Fownes.) The ordinary "steel drops" sold by chemists will serve every purpose required here.

Acetate of Mercury.—A solution of this salt will deposit its metal on iron by simple immersion. Prepared similar to acetate of silver.

Acetate of Alumina.—A gummy mass used in calico printing.

Acetate of Cobalt.—A violet-coloured deliquescent salt.

Acetate of Nickel.—A green salt of this metal, soluble in water. Of no special interest to the electro-plater.

(*To be continued.*)

WHY DOES A TOOL CUT?

BY J. H.

II.—Sensitiveness of Tools—Impairing Wedge Form—Grinding Chisels—Facets made in Sharpening—Grinding, when Necessary—Drills—Lip Drill—Twist Drill—Reamers—Taps and Dies—When such Tools cease to operate—Saws and Files—Work done by Tool—Its Teaching—Presentation of Tool.

I will now briefly illustrate the principles laid down in my previous article by examples taken from common tools. Of these, the kinds used for wood working are more sensitive to ill-treatment than those used for working metal, and of the latter those which are operated by hand than those actuated by machine. The reason is, of course, that the more delicate the nature of the work, the more readily is the action of the tool felt. There are numbers of tools in daily use in the machines of our factories which are badly formed, so causing a great waste of power, that would not and could not be tolerated if they were hand worked, because the hand and arms soon rebel against the excess of energy required to operate badly formed tools. The stresses on the machine-worked tools on the other hand are only apparent in excess of friction, the evils of which are not so evident to some workmen as excess of muscular effort.

Take first those cases in which tools do not cut because the wedge form is impaired. The chisel, and all chisel-like tools, should be ground with one facet only, not with several. This applies alike to the chisel for wood working and for metal cutting, to the gouge, the axe, adze, knife, razor, plane-iron, spokeshave, and others of similar type. The reason why it must be so in order to develop the full efficiency of these tools is apparent from the illustrations.

Thus, comparing Figs. 6 and 7, which are slightly exaggerated for the purpose of illustration, Fig. 6 shows how a chisel-like tool ought to be ground, the concavity of the facet exactly corresponding with the curve of the stone upon which it is ground. To grind it like this requires some practice in the case of broad chisels and plane-irons, the tendency in unskilful hands being to produce a succession of facets like Fig. 7, due to the slipping up and down of the tool on the revolving stone. But the advantages of Fig. 6 are very great.

First, the necessity for regrinding is delayed much longer than in Fig. 7, where the facet is on the whole convex instead of concave. Fig. 6 approaches to the hollow razor form, Fig. 8, and for some little time the grinding angle and the sharpening angle will coincide; after awhile it becomes necessary to tip the facet in sharpening, Fig. 9, and the sharpening angle is gradually rendered more obtuse until regrinding becomes necessary. But in Fig. 7 the sharpening angle is obtuse from the commencement, and regrinding is soon required. Moreover, since the angle is so obtuse, a greater expenditure of energy is necessary to remove the shavings than in the former case, because the latter has less penetration than the former. This is apparent from the dotted lines, which show the effective angles of the two by comparison.

A good workman, therefore, always endeavours to preserve the wedge-like form to his tools as long as possible, regarding the grinding of the hollow facet as a matter of cardinal importance.

Chisels are often badly sharpened by tilting up the face for the purpose of turning back the wire edge. The result is that the face is like Fig. 10.

This again detracts from the wedge form. Worse than that, it vitiates a very important point in chisels worked by hand; it destroys the guidance afforded by a perfectly flat face. The chisel must be tilted before it will cut, and being so placed, there is no longer that contact of broad faces which is conducive to the guidance of the tool, and the difficulty of cutting surfaces and ends is much increased thereby.

No matter how flat the general area of the chisel face is, if there is a second facet, however narrow at the cutting edge, that determines the action of the tool. The tool angle is measured between that and the sharpened facet on the bevelled face. Hence the need of care in these little matters where amateurs are so apt to fall into error.

Of course, with all tools the labour of cutting becomes increased as the wedge form is unavoidably impaired by legitimate use, that is as their keen edges become dulled, in other words as their angles become more obtuse. When the amount of this is slight only, we resort to *sharpening*. When, by repeated sharpening, the tool angle becomes very obtuse we remove material in greater quantity by *grinding*.

There are many serviceable tools which we are accustomed to class with the cutting tools, which cannot be said, literally and strictly, to cut because they have not the wedge form. Among these are included the common drills, the screw taps and dies, the reamers, and other forms. Thus the common drill, Fig. 11, by reason of the overhang of its cutting face, A, makes an angle greater than 90° with the face of the work, and it is simply a scrape, though, by reason of the coercion exercised upon it, it really removes tolerable chips or shavings. But the lip drill, Fig. 12, is a cutting tool, being a true wedge.

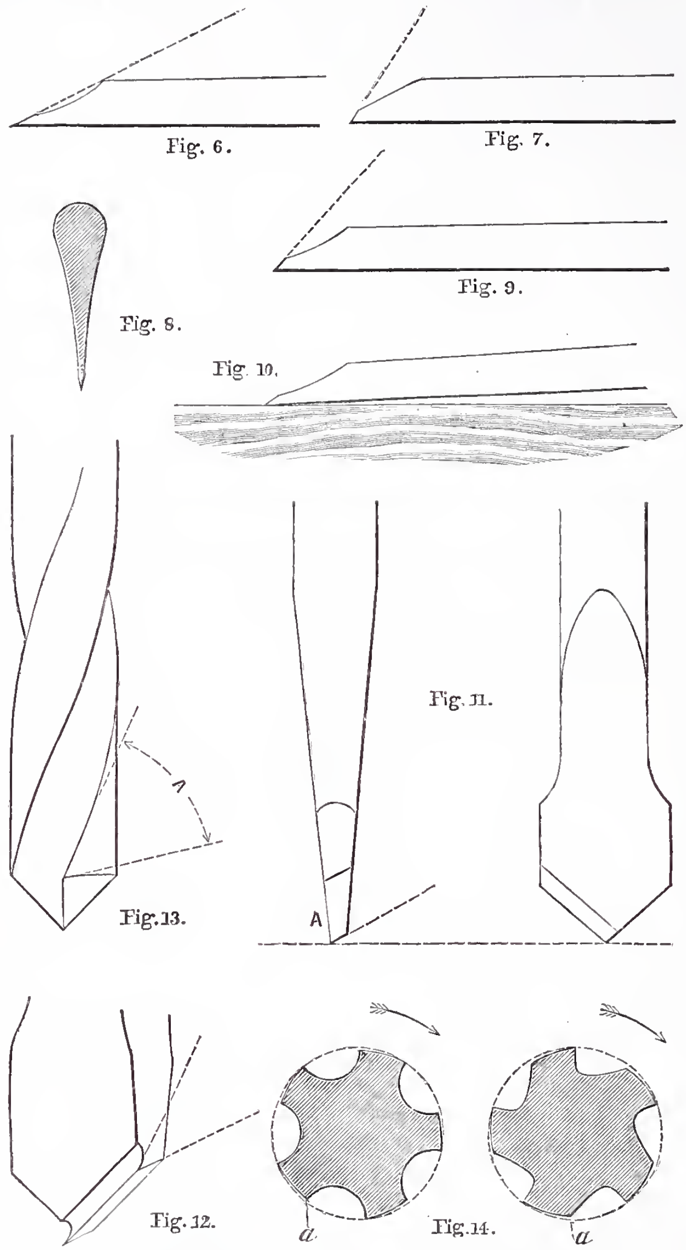

Fig. 6.—Chisel Ground Correctly. Fig. 7.—Ditto, Incorrectly. Fig. 8.—Section of Razor. Fig. 9.—Obtuse Sharpening of Chisel. Fig. 10.—Chisel Tilted by Bad Sharpening. Fig. 11.—Common Drill. Fig. 12.—Lip Drill. Fig. 13.—Twist Drill. Fig. 14.—Sections of Reamers and Taps.

But much superior as a cutting tool is the twist drill, Fig. 13, whose angle, A, is acute or wedge-like. The angle of the spirals remains constant throughout the life of the drill. Figs. 12 and 13, therefore, have the top rake, which is absent in Fig. 11. All alike have sufficient clearance, or relief angles. Very few reamers or taps have any top rake, and they are not therefore wedges. Even in the best designed forms the top or cutting face is perpendicular to the work, as in the reamer, two of whose sections are shown in Fig. 14, and the taps, whose sectional forms are similar to those which are shown in Fig. 14.

But then these remove material in fair quantity because of the strength and coercion exercised in operating them, and because they are all backed off, as at *a*, *a*, preventing excessive friction between the tool and the work. Each of these tools ceases to operate when the primary conditions become vitiated chiefly in their case by the wearing back of the keen edges obliterating the angles of clearance, to which the efficiency of Fig. 14 is largely due. Because their form is unfavourable for cutting, and because they so readily lose their pristine edges, very great care is necessary to avoid all contact with rough cast or forged surfaces, the case may be.

Saws and files operate not as wedges but as a multitudinous assemblage of scrapes. The minute teeth have abundant clearance, a highly important matter; but as the front faces of the teeth lean back beyond the perpendicular they cannot penetrate as wedges. One thing which tends to sweetness of working by diminishing the friction is the diagonal sharpening of the tooth faces in the case of the saws, and the diagonal arrangement of the lines of teeth in the files. By these devices the material is attacked in detail, just as when using a broad wood-working chisel we move it diagonally across the face of the material to ease the labour of cutting, or just as the shears or scissors divide material in detail.

The vast difference in the amount of work done by a tool that cuts efficiently and one that only scrapes, should read an instructive lesson both on the importance of correct tool formation and the maintenance of the same, which is seriously impaired by every departure from the wedge-like form.

The wood-worker's chisel, axe, and adze, keen and acute, remove material in large quantity. The screw tap, the die, the reamer, the file, the saw, remove only fine scrapings or "swarf" even when working at their best. The turner's roughing tool cuts off great shavings to a considerable depth; the broad finishing tool and the scrape remove only thin parings. In the one the wedge-like action is perfect, and seen at its best, in the other that action is nearly or quite absent.

Much might be said about the influence of the method of presentation of the tool to the work as affecting results. But this would really be resolvable into conformity with or departure from correct tool angles, so I need say nothing on this point just at present.

The whole subject of tool formation is one of a highly interesting and practical character, and one which every workman should study. I have simply endeavoured to touch the fringe of the subject by showing why some tools cut while others do not. In subsequent issues I shall have more to say about some of the common tools, their principles of action, and the manner in which they are used.

OUR GUIDE TO GOOD THINGS.

17.—Britannia Company's New Lathe Dogs for Face Plates.

In No. 2 (page 17) of this magazine instructions were given for making a home-made dog chuck or face plate, and the method to be followed in making lathe dogs for it was described as well. There may be some workmen, especially amateurs, who, though they may contrive to make the chuck, may not have either the skill or the time to make the dogs, and it is in the interest of such as these and many others who may be desirous of purchasing lathe dogs ready to hand, that I give in Fig. 1 illustrations of some excellent things of this kind that have been recently manufactured by the Britannia Company, Colchester, and may now be had from the Company direct or through any dealer in tools. The three varieties figured clearly show the purpose for which they are intended and the way in which each is to be used, so any detailed description is unnecessary. The price of the dog in the centre is 1s. 6d.; of the one on the right, 3s. 9d.; and of the one on the left, 5s. They are well made of black iron, and the screws externally and internally are carefully cut.

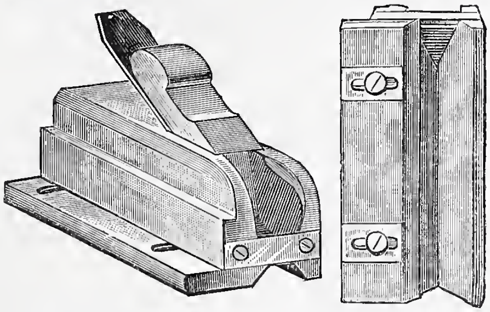

Fig. 2.—Chamfer Plane.

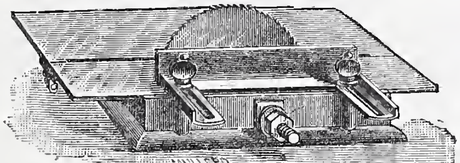

Fig. 6.—Circular-Saw Bench for Work-Bench.

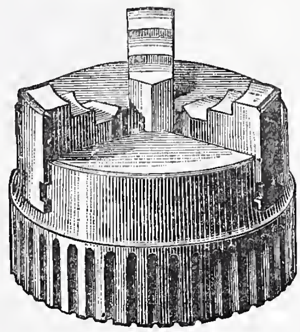

Fig. 3.—Small Three-jawed Chuck.

18.—Melhuish's Chamfer Plane.

To save repetition of names and at the same time to let every reader know where the articles mentioned may be obtained, if he cannot get them nearer home, I may say at once that the chamfer plane now under consideration and every other article yet to be described in this notice is supplied by Messrs. Richard Melhuish and Sons, 85 and 87, Fetter Lane, E.C., who have submitted specimens to me for examination. The make and action of the plane may be gathered from Fig. 2, in which the cut to the left gives a view of the plane when looked at from above, and that to the right of the bottom of the plane. The merit of this plane is that the cutting edge of the iron goes nearly up to the strip of brass that is screwed on to the front of the plane, so that even in the case of a stop chamfer the chamfer may be carried nearly close home to the stop. By means of the fence that is attached to the bottom it may be regulated by loosening the screws and permitting the fence to travel either way as may be required as far as the slots will permit. Chamfers ranging from $\frac{1}{8}$ in. up to 1 in. within may be readily cut. This plane is made in beech in two sizes, $4\frac{3}{4}$ in. and 6 in. in length, sold at 4s. 6d. and 6s. 6d. The fence of the larger plane is of boxwood. It works well and easily when in use, and should be found in the stock of every wood worker, being preferable in every way to the spokeshave-like tools of this class, which, although they are good and serviceable in themselves, are not nearly as handy as the tool just described.

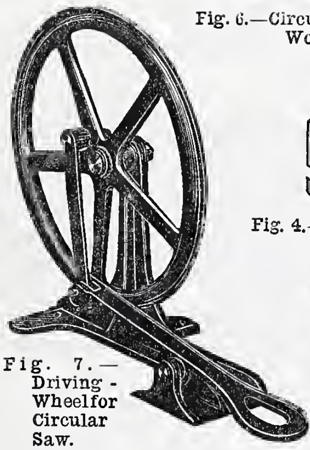

Fig. 7.—Driving-Wheel for Circular Saw.

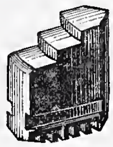

Fig. 4.—Jaw of Chuck.

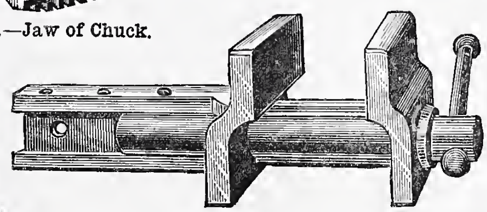

Fig. 5.—Joiner's Parallel Grip Vice.

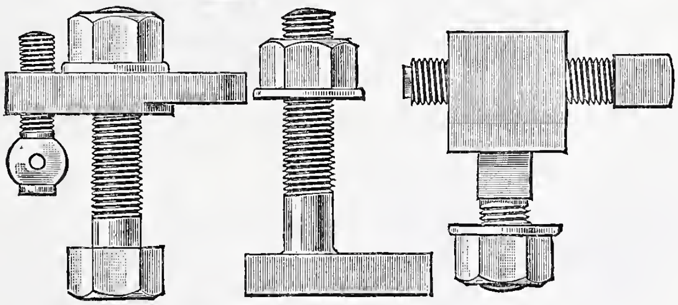

Fig. 1.—Britannia Company's New Lathe Dogs for Face Plates.

19.—Small Three-jawed Chuck.

This little Three-jawed Chuck which is illustrated in Fig. 3 is of French origin, and being much better finished than chucks of this kind usually are, will doubtless be welcomed by those who require a small appliance of this kind for light work, although its price is 32s. The general character and formation of the chuck is exhibited in Fig. 3; and in Fig. 4 is shown one of the jaws of the chuck, these being removable at pleasure. Each chuck has two sets of jaws. The jaw in Fig. 4 is formed reversely to those shown in the chuck in Fig. 3, being intended for drill work.

20.—Joiner's Parallel Grip Vice.

Vices of this pattern are apparently not so widely known and used as they ought to be, and many a carpenter and joiner still keeps to the old wooden bench vice with its wooden screw, although by the adoption of the Parallel Grip Vice much time is saved, because by the latter wood can be seized and secured instantly by the third of a turn of the hand, while with the former the jaws must be opened, perhaps with many a turn, to a sufficient extent to receive whatever it is wished to place between them, and then tightened with more turning—a marvellous contrast to the rapid and effectual action of the grip vice, whose rack can be thrown out of gear at once by an upward motion of the hand, and the front jaw pulled out, pressed against the wood, and then tightened in an irresistible and unmovable grip by a similar movement of the hand downward. The pattern shown in Fig. 5 is fixed to the bench from beneath as indicated, and the top of the jaws are level with the surface of the bench. Like all the grip vices, its holding force is so great that if a long piece of wood be clutched by one end in the vice its weight will be powerless to alter its position in the vice in the smallest degree. Its cost is 13s. 6d.

21.—Parallel-jawed Pliers.

When pliers of the old style are opened it will be noticed that, as a matter of course, there must be a greater divergence of the jaws at their extremities than nearer the axis about which they move, and this occasions a certain amount of inconvenience when trying to hold a piece of metal with them without injuring the corners or surface. In this tool, however, parallelism of the jaws is maintained by a simple mechanical arrangement contained within the jaws themselves. In the pliers before me the surface grip of the jaws is $\frac{3}{4}$ in. by $\frac{1}{8}$ in. at the extremities, and the jaws open to the extent of $\frac{1}{8}$ in. Thus a firm, solid hold is effected on the object grasped, and from the nature of the mechanical construction of the pliers, the power applied is from twice to four times that of the force exerted by the old kind of pliers. It is true that pliers of this kind have been in use for some little time, but not so long as to be generally known and used. They are made in three sizes—namely, $4\frac{1}{2}$ in., $5\frac{1}{2}$ in., and $6\frac{1}{2}$ in. in length. Sold respectively at 3s., 3s. 9d., and 5s. per pair.

22.—Circular-Saw Bench for Work-Bench and Driving-Wheel.

Maybe there is many a workman who desires, beyond all measure, to have a small circular saw for light work, but who has not a lathe which he can furnish with one or other of the circular-saw rigs described and illustrated in No. 1 (pages 8 and 9), or something similar. At all events, he has his work-bench, and on this he may easily place the handy little iron circular-saw bench figured in the accompanying illustration, cutting two or three holes in the top of the wood-bench, so that the saw itself may be actuated by the driving-wheel shown in the engraving (placed immediately below the illustration of the circular-saw bench) which is placed under the bench, and turned by means of the treadle.

The construction of the saw-table is apparent from the illustration in Fig. 6. It is made in halves, which are supported on the framing below, and which are removable, to allow of the easy removal or replacement of the saw when necessary. The fence is movable, and can be fixed at various distances from the saw, as may be required, by means of the thumb-screws, which pass through slots in pieces of metal projecting from the fence at right angles to it, and which work in projections from the frame which supports the table, being properly bored and cut with a screw-thread to receive the screws. The axle on which the saw revolves, is shown projecting from the frame, and secured by a hexagonal nut working on the screw-thread with which its end is furnished, as shown in the illustration.

The saw-table is 13 in. long by $7\frac{1}{2}$ in. broad, and its upper surface is just $1\frac{1}{2}$ in. above the level of the work-bench. The bottom of the frame projects beyond the face of the upper part, and is bolted to the work-bench. The saw is 6 in. in diameter, and projects 2 in. above the surface of the saw-table. The driving-wheel needs no description, as its construction is self-evident from the illustration given. The price of the saw-table, including saw, is £1 15s.; and that of the driving-wheel £1 10s.; or both are supplied together for £3 3s. The weight of the driving-wheel, it may be said, is 50 lbs., and can be used to drive any small bench lathe. Those who may desire to have the saw-table placed otherwise than on the work-bench can obtain it mounted on a strong and serviceable table or bench, which is 2 ft. 10 in. high, having a top 18 in. by 14 in. I must not omit to say that the iron saw-table is reversible, and can be reversed when required in a very short space of time. I have described the fence placed on one side for work parallel to the plane of the saw. On the other side are fences or flanges arranged at an angle of 45° for cutting mitres. Thus the whole affair is rendered of utility for a great variety of work, and will be prized by the workman who is engaged in light trades, such as picture-frame making, etc., as well as by the amateur.

The whole, indeed, may be said to form a very handy little appliance, well worthy of the attention of the amateur, and even of the professional workman, for carrying out such work as comes fairly within the capability of the circular saw with which it is furnished.

23.—New Adjustable Callipers.

To all callipers whose legs are drawn further apart or brought closer together by means of a screw, the chief objection has been the length of time that is taken up in working the screw, in order to bring the points of the legs into the required relative positions. A new and desirable make of callipers, however, has been recently introduced in which any delay of this kind is entirely obviated. The legs are fastened together by a steel stud at the top, and further connected by a strong steel spring, secured in place by wires or pins passing transversely through the legs, and which by its contraction causes extension of the legs to their utmost limit. At the distance of 1 inch from the stud that passes through both legs, and acts as a rivet to hold them together, are two more studs, one on each leg, projecting ⅜ in. beyond the surface of the side to which each is attached. In one of these a bar cut with a screw-thread for the greater part of its length is fixed by a pin with sufficient play to permit the end of the bar, which is about 2¾ in. long, to move freely in a plane parallel to the surfaces of the legs for about ⅛ in. Along the bar, when the legs are held tightly together, a broad piece of metal like a thick conical washer, and a steel tube with a broad milled flange at the outer end, move freely up and down. This steel tube is in reality an eccentric, which may be thrown out of, or brought into, gear with the screw-thread cut on the bar by a slight pressure on the milled flange. Thus supposing, for example, that the callipers are adjusted to take a measurement of ½ in. in diameter, and it is wished to increase the distance between the points to 2 in., all that need be done is to release the eccentric, allow the legs to fly apart under the extending power of the spring to the required distance as nearly as possible, and then to bring the eccentric and washer, as I may call it, in close contact with the stud through which the bar works, and finally regulate the distance required between the points with the utmost exactness by the aid of the eccentric, which falls into gear on the screw-thread as soon as it is brought into position and feels the pressure of the spring. The specimen pair of callipers before me opens to the extent of 5½ in., and costs 5s. Callipers of all shapes for inside and outside measurement are now made in this way, and are in every way preferable to ordinary callipers for the reason stated. THE EDITOR.

*** The London Lathe and Tool Company write:—"In describing the Simultaneous Grip Chuck and the Independent Grip Chuck, we should perhaps have stated that these chucks are American." It was too late to note this in the description of the chucks in "Our Guide to Good Things" in No. 3, but the earliest opportunity has been taken of supplying the omission.

SHOP:

A Corner for Those who Want to Talk It.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

Building Construction.—G. C. (Kennington).—Every branch of the building trades will be treated in WORK, not, perhaps, in a set series of lessons on the subject beginning with excavating and laying the foundations, and ending with the finishing touches imparted by the paperhanger and decorator; but in papers that will deal sufficiently and readably, if I may use the word, with various parts of the subject. Thus in Nos. 3 and 4 you will find chatty articles very much to the point and purpose on "A Simple Ceiling in Wood," which I am sure will be suggestive and helpful to many. In many of the Devonshire farmhouses there is nothing but the "planching," as the floor boards are called, between the rooms above and the rooms below. Note, please, how these very papers show how to make the joists themselves ornamental, and how to cover the chinks between the floor boards, and if it is desired, to stop as far as possible the transmission of sound from one room to another. Suppose you write again and afford some tangible idea of the "series of lessons" for which you seem to wish.

Wood Carving.—E. B. (Eton).—I fear it is not possible to give the interesting little pamphlet you kindly send in WORK. It would serve as introductory matter to a study in wood carving, and as a series of remarks advocating the adoption of this art either as a trade or as a hobby. Why could not a skilled carver, as you appear to be, send in some studies in wood carving, with matter descriptive of the method to be followed in producing the effects depicted by the drawings?

Keys for Pianos, Organs, and Harmoniums.—G. D. (Upper Holloway).—Certainly your request shall be complied with whenever opportunity offers, and the subject of building these instruments is sure to come to the surface in WORK ere long. Meanwhile, why not advertise in our pages? There is nothing like advertising for nursing, helping, and making a business in the present day. Success, be it what it may, must be purchased by preliminary sacrifice. Even omelets, you know, cannot be made without breaking eggs.

Photography and Fretwork.—D. H. (Wandsworth).—See replies in respect to papers on the first-named subject in No. 3. With regard to the second, why not send in specimens of your work if you are a designer of fretwork patterns? I have on my staff very efficient writers on fret cutting.

Photography and Saddlery.—A. H. (Theale).—You will see what I have said above about papers on photography. With reference to the second subject please write again, giving more definite information and proposed mode of treatment, as it is now under consideration as one to be dealt with at no very distant time.

Wire Thread Fret Saw.—G. C. (Nunhead) writes:—"It is really a singular fact that there is nothing new under the sun. In your admirable little welcome arrival, WORK, I see you notice a 'New Wire Thread Fret Saw.' Perhaps you will be surprised to hear that the Chinese fret workers and the jade stone ornament makers of Canton use precisely the same wire jagged or tooth saw for their work, and have done so from time immemorial. I have seen these skilled ingenious workers plying their trades many times, and as far back as the year 1872."—[I am much obliged to you for the interesting nature of your communication, and so, doubtless, will be many of the readers of WORK. It is true that there is nothing new under the sun, but there is a time when anything and everything under the sun must be new to the person who comes across it for the first time. Thus the wire thread saw was new to me, and will be new to many besides myself.—ED.]

Wire Thread Fret Saw.—G. D. (Rhayader) writes:—"Your new Wire Thread Fret Saw is not a new thing. I have seen it used twenty-five years ago."—[Will you kindly write again and tell me for what purpose it was used—if for fret cutting, and under what circumstances? Also in what sizes it was made, and if it was an article commonly and constantly on sale.—ED.]

Our Advertising Pages.—L. S. L. (Kirkcaldy).—These in no way impair the utility of WORK, but, on the contrary, add to it. Your suggestion, however, shall be noted. Every suggestion, indeed, I may say, is carefully considered. If you will send in the article you name in your letter, on approval, it will be read with a view to acceptance, if suitable.

Theory and Practice.—W. B. B. (Brannox Town).—The title was very carefully considered; and although it may seem to you that Theory should precede Practice, the arrangement of the words was made purposely, because, although both Practice and Theory will find a place in the Magazine, there will be more of the former than of the latter.

*** *Many answers are held over for want of space.*

Trade Notes and Memoranda.

SOME TOPICS OF THE HOUR.—Professional differences as to Quantities.—Wall Papers.—Fireproof Construction.—The Dangers to Health of Stoves.

NOTES.—Hastings wants a harbour at a cost of £60,000.—The Department of Science and Art will hold Examinations from May 6th to 31st.—The new Post Office for Birmingham will cost £70,000.—Filtering of sewage is being successfully experimented in at Acton.

LITTLESTONE-ON-SEA, between Dungeness and Folkestone, is to become a new Sussex watering-place.

THE charge for ascending to the top of the Eiffel Tower is to be 5 francs; for ascending to the second platform, which is 700 feet high, 3 francs; and 2 francs to the first platform, 200 feet high. Visitors can use the lifts or walk upstairs.

THE new Berlin Cathedral will cover 7,053 square metres, or 900 more than Cologne Cathedral. The building will cost 22 million marks, and contain room for about 2,500 persons.

THE Metropolitan Police Receiver invites tenders for 11,500 pairs of boots, due August 1, 1889; and 13,000 pairs, due February 1, 1890.

THE Spiral Wood-Cutting Company (Limited) has lately been registered. Capital £1,500, divided into 1,500 shares of £1 each. Objects: To acquire letters patent of an invention of a new and improved tool for spiral turning, and to carry on the business of spiral turning in wood of every description.

PARCELS not weighing more than 7 lbs. can now be sent to Mauritius by the parcel post at a minimum charge of 3s. 2d.

OF the suburban bridges freed in recent years, Kingston cost £15,600; Walton, £7,012 (the amount of the claim being £29,510); Staines, £20,125 (the amount of the claim being £80,500); Kew, £57,300 (the claim being £73,832); Hampton Court, £48,048 (the claim being £61,600); Tottenham Mills, £1,750 (the claim being £7,245); Hellyer's Ferry, £1,568; Chingford Ferry, £4,082.

IT is proposed that the sum of £2,000 per annum for two years be given out of the City's cash in aid of the objects of the City and Guilds of London Institute, for the advancement of Technical Education, the first payment to be made forthwith, and the second payment on January 1st, 1890.

THE City of London School Committee intend to ascertain how best the space at their disposal can be utilised for the erection of a building suitable for the education of boys in carpentering and other useful pursuits.

AN artistic piece of wall decoration has been completed in the Nurses' Refectory, Guy's Hospital. It is the work of Mr. H. J. Draper, who in 1886 gained the Royal Academy students' prize of £40 offered for a design for the decoration of a public building.

Moulding Dept., 41, 42, 43, Russell St., Covent Garden, London.

SCOTT'S EMULSION

OF

PURE COD LIVER OIL

With Hypophosphites of Lime and Soda

Is three times as efficacious as the plain oil.
It is almost as palatable as milk.
It does not nauseate or produce a loathing for food like the plain oil.
The Hypophosphites and Oil are so skilfully combined that they are much more potent in building up flesh and strength than if taken separately, and it is, doubtless, to-day the best remedial agent for the cure of

CONSUMPTION, CHRONIC COUGHS, BRONCHITIS, ANÆMIA, WASTING DISEASES OF CHILDREN, And GENERAL DEBILITY that exists.

Physicians universally prescribe it in preference to the plain oil, having seen its remarkable curative effects.

Scott's Emulsion of Cod Liver Oil can be bought of any Chemist at **2s. 6d.** and **4s. 6d.**

A Free Sample **4-oz.** Bottle will be sent to anyone who will write for it if they will pay carriage on receipt.

Address—**SCOTT and BOWNE, LIMITED, 47, Farringdon Street, London, E.C.**

ASPINALL'S ENAMEL.

A DRAWING-ROOM OVERMANTEL

With Lincrusta Decoration.

BY E. BONNEY STEYNE.

No sooner is a pretty fancy in furnishing floated and fashionable, than imitations abound and weary one. If the Venus of Milo were in every house, we should welcome "You dirty boy," by way of variety. Governed by this idea, I wanted to design a drawing-room overmantel that was not exactly after the sort so widely advertised, now almost as conventional as the old gilt-framed looking-glass they replaced. Two ends were clearly desirable — economy of material, and newness in shape and effect. Whether I secured them in the overmantel now to be described my readers can decide for themselves. I can answer for the economy, and am content to let the novelty plead for itself. If there is one distinctive feature common to nine-tenths of these things, it is that they are angular in plan, in section, in elevation—all square right angles. A right angle is a good angle, and if we must be overdone with any variety, certainly it is about the best; but in a room of rectangular furniture, a bold curve tells with increased effect. But working on a curved plan is wonderfully hard to an amateur, and in spite of my wish to indulge in sweeping lines, I feared I must stick to the simpler plan. But a way out of the difficulty soon appeared. It was obvious to the meanest intelligence—in this case my own—that a curved plain edge to a piece of wood was not extremely difficult; it was when mouldings on the curve, or panels constructed on that plan, came to be thought of, that discretion suggested a more simple shape. But reckoning up available material I thought of lincrusta as possible, and then planning how to keep the curved notion, soon found a way out of the wood. First I decided upon two panelled ends, fashioned in ordinary manner: these were fixed to a bottom board 5 in. by 8 in., itself raised about 3 in. above the level of the marble shelf on which it was to stand. Among the available material were a quantity of turned spindles in deal, that M. C. Duffy and Co. had worked for me at a cost of ten or twelve shillings a gross, I forget which. These were about $4\frac{1}{2}$ in. long. To avoid lodgment for dust, and economise my spindles, I cut them each in four pieces—that is, one across, and once in half, leaving half-round pieces $2\frac{1}{2}$ in. long; these I put on to a thin piece of wood, with a bottom rail, and so filled up the space just above the shelf. But in my case this base was larger than the stone ledge, and so hid it completely from view, which was, to me, a decided advantage. (I may say, in passing, that a mantel border of close-falling imitation Spanish lace and curtains were afterwards added, and hid the unsightly mantelpiece entirely.)

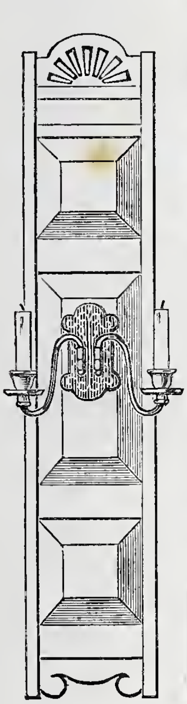

Fig. 3.

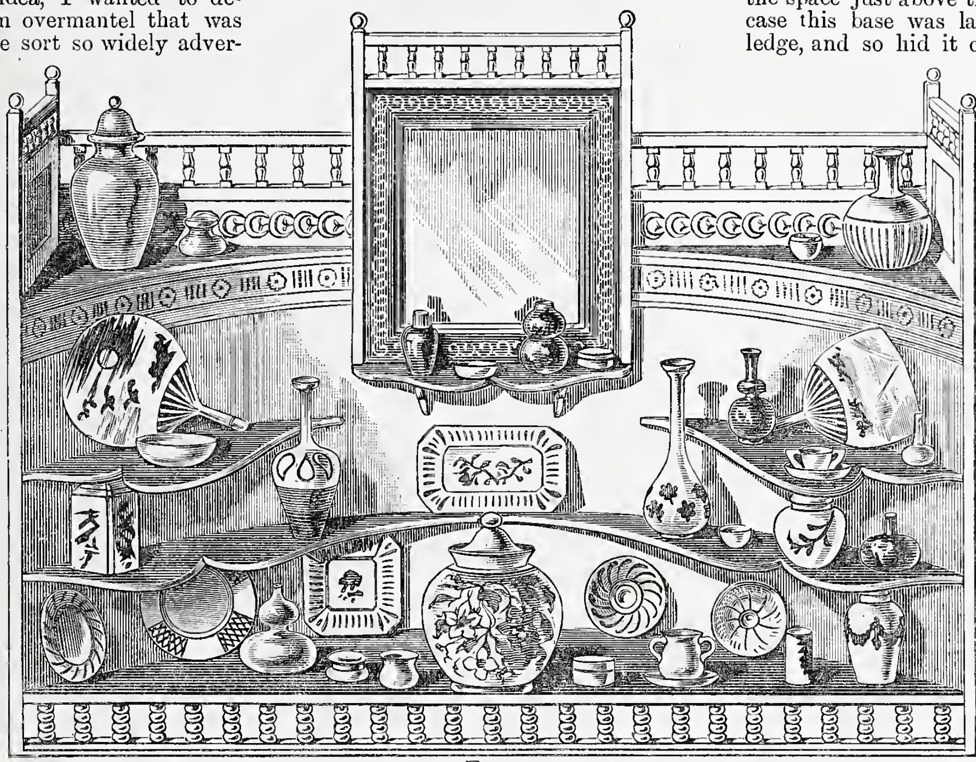

Fig. 1

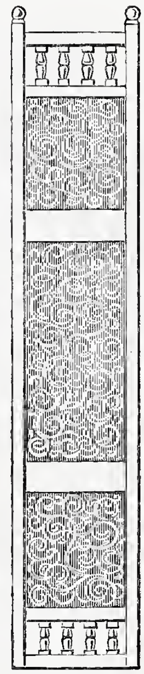

Fig. 4.

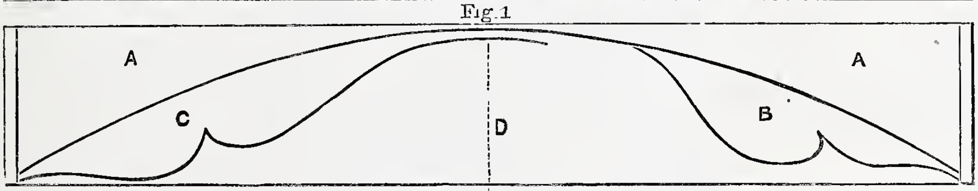

Fig. 2.

Fig. 1.—Sketch of Drawing-Room Overmantel, Painted: Lincrusta and Turned Ornaments. Fig. 2.—Plan showing Top Shelf (A), Second Shelf (B), Third Shelf (C), and Bottom (D). Figs. 3, 4.—Alternative Ends.

To this base I added a back, framed as shown in the sketch, but not solid, merely a rail here and there for the sake of stability.

Then taking the arc of a circle 4 ft. $7\frac{1}{2}$ in. in its radius, I cut out three pieces of common $\frac{3}{4}$ in. deal to this plan; this left a bare eighth of an inch in the centre, just enough to keep it from breaking. Having fitted these shelves in place to the uprights at the ends—one at the base, one at a foot above, and one at two feet—I obtained a piece of tin the required length—I forget the exact size—about 6 ft. long and 2 ft. high. I then nailed the tin round the sweep, as shown in the drawing, being careful to join it very truly to the top curved shelf. Next I cut out shelves of half-inch pitch pine, free from knots—sequoia wood would have been better had it been at hand—as shown, and fixed them from the back, screwing them to the tin, and adding small brackets, which I fixed to supports placed behind. This sounds complex, but was really a very easy process, for the back of the mantel now growing into shape was as easy to work from as the front. Having framed a looking-glass, with a rail of the same spindles cut to about 2¼ in., and carried a similar rail across the top, the whole was roughly ready for decoration.

Whether I have given the actual order I adopted matters little, provided the result is clear. Now looking from the front the mantel was like the sketch annexed, but, of course, perfectly plain. Having unscrewed the shelves, I covered the whole tin curve and the panels of the ends with a low-relief all-over pattern in lincrusta, adding a border at the top edge, and using a similar border beneath the top railing and between the outer and inner moulding of the mirror. As the widths varied, I chose the patterns as nearly in character as I could that were of the right size for each place.

The woodwork being all smoothed, I painted the whole a creamy white, and, as it suited the room, left it so; but I fancy a solid gold treatment of the lincrusta, or the design worked in different shades of metallic bronze to emphasise the pattern, or a gold Japanese paper used in its place, would suit many rooms as well, or better.

The overmantel thus made is, perhaps, the most satisfactory one for its cost that I know. Having so many of the materials by me, I cannot give the exact price like a cookery book, but a few shillings ought to buy them all and produce a rival to one at a dealer's shop costing some pounds; while not entirely destitute of individual character, and, if I may say so, of artistic effect. Although its construction is not calculated to survive a railway journey, if packed in wrappers only, an overmantel is not a piece of furniture given to roaming over the house, like milking stools or music stands. Consequently, if capable of holding well together when fixed to the wall, it may be claimed to have fulfilled its object in life.

FRIENDLY HINTS TO AMATEUR WOOD WORKERS.

BY DAVID DENNING.

II.—Le Page's Liquid Glue—Its Advantages—Treatment—Cane Glue Brush—Defects in Work Done by Amateurs—Accuracy in Marking Necessary—Testing—Superfluity of Tools a Hindrance—Planes—Utility of Scraper—Treatment of Edges—Fitting Joints—How to Cut Mortises and Tenons—Dowels and Dowelling.

Perhaps it may be expected that something should be said about the liquid glues, such as Le Page's, which have become so popular of late years both among amateurs and professionals. The advantages of these liquid glues are that they are always ready for use, requiring no heat, and they do not spoil by being kept if, be it said, the can is covered when not being used from. Even if exposed to the air the chief or only deterioration consists in the glue becoming thick, simply from the evaporation of moisture. The remedy, of course, if this happens, is to add a little more water, but in practice, with ordinary care, this is seldom requisite, and is not altogether desirable. In very cold weather a little warmth is necessary, but if kept in a warm room or placed near a fire for a time, it is soon fit for use. It does not require to be applied hot. For some kinds of work requiring a colourless or almost colourless glue it is unsurpassed, and as it does not set so quickly as the ordinary kind it is well adapted for marqueting and inlaid work generally. When it does set it possesses great tenacity if properly used, that is, thinly applied and well rubbed in. Without going the length of saying that it is better than animal glue, when this is of the best, and employed under the most favourable conditions, there can be no question that it is superior to ordinary common glue which has not been made, mixed, and used with skill and care. At first sight its cost may seem to render it rather an extravagant luxury, but as a little of it goes a long way, and it does not waste by keeping, practically it will be found to cost in the end little, if any, more than the usual kind. Mind, I do not say that where large quantities of this are used this would be so, for even if I cared to express a definite opinion it would not concern the amateur worker.

Before concluding these remarks about glue, it may just be suggested that as effective a brush as any may be made out of a piece of common cane. Whether from the ease with which it is made, its cheapness or its adaptability to its object, the cane brush is preferred by many competent and practical workers to any other. To form one, all that has to be done is to take a piece of cane, cut away the flinty skin for an inch or so at one end, and then hammer this till the fibres are softened and loosened, the only care required being not to cut them off while doing so. Such a brush will last a long time, in fact, as long as there is any stick left to hammer out a fresh end from.

Having done with glue for the present, it may be well just to consider how it is that beginners' work when glued or otherwise fastened up has such a lop-sided, out-of-the-straight look about it. Of course, a good deal must be put down to want of manipulative skill, but even after making due allowance for this there is no doubt that much is still left unaccounted for, and many defects which a little care would have prevented. How do they arise? Well—altogether apart from skill—there is undue haste in working. The practised workman may be able to do a thing quickly, but then if he be a rational being he puts accuracy before speed. Watch the skilled mechanic—see in what an apparently slap-dash manner he saws through a plank; but don't let the beginner try to do it in the same space of time, or the result will be disastrous. It cannot be done without practice. On the other hand, the most capable man would never think of sawing without some guide to cut to; yet, what he cannot manage, how often does one see the almost unpractised amateur, who probably does not saw as much in a twelvemonth as the other does in a week, attempt!

Let the hint therefore be taken to mark the work, and to do so as accurately as possible, whether it be plain cross-cutting, ripping, making dovetails, mortise and tenons, or anything else. Use the square and the gauge, and many a fault in work will be found *non est.* Never be afraid of *testing* the work as it proceeds, and don't pass on to the next part till that in hand is as nearly perfect as it can be got. I sometimes fancy if novices saw the frequency with which a skilled cabinet maker uses tests either by square, bevel, or winding sticks they would derive more substantial benefit than by laying in a whole roomful of the best tools, even though they included all the profusely advertised American novelties and so-called labour-saving inventions. Here again the amateur often makes a mistake. Good tools are an advantage, and so are plenty of them, but a superfluity is likely to be a hindrance rather than an aid. Let a man learn to use and understand a few tools thoroughly, rather than go in for everything he can lay his hands on. Some of our best workers use such a limited stock of tools that the well-to-do amateur would hardly say thank you for the whole chest full. I speak only of the general working tools rather than those out-of-the-way appliances which are seldom required, for, of course, there are some operations which can only be managed well with these. To use them and all the finer and more complicated tools, however, implies a power of handling the ordinary ones which can only be begotten of practice. The finest and most ingenious tools can only be appreciated or made use of to the full extent of their capabilities by those workers who are masters in their crafts. If there should be any doubt in some minds about the correctness of this, let me suggest, by way of example, a very finely set smoothing plane, and ask whether any man who could not manipulate an ordinary one would be able to work it as it might be worked. Could he by any possibility appreciate it and execute work worthy of it? It stands to reason he could not. Therefore, my amateur friends, especially novices, do not be discouraged if you cannot get the best of everything in the tool line, but make yourselves masters of those you have, and do not grudge a little extra time and trouble to do all that may be done with plain good tools. Speaking of using planes reminds me of another cause why amateur's work in cabinet making is so often rough-looking, not so much in the joints at angles, but in actual roughness or unevenness of surface. Much of this might be removed by the application of that somewhat, I fear, despised and neglected tool, the scraper. Its name is so significant that even those who have never seen or heard of it will have no difficulty in recognising its functions. By its aid all the little edges which are so apt to be left by the plane, and which show up so when the wood is polished, may be quickly removed, and the surface rendered so smooth that glass papering may not be required, though for cleaning up work this is invaluable. In using it, however, care should be taken not to round off the edges which are intended to be left square and sharp. To an educated eye—I mean technically so—nothing can look worse than a characterless-looking edge, whether on the square members of a moulding or other part. It is just by these little signs that the careful and skilful worker is distinguished from the sloven and the beginner.

Another matter on which caution may be counselled is that of fitting of joints. How often one sees these loose instead of firm and tight. Two pieces of wood dovetailed together, for example, fit almost as though there were an incipient hinge at the angle. Glue is trusted to to stiffen up the joint, but after what has been said it will be seen that this is not desirable, and it would be far better to make the joint, whether dovetail or tenon, as tight as possible. All very well to say that, some readers may think, but how is it to be done? Well, of course, I know that to make even a plain dovetail or tenon joint requires skill and practice; nothing more so, for if one can make a thoroughly good dovetailed drawer, say, he can scarcely pose as a novice, but need have no hesitation in taking rank as a competent workman. Still, many failures may be avoided by a little forethought and extra expenditure of time. How do I mean? Well, simply this. Instead of cutting either mortise and tenon or dovetail joints even a shade too slack make them rather too tight to fit, and then very carefully cut away the surplus wood till the parts fit each other. In cutting away mortises and spaces for dovetail joints do so from both sides of the wood, sloping the chisel slightly inwards, and be careful to have the wood scribed on both sides with the gauge. With attention to these apparently insignificant details a good joint, or at any rate a passable one, is to be made even without much skill. As a substitute for the mortise and tenon joint the dowel is not to be despised. It is easy and, if properly made, so good and reliable that even the purists who insist on the former cannot find much to urge against it, while many prefer it. To go into all the *pros* and *cons* of tenons *v.* dowels would, however, be beside the question at present, but as there is so much to be said in favour of either it may fairly be considered that each possesses merits peculiar to itself. The requisites for good dowel joints are that the pins or dowels should be thoroughly dry, so that they will not shrink and become loose after they have been inserted, and that they must fit tightly and be long enough to fill the holes they are put in as nearly as possible. These are the principal points, and if they are attended to the joint will be strong enough for any practical purpose in ordinary circumstances.

Many other matters might have been touched on, and perhaps may be at some no distant date. In the meantime, enough has been said to show the amateur a few of the pitfalls which beset him in his endeavours, I will not say to surpass, but to equal, his professional *confrère*, and it is to be hoped that while profiting by these hints he will take them in the friendly spirit in which they are given.

A GOSSIP ABOUT HYDROQUINONE.

BY AN AMATEUR PHOTOGRAPHER.

Hydroquinone has long passed the primary experimental stage as a developer, but many and various are the opinions which have been expressed about it. Some advocates of it would apparently wish us to believe that it possesses almost magical qualities, that no matter how it is used, or whether on under-exposed or over-exposed plates, the resulting negative will be equally good. Others again charge it with various kinds of disagreeable qualities. It is said not to produce density, to be very slow and unreliable. As all experimenters may be assumed to pursue their investigations without prejudice for or against a new claimant for favour, the varying opinions given are apt to create astonishment. They are not to be accounted for except by the supposition that the various ingredients which compose the formulæ of which hydro is the developer are the cause of such widely divergent results. It is perhaps a fortunate thing that so many experiments are made; but certainly the number of formulæ which have been given for hydro developers is apt to discourage those who have neither time nor desire to investigate. The most cursory glance over any half dozen of the formulæ will be enough to convince any one that they cannot possibly all be the best or give equal results.

Many of the hydro developers seem unnecessarily complicated. The one I use was first published, I believe, by H. C. Taylor, in the "Amateur Photographer," although I have made some slight modifications, as any one will see by comparing the following formula with that alluded to. The ingredients and proportions are, however, in the main the same :—

¼ oz. Hydroquinone, dissolved in 3 oz. water.
½ oz. Sulphite of Soda, dissolved in 3 oz. water.
½ oz. 5% Solution of Sulphurous Acid.

The hydroquinone dissolves only slowly in water, but the quantity named will be readily taken up by 1 oz. of alcohol, which may be substituted for 1 oz. of the water. However, with moderate heat, the water alone will dissolve the hydro, so that there is no actual necessity for the use of spirit. The sulphite will also dissolve more freely in warm water. When this has become cool, add the acid. The two solutions are then mixed in one bottle.

For the remaining portion of the developer ½ oz. sulphite of soda and ¾ oz. carbonate of potash are dissolved separately in three ounces of water, and then mixed. We have thus two stock solutions, which seem as though they would keep indefinitely. At least, I have some which were prepared months ago, and they remain as good as when they were prepared.

To use these for ordinary exposures 1 dr. of each is mixed with 1 oz. of water.

The development is slower than with a quick pyro developer; but speed may be increased by using the developer warm. This may easily be managed by standing the bottles of stock solutions in hot water for a few minutes, and using tepid water instead of cold to dilute them. If the water is too hot it will dissolve the gelatine on the film, so care is necessary. An ordinary Ilford plate, which is the brand I generally use, begins to show high lights in about a couple of minutes, and though the first appearance of the image is slow, the action of the developer afterwards seems to increase in rapidity, so that in from five to eight minutes the negative is ready for removal.

Plates so developed are beautifully clear, without any trace of chemical fog. In colour they are a bluish grey, which allows of very rapid printing, and owing to this freedom from any yellow stain, the density should be pushed in, developing to a greater extent than is necessary with pyro, though I am not altogether sure whether I should not say "apparent" density. Owing to this freedom from stain the hydro developer is admirably adapted for transparencies, lantern slides, and bromide prints.

One great recommendation that hydro has is the immense latitude which can be allowed in exposure for plates to be developed with it. Some writers have found it equally useful for under and over exposures. My own experience is that it is not so good for under-exposed plates as for over-exposures. At the same time, I have developed several instantaneous photos very successfully, but, as a rule, it may be said, I fancy, that under-exposed plates are not a success with hydro. However, even if this be granted, which it would not be probably by enthusiastic admirers of the hydro developer, there is still much to be said in its favour: for instead of being in doubt about time of exposure, all we have to do is to let this be full. A plate that would be altogether a failure under pyro, from over exposure, may be saved by hydro development. It may be a slow printing one, but detail will be there. While speaking of this I should say that I am referring specially to its action on Ilford plates, for not long ago I had a few of another brand—name forgotten—which, treated in the same developer as the former, came out a most gorgeous golden colour, looking very much as though they had been intensified with uranium. Possibly other brands may show similar or analogous vagaries.

If a plate is known to be very greatly over exposed, it is well to develop it with a developer that has already been used instead of with fresh. As the developer, even after it has been mixed and used, remains good for some time, a separate bottle may be kept for old developer. After a time it darkens, but not sufficiently so for some days to render it useless.

The cost of new chemicals is sometimes against their general adoption, not to speak of the difficulty of getting them. These objections might have been urged a year or two ago against hydroquinone, but they are no longer applicable. It is, I believe, kept by most dealers in photographic materials, but in case any difficulty should be experienced in getting it locally by any one, I may say that I buy mine from Atkinson and Son, Manchester Street, Liverpool, for 1s. 9d. per ounce bottle. This price, compared with pyro at 1s. per ounce, may appear high, but I question whether there is much difference in use, it being possible to develop so many more plates in the same lot of developer without staining them. I have developed half a dozen, one after the other, without, so far as colour was concerned, being able to distinguish between first and last. This could hardly be said if they had been developed with pyro.

The cleanliness of hydro is one of the greatest points in its favour. It does not stain the nails or fingers; and this good quality, apart from any others it may have, will assure it a welcome in many a photographer's laboratory. Ammonia should not be used with hydro as an accelerator. The use of bromide is also unnecessary.

Enough, I think, has been said to show that hydroquinone is worthy of serious consideration by all who desire to get fair results easily.

HOME-MADE TOOLS.

BY J. H.

II.—Iron Smoothing Plane—Chariot Plane.

In this article I will describe and illustrate a common iron smoothing plane and a chariot plane.

Fig. 4 shows the casting for an iron plane of the first-named type. There is nothing special to be said about the pattern. It is precisely like its casting. Two curved sides, and two ends, each ⅛ in. thick, will be prepared and glued upon the bottom, the merest shade of taper being imparted to the inside faces. The curved sides are properly cut from a piece of stuff which is planed to the depth of the pattern, its curves struck to the radius required, with a pair of trammels, and cut with paring gauge, chisel, and spokeshave. If a thin bit of stuff is planed, and simply bent to the curve, it will be of a less curvature at the top than at the bottom edge, and this will have an unsightly appearance; hence the reason for cutting the sweeped pieces from solid stuff. The bottom will be $\frac{1}{32}$ in. thicker, to allow of trueing up. The mouth will be a trifle narrower than the casting, for the same purpose.

The remarks made in the last article with reference to the soundness of the casting, and the operation of filing, will apply in the main to these examples also, and need not be repeated.

In thin patterns such as these, there is risk of the comparatively deep sides becoming rammed somewhat out of truth in moulding, and this not only involves more labour in filing up the outside, but also increases the trouble of fitting the wood-blocking. I need hardly say that the fitting of the blocking needs to be very close, and in its fitting there is the risk of fracture of the casting occurring if the blocks are driven in too hard. But the more accurate the inside faces of the casting, the less risk is there of fracture occurring. If the casting is not very true, therefore, it will be a judicious plan to true and smooth up the inside with a file before commencing to fit the blocks. Of course we cannot do very much in this way, but we can at least obliterate any rough excrescences; and if the space between the sides, measured at the top edge, is slightly less than that at the bottom, we can produce a fair approach to parallelism.

If several men in a shop were to club together to make several of these planes, it would pay to have a metal pattern—casting it first from a wood pattern made as here described. The metal pattern could then be filed all over carefully, and there would be no risk of its becoming rammed out of truth. All castings would be practically alike, the pattern would be everlasting, so that any number of moulds could be taken from it. This is a suggestion which holds good with regard to many other cast-iron or gun-metal planes.

The advantage of the use of an iron pattern is chiefly found, of course, when the pattern is like its casting, as in Fig. 4. When the casting is cored out as in Fig. 7, there is little advantage in the use of a metal pattern.

A pattern for a lever, to be cast in brass or gun metal, will have to be made to the dimensions in Fig. 5, also a pattern for the pinching screw, Fig. 6 A. In each case the dimensions will be slightly in excess of those of the drawings, to allow for filing, turning, and screwing—$\frac{1}{64}$ in. will be a proper allowance on the surfaces of the lever for filing, and $\frac{1}{32}$ in. on the screw for turning and tapping.

Prepare two blocks of beech, rosewood, or ebony, and fit them into the iron carefully, using red lead paste to indicate contact, and tapping very lightly with hammer or mallet, so making a perfect bedding, without risk of fracture of the iron. The blocks should touch on the bottom, and also be shouldered to fit the upper edges neatly. When fitted, put in the wood screws. The screws should be driven in normal to the curve of the plane body, not standing askew; and their heads may stand a trifle above the face to allow of filing off level. Mark the outlines of the blocks, and work them to shape, Fig. 6. Use a parallel iron, as in the trying plane, make its bedding on the hinder block perfect, and notch the block to allow the tightening screw, A, to pass freely down. Mark the centres of the screws upon which the lever pivots, keeping them precisely at right angles with the centre line of the plane, and at equal heights from its base, so that the lever shall not stand askew. Drill holes of $\frac{1}{8}$ in. or $\frac{3}{16}$ in. diameter at these centres, file the lever true and smooth, and mark on its edges corresponding $\frac{1}{8}$ in. or $\frac{3}{16}$ in. "tapping" holes; drill and tap. Two button-headed screws will be preferable to those of the common form, which would require counter-sunk holes for their heads, and so weaken the metal near the edge of the plane. When these screws are inserted and the lever thereby pivoted, try its bedding on the cutting iron, and ease it where necessary, until it beds fair right across the iron.

Now take the casting for the screw and chuck it in the lathe—either between centres or in some form of grip chuck—letting the free end run on the poppet centre. Turn first the end which has to be screwed, and then reversing it, turn the head. Mill the head—properly with a milling wheel in the lathe—or if such is not available, the serrations must be laboriously formed with the edge of a slitting or of a half-round file, the sharp edges being then removed with emery cloth. A milling tool used for this purpose consists of a hard steel wheel having a number of hollowed serrations around its circumference, and pivoted on the end of a stiff bit of bar iron so that it is free to revolve. The wheel may be about 1 in. in diameter more or less, by $\frac{1}{4}$ in. or $\frac{5}{16}$ in. in width. These serrations are cut in a lathe before the steel is hardened by means of a "hob," or master tap, set revolving slowly between centres, so gradually cutting the corresponding grooves in the wheel. The hob both turns the wheel and cuts the grooves. After hardening, the wheel is fit to cut a mulled head in a similar fashion. Thus, setting our brass screw revolving between lathe centres with its head next the poppet, support the shank of the mulling tool on the rest, and press the wheel against the edge of the screw head. The wheel will be thus set revolving by contact with the revolving head, and the pressure exercised will cause the hard steel to indent the soft brass, giving the counterpart of its grooves thereto. The latter must be run slowly, and the wheel be held steadily and stiffly to its work, to prevent slip, and the consequent formation of over-

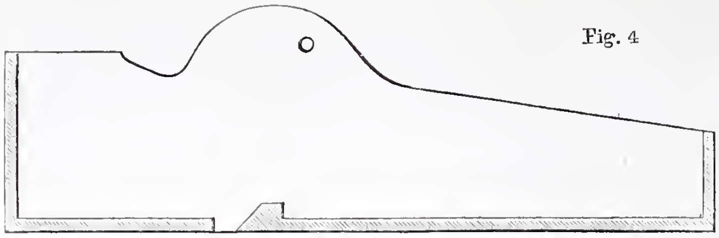

Fig. 4A.

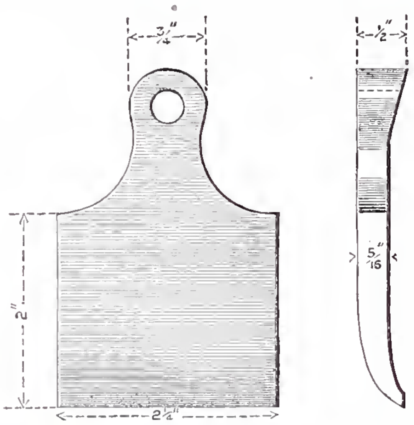

Fig. 5.—Lever: Front View. Fig. 5 A.—Ditto: Side View.

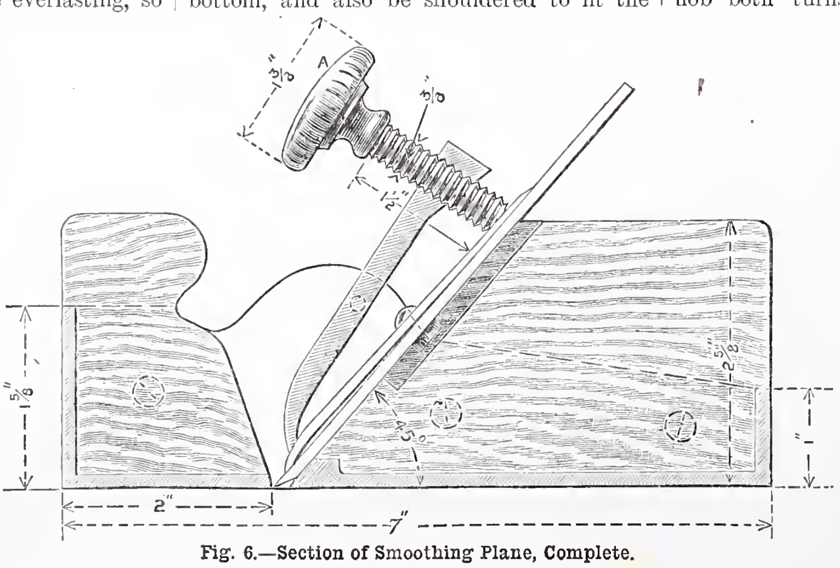

Fig. 6.—Section of Smoothing Plane, Complete.

lapping or of bastard cuts. Use $\frac{3}{8}$-in. dies for the screw. Drill the holes in the wedge to $\frac{5}{16}$ in. bare, and tap, and make the screw fit its tapped hole with as little slackness as possible.

The iron being now bedded, and the lever and screw fitted, slide the iron down into position, tighten it, note the mouth of the plane, and give to it such enlargement as may happen to be necessary to afford room for the escape of the shavings, but not a particle beyond that. Cleaning up the metal work with emery cloth, the wood work with glass paper, and polishing, will finish the plane.

Our next illustration is that form of smoothing plane called sometimes a "chariot plane." These are made in various sizes, but the dimensions given in the illustration, Fig. 7, are the most useful for general bench purposes. This plane differs from each of the forms yet described in this respect: that its pattern cannot easily be made like its casting, because of the presence of the bridge piece which takes the resistance of the wedge, and it is therefore properly cored out —that is, the interior is formed of a core made in dried sand, and prepared in a special box distinct from the pattern itself.

Fig. 8 shows the pattern of this plane with the outlines of the casting indicated thereon. Fig. 9 shows the core box by which the interior is formed. A comparison of the figures will render the following description clear :—

A piece of wood is planed to the thickness, A, corresponding with the inside dimensions of the plane, also to the depth, B, and one end is cut to the shape of the end, C. Upon this block are nailed the two pieces, D, D, forming the plane sides and the end E; and this completes the pattern. The portion marked F is the core print, into whose impression the core made in the box (Fig. 9) is placed.

The core box is framed together with grooved ends, as shown in Fig. 9, and its inside length corresponds with the length, G, and its width with the width, A, in Fig. 8. Into this box are fitted the pieces shown, which correspond with the interior faces and fittings of the plane. Some of these, it will be observed, are nailed on the "bottom board," A, which is a piece of wood dowelled on the box bottom specially to carry them. The piece, B, which takes the resistance of the wedge, is slid through holes cut in the box sides, and is drawn out sideways after the core is rammed, and before the box sides are taken apart. Screws, or else wooden clamps, hold the box sides together during the ramming of the core.

I think this description will be quite clear even to those who do not happen to have any knowledge of the processes of pattern making and of moulding.

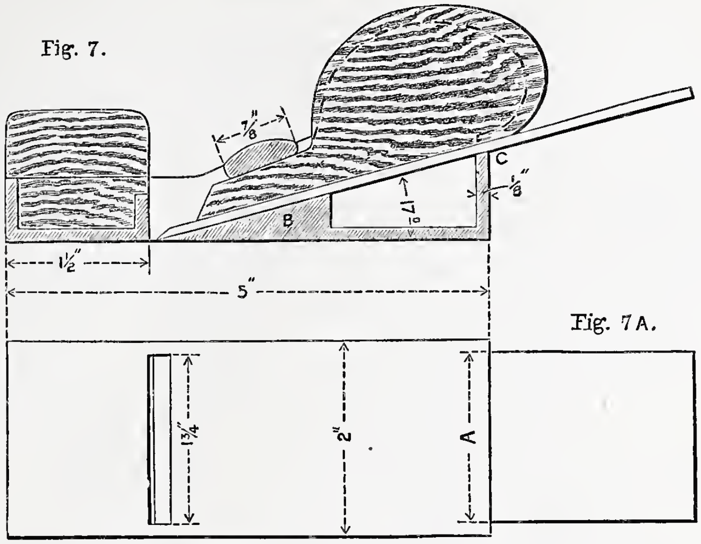

Fig. 7.—Chariot Plane, in Section. Fig. 7 A.—Ditto, in Plan.

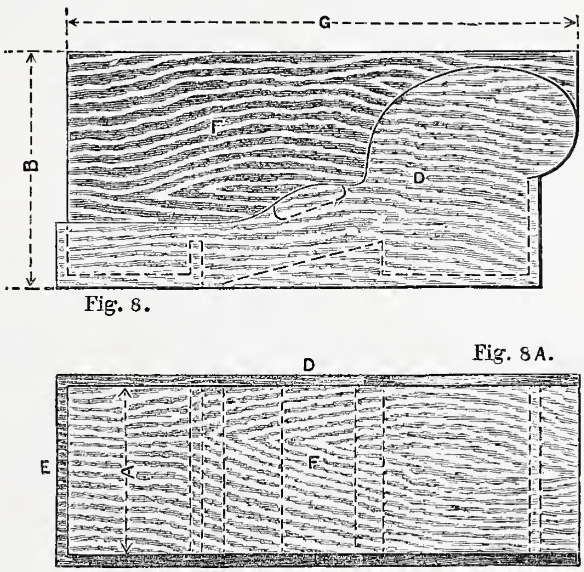

Fig. 8.—Pattern of Chariot Plane. Fig. 8 A.—Ditto: Plan.

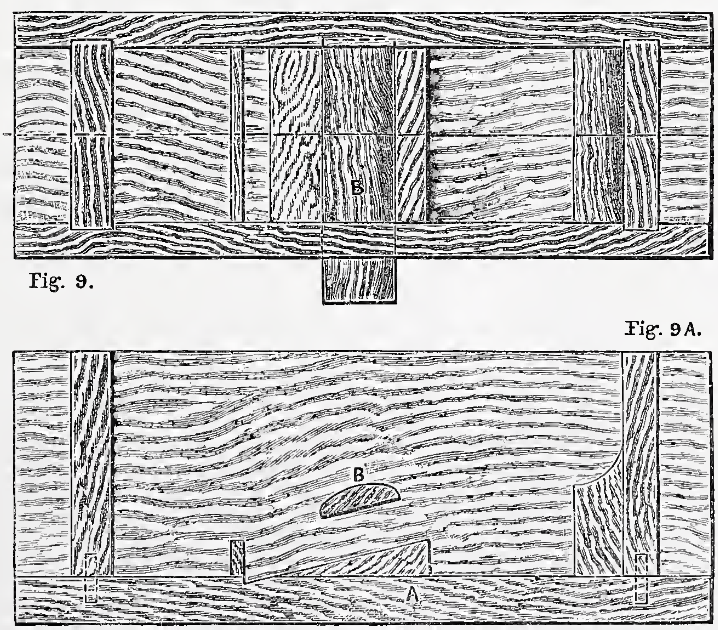

Fig. 9.—Core Box, viewed from Top. Fig. 9 A.—View of Side and Section.

The pattern might be made equally well by making the core print continuous with the outsides of the plane, in which case the pieces which are to form the plane sides would have to be planed to thickness, cut to outline, and put on the inside faces of the core box.

It is a matter of indifference which method is adopted; the important point in either case is to have absolute coincidence of dimensions in corresponding parts of pattern and core box, so that all thicknesses, etc., shall be accurate in the casting.

The filing and fitting generally will have to be done pretty much on the same lines as in the other examples. The under face of the bridge piece should have careful attention, in order that the wedge shall slide smoothly, and bed equally on the iron. The upper face of the V piece, B, in Fig. 7, must be filed very true also, so that no possible rocking or chattering of the iron, due to imperfect bedding, shall ensue.

In order to prevent the bruising of the plane—which follows on frequent repetition of hammer blows at the hinder end, for the purpose of loosening the wedge or cutting iron—it is a frequent practice to tap a screw into the hinder end. The hammer blows are then delivered upon its head, and the body of the plane need never be struck. A $\frac{1}{4}$-in. button-headed screw will be suitable, and it should be tapped in at about the central portion of the face of the back end of the plane. The screw is turned in until its head beds down firmly upon the face.

It will be noticed that the bevelled facet of the iron is placed upwards in this example, instead of downwards, as in previous examples. This arrangement is frequently followed in iron planes, as tending to sweeter working. The angle at which the iron is set in the block is correspondingly lower, so that there is really no difference in cutting angle in the two cases. In the former, however, while the lower or clearance angle is being constantly varied by resharpening: in this it remains constant, while the angle of top rake varies with the sharpening of the bevelled facet.

The great advantage which iron planes have over those of wood is, first, that they cut sweeter than wood, being more entirely rigid; and the other, that they are unaffected by changes of temperature. For cabinet makers, pattern makers, and joiners they are, therefore, of much service. There is a good deal of elasticity inherent in a plane made of wood which is absent in those of iron. Elasticity of wood tends to produce more or less of chattering and choking, especially on working hard, cross-grained timber. A good iron plane having its cutting iron well fitted, well bedded, and secured, will operate in any direction or condition of the grain in a superior manner to the best wood plane.

If any workman finds difficulty in following out the instructions I have given, I trust he will communicate with the Editor and so give me an opportunity of putting him in "Shop." I shall also be glad to hear from any workman who may be desirous of information on the method that he may best follow in making any special tool that he may require. I shall always be ready to help to the best of my power.

NOTES FOR ELECTRO-PLATERS.

BY GEORGE EDWINSON BONNEY.

II.—Acetate of Potash—Acetate of Soda—Acetate of Ammonia—Accidents — Agate —Alkali — Alum — Alumina—Aluminium — Alloy.

Acetate of Potash. — French : *Acètate de Potassa.* The name of this salt is sometimes printed potassic acetate, and acetate of potassa. This salt is used in the preparation of metallic acetates, and in the formulæ of some brassing solutions. It is obtained by neutralising carbonate of potash with acetic acid, evaporating the liquid to dryness, and heating the salt to fusion. It is usually met with as a white, foliated, crystalline mass. It is extremely deliquescent, and easy soluble in water.

Acetate of Soda.—French : *Acètate de Soude.* This salt has uses similar to those of acetate of potash. It is prepared commercially on a large scale during the process of manufacturing acetic acid. The crystals of this salt are large, colourless, and transparent. They effloresce in dry air, and are readily soluble in hot or cold water, and in alcohol.

Acetate of Ammonia.—This is named in some old recipes "spirit of minderus." It is a liquid, prepared by saturating strong acetic acid with carbonate of ammonia.

Accidents.—Electro-platers and workers in trades where "chemicals" are used are liable to serious accidents, caused by ignorance of the nature of the materials, or a carelessness born of familiarity with their uses. These accidents are of such a nature as to demand the prompt application of remedies. These should be always kept handy, on an easily accessible shelf in the workshop, and every workman should know how to apply them when necessary. The accidents most likely to happen are those arising from careless handling of bottles containing acids; reckless handling of cyanide of potassium, or carelessness in working with its solutions; mixing one chemical with another in ignorance of its properties; indiscriminate experiments without any previous plan, "just to see what will happen, and what the mixture will do;" and poisoning of the hands and face through absorption of poisons in cuts and other injuries. To these may be added, injury to breathing and digestive organs by inhaling poisonous fumes whilst preparing pickles and other solutions.

Only a madman, intent on suicide, would attempt to swallow any of the poisonous preparations used in the workshop and laboratory, therefore, injury caused in this way can scarcely be regarded as an accident. Provision is made in these notes for all contingencies, and full instructions are given to guide any person in dealing with all accidents likely to occur. In addition to cautions respecting the proper and improper uses of dangerous substances given under their respective heads, consult also the sections on *Antidotes*, *Poisoning*, *Hygiene of the Workshop*, etc.

Agate.—This is a precious stone with a composition resembling flint, and almost identical with that of chalcedony, opal, quartz, and rock crystal. It is extremely hard, and is capable of receiving a high polish, only a little inferior to that of the ruby and diamond. It is much used in furnishing chemical balances with bearing points, and in the manufacture of the best burnishers in use by electro-platers.

Alkali.—This is the Arabic name originally given to potash, but now applied to those substances which are opposed in their nature to acids, as having the property of neutralising their action when added to them, and forming with them compounds named salts. They also restore the blue colour to litmus and other vegetable blues that have been turned red by acids. In commercial circles the term alkali is usually applied to carbonate of soda, to soda crystals, and sometimes to caustic soda. The principal alkalis are ammonia, lithia, potash, and soda. The two last in various forms and combinations are largely used by electro-platers. An alkaloid is a vegetable substance having many properties in common with the alkalis.

Alum.—Common alum is a complex compound of sulphate of potash and sulphate of alumina, represented by the chemical formula $Al_2 K_2 4SO_4 + 24H_2O$. It is obtained on a large scale whilst roasting shale containing clay and iron pyrites. *Ammonia alum* contains ammonia instead of potash. *Soda alum* contains soda instead of potash. It is more soluble and more difficult to crystallise than the other alums. *Chrome alum* contains the metal chromium instead of aluminium. *Roman alum* is made from alum stone, a felspathic rock. *Alum cake* is a mixture of silica and aluminium sulphate. It is used as a base by dyers. A solution of common alum in water has the property of absorbing the heat rays of the spectrum, whilst it allows the light rays to pass through freely. Its crystals readily dissolve in their own weight of boiling water, but form again as the water cools. Alum is an important ingredient in mixtures for colouring gold, and in the manufacture of acetate of aluminium. (See *Colouring Mixtures.*)

Alumina.—The earthy oxide of aluminium. It is found combined with silica in clays and felspathic rocks. It is the source of all our supplies of the metal aluminium. "It occurs native in a nearly pure and crystalline state as *corundum*, *ruby*, *sapphire*, and in a less pure state as *emery*." (Roscoe.)

Aluminium.—Sometimes named and printed *Aluminum.* French, *Alumine.* Chemical symbol, *Al.* A bluish-white metal obtained from alumina. It is the lightest of metals. Specific gravity 2·6. Combining weight 27·4. Melting point 700° C.

It stands third on the list of useful metals for tenacity; fourth for malleability; and sixth for ductility. Hardens when drawn or hammered, and is capable of receiving a high polish, nearly resembling that of silver. Does not readily tarnish in air. Castings of this metal acquire a delicate sharpness. Aluminium is not soluble in nitric or sulphuric acids, but is soluble in hydrochloric acid and in the alkalis. It is readily soluble in solutions of cyanide of potassium, ammonia, and the caustic alkalis. It is electro-positive to antimony, bismuth, cadmium, carbon, cobalt, copper, gold, iron, iridium, lead, manganese, mercury, nickel, palladium, platinum, silver, tin, and zinc; electro-negative to magnesium, and metals of the alkalis and alkaline earths. Owing to its characteristics and ready solubility in the free alkalis of depositing solutions, it is not suitable as a base on which we may deposit a coat of the precious metals. Articles made of pure aluminium will not receive an adherent deposit of gold or silver in the ordinary plating solutions, but will dissolve if left in them and spoil the solutions. This is a serious drawback to its use in the manufacture of ear-rings and light articles of jewellery. "Aluminium solder contains six parts of aluminium, four parts of zinc, and ninety parts of copper." (Bloxam.)

Copper, alloyed with ten per cent. of aluminium, so closely resembles gold in colour as to secure for it the name of aluminium gold. This alloy makes up well into pencils, chains, watchcases, and similar articles, and is most suitable as a base on which to deposit a good coat of gold. In the hands of the electro-gilder it should be regarded as brass, and treated as such in preparing it for the bath. An alloy of one part of silver added to three or four parts of aluminium is said to be strong, light, and very serviceable, being four times as light as silver. An alloy of steel with aluminium has been patented, and is said to be very useful.

Aluminium has been electro-deposited from a solution of aluminium and potassium, also from a solution of the double chloride of aluminium and ammonium. It has also been deposited from a solution of its chloride. No practical use has been made of the results thus obtained. Information respecting the processes employed in the reduction of aluminium may be found in "Watt's Electro-deposition," pp. 360—363. "Salts of alumina, when moistened with a solution of nitrate of cobalt and heated in the flame of a blowpipe, assume a characteristic blue colour." (Fownes.)

Alloy.—"To alloy," in the common acceptation of the term, is understood to mean the mixture of a baser metal with a finer one to depreciate the quality of the latter. But this meaning of the term has no signification or weight with the metallurgist, who mixes metals and melts them together to achieve a given purpose apart from the thought of debasing a fine or a precious metal. Alloys are usually formed by melting the metals composing them in a furnace, but they have been and can be formed by electro-deposition. Copper and gold may be deposited together in varying proportions to form red gold. Silver and gold may be also deposited as an alloy, the effect in colour being a pale yellow inclining to green in proportion to the quantity of silver deposited with the gold. Copper and zinc may also be deposited together to form brass or bronze, and copper and nickel to form German silver. The metals to be deposited may be melted together and cast in the form of a plate, or an anode plate of each metal may be hung in the depositing solution. The electro-deposition of alloys is far more difficult and uncertain than the deposition of a single metal by itself. Although the two metals to be deposited together are present in the solution in the right proportions to produce the desired alloy, and although they are also rightly proportioned in the anodes, the inexperienced depositor cannot be sure of success, for the deposit will vary in its character as the strength of the current of electricity varies, and the temperature of the solution alters. Only skilled experience can determine the right conditions all round, but a few hints may be helpful, and these will be found under the heads of *Brassing, German Silver, Gold, Deposition*, etc. Alloys of metals have superseded plain metals as bases for the electro-deposition of gold, silver, and nickel. The use of copper as a base for silver-plating has been superseded by brass, and this in its turn by whiter alloys resembling silver, such as German silver, nickel silver, and silveroid. It has also been displaced as a base for gold by such alloys as yellow brass, pinchbeck, and aluminium gold. Alloys of lead with tin and copper to form pewter and britannia metal have been largely used as bases for silver, but they are being superseded by the stronger and better white alloys now employed in the manufacture of best plated goods. This is a distinct gain to the electro-plater and to his customer, for the better alloys are not only less troublesome to plate, but also look well and wear longer.

(*To be continued.*)

FRAMES À LA MODE.

BY J. W. GLEESON-WHITE.

ARTISTS' DESIGNS FOR FRAMES — WHISTLER'S FRAMES—FRAMES BY MENPES—DECORATION OF ROOM IN JAPANESE STYLE—FRAMES SHOULD BE SUITED TO PICTURES — STEEL FRAME — FRAMES IN NATIONAL GALLERY—FOREGROUNDS ON FRAMES—OLD STYLE FRAMES—CHOICE AND POSITION OF PICTURES—FRAME COVERED WITH SACKING—FLAT OAK FRAME, GILT—FRAME WITH PILASTERS—WHITE MOULDED FRAMES—FRAMES IN FORM OF MEMORIAL TABLETS—TRIPLE FRAME—FRAME WITH FRET WORK—MENPES' JAPANESE FRAMES—FRAMES OF ROUGH SAW-CUT WOOD — FRAME WITH MOULDINGS AND PILASTERS — CORNER OF FRAME FOR ETCHINGS—WHITE FRAME STRIPED BY HAND —CONCLUSION.

ONE marked feature in the artistic temperament of to-day is that the painter is by no means indifferent to the setting of his picture, and having polished and wrought his jewel, no longer allows a mere workman to set it as he will. On the contrary, he is not only apt to design the frame himself, and bestow much thought thereupon, but, unless appearances are deceptive, occasionally does not disdain to add certain decorative adornments with his own hands.

Of modern artists who have specially distinguished themselves in this respect, Sir Frederic Leighton, P.R.A., Mr. Poynter, and Mr. Holman Hunt, may be named representing those who design their own frames upon the more conventional lines, but yet distinctly intended for the actual picture they enclose; while for those who have gone farther and pressed novel materials into their service, or struck out completely independent methods, the late Dante Gabriel Rossetti, Mr. Whistler, and Mr. Mortimer Menpes may be cited.

Since the frames of the first group are those calling out all the resources of the professional frame maker they do not concern the object of this paper; while those who were fortunate enough to see the two exhibitions of Mr. Rossetti's work, held respectively at Burlington House and the Burlington Fine Arts' Club, will realise that the gorgeously-designed shrines he adopted belong to the province of the carver and gilder, since their technical manipulation demands the highest skill to carry out the original design of their inventor.

Mr. Whistler, however, with still more novel treatment, has often suggested many motives that an amateur might paraphrase, if not actually copy. This artist, too, devoted no small thought to the production of novel and decorative frames, for water colours, pastels, and etchings, which are more likely to form the staple of the amateur's collection. To Mr. Whistler is probably due the more frequent employment of white frames, which have of late found such high favour, and most deservedly acquired it, for the white border is most effective, or, to speak more exactly, the white *and grey* borders, for the shadows cast by the projecting mouldings are an integral part of the scheme, and all-important in the production of the desired effect. Mr. Whistler was, perhaps, also the first English artist to forsake the monotony of ordinary yellow gold, and select from all the shades of metallic lustres from silver to copper colour; at times adding actual colour in broken Japanesque patterns of stencil work to the various shades of bronzes (as they are often called) that he selected.

Mr. Mortimer Menpes went still further afield in search of novelty, and brought home from Japan native-made frames of exceedingly novel fashion, which delighted the art-loving public at his exhibition of Japanese drawings, as much by their intrinsic beauty and simplicity as by their newness. The effect of his show was, perhaps (in spite of Mr. Whistler's Harmonies in Various Colours of previous years), the prettiest thing of its kind ever seen in England. For the benefit of those who were unable to visit it, a brief description as it looked on the morning of the private view may be pardoned. A gallery of moderate size was hung with material strained tightly over the walls, looking like silk in its texture, of a pinkish-purple colour—the colour of a particular chrysanthemum beloved of the Japanese, it was said. Festoons of the same material hung stiffly around the upper part of the walls, the ceiling was clad in white, the floor and the central settee being covered with a greyish-white felt; add to this a pure white chair and table, by the side of which a Japanese female attendant, in native costume of harmonious, low-toned, embroidered silks, with a poppy colour bow in her lustrous black hair, kept guard over the catalogues, and the room itself is suggested. But this was, of course, the background only, for the pictures—those in frames to be more fully described—hung in irregular fashion, like flights of birds on a Japanese fan, across the walls. These frames were of black and white for the etchings, and every shade of silver, copper, and gold for the water-colour drawings. It was hard to say which detail was most valuable in the general scheme, but since we cannot have peach-coloured silk hangings, or Japanese handmaidens, it will suffice to consider for our argument's sake the frames as being the next important item, after the pictures they enshrined.

In face of an easy objection that the pictures are of infinitely more importance than their frames, the fact may be frankly conceded. Yet while the face of an English maiden is more beautiful than her dress, she does not neglect the latter, or does so at her peril. The binding of a book is of small consequence compared with its contents, yet a tasteful and decorative cover is rightly held to be a necessity for a book of any value. Perfection, our ultimate aim, demands care for the trifles as much as for the important features; and a regard for beautiful frames by no means implies a neglect of appreciation for their contents. It is just those artists and amateurs who recognise the more subtle beauties of form and colour—those who demand *every* quality in a good painting—who also insist on the frame fulfilling its true purpose.

Briefly the ideal frame may be held to be one that best suits the picture, but keeping this end in view it may be as beautiful in itself as skill or thought can make it, provided that it never forces itself into the first place. Like a well-played accompaniment to a solo, it is only after the solo is ended that one should recognise how beautiful in its unobtrusive support and self-effacement the accompaniment was.

What a frame should not be was exemplified in a striking example in a recent show, when a portrait of Madame Sara Bernhardt, by Bastien Lepage, was exhibited in "a frame of carved polished steel. The completion of same took two and a half years, at a cost of no less than £720. It is considered a perfect work of art"—so ran the catalogue. Naturally such a paragraph set one looking at the phenomenal frame, in itself no doubt an admirable work of art, but challenging directly rival interest with the exquisite panel it professed to adorn. Small wonder if to many the portrait was remembered chiefly by its frame. This is, of course, a "frightful example," as a lecturer would say, and one fortunately out of the reach of most readers of this paper, who are not likely to copy its faults, but may easily err in the selfsame fashion by making the frame the chief end, and afterwards choosing a picture that happens to be of suitable size to fill up the previously planned opening. This is as absurd as it would be to design a wedding dress and, when it was finished, choosing a bride for yourself who happened to fit it.

There are frames which cannot well be made at home, and fortunately they are just the ones that are least suitable for the average house. Of burnished gold arabesques and marvellous plaster volutes and scrolls no word in praise or blame; they have their right and wrong use. In the National Gallery there are splendid examples, and horrors worthy of all rebuke are not unknown in our large exhibitions. Some on view this year, wherein the foreground of the picture was carried into high relief on the frame, or where by cheap symbolism (a tennis racket and ball for example) the motive of the picture was repeated on the frame, deserve a word of dispraise. But it may be sadly said, if the owner's taste is unconscious of the vulgarity of such meretricious adjuncts, there is little use in quoting instances. Even if he be polite enough to accept the warning and henceforth shun that particular form of vice, he will probably develop others seven times worse. If asked to define "good taste," it is to be feared "our own" would be the inward reply, whatever ingenious phraseology we used to express it. But there are canons of good taste easy to acquire in these days of much teaching, and while the best may sin at times, yet a man who has read his Ruskin and Pater, who has some knowledge of the tendency of modern art, is likely to abstain by a sort of acquired instinct from the most flagrant examples.

The orthodox gilded moulding, the ordinary oak or ebonised beading, and the once popular Oxford frame may be mentioned only to be dismissed without comment; their merits and demerits ought to be self-evident now. Each and all are the very best in the right place, and of varying degrees of badness in the wrong use. While simplicity looks so easy to novices, older hands know that perfect simplicity is the outcome of art, the *ars celare artem*, that is a proverb for refined expression. Novelty has a charm, say what one will; half of our lives are spent in search of it. The love of change is even more dominant than that of life or food, as we see by the countless numbers who leave every apparent comfort in search of what is new. Therefore let us not despise it, and profess to like old things best, for it will be found that, as a rule, it is only when the old has become rare, and therefore novel once more to common experience, that one begins to value it.

Again novelty is, like morality, a question of latitude. To an Orkney Islander a worn-out fashion of seasons ago in London may come with its original zest. Mindful of this, I have selected many examples that are well known to dwellers in large towns, nor have I, on the other hand, kept to the theory which I have tried to expound. It is so easy to quote the text, so hard to live up to it. Consequently, if the suggestions to be made embrace some flagrant examples of bad taste, I can but cry Peccavi! and implore those who discover them on no account to be tempted into imitating them, but rather practise a Spartan-like renunciation, and shun their meretricious allurements. But to the point; a preacher tries to bring you to a happy frame of mind by special pleading and winsome arguments. The happy frame I would bring you to, is the one of those to be described that suits you best.

The ordinary formula that oil paintings only suited a dining-room, water colours a drawing-room, and engravings and etchings a library or morning-room, is as conventional and absurd as most other formulas. The only sound advice is to choose the picture you like best, be it bad or good, hang it where it may be seen (otherwise why buy it?), and proclaim your own taste in your own house — better personal taste of the most vulgar kind, than badly digested "culture" which is a mere laughing-stock. I think as I write of a "Rossetti" that its owner fancies makes the most vulgar of vulgar drawing-rooms a temple of beauty. The room certainly fails to kill the picture, although it tries to do so; but the one bit of good art makes the rest more pinchbeck and more vulgar than ever. Then I recall another room plainly furnished in almost lodging-house simplicity, where a Corot reigns, yet the splendour of the picture, having no vulgarity to overcome, stands out the most precious thing of course, but making a commonplace room beautiful by its own great beauty.

This may be discursive, but frames are so varied, and their kindred pictures so near the subject, that it is harder than usual to keep to the point.

First, to dispose of a few simple materials. This year a frame made of common sacking, either in its native tint, or more often dyed a dull green or heavy peacock-blue, has found many admirers. The pictures in such were surrounded by a gilt moulding of rather ornate pattern as a rule, about half an inch to an inch wide, according to the size of the painting, then a plain deal border covered with the canvas or sacking surrounded the whole; this was at least six inches wide, often a foot, for large pictures. If the whole moulding and sacking is gilded in one shade of gold, the effect is really beautiful in itself, and isolates the panel from its surroundings. (Fig. 1.)

Admirable, also, was a frame of plain, flat oak, gilded to show the grain of the wood. About a fifth of its width from its edge was, apparently, a row of brass-headed nails, touching each other, or else a moulding inserted that simulated nail heads. (Fig. 2.)

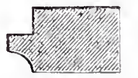

Fig. 15.—Section of Fig. 14.

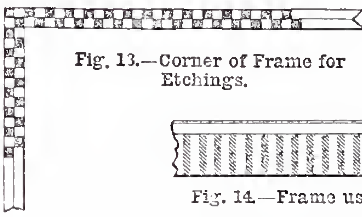

Fig. 13.—Corner of Frame for Etchings.

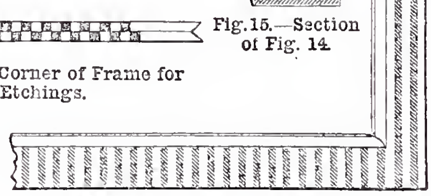

Fig. 14.—Frame used by Mr. Whistler.

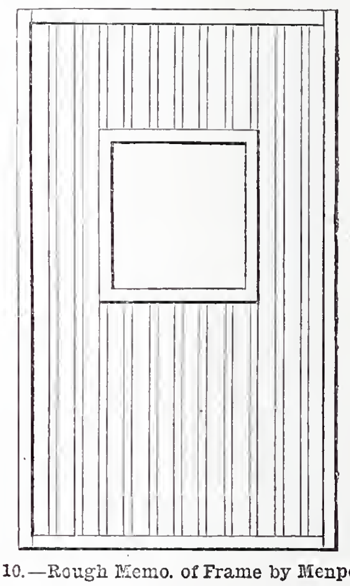

Fig. 10.—Rough Memo. of Frame by Menpes.

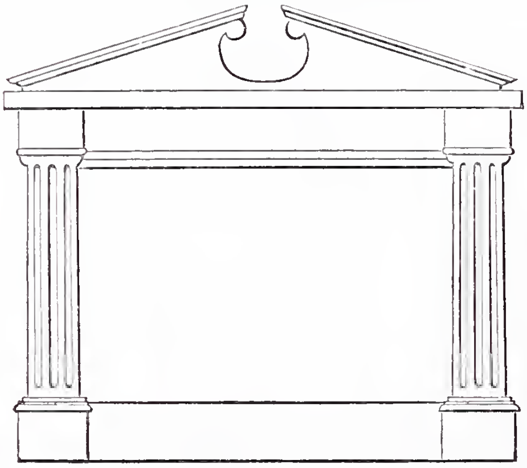

Fig. 7.—Memorial Tablet Frame, No. 3.

The frame in Fig. 3 is a most effective style for figure subjects, yet very simply made, as all the pseudo-classical decoration is applied, the twin pilasters being merely a bit of ordinary turned work, cut in halves. The mouldings and fillets are of the most elementary character, yet the whole frame, finished in pure white enamel, is exceedingly effective. It may be worked in oak and gilded with bronze powder, or in ordinary deal, with the usual plaster and gold-leaf finish. No frame of those chosen is less costly, and few look better when on the walls, as I can prove from experience. Of course, this idea may be enriched by the use of lincrusta frieze decoration, with very happy effects. In this and other frames to be described when a flat surface with low relief ornament is needed, lincrusta is admirable, being inexpensive, easily worked, and a capital surface for after decoration.

The design (Fig. 4) is intended to represent a white moulded frame, with an inner frame also white, the space between the two being filled with the monochrome paper of quiet design, such as one sees on the fly leaves of modern books. The same motive with richer mouldings and lincrusta, or Japanese leather paper substituted for the white and monochrome paper, makes a very effective and useful frame for water colours of a certain class, or oils. The proportions must be decided by the character of the painting; some subjects demanding a wide margin, others exacting very little, lest they are overweighed by their surroundings.

A society for the promotion of art has of late constructed frames somewhat after the fashion of the memorial tablets in churches of the Wren period. These, either finished in white, worked in dark rich polished woods, or solidly gilt, have probably a wide popularity in store. Every church suggests motives for adapting in this way, and the few sketches (Figs. 5, 6, 7) are intended less as designs for reproduction than rough memoranda of possible shapes worthy of being tried. The amateur who makes a good frame does a good thing, better than a useless piece of fret work, or an irritating dust collector of some passing fancy work. If he is not carpenter enough to mitre and dovetail it himself, he may yet draw out the design, and see that it is carried out by an ordinary workman,

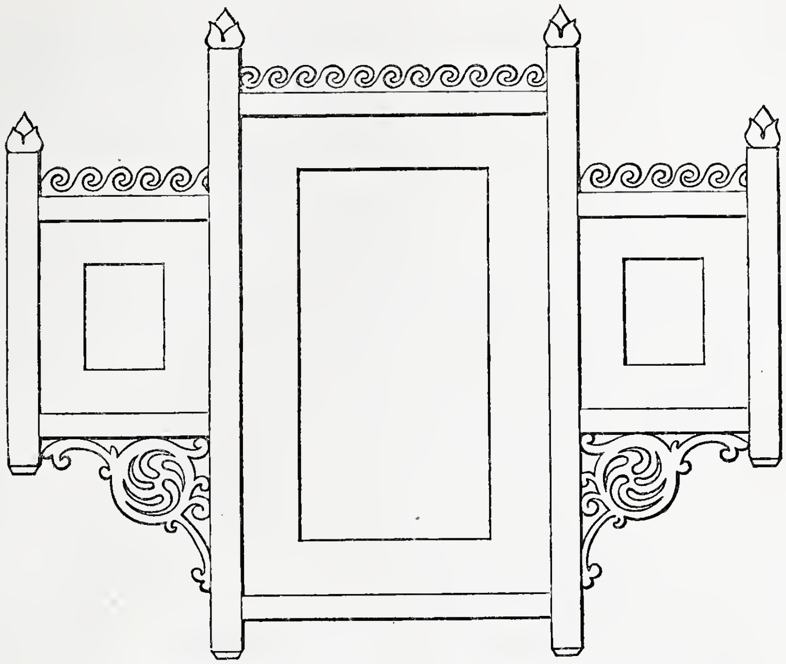

Fig. 8.—Suggestion for Triple Frame in Joinery and Fret Work.

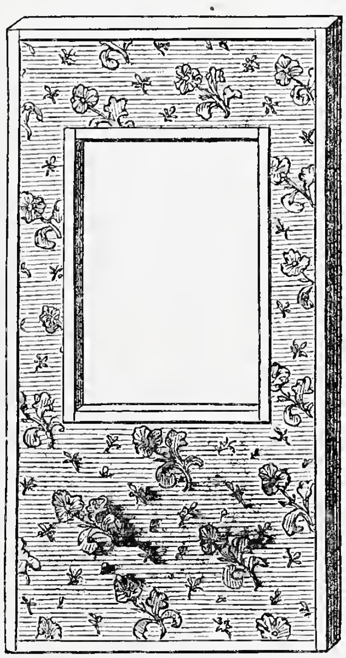

Fig. 12.—Frame, enclosing Panel covered with Japanese Leather Paper between two Mouldings.

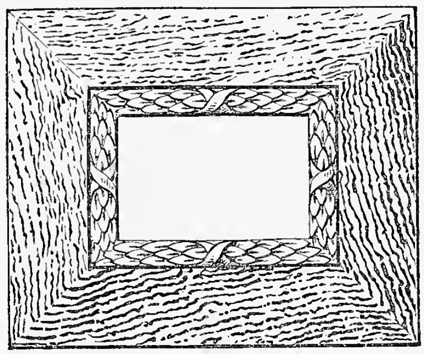

Fig. 17.—Rough Saw-Cut Frame.

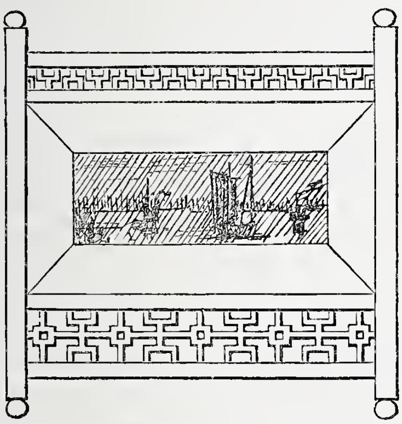

Fig. 9.—Gilt Frame with Oak Fret-work Strips.

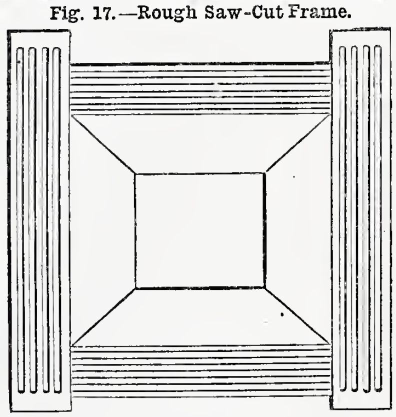

Fig. 16.—Frame of Reeded Wood without Mitres.

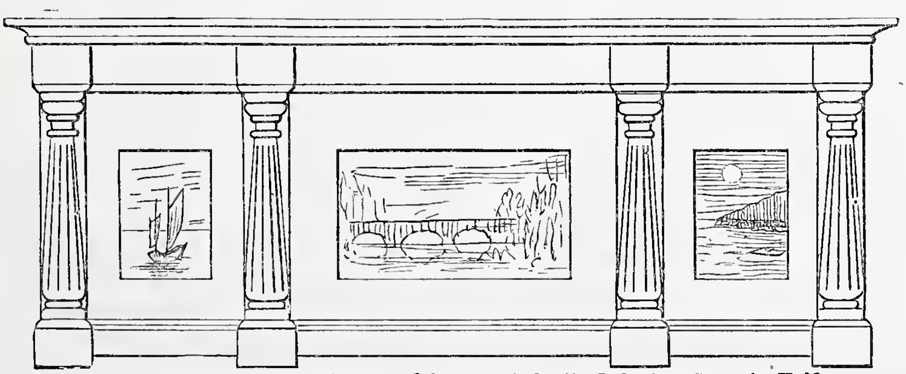

Fig. 18.—Frame with Mouldings, and Ornamented with Balusters Sawn in Half.

the acting partner doing his share, and the brain partner — ironically known as the sleeping one—doing his part, in the success of the whole. But with one of Melhuish's mitre-cutting machines, and set of cramps—costing less than a sovereign—the mystery of the art vanishes, and the most bungling of amateurs may equal a trained workman in the exquisite neatness of his angle joints.

A suggestion for a triple frame (Fig. 8) in simple joinery and fret work is given, under protest. If done simply and without undue fussiness it might look well; it is certainly in sympathy with the very popular so-called Early English of to-day (why so-called is a mystery too deep for probing). If worked in black and gold, or all black, it would balance the overmantel in a small room, or harmonise with the art furniture of the period, but I confess I love it not myself, although, so far as I know, it is my own suggestion.

The style of Fig. 9, also new (I believe), I must confess to liking, believing that the idea it embodies is both novel and workable, and in many variations calculated to make a pleasant bit of wall decoration, yet in no way to the detriment of the picture it encases. I should prefer it entirely gilded, but with the oak fret work strips and the flat oak mount gilded, and the framework finished in black, it might look well and please many people better. When I use the term gilded I do not mean the ordinary gold leaf, but bronze powder, applied easily by any amateur, for all to be done is first to paint over the surface with gold size, and when it is nearly dry—tacky is the technical term—powdering the gold on to it with a dabber of cotton wool. The said bronze can be had in a hundred shades of colour, is not expensive, yet extremely good in effect. The cheap bronzes look equally well at first, but for lasting work only the best should be chosen. There is a pale green-gold very pretty, also a deep copper-red, that in each case helps to break away from the monotony of the ever-present (except in our pockets) yellow-gold.

The sketch (Fig. 10) is a rough note from memory of the frames adopted by Mr. Menpes. These, however, merit fuller description.

Fig. 11 shows the section of the outer frame, a piece of simple dovetailed joinery, exactly like the carcase of a box or a drawer; this encloses a panel probably grooved into its place, like a drawer bottom, for instance. The hole for the picture is bordered by a beading also of plain square wood, the glass being either rabbeted into this or fixed with tiny wood beads. It will be noticed that the proportions of the frame are entirely distinct from European ones, and vary greatly. But roughly, it may be said, the sides are narrow, the top somewhat broader, but not so wide (or deep, call it which you will) at the bottom. The panel may be either of grooved wood—a wood panel with simple square grooves running vertically—or else covered with silk or brocade. The *whole* of the framing is gilded with the same shade of gold, and the effect is most sumptuous. The grooves should, I think, be nearer together than in the sketch, giving almost a corrugated iron effect (but not rounded projections and depressions); but this detail may be left to the operator. The round spot is a tiny speck of brilliant scarlet let in, as it were, bearing the monogram of Mr. Menpes, the well-known Japanese design on all his later work.

Not knowing whether or not these frames are "registered" designs, I must explain that the above is merely a description of the manner in which they appeared to be made, and that those who copy do so at their own risk. There was no warning, either in the catalogue or the exhibition, of the frames being protected against imitations.

In Fig. 17 is sketched a frame much used of late, but hardly within the amateur's power to finish; it is made of saw-cut wood, rough as it leaves the saw-pit, gilded with gold leaf, and adorned by a moulding of rich ornamental design around its opening for the picture. The surface of the wood should slope outwards—that is, the inside edge should be thicker than the outside. In spite of a little affectation of simplicity and luxury mixed, the broken surface of the gilded wood is very gorgeous, and admirably adapted to its purpose.

In Fig. 16 a suggestion for using reeded wood, without mitres, is given; this is as yet rarely adopted, but might be well worth trial, in the right proportions; it would be fairly dignified and individual in its expression, without the air of straining after mere bizarre novelty, from which some of those described are scarcely free.

In the diagram (Fig. 18), a simple frame, with mouldings, and the ends of two of the ordinary turned balusters, procurable for a few pence each, makes much effect at small cost. The round turned work is sawn in half and applied pilaster fashion to the skeleton framework. For an overmantel to a small room, or the wall above a piano, or a sideboard, this might look well, and be found perfectly manageable. In Fig. 12 a variation is shown, suggested by the "Menpes" frames, Japanese leather paper covering the panel, the frame itself being gilded to the exact shade to match, or, if that is not possible, the whole repowdered with bronze to be in harmony. These frames look so extremely well in actual use, that in spite of the crudeness of the sketches, which, roughly drawn and colourless, are lacking in charm, it is as well to reiterate the advice to make them. They also look exceedingly nice with white moulding, and a low monochrome paper, or white brocaded silk in place of gold; photographs or etchings might be framed in this fashion, but a gold frame would probably be too sumptuous and overweigh a monochrome picture, killing it entirely.

Fig. 13 shows a corner of some frames of Japanese manufacture. These were mere frames, with no inner panel, but just a white cardboard French mount for the etching; the moulding was inlaid (veneer) in black and white chequer pattern.

In Fig. 14 will be seen a frame used by Mr. Whistler; it is of a wood moulding, the section (Fig. 15) painted white, and striped with lines hand-painted in neutral tint, all going vertically as indicated; this also had a white cardboard mount. The mouldings of these last frames were about ¾ of an inch wide, certainly not more.

In concluding, it may be said that what the taste of generations has approved is more likely to be of value than a passing fashion, and that the conventional frame of old days needs little change. This is certainly true, yet there are divers kinds even of good pictures, and some are not in themselves decorative in their effect, neither do the old-style frames harmonise so happily with the bric-à-brac of a modern room. This last reason is probably the chief one for these suggestions, and may serve as long as the present taste in house decoration holds sway, to render the modern frame in some of its hundred-and-one varieties more desirable to its owners.

A point too sordid for dwelling upon at length need not be entirely overlooked. An attractive frame *does* draw attention to a picture, more particularly at an Exhibition; and since an artist must sell his pictures to live, he will not despise any harmless advertisement that brings his works to notice among the crowd of those that wait to be admired. Art disdains Commerce in theory, but in practical everyday life is as much swayed by the mighty £. s. d. as other things. Where a question of morals or truth is involved it is beyond question the nobler course to disdain novelty if it conflicts with either; but when the issue is but a question of taste, the rule may be less stringent; and even in so small a matter as the framing of a picture, some concession may be made to the passing fashion of the day, with no loss to the dignity of the artist, or the progress of education in art matters among the people. So, granting that the theme of this paper deals with ephemeral trivialities; yet are we *all* immortals, leaving work not for an age but for all time! As a poet has expressed himself in the envoy to his book—

> "There you and I at last will have to go,
> And if this book prevene us there or no,
> 'Tis but the difference of a year or twain
> If we or it find earlier sleep below;" *

so we may enjoy innocent trifles, in spite of the lofty scorn of severely "thorough" people.

HINGES:
THEIR VARIETIES AND APPLICATION.
BY D. ADAMSON.

I.—The Butt Hinge—How to Hinge and Hang a Door.

Among the difficulties which beset the amateur worker, or even the young workman, those of a minor character are often those upon which he is most likely to stumble. Whether it is that he does not regard little details till he actually wishes to put them in practice, or whether it is because technical writers consider it beneath them to write on elementary work, the fact remains that the amateur artisan is often at a loss how to proceed with some small matter which, to those trained in the ordinary workshop, seems to come as a matter of course. Writers on technical subjects freely discourse on out-of-the-way methods, but they very naturally assume that it is no use going into minute details of simple work. It is on this point that purely technical journals, valuable as they are to the professional worker, are of little assistance to the amateur; and it is just here that Work steps in and supplies the want. Were it not so, I should hesitate to offer any remarks on hinges, but as I have derived many a valuable suggestion from amateurs, not only in connection with "hobbies," but immediately concerning my own business, I venture to give a few hints which, however crude they may be, will possibly prove of service to novices in the wood-working handicraft.

The remark was once made to me, when I asked a question about the rules by which hinge fitting is done, that the only rule is to be guided by common sense. This might be sufficient for those who have already a general knowledge of the various kinds of hinges, and have acquired an almost intuitive perception how to act in any ordinary circumstances, but in my case it was somewhat equivalent to telling a man, who does not know the alphabet, that if he can't

* "On Viol and Flute." Edmund Gosse.

read he must spell the words. Since then, however, by keeping my eyes open, which, by the way, is not a bad plan to acquire knowledge, I have noted a few matters in connection with hinges which, in the absence of positive rules, may be of interest and save the amateur a more or less wearisome journey over the road of experience. A satisfactory path to have travelled, and one to be looked back on with respect; not, however, unattended by mishaps and delays which, perhaps, others may be enabled in some degree to avoid by the following hints. They are offered with diffidence, though so far as they go they are correct; and if the matter be stale to some, doubtless it will be new to others, and for the sake of these I write. This will explain any omissions, and also the elementary character of the hints.

It might prove an interesting task to trace the hinge from early ages, when some rude savage, an inventive genius though in his way, first applied the principle of the hinge by connecting two boards with a flexible joint—whether of raw hide or twisted fibre, who shall say?—to the ornate metal work of later times, and onward to the more serviceable if more prosaic contrivances of the present day. It is with these latter that we have to do; and, however pleasant from an antiquarian point of view it might be to dwell on the older forms, doing so could assist the worker little. We may be pretty well certain that, apart from mere ornamental variety, no useful form has been allowed to lapse; although, as in other directions, fashion exercises a powerful influence, and some hinges are no longer in such demand as they were. The tendency at the present day seems to be towards simplicity, and if one may venture to express an opinion on the subject, it is a move in the right direction, for surely there is no occasion to multiply work, unless there is something more than a fancied advantage to be gained by doing so.

Of course, I am now referring specially to hinges, and, as an instance, I may take the cranked centre hinge. This form, which was fastened at the top and bottom of, say, a wardrobe door, is no longer in such general use as it was only a few years ago. It has been superseded by the "butt hinge." This, in cabinet work, is *the* hinge, and, indeed, it may be taken as the typical form, or, at any rate, of that class which I think has somewhere been described as the "double jointed edge hinge." Under its technical name of "butt," it may not be known by the uninitiated, who will, however, have no difficulty in recognising it as the ordinary door hinge, as shown in Fig. 1. The general construction can so readily be perceived by any one who will take the trouble to look at a hinge that a tedious verbal description may be omitted. Suffice it to say, that it consists of two flaps connected by a wire, on which they are moveable to a certain degree. The side shown in Fig. 1 is known as the front, the reverse as the back. By back, however, is often understood only the rounded part, which is visible when the hinge is fixed and the door, or whatever it may be attached to, is shut. In the finer qualities of hinges, the "backs" are often polished and lacquered; the fronts also may be finished in the same way. Beyond this, it is hardly necessary to refer to quality, which varies considerably, both in weight of metal and general style. Roughly speaking, a good hinge is one in which the parts work smoothly against each other without twisting or straining.

It may be of interest to note that the joint of a hinge is usually unequally divided; for example, in Fig. 2, where the two flaps are shown apart, one of them has two projections, and the other only one. However many of these there may be, it will generally be found that one side has an even number of them, and the other an uneven; thus, two and three, the total consequently being an odd number. The side with the even joint pieces, however many there may be, is technically called the "double," and the other the "single." I have said hinges are made so usually, for the custom is not invariable, as in some, each side has the same number; but, with the exception of "lift off" hinges, where the reason is obvious, so far as my observation goes, such are generally of a lower quality; not perhaps sufficiently poor to warrant their rejection, but enough to justify the hint. Mind, I only say what I have noticed myself, for I do not pretend to have been a specially critical observer of hinges, and there may be good makes in which the usual custom is departed from.

Now with this preliminary talk about the "butt" let us see how a door is to be hung by it. The easiest way would be to screw the hinge to the outside, but such a mode of procedure would at once proclaim the novice. It would do for rough-and-ready work, but we aim at something more than that, and the butt hinge lends itself easily to neater manipulation. First of all let us take an instance where the door is hung *within* the ends, as in Fig. 3. The door ought to fill the whole of the opening, so that it is evident a space must be cut into which the hinge can be sunk. Must this recess be made in the door or in the end? To get an answer to this satisfactorily let us use a little of the "common sense" referred to a page or so back, for it will generally be found that where one method is almost universally adopted to the exclusion of another by skilled artisans there is some good reason for the preference. A moment's consideration shows us that, in such a case as the one before us, it will be a far simpler operation to let the hinge into the door than into the end, and recognising this we have the answer to the question.

A similar mode of reasoning will get us over the next question that may arise—viz., whether the hinge is fastened to the door or the end first, for it will hardly require a practical trial to convince any one that it is easier to screw the hinge first to the door, and then to fit this in its place. To do this in a workmanlike manner a marking gauge or similar contrivance should be used. With an ordinary butt the gauge is set from the pin in the joint of the hinge to the edge of the flaps, or, expressed otherwise, the distance between the marking point and the block of the gauge is equal to half the width of the hinge when opened out flat. This is then to be gauged on the edge of the door from its front, which will give the width of the recess for the hinge. Its length is easily arrived at by marking direct from the hinge, but it will be as well not to trust to this entirely, or if so to take care that the centre of the knuckle—the pin—of the hinge is exactly true with the edge of the door. Were one hinge of a long door to be inclined in a contrary direction to the other, instead of both being parallel with the edge, there would be an undue strain, and perfect action could not be expected. All risk on this score, however, may be avoided by the use of the square to mark off the ends of the hinges. The space thus marked out should now be cut away to a sufficient depth to allow the closed hinge to be laid in it so that no part of the flap is above the level of the wood. In actual practice it is customary to cut away the wood a little deeper towards the back than at the front, or where the joint of the hinge is. This, it will be understood, though flush on the end of the door, projects a little in front. The only reason for letting the hinge in deeper at the back is to provide against any accidental projection of a screw head above the hinge plate, which would prevent the hinge folding close.

The next thing is to screw the hinges to the doors, using screws of such a size that their heads can be properly sunk in the holes prepared for them. It will save a good deal of time to knock the screws in with a hammer for a short distance, not sufficiently to drive them home, but merely till they are far enough in to allow the screwdriver to be used without causing them to "wobble."

When the hinges have been firmly fixed, the hanging of the door may be proceeded with. In the case of large doors this is a somewhat troublesome operation, but in small work it only requires a little care. The method is the same, or may be, though later on a slight difference will be named applicable to large doors, though not absolutely necessary. Open the hinges out, and place the door against the ends in the position it is to occupy when the work is completed, holding it partly open, in order that the loose hinge plate may be got at. As a rule, doors in cabinet work are set back a little within the ends, an eighth to a quarter of an inch, according to the size of the article, but there is no practical necessity for this being done. The only reason is that it looks better, and as one way is as easy as the other that which appeals most to the eye may as well be chosen, for it is the attention to such apparently trivial matters that often makes the distinction between good and careless workmanship. As the door when fixed ought to open and shut freely without scraping against the bottom, the necessary space must be left between the two parts. This should not be great in a well-fitting door, and a sheet of glass paper or thin veneer will come in handy. Place anything of this sort on the bottom, and let the door rest on it. The top of the door may be left to take care of itself, for it can be eased off if it fits too close, and till the actual fitting up is all but done it is as well for it to fit tightly. The thickness of the paper which is between the door and the bottom will be sufficient space for them to clear each other. It is seldom that a door has only one hinge. Bore a hole for one screw through the top hinge, especially if the door is a long one, and drive the screw in. This will afford temporary support, and allow of adjustment of the door, which can be regulated till it hangs truly. Then fasten the other hinge or, in the case of more than two, the bottom one with another screw. The door may now be opened and shut, and if it can be moved properly the remaining screws may be driven in.

It may be wondered why only one screw is recommended before all are bored for or fixed, as it might seem simpler to finish off with each hinge before proceeding with another. If so I may explain that the reason as given to me by an experienced cabinet maker is that, in the event of a misfit, when the door is actually swung, one screw is more easily removed than a greater number, and that the bite of the screws is not weakened by unnecessary holes or enlargements of holes which may be required if the position of the door, or rather the hinge, has to be shifted a trifle. One hole to a hinge being a little bit out does not

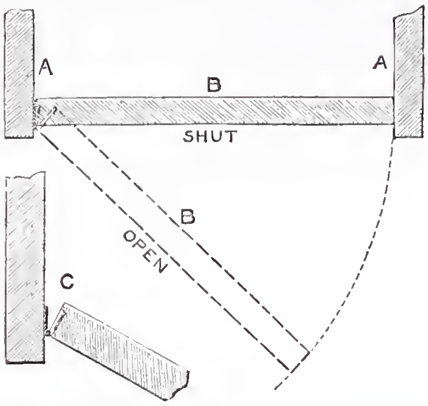

Fig. 3.—Diagram showing Door Hinged within Ends. A, A, Ends; B, Door; C, Enlarged View.

signify, as the other screws will hold well enough, and they can be fitted with certainty. We amateurs can learn a good deal from the professional worker in our favourite recreations, though some of us who have succeeded

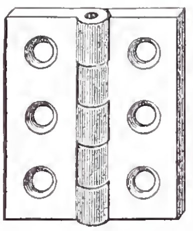

Fig. 1.—Butt Hinge.

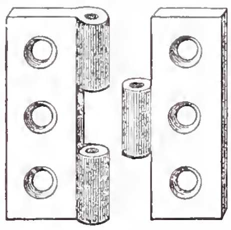

Fig. 2.—Hinge Divided.

in making a box or some equally complicated structure with its corners not so very much out of the square, and its dovetails easy—yes, that's better than badly—fitting, are perhaps rather apt to pride ourselves on our skill as being of quite a superior order. This, however, by the way; and having now given a few hints on one mode of fixing butts, I hope to treat of others, with remarks on varieties of hinges, in a future article.

BORING SMALL CYLINDERS.

BY OLLA PODRIDA.

I.—Chucking and Boring in Self-Acting Traversing Lathe with Slide Rest—Hand Tools, etc., in Ordinary Lathe with T Rests — Makeshift for Boring without Lathe.

To those possessing a lathe with traversing, or self-acting, motion, or even a good slide rest, the boring of a small or moderate-sized cylinder presents little difficulty; but in carrying out work of this nature in a common lathe provided with T rests only it becomes much more troublesome to produce a satisfactory result, owing to the necessity for special tools—such as D bits, broaches or rose bits, or parallel drills wherewith to finish the required bore, the preparation of which means an expenditure of time, labour, and material, the last-named being in many cases a serious bar in itself.

The immediate object of this paper is contained in the illustrations herewith, which represent a cheap and efficient makeshift wherewith such work of the smaller class may be successfully grappled with. Before proceeding with the description of this particular means, a few remarks, explanatory of the procedure followed under the conditions referred to in the opening clauses of this article, may be of assistance to those who may happen to lack the necessary practical experience.

Taking the first case—viz., a good self-acting lathe, fitted with a proper four-jawed expanding chuck of suitable size—then, under such favourable conditions the operation becomes a simple and easy one. First, the cylinder is set truly and gripped firmly by the back or bottom flange, it being important that the front or top flange which receives the cover carrying piston-rod stuffing-box shall be faced before shifting the cylinder after boring. This remark applies to all cases of facing and boring where truth is indispensable. If possible, sufficient clearance should be contrived for between the back flange and face of chuck or dogs, so that a hook tool may be used for partly facing this one also before removal; this will be found very handy in resetting the cylinder when turned end for end to finish the flange. In boring, an ordinary hook tool may be employed, or a cutter bar, but in either case they should be very strong and stiff, to guard against "chattering." In the case of a small cylinder, and in the absence of a four-jawed expanding chuck, a suitable bell chuck may be advantageously used.

With reference to the second case, where the boring has to be carried out in a common lathe provided only with T rests, it becomes a more difficult matter. D bits, broaches or rose bits, or drills, have to be specially prepared in accordance with the bore required, and this has to be done beforehand while the lathe is unoccupied by the cylinder. The method of procedure is as follows:—The D bits or other tools having been prepared, the cylinder is first chucked and set; then with the hand tools it is bored out to size of drill for a short distance—say one-eighth or one-quarter of an inch—so that the bit, broach, or drill may be started truly. The feed or advance of the tool is given by the poppet-head, and to facilitate this, the centres upon which the tool has been prepared must be left in. The tool may be kept from turning, under the strain of cutting, by means of a carrier or spanner, and the edges must be kept well lubricated with oil during the whole process. The rate of feed must also be, as far as possible, regular. One flange may, of course, be faced without shifting, but the other must be finished on a mandrel.

But comparatively few people possess first-class lathes replete with expanding chucks, etc., and it is not every one who can afford special bits and drills. It becomes necessary, therefore, that many cases of need must be met by makeshifts in some form or other, and this particular example may be overcome by the employment of a tool similar to that which is illustrated in Fig. 1, where it is shown in the act of boring a cylinder.

This simple but serviceable boring tool consists of a piece of hard wood—such as beech or oak—turned up truly in two sizes as shown, the larger equal to the finished bore, and the smaller to fit the rough bore as cast. Each of these sizes must accommodate the length of the cylinder. The large diameter should be rather longer, and provided with a squared end whereby it may be driven. A saw cut must be run up the centre, and a thin steel cutter fixed by screws, as shown. The thickness of this tool may be regulated by the saw cut, and the shape is given in Fig. 3. It must fit very nicely into the boring stem, so that when screwed up tight the cylindricity of the stem is not affected. Clearance, as shown at C, C, Fig. 2, must be cut along the small part to allow the borings to fall away and prevent jamming in working.

The tool may be actuated by means of a wooden cross handle fitted on the square, the motive power being supplied by hand, and the feed given by means of a suitable weight laid on the handle. The cylinder under operation may be held in a vice, or otherwise secured, provided always that there is room for the end of the tool to clear through the bottom. After boring, the flanges must be faced on a mandrel. It is advisable to smooth the rough bore, as it comes from the foundry, with a round file, so as to give the tool as much fair play as possible.

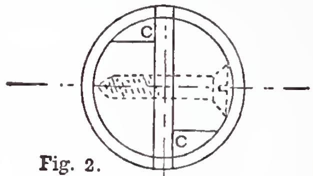

Fig. 2.

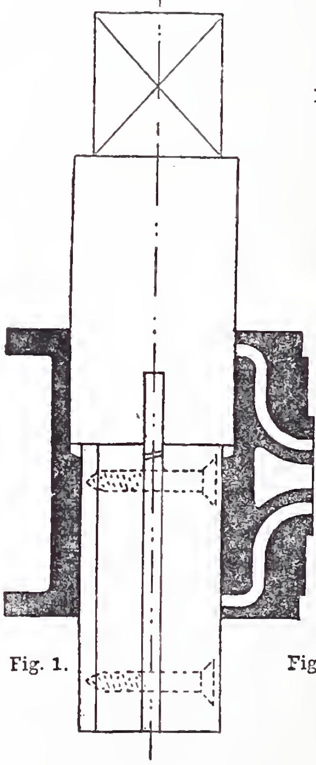

Fig. 1.

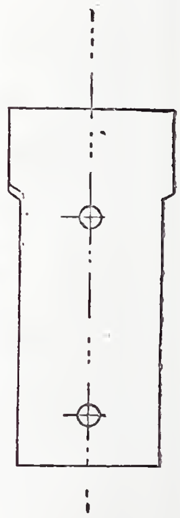

Fig. 3.

Fig. 1.—Tool in Position in act of Boring Cylinder. Fig. 2.—Sectional Diagram showing Mode of Effecting Clearance. Fig. 3.—Shape of Boring Tool.

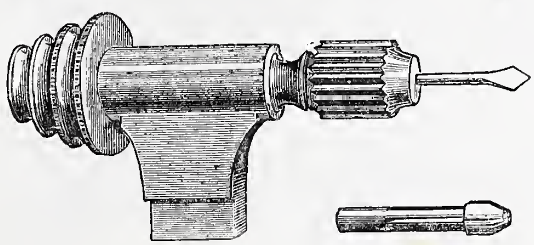
A very decent bore can be obtained at one cut, but to ensure accuracy, two operations with different-sized tools are necessary. Having successfully bored new, and re-bored old, cylinders by this method, I hope that a similar result may occur to all who feel the need of such a contrivance. In another paper a simple way of boring cylinders in a self-acting lathe with a saddle will be described, a process attended with many advantages.

(*To be continued.*)

OUR GUIDE TO GOOD THINGS.

24.—Handy Drill for Small Work.

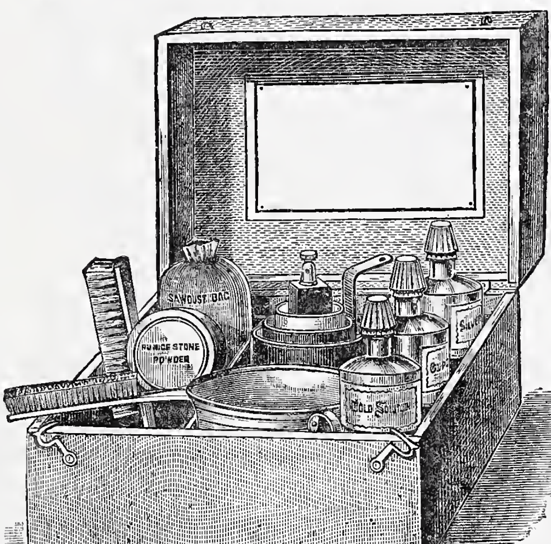
The drill that is represented in the annexed illustration will commend itself to the readers of Work as being an appliance that is admirably adapted for small work, in doing which it would be inconvenient to use a drill of a larger size or of a different kind. The drill itself (by which I mean the entire part of the apparatus that is set in motion, and not the drill point) passes through a steel tube, which is fitted with a foot rebated, so to speak, for $\frac{5}{8}$ in. from the bottom, by which it is grasped and held in a vice while the operation of drilling is being carried out. On one end of the shaft that passes through this tube is placed a pulley with three speeds, by which the drill is actuated by means of a bow, the string of which is passed round the groove that it is considered most desirable to use. The other end of the shank is hollow internally—a piece of iron tubing cut longitudinally through the greater part of its length into three jaws which hold the drill. A cap (surrounded with a band projecting slightly, and deeply grooved to render the operation of screwing and unscrewing it all the more easy) is used to tighten the jaws on the drill, and hold it fixed immovably. Internally the cap is cut with a screw thread, by which it is screwed on to the end of the shank from which the drill projects. Each drill is furnished with two sets of jaws for holding larger and smaller drill points; the drill points themselves ranging from a very small size to $\frac{1}{4}$ in., which, I am inclined to think, is about the largest that could be used with good effect in this appliance. It will be found useful in many trades in which small drills are required, and it will be highly prized as an addition to his ever-increasing stock of tools by the amateur. The specimen which I have described was shown me by Messrs. R. Melhuish and Sons, 85 and 87, Fetter Lane, London, E.C. Its price, as shown in the illustration, is 5s. I should say that the length of the drill, exclusive of the drill point, is $3\frac{1}{2}$ in., its depth $1\frac{1}{2}$ in., and the diameter of the speeds $\frac{3}{4}$ in., $\frac{5}{8}$ in., and $\frac{1}{2}$ in. respectively.



Handy Steel Drill for Small Work.

25.—The Practical Electro-plating and Gilding Outfit.

I am glad that it has been put in my power, at last, to call attention to something that is entirely different to the lathes, tools, and appliances that have hitherto been the subjects of notice. With regard to these, let me remind my readers, I have but little, if any, choice; for it is simply my duty to bring under their notice anything that is sent me, that appears likely to be useful and, therefore, worthy of mention. I trust that all inventors, manufacturers, and dealers will understand that "Our Guide to Good Things" is open to all alike for a description of their specialities, and that in order to obtain a notice, they have only to put themselves in communication with me, supplying me with some account of the object to which they desire attention to be called, if the article be too large to be sent to La Belle Sauvage for examination. The Practical Electro-Plating and Gilding Outfit, of which an engraving is given in this page, consists of a Bunsen battery, enamelled depositing cup, scratch brush, washing-out brush, boxwood sawdust, powdered pumice, copper wires, copper solution, silver solution, and gold solution, all contained in a neat polished case, or wooden box, as represented. With each outfit instructions are supplied, showing its possessor how to charge the battery in the first place, and then how to manage the plating process with copper, silver, or gold. Some practical hints which are concise, and apparently to the purpose, are further given to instruct the beginner in the management of the battery. I say "beginner" purposely, for it is only to such that the outfit really appeals; for those who are inclined to go into the work of electro-plating and gilding thoroughly would require plant on a more extended scale. I am the more inclined to think well of it, because one of my numerous correspondents wrote to me the other day to call my attention to it, and he spoke of it as being likely to be useful to many. If any reader tries it, I shall be glad if he will send me his opinion of it. Its price, complete, is 24s. No maker's name is attached to the instructions sent out with the outfit, but I believe it may be purchased of ironmongers and dealers in tools, and, probably, of chemists, who now deal largely in photographic appliances and goods of this sort.



Practical Electro-Plating and Gilding Outfit.

26.—"Ornamental Turning."

No turner, whether professional or amateur, who can afford to give a guinea for a book, should be without the very handsome volume entitled, "Ornamental Turning," a work of practical instruction in the above art, which has been produced and published by Mr. J. H. Evans, 159, Wardour Street, W., who is an authority on the subject, and a proficient in the beautiful work that he so ably describes. The work, to use the author's own words, has been "introduced with a view to assist amateurs who are interested in the development of the resources connected with this most interesting and scientific amusement; and it is hoped that the large amount of detail displayed will facilitate the manipulation of the various instruments and apparatus described." Mr. Evans enters at once on the subject of decorative turning, because plain turning has met with treatment by so many writers, that he deems it to be neither necessary or desirable to touch on it, so he commences immediately with a description of the ornamental turning lathe, the overhead motion, and the appliances that are used in connection with it; and the mode of chucking and adjustment of work, tools, chucks, etc., the division plate and index, the height and centre of the tools, and how to grind them and set them. From this, he passes on to the consideration of the different materials most appropriate to the work, and the mode of polishing, and the use of lacquers. Next, he brings under the reader's notice the numerous and various apparatus used in connection with the ornamental turning lathe, including the overhead motion, the sliding rest and its tools, the eccentric, vertical, horizontal, and universal cutters, the drilling instrument and curvilinear apparatus, the eccentric, ellipse, rectilinear, and dome or spherical chucks, the spiral apparatus and spherical slide rest, geometrical slide rest, and various cutters. Descriptions are also given of the modes of producing various elaborate pieces of turned work, including elliptic caskets, ivory candelabra, vases, frames, etc.; and the author concludes with a chapter on the advantages derived from electrotyping in intaglio and kindred work. The book is illustrated with numerous diagrams and illustrations of the ornamental lathe, and the apparatus used with it; and seventeen full-page autotype plates, exhibiting beautifully executed examples of the various kinds of work that may be executed by the aid of these appliances. I have sought, rather, to give the reader some idea of what he will find in the book itself than to select isolated portions for particular notice and comment; because I think that the former mode of treatment is more truly useful than the latter. Space has prevented me from doing anything like justice to Mr. Evans's work, and whoever becomes the owner of a copy will be agreeably surprised to find how much I have left untouched.

27.—Patterns for Fret Work, Stencilling, Turning, etc.

Amateurs and young workmen who are on the look-out for patterns of this kind will find much that is useful and suggestive in the parcels of these designs that are prepared and sent out by Mr. Fritz Collins, publisher of designs, Summerlays Place, Bath. They include examples for fret work, stencilling, turning, and even repoussé work, and the purchaser must be hard to please who cannot get out of them sufficient to remunerate him for the outlay of the shilling that is asked for each separate packet. Buyers must not expect to obtain highly-finished printed examples, because the patterns are all stencils, executed by Mr. Collins himself, and those in his employ; and, therefore, they present a certain degree of roughness, and, perhaps, unevenness of colour, that at first may prove somewhat disappointing. The forms given, however, are good; and the stencil patterns, especially, are useful for combinations, which any one can make for himself by the exercise of a little judgment. Mr. Collins also supplies all tools, materials, and appliances required in fret working, a detailed catalogue of which may be obtained for 3d.

28.—Trying Square for Metal Work.

In metal working it is always desirable to have means of testing its accuracy in a manner that will admit of no mistake, and will not allow any error to be allowed to pass undetected. For all rectangular work, and even for testing surfaces of no great extent, an excellent little Trying Square or T Square has been recently introduced, which is most accurately machined and may be declared infallible. It consists of a gun-metal bar nearly 4 in. long, $\frac{1}{2}$ in. wide, and about $\frac{1}{4}$ in. thick, being wider towards one end than at the other. A slot is cut in this projection about $\frac{3}{4}$ in. long by $\frac{3}{8}$ in. wide, and the metal at the top and bottom of this slot is perforated to admit of a steel bar which works up and down at right angles to the gun-metal bar. The steel bar is held immovably fixed at the will of the operator by a set screw with a milled head, which presses against a spring set lengthways in the slot in the gun-metal bar. This handy appliance, which was shown me by Messrs. Melhuish & Sons, costs 2s. 6d. The Editor.

A Corner for Those who Want to Talk It.

**** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

Delay in Replies to Queries.—Correspondents must not think that their queries have been put on one side because they are not immediately answered. Mr. Bonney writes in reference to a question on electrical matters propounded by a correspondent:—"The query sent me from A. G. is of greater import than appears on the surface, and necessitates some experimental calculations which will take time to conclude. I have to decide upon the 'greatest weight' capable of being lifted with two cells, and the form of magnet best calculated to develop the full powers obtainable from two cells. I am anxious to give correct answers to all such queries, so as to make Work a reliable source of information. Knowing this, you will kindly excuse a little delay."

Choice of a Trade.—Excelsior.—Your query is a little out of the beaten track, but I do not like to refuse to answer it on that account. You are now, you say, a warehouseman in a tea establishment, aged twenty-five, in which you find there is no chance of obtaining a better position. The weekly earnings of some of your friends, who are mechanics, are considerably above the sum that you yourself receive, and you wish to qualify yourself for some trade. Your hours are from 8 a.m. to 7.20 p.m., which does not leave you much time. You ask me to recommend you "any trade in which by private study and class work at, say, a Technical College," you could fit yourself to earn a living. You should first ask yourself what trade you feel most inclined to adopt. If I were in your place my own tastes would lead me to take up with carpentry, joinery, cabinet making, or wood carving, and as a preliminary step in this direction, go and see Mr. Thomas Syer, who has, or had, a Technical School of his own at 1 and 2, Finsbury Square Buildings, Chiswell Street, E.C.

Leaded Glass Windows.—N. W. (Kilburn).—This subject, with Glass Painting, will be treated effectually in Work, and in the papers that will appear on this subject you will be told where to obtain the necessary tools and materials. You may rest assured that all articles in Work that can be illustrated will be illustrated as fully and as completely as possible.

Ladies' Glove and Handkerchief Boxes.—You tell me that you want designs for these "in oak with monogram L.K. carved on the lid." For the benefit of such amateur carpenters as yourself, illustrated papers giving designs for and instructions in making such articles as these, and others of a similar kind, shall be given from time to time in Work. It would occupy too much space to give what you require in "Shop."

Advertisements in "Work."—G. B. (Tadcaster).—Without doubt Work will be found in every way worthy of binding and preserving. It is not in any way an easy matter to regulate the advertisements as you wish and suggest. If it were possible to do so I can assure you it would be done. Thank you for your good wishes.

Patent Brass-Capped Bradawl.—C. C. E. writes:—"As to the Patent Brass-capped Bradawl, I made one fifteen years ago, and have it now, so there is not so much 'patent' to hold good." [It is a simple contrivance to be sure, but none the less useful and effectual because simple. You must have been aware, when you made the capped bradawl that you now have, that it was much superior to the ordinary bradawl, and as you did not take advantage of your discovery, or invention, call it what you will, the rights of the patentee of the bradawls thus made and now on sale must hold good.—Ed.]

Lukin Lathe.—C. C. E.—Your remarks, which I perfectly understand and appreciate, shall be submitted to the designer and manufacturer of the lathe in question.

Picture-Frame Making.—Mitre.—This trade, with carving and gilding, will be fully treated in due season in Work. In the meantime, you might apply for what you require to Mr. George Rees, 41, Russell Street, Covent Garden, and the Savoy, Strand. I am not acquainted myself with any special work on the subject.

Boatbuilding.—L. W. L. (Wolverhampton).—This subject will be taken up and thoroughly treated; but I fear it will not be possible to do much with reference to the approaching season, which is close at hand. At present I must ask you to be satisfied with the assurance that writers will soon be at work on the theme.

Working Mother-of-Pearl.—Edward.—Mother-of-pearl is cut into the shapes and forms required by means of a saw, and such devices, letters, and words as you describe in your letter are also cut in this material by drills, fine saws, and files. It would require a paper or two to describe the mode of procedure clearly enough to guide you in every step, and possibly some worker in mother-of-pearl may see his way to give instructions for the benefit of yourself and others. Etching on mother-of-pearl is executed in the same way as etching on metal. If a raised device is required on the pearl, the design is first drawn upon it with an opaque varnish, and the surface unprotected by the varnish is then brushed over with strong nitric acid. The acid eats away the pearl, and when it has been sufficiently treated in this manner the varnish is removed by washing, and the design appears in relief.

Gardening.—J. P. A.—It will not be possible to give papers on gardening in Work, as it is a subject that requires a periodical all to itself; but the appliances used in gardening and by gardeners indoors and outdoors will be described in due course. You will, I am sure, readily understand that it is not possible to take up every subject at once, but that every subject will have its turn in due season.

Suggestions for "Work."—S. (Edinburgh).—I have to thank you for your suggestions, to carry out which would take up much more space than can be spared, and require a very large editorial staff. Technical terms can be easily understood by reference to any good technical dictionary, or dictionary in which the leading technical terms are dealt with. Those who read Work are certainly supposed to know the uses of lathes, and tools, and appliances mentioned in its pages, and very few would look for an enunciation of first principles. You can scarcely be in earnest in expecting me to explain in "Our Guide to Good Things" that a bradawl is meant for boring holes in wood for the reception of nails, and to make provision for driving them home as straightly as possible, and to point out that a wrench is used for loosening or tightening a nut. These are things, to fall back upon a very threadbare expression, which "every schoolboy knows."

New Invention.—Quintuple.—No charge will be made for giving a description of your patented invention in Work. Send in an account of it on approval.

Dyeing Osiers.—Bunsen Battery.—Dyeing is chiefly resorted to for veneers, in which it is desirable that the colour should penetrate through the wood that is subjected to this process. For colouring the surface staining is generally practised. Possibly osiers or willows peeled for basket making might be stained by means of Judson's dyes, but I am not certain about this; but, perhaps, the safer plan would be to subject them to the action of dyes, treating them in the same manner as veneers. To give recipes for the preparation of all the colours you ask for, namely, "black, blue, scarlet, green, violet, yellow, and orange," would take up far more space in "Shop" than can be spared, and I can only promise you that the subject shall not be forgotten, and that a paper giving you the information you are seeking for shall appear in Work at the earliest possible date.

Strictures on "Work."—R. S. C. (Leeds).—Hammer away as much as you like. I am used to that sort of thing, and it does not in any way hurt me. I always bear in mind the fable of "The Old Man and his Ass," and steadily decline to imitate the Old Man, and try to please everybody, because I have long since recognised the utter impossibility of doing so. No writer in No. 1 said a word more than he ought to have said, and in that same number there was not an atom of "rubbish."

Practical Soldering.—Hohenzollern.—You shall have instructions on this subject very shortly, as an apt and clever writer, a thoroughly practical man, is engaged on it. In "Our Guide to Good Things," articles that are costly must be described as well as small things. I endeavour in this part of the Magazine to gather and give information that may be useful to all in turn.

Cyanotype Process.—J. W. (Darlaston).—The formula you refer to is correct, but may be misread through a comma being inaccurately placed immediately after ammonia, making it appear as if the ingredients are three. There are only two—viz., ammonia citrate of iron and ferricyanide of potassium. By using these in the manner directed, results ought to be satisfactory; but if you cannot manage, write, stating your difficulty, and I will endeavour to point out any error into which you may have fallen. An article will probably shortly be devoted to the Blue printing process. Thanks for your good wishes.

Circular-Saw Rigs for Lathe.—G. E. (Camberwell) writes:—"As a practical mechanic of twenty-five years, I have been much pleased at the way in which No. 1 of Work is presented; but with every apology, if you will kindly allow me, I would venture on one or two suggestions in connection with circular saw. Fig. 1 represents a superfluous amount of work for small results to an amateur in the screwing or tapping a chuck to obtain a counterpart. Fig. 3 much better adapted, but the square should taper 15°; yet again, the saw which is driven between centres of 60° is the most lasting—less liable to run out of truth. As regards the table, certainly the best is that let into rest bottom—wide but shallow shoulder to allow it passing below the saw spindle—the cut in the table (supposing it to be brass ¼ in. thick) to be made by taking diameter of saw, centering the table, drilling one hole at each end, then following line of holes opening one into the other with warding file. Again, you consider lathe saw essential to amateurs. Quite so; I take it to be equally so to practical men; that is my experience.—[Comments and criticisms are always welcome, as free discussion is always helpful all round.—Ed.]

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the **Inventor** *and Manufacturer,*

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

SCOTT'S EMULSION OF PURE COD LIVER OIL

WITH HYPOPHOSPHITES OF LIME AND SODA

Is three times as efficacious as the plain oil. It is almost as palatable as milk. It does not nauseate or produce a loathing for food like the plain oil. The Hypophosphites and Oil are so skilfully combined that they are much more potent in building up flesh and strength than if taken separately, and it is to-day the best remedial agent for the cure of

CONSUMPTION, CHRONIC COUGHS, BRONCHITIS, ANÆMIA, WASTING DISEASES of CHILDREN, and GENERAL DEBILITY that exists.

Physicians universally prescribe it in preference to the plain oil, having seen its remarkable curative effects.

Scott's Emulsion of Cod Liver Oil can be bought of any Chemist at **2s. 6d.** and **4s. 6d.** A Free Sample 4-oz. Bottle will be sent to any one who will write for it if they will pay carriage on receipt.

BINDING MADE EASY.

A CHEAP, STRONG, AND TASTEFUL METHOD OF TREATING PAMPHLETS, MUSIC, ETC.

With a Few Words on Portfolios and Blotting Books.

BY E. BONNEY STEYNE.

To hazard a guess concerning the regular contributors to this periodical, it would, probably, be safe to surmise that among the number are many professional men, experts in their own craft, who translate the technicalities of their profession into terms easily grasped by amateurs, and simplify the non-essential difficulties of the orthodox methods they are wont to employ by suggesting substitutes within the reach of unlearned people.

Also, that there are amateurs who tell the story of their own experience — the forecasts, failures, and ultimate triumph of a rough-and-ready method, evolved by themselves, to accomplish a certain aim—which, being to them good and useful, they offer as ensample to other unskilful ones to secure the desired result by unconventional ways and means.

In this paper, however, I wish to speak from the stand-point of one in the rather unusual position of having been in the first of these groups, and yet now quite in the second class. That is to say, not as an amateur who has acquired technical knowledge; but as one who, knowing the right way to achieve the end, has, by force of circumstances, entirely set it aside, and gradually evolved a makeshift, which suffices in its way.

Years since, I went through the various stages in learning the art of bookbinding, and bound unaided, at least, one volume, after the most strict precedents. I do not say it was a fine specimen of the craft, but it was a respectable second-rate attempt; differing only in its lack of that precise manipulation and exact finish which, at its highest, translates the trade of bookbinding to a fine art, and sets its artificers among the great names in the army of creative workers. My volume was sewn, hammered, and pressed in the routine way; it had mystic gluings to its back, slips of cardboard for the raised bands across it, edgings of coloured silk immediately at the top (the technical term for which has slipped from my memory), calf back and corners, richly tooled gilding, cloth sides, and marbled edges, after the ordinary pattern of half calf, extra bindings. This thing I did—myself—and yet I now explain a process that is makeshift and transitory, but to me (be it whispered where no professional may hear) seems really better for its particular purpose than any of the cheap and unsatisfactory bindings of the common bookbinder.

To a book lover—bibliophile is, I believe, the correct term now—the outside of a book either charms or repels one, quite apart from its contents; and from the yellow back paper novel, or the cheap cloth, with a mass of black printed lettering over it, to an inferior specimen of half morocco extra, each is unpleasant. Of course, good leather binding is far and away better than any substitute; the charm of a book well finished, be it in morocco, calf, or parchment, surpasses any inferior material; but not only are the substances costly for such work, but the time required in the process, too, adds to that cost, that it makes their use prohibitive for every-day purposes. Then, too, a cheaply printed book is ill-set in too luxurious a binding, unless the thing, by its accidental rarity, has acquired a value not its own; it gives as much disappointment to open a gorgeously bound tome, and discover the average "cheap edition" paper and ink, as it does to see an Elzevir or Aldine bound in half cloth, with marbled paper sides.

The wish to preserve in sightly fashion, clean, and handy for reference, many of the ephemeral publications of to-day, resulted in various attempts, which finally grew into a rough method of procedure, that I propose to explain fully.

This way of covering a few pamphlets, or similar publications, is not suitable for large volumes. When I want to have WORK bound I shall send it to my binder; but, with respect to that copy of Dickens' rarest tract, "Sunday under Three Heads," in facsimile, or these odd (ten or a dozen) numbers of the Browning Society Papers, or this first edition of "Called Back," and a hundred other little volumes, I bind them for myself, with great advantage. First, in saving of money, since the commonest binding costs almost as many shillings as these cost pence. Next, in perfect certainty that the thing, so bound, will be kept intact, with not only its original wrapper and uncut margin, but all its "waste" as issued (waste being the technical term for the added advertisements, wrappers, and all additions to the carcase of the book itself). Also, with the power of withdrawing any one pamphlet from the volume into which it has been stitched, or even adding a thin one or two to the already inserted group. And lastly, being able to clothe such volumes in vegetable parchment, Japanese leather paper, rich brocade, or plain brown paper, as the subjects treated, or the future use of the booklets themselves demand.

Although this expeditious and economic makeshift perfectly satisfies its contriver, yet I should have hesitated to offer it to others, had not I been so frequently asked by friends to give them a working lesson of the process. Fortified by these private demands, I have dared to address the wider circle of our readers, old and new friends as they are, although we wot not of each other's faces; and in this illustrated address, wish to speak as a fool—to fellow-fools—(after all, we are in majority, are we not?) instead of as a sage teacher to receptive pupils.

Suppose, then, that we have an imaginary pile of paper-covered books: a few of the "Book of the Words" of the Savoy Operas; two or three "Parliamentary Blue Books" of twenty or thirty pages each; a copy of "Pictures at Play"; three or four paper-covered "Cassell's National Library"; a pile of MSS. poems, written on ordinary note paper; a few specialists' pamphlets and scientific monographs; a similar heap of theological tracts. I take an actual pile by me to illustrate the various modes.

The first thing is, of course, to sort into sizes, but it is still more important, for future reference, to group into subjects. Clifford on "Atoms," and the libretto of a burlesque, may be the same size, as are three severely orthodox tracts near; but it would be a misuse of words to say there was any method in such mad grouping.

For this style of binding, the thinner, in moderation, the collected volume is the better. One inch in thickness is the most that I have accomplished successfully. More bulky volumes are loose and untidy, and in this case—thereby differing from orthodox binding—are more tedious to manipulate than the same material split into two or three volumes.

We begin, therefore, with the "Book of the Words" groups. The excellent wit and caustic satire of Mr. W. S. Gilbert are well worthy a lasting place upon one's shelves; but as he has already published a collected edition of his earlier works, we may reasonably hope for a third or fourth volume later on, and not have these bound formally. As these blue-covered pamphlets are the same size, and at present in good condition, they will be a simple first attempt. The initial step is to choose a piece of thin cheap cardboard, costing about one penny a sheet, as for these I intend to use vegetable parchment for the finishing covering. The cardboard should be white; for other materials, the common dark-blue "bonnet board," as it is called by the trade, will answer equally well.

On this card I place one of the pamphlets (Fig. 1). I mark the outline with a pencil, calculate the distance for the thickness of the back, rule a line there and then, and at equal distance rule the line for the cut. Here it may be said that all material cut with a sheet of glass underneath gives a clear edge to the cut, without the burr that is always present, if wood or cardboard is used for the table, which, with a sharp penknife, I run through the card at A, A, and B, B. At C and D I "score" the cardboard to ensure a clean fold; that is, I cut it half through with a lightly drawn knife, so that it folds without parting. Before going to the next process, it is necessary to impress the importance of judging correctly the probable thickness of the matter to be inserted in each cover. If insufficiently wide in its back, the covers will not close nicely; if too wide, the whole will be loose and untidy. As the thread for the stitching takes a certain space, it will be found that the natural thickness of a pile of pamphlets, after pressure, just when the pressure is withdrawn, will give a fairly accurate idea of the needful width.

I next cut out a piece of "ticket buckram" for the back. This is a stiff white material sold specially for ticket purposes. It costs eightpence a yard, is very wide, and fulfils its purpose so much better than any other substitute I have tried, that I should advise its use. Bookbinders' cloth or ordinary glazed calico are each possible alternatives, but neither take the paste so well, both stretching when moist, and shrinking when dry, which is not the case with the buckram; nor do they adhere so easily, or keep so firm and smooth when they are dried. For putting under parchment, the white buckram is the best, as its colour gives the vegetable parchment the look of the more costly material it imitates.

The buckram is pasted now on the outside of the cardboard; by outside I mean the side where the scoring was cut. While it is wet, cut out the gussets at A, A (see Fig. 2), or when the case is folded it will pucker at the back and disfigure it. Then turn down the buckram, and leave for awhile to dry under a light pressure, if convenient. For mucilage, I generally use the bottles of White Cross Official Paste, or Stickphast; but for any quantity it is much cheaper to use flour paste. Since, in many households, the art of making bookbinders' paste is unknown, I had better repeat it here; knowing that when, in most households, you send down an order for paste, the cook forwards a breakfast-cup of a thin drab-coloured gruel that is sloppy and wet, and peculiarly non-adhesive to the object to which it is applied, while it clings with impish vehemence to the various surrounding things it clothes, but does not adorn.

For good paste, mix a tea-cupful of flour smoothly with a very little cold water (it takes a little time to get the flour to a thick cream without lumps), then have ready sufficient *boiling* water in which a tea-spoonful of powdered alum has been dissolved, pour it gently into the basin where you have been mixing the flour, stirring it all the time, then pour back the paste into the saucepan and boil, still stirring until it gets to a thick consistency. Thus made, it is glutinous, a paste actually, not a liquid, and keeps for some weeks. It may mildew on the surface, after a time, but does not decompose. A drop of oil of cloves is often added to assist its keeping and impart a pleasant scent.

Now, the cover being dry, it is ready for filling; take it as shown in the diagram (Fig. 3); place it on the edge of the table. Take your first pamphlet. If it is composed of one set of leaves only, turn to the central one. With a large needle, and a long strong thread, pass the needle from the inside to the out, about an inch above the bottom margin of the page, and back into the centre of the book, say two inches above. Tie the loose end firmly to this as shown in Fig. 4; then running the needle out and in in wide stitches, go through the pile of pamphlets, laying each on face downwards on its predecessor until all are sewn, passing the needle at the last stitch back to the first knot, and securing the loose end.

Care should be taken to stitch each set of pages. For instance, in a weekly issue of this journal there is but one such set; in a monthly part four or five; now, to secure strength, each one must be stitched. It may happen, as in German music, that every two pages require a separate stitching, but if you would have the book open flat, and keep open, there is no other way to obtain it than this patient stitching of each group of pages. See, too, that the needle enters the cardboard back at the right place to exactly hit the fold of the pamphlet, not coming through the margin of the pages, some distance off this central crease. Be careful also that each successive pamphlet is pressed close down to its neighbour, and that each new line of needle holes in the back comes exactly where the thickness of the papers demands them; otherwise, the book will be loose and flap in its covers, showing the bare cardboard back when opened between the pamphlets, which it does not do if these hints are obeyed. This sewing is all important; if some of the pamphlets are likely to be wanted loose at any time, fasten each one separately, starting with a loose thread, and tying the ends once to each pamphlet. Then any one may be withdrawn and replaced by another without loosening its neighbours.

This sewing is very hard to describe, but very easy to do, and most important of all the stages of the process. In the cheap binding of to-day, the faulty sewing is the chief annoyance; either the thread used is rotten, or some carelessness in the work must occur, since nothing is more common, even in high-priced volumes, than to find a group of pages suddenly come loose, to the danger of their loss and disfigurement of the volume.

The use of the buckram back is now seen; it not only keeps the covers in their place with a strong joint to each, but also strengthens the back, for stitches into the bare cardboard would quickly tear away from their holding and render all the labour fruitless.

It is best to bind these loose pamphlets while they are in good condition, and to make a special point of this, taking occasional "wet days," or odd half hours, to overhaul their constantly accumulating mass, and bind a few volumes at a time, *before* they imperatively demand it. That is the secret of success in this home-binding; not to wait until loose pages, dog's-eared leaves, and torn wrappers insist upon being repaired, but to tackle the work while the pamphlet is yet clean, fresh, and tidy, and so prevent all these disfigurements. Then, with ordinary care in after use, they keep as fresh as the pages of a well-bound book, besides opening easily for use.

That they may open easily, it is well to use a thin cardboard. In my anxiety to obtain solid covers, I tried first very stiff cardboard. Not to recall the unspeakable agonies of stitching through a mighty piece of pasteboard, miscalculating the force, and pricking my fingers as often as the paper, when the whole was done, the volume would not keep open easily, and was not half so pleasant to handle as the flexible covers when thin card is used.

The cardboard case now will be somewhat unsightly, since it will have long stitches irregularly marking the buckram back, as in Fig. 5, and a very unfinished look about the sides.

It is best at this stage to rub a little paste along the thread at the back, working the brush under the stitches somewhat, so that the thread is well pasted down to the buckram.

For covering, there are several courses open, but vegetable parchment gives the best effect on the whole. To my own books I have almost invariably applied it, and find people generally prefer it to any other style.

The vegetable parchment is made in many qualities, and differs in thickness and appearance no less than in price. I have been charged so many different prices for this material that I hesitate to quote either. The sheets are a good size, cutting into at least four pieces for ordinary octavo books. As a rule, twopence to threepence the sheet would be probably the average cost. It is somewhat difficult to obtain. I have bought it of stationers and of chemists, and expect the various stores keep it on their list. But do not be tempted to adopt the thin cheap sort in spite of its price. It has a tendency to "cockle," it tears, and is generally unpleasant to use. This material defies pasting; it either refuses to stick, or if so, shrinks and curls up the cardboard on which it is mounted, and loses almost completely its skin-like appearance, looking like ordinary whity-brown paper.

But if cut as a loose cover, after the form shown in diagram (Fig. 6), and turned over firmly, the edges being creased down with a bone paper-knife, it keeps its place without any further fastening; but the turn-over must be left at least two inches wide to ensure this result.

It is best to fit the parchment to its place, and then remove it for lettering. I have tried gold ink, with only moderate success; probably gold size, with either bronze powder or gold leaf, would give a more workmanlike result. But gold lettering challenges directly the effect of the genuine impressed lettering on an ordinary leather-bound book, and fails dismally to equal it. Therefore, it seems best to be content with black letters and ornaments. In this, as indeed for all and every ornamental design or drawing, I use, not ink, nor Indian ink, but Stephens's ebony wood-stain. When an artist friend recommended this to me, he said, "that tip is well worth a guinea;" and his words did not exaggerate the case. If it were needful to pay a guinea, rather than forego the use of this excellent fluid, I would willingly do so. It flows freely, and gives a solid photographic black surface, as even and rich as the best impression by letterpress or lithography. Being black (not merely dark purple, like ordinary writing ink) it photographs satisfactorily, and is used by all who know of it for pen and ink work intended for reproduction by any of the numerous processes which supply a direct facsimile block for printing duplicates in any size of the original drawing.

There is a very fair imitation of leather known as leatherette that is good for some work, but possibly from the technical knowledge of consistent treatment of the material, I dislike any attempt to get the appearance of a leather-bound book without the inherent quality of lasting strength which the real material implies, and devoid of the artistic excellence of workmanship that it deserves. A really well-bound book is as much worthy of admiration as a finely inlaid cabinet or cunningly chased goblet. In no decorative art is there more need for intense care and manipulative dexterity, combined with true artistic knowledge, than in binding. The limit where beautiful design passes into vulgar ornament is keenly felt in this art. The true artist needs a complete repression of all meaner ends. No mere dexterous handling of his tools for display alone; fitness, as well as graceful design, is needed to make a good binding. A panel, gorgeous in itself, may be a poor book cover, and the more one studies the works of such men as Eve, Pasdeloup, Grolier, or Roger Payne, of older times, or of Zaehnsdorf to-day, the more we realise what a fine art it really can become. For most purposes in this home-binding, a few black lines, the title and the author's name, suffice. A book collector likes the imprint of the tome and the date at the foot on the back. It is handy for easy identification to have the title repeated in the right-hand corner of the side, as in Fig. 14, while the signature of the owner, somewhere outside the cover, may be made decorative as well as useful; for if a book, or umbrella, bears "its owner's" name conspicuously, it assists weak memories to return each to its rightful owner, and saves weak consciences hours of bitter misery, which, if vice be its own punishment, they must certainly suffer in secret, although we never, *never* see any trace of the hidden guilt.

But although sham leather is unsatisfactory, yet a substitute, in place of a richer material, is not necessarily bad. A pewter dish, in its way, may be infinitely better art than a poor design in electro-plate. The nineteenth century has been characterised as an age of shams, and, therefore, we need not to-day add to its heavy list of sins by suggesting imitative falsities in leather. There is, however, a paper leather of real Japanese make, so perfect in its colour, grain, and substance, that it would deceive even the elect, but it is rather thick and clumsy for an amateur to use, and when pasted, loses much of its beauty. The Japanese gold leather-paper is a totally different thing; for certain books it has a splendid effect, and used in one particular way, to be noticed later, it yields a novel and rich cover, in no way imitating anything we are accustomed to see in bindings.

In place of the vegetable parchment, a small printed cretonne, or some of the dainty cotton stuffs, with an all-over pattern, after the style of old chintz and the Liberty printed fabrics, look extremely well. But if the volume is thick enough to afford space for a label with title on the back, it is rather difficult to write one sufficiently neatly. It sometimes happens that the cover supplies a slip, which may be cut out and mounted for title, but this should be only resorted to in the case of really valueless books.

But here the exigences of space, as inexorable, after its fashion, as Time and Tide, compel me to reserve what I have yet to say for a future occasion, when I shall be able to explain the import of the remaining diagrams to which I am not able to call attention now.

(*To be continued.*)

A HOME-MADE WINDOW CORNICE.

BY OLLA PODRIDA.

Hanging Curtains—Undesirable Methods—Pole and Rings—Cornice—Plan and Elevation—Rod for Curtain Rings—Dimensions of Members—Members in Detail—Preparation of Upper Members—Length—Working of Members—Gauge or Template—Mitring—Fitting Together—Cutting Drops in Lower Members—Gluing up and Screwing Together—Corner Pieces—Pendants—Supports—Finishing.

The methods adopted in hanging window curtains are varied, and generally—not always—in accordance with means and circumstances. A simple and cheap, but—to the curtains—destructive, means is found in the humble nail and domestic tack.

A treacherous improvement on this primitive method is attained by threading the curtains on tape stretched between a pair of nails, one at each corner, and supported by a third nail in the middle. Either of these methods, when viewed from the exterior, or the street, leaves little or nothing to be desired in appearance, but seen from within, and the other side of the question raised, the most unprejudiced eye must admit that the effect is—well, rather bare, and that simplicity does not, at any rate in this case, possess much charm.

The height of ambition is reached, in other cases, by means of the antiquated window pole with clumsy rings in its unprogressive descent and guise of a family heirloom from generation to generation. But, putting this on one side, it must be admitted that the *ne plus ultra* of grandeur is attained when the best front room curtains flow gracefully from a fountain head of gorgeous gilding or cunningly carved handiwork — to wit, a cornice.

Now, it is not everybody that can afford such expensive ornaments, and they are expensive unless satisfaction is obtained from a common article probably not worth half the outlay. The question therefore resolves itself into this, either to do without such or manufacture them yourself. Speaking from experience, I support the latter alternative. It is easily done, and of this I hope you will be convinced after perusing the instructions herein. It will not by any means be found a complicated subject, but the appearance is good, and even if it does not please the more critical friends, you can stop the mouths of fault-finders by informing them that you made it all yourself, and your generous disposition will doubtless lead you to add something nice about Work.

Fig. 3 shows the cornice in elevation complete as seen from the front. Fig. 4 is a plan of the same looking down upon the top of it, showing the distance it stands out from the wall—this is a matter of taste or choice—and the position of the rod, R, for carrying the curtain rings. This rod is a plain round piece of wood, $1\frac{1}{2}$ inches in diameter, cut to fit between the upper end members, G, G, and notched or cut away at its ends so as to fit flatly and firmly on the second members, H, H; it is further secured at each end by small dowels or French nails, fitted so as to permit of its being easily unshipped if required. The length of the cornice is governed by the extreme width of moulding around the window frame or recess. This length is determined between the inside of the lower members at the ends, as shown by the arrows in Fig, 4, and it should be a couple of inches wider than the moulding referred to. The example in Figs. 3 and 4 is drawn to a scale of $\frac{3}{4}$ of an inch to the foot, and is suitable for a window recess 5 feet 8 inches over the moulding, thereby giving 2 inches clear each end. By thus spreading it slightly the appearance of a narrow window is greatly enhanced.

Fig. 1 is a half-sized section of the cornice, showing clearly the method of putting the various members together. Fig. 2 is a part front elevation at one end, and drawn to the same scale. Figs. 1 and 2 contain all the information necessary in building the cornice, except for the length and depth from the wall. The former is, as previously observed, governed by circumstances, and the latter is arbitrary. In the example under discussion, the length at the starting point between the arrows in Fig. 4 will be taken as 6 feet, and the depth or distance which it stands out from the wall as 9 inches. The dimensions in section of the various members are as follows:—A, the upper front member; G, G, the upper end members; B, the second front; and H, H, the second end members, are all 2 inches wide by $\frac{1}{2}$ inch thick, finished; stuff required, $2\frac{1}{8}$ by $\frac{5}{8}$ inch thick in the rough for these. The principal members, C in front, and J, J, at the ends, are formed out of stuff $4\frac{7}{8}$ inches wide by $1\frac{3}{4}$ inches thick. The lower members, D, D, and E E E, in which the ornamental drops are formed, are $4\frac{1}{4}$ inches wide by $\frac{1}{2}$ inch thick; F, F, are merely filling pieces $\frac{3}{4}$ inch square, and assist the mitre joints in lower members, D, D, as well as forming accommodation for the turned pendants or drops, P, P. The next thing to be obtained is the lengths of the various members. This, although at first sight, perhaps, confusing, is really very simple. Starting with the assumption that the inside distance by the arrows is 6 feet, it will readily be seen that the length of the front lower member, D, must be 6 feet 1 inch to cover the end members, E, E, which are each $\frac{1}{2}$ inch. D being settled, we find next the length of C, and this is done by adding to D twice the extreme amount by which C projects at one end; referring to Fig. 2, we find this to be $3\frac{1}{2}$ inches, which doubled amounts to 7 inches, and added to the length of D gives 6 feet 8 inches for C. The same remarks apply to B and A, and these are found to be respectively 6 feet 9 inches and 6 feet 10 inches long when finished. After what has been said the lengths of the end members should be found easily, but it may be as well to give them here. For *both* ends, E will be 19 inches, J, 26 inches, H, 27 inches, and G, 28 inches. A margin should be allowed on all the foregoing lengths to guard against accidents in mitring and fitting the joints.

The preparation of the two upper members and blanks for the lower members is a simple matter, and scarcely calls for any remark, except that each must be gauged carefully to uniform thickness with the edges, straight, especially on the front. The rounded or beaded members, B, B, and H, H, can be readily formed with a smoothing plane and finished with glass paper.

The working of the principal members, C and J, will involve the most labour. As already

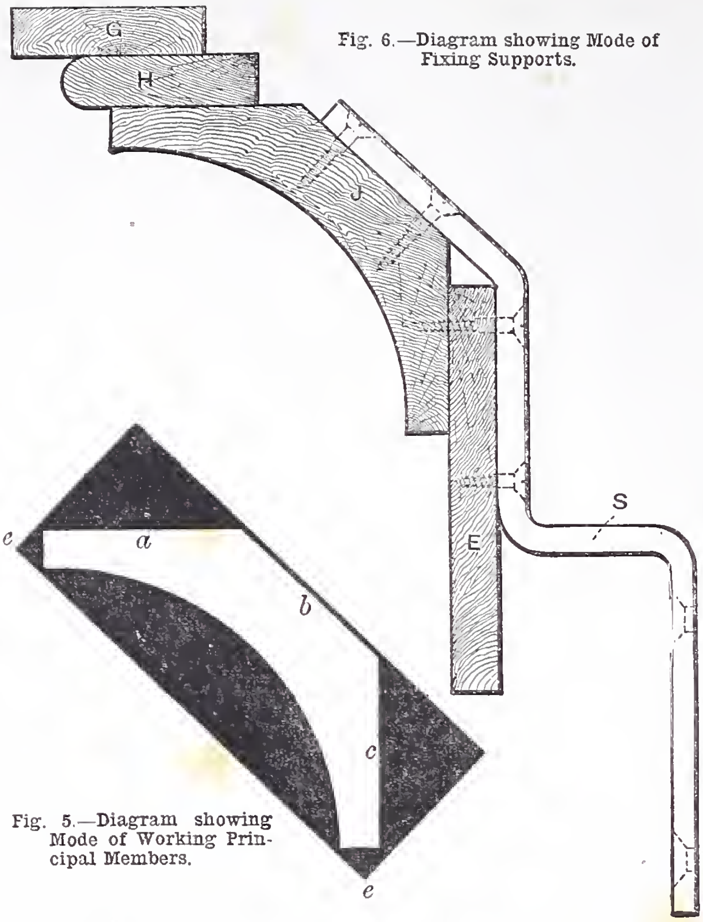

Fig. 6.—Diagram showing Mode of Fixing Supports.

Fig. 5.—Diagram showing Mode of Working Principal Members.

Fig. 3.

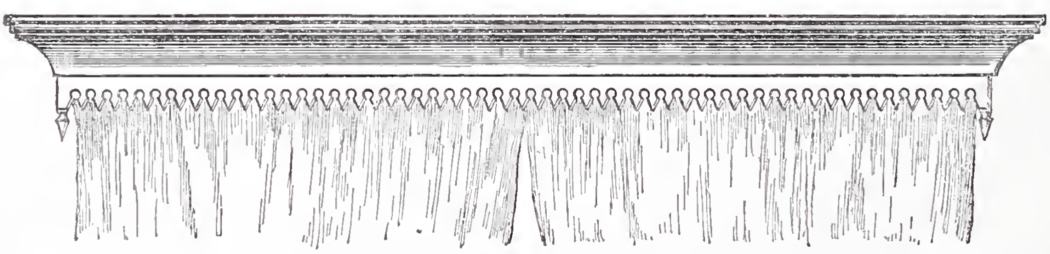

Fig. 3.—Elevation of Cornice Complete, as seen from Front.

Fig. 4.

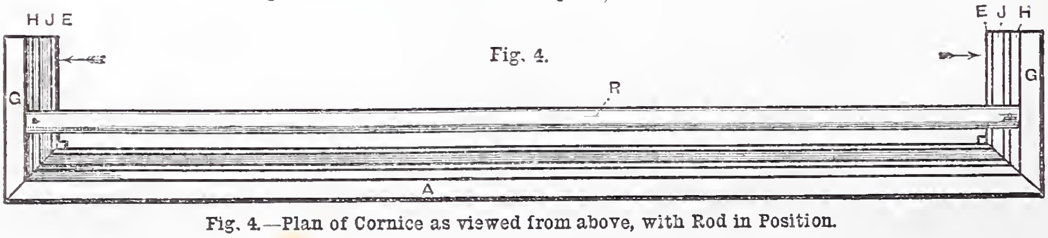

Fig. 4.—Plan of Cornice as viewed from above, with Rod in Position.

stated, these are obtained from stuff $4\frac{7}{8}$ inches wide by $1\frac{3}{4}$ inches thick. The method of working these out will be comprehended on reference to Fig. 5, in which the parts to be cut away are shown in black and the finished article in white. In commencing these the stuff should first be planed up straight and square to the outside sizes, and the outline marked on the ends, which must be trimmed to admit of this being clearly done. One of the sides, say that at *a*, must first be formed and carefully planed to an angle of 45 degrees, or strictly speaking 135 degrees with the back, *b*. This done, the other side, *c*, must be treated likewise, and worked square to *a*. The edges at *e*, *e*, are next planed square to *a* and *c* and the thickness gauged to $\frac{3}{8}$ of an inch for guidance in forming the hollow part. This latter is accomplished by first roughing out the bulk with a suitable-sized gouge, and finishing with a round-nosed plane and glass paper. Care must be exercised in gouging, and the grain of the stuff studied in order to avoid detrimental splintering or "spalling." The same caution applies to the using of the plane, the "rounding" of which should be to a much lesser radius than the required hollow, it being much better and easier to work out in shavings; besides, a round nose does not work freely when buried to the full depth of the iron. A male gauge or templet made to the radius of the hollow, and with projections to meet the edges, *e*, *e*, when down to the right depth, will be found of great value for checking the progress of the work in gauging and planing, and also in ensuring similarity between C and the end pieces, J, J.

Before putting the members of the front together, it will be an after advantage to mitre one end of each with the saw; but before doing this their relation must be noted, so that when put together the ends so treated shall mate and match. The end members will be likewise treated, but the square ends of these which butt against the wall must be left till the last. The various members in each part—front and ends—may now be screwed together, as shown in Fig. 1, bearing in mind that the lower member, D, need only be fixed temporarily on account of its having yet to be cut into a pattern on the lower edge. In mitring and fitting the ends and front together, the parts should be laid upside down on a level table or bench, and compared with adjustment by planing until they match accurately in the joint. Any trifling inaccuracies in matching of the members can be mutually adjusted after being finally put together. The mitring of the remaining front end will be materially assisted by measurements off one of the finished ends.

After the parts have been fitted together, the bottom members must be removed for cutting out the "drops." This is done by boring with a sharp bit a number of $\frac{3}{4}$-inch holes, one inch from the lower edge and about $1\frac{1}{4}$ inch from centre to centre; but the centres must be marked out first to ensure their coming right at each end. This having been ascertained, the diamond portion must be marked by means of a bevel to ensure similitude. The holes are then to be bored, and starting from one end, each space between the drops must be sawn out with a fine tenon saw, and finished with a sharp chisel. Care must be taken to avoid breaking any of them, but should this occur they can be glued back again. The "drops" in the ends need not be cut into the wall. After cutting out, the members must be carefully replaced.

The front and ends must be glued together at the mitres, and further assisted by means of French nails or slight screws where practicable. If these auxiliary fastenings are used—and they should be as provision against damp—they must be driven in the ends and not from the front. The cornice must be laid upside down on a level surface for gluing, same as in fitting the mitres, and one end only at a time must be treated. Care must be taken to get the ends fair with each other without twist. The corner pieces, F, are next glued or, better still, screwed in place as shown. The pendant, P, is a simple piece of turning, and is not permanently fixed, but merely a hand-fit, so as to be easily removed. After the glue has set properly and the joints been secured, the wall ends must be squared and the supports fitted, as shown in Fig. 6 at S. These supports are simply strips of iron $\frac{5}{8}$ or 1 inch by $\frac{3}{16}$ or $\frac{1}{4}$ inch thick, bent to shape, and screwed to the cornice and the projecting moulding around window. It may be found necessary to modify the support, and if there is no moulding or framework, pieces of wood about $1\frac{1}{4}$ inch thick may be fitted to the inside and under lower member of cornice and securely nailed to the wall, the cornice being afterwards shipped in and secured by screws.

The finish of the cornice is a matter of taste. I stained one of mine in imitation

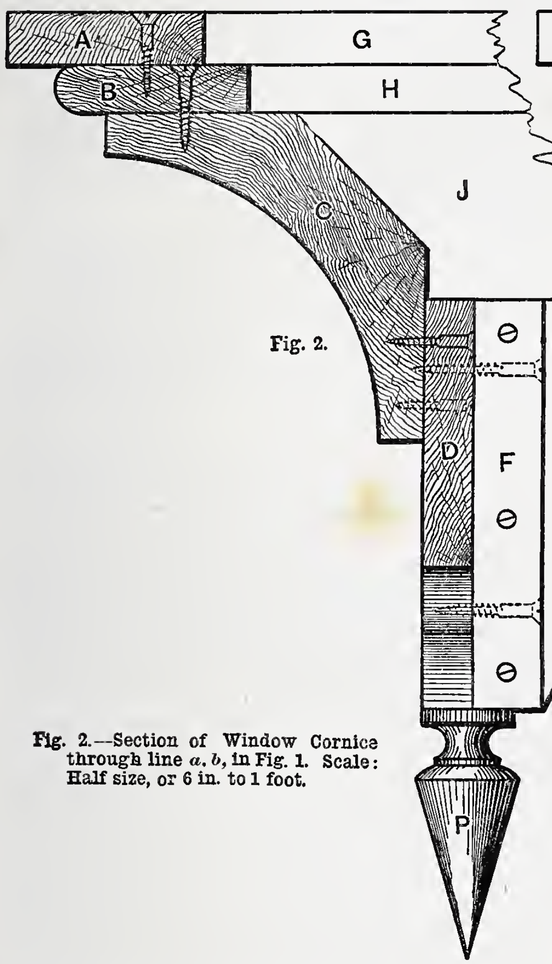

Fig. 2.

Fig. 2.—Section of Window Cornice through line *a*, *b*, in Fig. 1. Scale: Half size, or 6 in. to 1 foot.

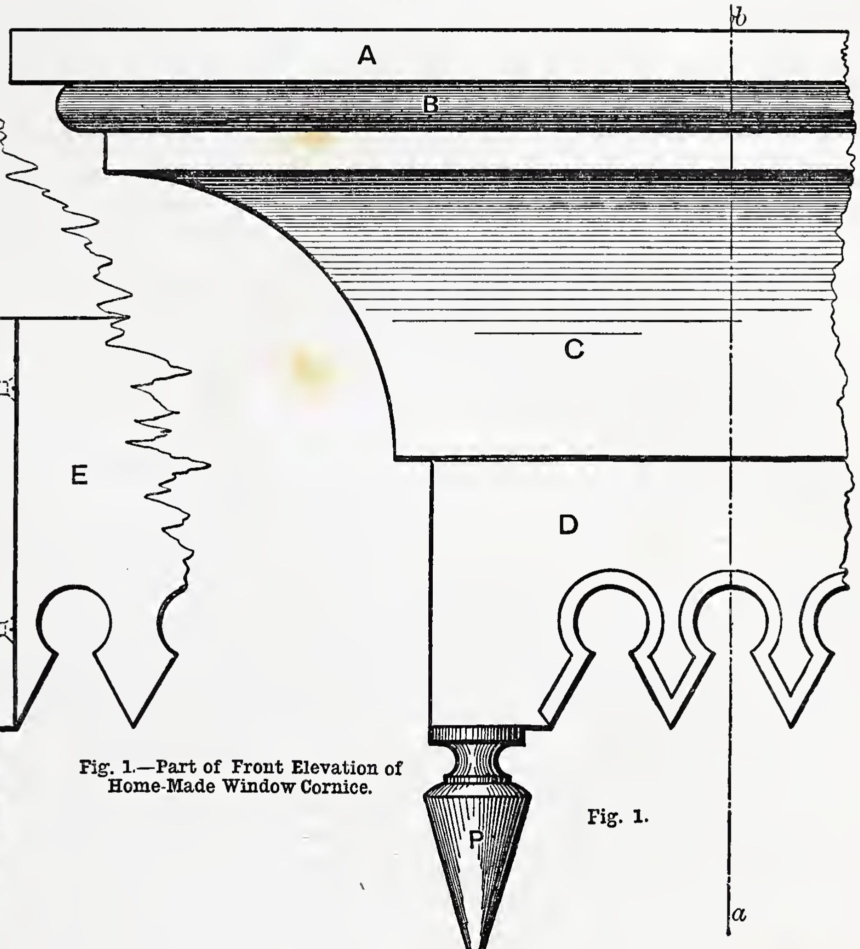

Fig. 1.

Fig. 1.—Part of Front Elevation of Home-Made Window Cornice.

rosewood, and when sized and varnished it looked almost as well as another which I painted in French grey and gilded the edges of the upper member, upper edge of the hollow moulding, and also a border round the open work in the lower member as indicated in Fig. 2. The inside edges of the open work were painted a warm brown, which might very well have taken the place of the gold leaf on the other parts. The conical portion of the pendants at the corners was also gilded.

I may add that in the case of a long heavy cornice of this description, and especially if it stands out far from the wall, it may be necessary to fit a stay or tie at the centre on the top to assist the supports in carrying heavy curtains or resisting juvenile larks.

In concluding this paper, it is hoped that the instructions therein will be easily understood, and that the matter will be of value to some at least of the *numerous* amateur workmen who read WORK. I am inclined to hope, too, that they will not be without their value to many professional workmen who may find a little job of this kind put into their hands when, perhaps, they may least expect it. If no other advantage accrues to them from the article itself, they will at least be able to show the drawings to any householder who may require a window cornice, and so give them a better idea of how the work will look when done than they could gather from mere words.

TONING PHOTOGRAPHS WITHOUT GOLD.

BY L. IVOR POOLE.

No photographer need be told that the recognised chemical for toning photographs is chloride of gold. Turn to whatever formula we may for the preparation of a toning solution we find that this in 15 grain quantity is the main ingredient. Those who are well up in the art may be aware that platinum, or rather some salt of this metal, may be used instead, but it seems to be regarded rather as a scientific curiosity than within the range of practical photography. So far as cost is concerned platinum compared with gold may be said to be out of the frying-pan into the fire. It must be admitted that the toning bath is an expensive item in the photographer's requirements.

Then again there is the liability to which it is constantly exposed of destruction by contact with hypo. If we have not practically experienced this through some temporary carelessness or slovenliness in handling our chemicals, most of us have, in our preliminary reading or teaching, been almost nauseated with the oft-repeated caution that the "smallest trace of hypo," etc. We all know how it runs. Further, there are in toning two operations involved, not to mention the intermediate washing between toning and fixing. If one can be made to answer it would be more convenient.

Now I don't profess to be well up in photography, but merely an amateur among many who are both better operators and more scientific in their aims. I know the general run of things and the difficulties which beset people like myself in riding their hobby. It was therefore with some surprise that I heard one day of something neither gold nor platinum which would do as a basis for toning solutions, and that by the use of this, to me then unknown, stuff, (as a toning medium) toning and fixing might be done together. Of course it is known that a combined toning and fixing bath may be prepared even when gold is used, but so far as I was concerned, the notion that common acetate or sugar of lead might be substituted for chloride of gold was an altogether new and welcome idea. As a matter of fact it was known in the early days of photography, but from inquiry among friends I am convinced that it has been so far forgotten that to the host of amateurs whom dry plates have produced acetate of lead as a toner will be regarded as a novelty. I don't want to affirm that it is as good a toner as gold, although a varied range of tone can be got with it; and, speaking for myself, I have no fault to find with it, but it may be said that few will object to be told about it. The knowledge may be convenient occasionally, and possibly those who have leisure to experiment may be able to improve its powers and produce better results with it than in former times. That prints toned with it and fixed with hypo at the same time are at least as permanent as those treated in the ordinary way, can be shown. My own trials have certainly not been sufficiently extended to enable me to vouch for this personally, but I am credibly informed that a local photographer, one of the pioneers in the art, has some prints which are now as vivid as when they were made some thirty years ago. To him, indirectly, I am indebted for the formula which was given me thus: Acetate of lead, ½ oz., hypo, 4 oz., dissolved in 1 pint water, and mixed. Simple and cheap enough, surely.

The best way to prepare the combined toning and fixing bath seems to be as follows: Dissolve the chemicals separately in about half the water to each. Warm water is best for the lead. Then mix, being careful to pour the lead solution into the hypo, and not the reverse. The mixture is then ready for use. The prints are washed in the ordinary way, and treated exactly as if the gold toning bath were being used. Almost immediately, owing to the hypo acting more rapidly than the lead, the prints will assume the peculiar colour caused by hypo alone, but they will gradually "tone" down through the various shades of chocolate to purplish-black or grey. The time required is a good deal longer than with the gold toning bath I use, but not so long as first toning, then washing, and finally fixing. As the formula given is very strong, comparatively, in hypo, which seems to act on the print the whole time simultaneously with the lead, it stands to reason that the photograph must be deeply printed to allow for the prolonged action of the hypo; and I may say that lately I have been trying the effect with half the quantity, viz., 2 oz. of hypo to ½ oz. of the acetate, with improved results. With the smaller quantity of hypo the reducing action of the bath is not so vigorous, and consequently the toning may be prolonged without detriment to the print.

The solution may be used over and over again till the lead is exhausted. I am not, however, prepared to say that it will keep indefinitely, for even if not used it seems to lose strength for toning purposes. It will, however, keep for a considerable time, and by having the solutions in separate bottles and mixing them when necessary for use, the bath can always be kept up to toning strength.

It will, I hope, be remembered that these notes are not written with any intention of persuading photographers that lead is better than gold for toning. It may or may not be, but it is at any rate an alternative, and a cheap one, obtainable from any chemist at 1d. per ounce—at least, that is what I pay for it. The cost, therefore, need not be an impediment in the way of any one wishing to experiment with this new old toner. Whether the fact of lead being usable instead of gold has ever been published before I know not, but I may say that I have not seen it mentioned in any handbook on photography, of which I have read a good many, and it is certainly not acknowledged among the standard formulæ of the craft. It will not, on that account, however, I trust, be less acceptable to readers of WORK, and if I, as one of many of those who admire this periodical as being unique, may venture on a suggestion, it is that any one who knows of anything useful should not keep it to himself, but send on word about it. Much valuable information can be acquired by this means, even though the subject is not treated from a more scientific standpoint than these few hints on lead toning.

NOTES FOR ELECTRO-PLATERS.

BY GEORGE EDWINSON BONNEY.

III.—AMALGAM—AMALGAMATION: AMALGAMATE—AMALGAMATING SALT—AMMONIA—AMMONIUM—AMMONIUM CARBONATE—AMMONIUM CHLORIDE—AMMONIUM NITRATE—AMMONIUM SULPHATE.

Amalgam.—When mercury is alloyed with another metal the mixture is named an amalgam. For details relating to amalgam, see under head of *Mercury.*

Amalgamation: Amalgamate.—To combine mercury with other metals. The process of amalgamation is carried on in gold mining, where the fine gold dust is caught in troughs filled with mercury, and this metal afterwards recovered from the amalgam by distillation. The word is generally applied by electro-platers to the process of covering zinc battery plates, cylinders, and rods with mercury preparatory to their use, for the purpose of protecting their surfaces from the action of the exciting solutions when the battery is at rest. The process of amalgamating zinc is, briefly—first clean the zinc from all traces of grease and dirt; next dip the zinc in a bath of mercury, and rub this metal well into the surface of the zinc; lastly, set the zinc in an inclined position over a vessel and drain off excess mercury. Now for the details. Zinc, as it comes from the maker of plates, rods, or cylinders, is often coated with some lubricant, such as grease, or some greasy substance. This may be proved by trying to coat it with mercury, when patches will be found to refuse the mercury. Even if we try to cleanse it with acid the patches remain obstinate. The zinc must first be cleansed in a hot solution of some alkali, such as potash or soda. Next wash in clean water. In the next part of the process, the zincs are pickled in acid and dipped in the bath of mercury. The acid pickle may be made of dilute hydrochloric acid, but I do not advise its use, for it gives off an abominable stench of hydrogen and chlorine. I prefer an acid pickle of one part sulphuric acid in three parts of water. This is mixed in a stoneware or good earthenware baking dish, and the bottom of the dish is covered with a layer of mercury. Plunge the zincs in the acid mixture whilst still hot, and they will take the mercury more readily than when the acid mixture is cold. Brush the mercury well over every part of the zincs, on all sides alike, using for the purpose a plate brush, a hare's foot, or a pad of flannel on a stick. If some fine copper or brass wires are introduced among the hairs of the brush, or in the flannel, the process of amalgamation is much facilitated. When the zincs are well coated, set them in an inclined position over a battery cell or other vessel to drain off the superfluous mercury. In amalgamating zincs be careful in the use of sulphuric acid, as its action is very corrosive on skin and clothes. Do the work carefully, without any fuss or haste, or splashing about, and then no harm will result. The zincs will probably get uncomfortably warm, but will not scald the fingers if their position is shifted a little. Brush the zincs downward toward the dish, and away from the person. Do not be afraid to handle the amalgamated zincs firmly, for the mercury will do no harm to the fingers. In reamalgamating zincs it is not necessary to use such strong acid mixture unless the zincs have got black from disuse.

Amalgamating Salt. — French: *Sel à Amalgamer.*—Various devices for lessening the labour of reamalgamation of zincs have been devised from time to time. It has been proposed to cast zinc with a small quantity of mercury added at the time of casting. This has not been attended with any practical benefit. The simple plan of putting a little mercury in the cell with the zinc when the cell is charged very much lessens the labour attending reamalgamation. In a book on electro-plating and gilding, by M. A. Roseleur, an amalgamating salt of mercury is mentioned as a means to lessen the labour of reamalgamation. This salt is made in the following manner:—Prepare a strong solution of nitrate of mercury, boil this for half an hour in a porcelain capsule, and add, whilst boiling, equal parts of bisulphate and bichloride of mercury in excess. Allow the liquid to cool, then filter it through a piece of linen or calico. A wine-glassful of this liquid is mixed with the acid mixture to be used in a quart Bunsen or Grove cell, and this will serve to amalgamate the zinc whilst the battery is working. A table-spoonful of the liquid added to each cell just when the battery appears to flag after a day's work will revive its energies, and the zincs will brush up as if newly amalgamated. This liquid salt of mercury is slightly tinged with green, but otherwise clear. It is very heavy, and very poisonous. It stains the skin a violet tint. When added to water alone, it falls as a yellow precipitate, but if the water is acidulated with sulphuric acid no such precipitate occurs.

Ammonia.—Chemical symbol, NH_3, combining weight 17, density 8·5. It will be seen that ammonia is a compound of nitrogen and hydrogen. It is obtained from the decomposition of animal or vegetable matter containing nitrogen and hydrogen, as from the horns, hides, and excrement of animals, and from coal when heated. Its name is derived from sal-ammoniac, a compound of ammonia and chlorine, obtained by Arabs from camels' dung, which they heated for the purpose near the temple of Jupiter Ammon, in the deserts of Libya. It is now mainly obtained from the ammoniacal liquors of gasworks.

Pure ammonia is a colourless gas of powerful and pungent odour, much lighter than air. This gas is soluble in water, and its solution is known as the ammonia (*liquor ammoniæ fortissimi*) sold in druggists' shops. In all operations wherein ammonia forms an ingredient, this is the solution intended, unless otherwise specified. Its action is distinctly and strongly alkaline. Its presence in solution is generally indicated by its odour, which is unmistakable. A very dilute solution of copper will indicate the presence of ammonia, unless cyanide of potassium is present in one of the solutions. Some very dangerous explosive compounds can be made by mixing ammonia with solutions of the noble metals. (See *Fulminates.*) The strong fumes of ammonia act as a poison by producing violent inflammation of the air passages and the mucous lining of the throat and stomach. The antidotes to this poison are dilute vinegar and olive oil. Ammonia must be kept in glass-stoppered bottles, with the stopper tied down.

Ammonium. — Chemical symbol, NH_4. This is supposed to be a metal, but it has not yet been obtained in a free state. It has been separated from ammonium chloride and made to form an amalgam with mercury, but this soon decomposes into ammonia, hydrogen, and mercury. It forms the base of several valuable salts of ammonium.

Ammonium Carbonate.—Chemical symbol $(NH_4)_2\ CO_3$. This is a compound of ammonium, carbon, and oxygen, obtained by heating a mixture of chalk and sal-ammoniac, and is named *sal-volatile.* On exposure to the air this absorbs water and carbonic acid gas, and becomes ammonium bicarbonate. This is, probably, the white crumbling salt obtained from shops under the name of carbonate of ammonia. It is used as a substitute for liquor ammonia in the preparation of some depositing solutions. It should always be kept in closely-stoppered bottles, or it will lose its most valuable properties.

Ammonium Chloride.—Chemical symbol, $NH_4\ Cl$. Named also, *muriate of ammonia* and *sal-ammoniac.* This compound of ammonium and chlorine is obtained by neutralising the distilled ammoniacal liquor of gasworks with hydrochloric acid, and evaporating the liquid to dryness. It is also prepared from a mixture of ammonium sulphate and common salt. Sal-ammoniac, when heated, completely volatilises without melting. It is very soluble in water, to which it communicates intense cold whilst dissolving. Its solution is used as an excitant in the zinc compartment of electric bell batteries, notably the Lèclanchè battery. It has also been used in making up solutions for electro-depositing iron and cobalt. For these purposes the crushed commercial sal-ammoniac will do very well.

Ammonium Nitrate. — $NH_4\ NO_3$. This is prepared by neutralising ammonia with nitric acid. It crystallises in long transparent elastic needles, very soluble in water. Used in making up Brunel's, De Salzede's, and Walenn's hot brassing solutions.

Ammonium Sulphate.—$(NH_4)_2\ SO_4$. This useful salt of ammonium is prepared on a large scale for commercial purposes by adding sulphuric acid to gas water, the liquor of gasworks. Used in making up the double sulphate of nickel and ammonium solution, and also in the make-up of Jacobi and Klein's and Boettger's iron solutions, Hermann's zinc solution, Walenn's hot brassing solutions, and the double sulphate of cobalt and ammonium depositing solution. The salts of ammonium may be recognised by their odour when heated with caustic lime, caustic soda, or caustic potash; the odour of ammonia being characteristic and well known.

(*To be continued.*)

PAPIER-MÂCHÉ.

How to Mould It, and how to Ornament It.

BY SYLVANUS WARD.

II.—CONSTRUCTION (*continued*). — PAPIER-MÂCHÉ IN CABINET WORK—WORKING IN PULP—A BRACKET—A DAVENPORT—PAPIER-MÂCHÉ AS A SUBSTITUTE FOR CARVING—ELIZABETHAN PANEL WORK — SIMPLER ARTICLES — TEA-TRAYS, ETC.

IN the present paper it may be well to explain the construction of more important articles than those mentioned in the last, and such as, together with moulding, combine a considerable amount of joinery work.

There are certain purposes in cabinet making for which papier-mâché has advantages over wood.

1st. It is lighter, because in many cases thinner work can be used without any sacrifice of strength.

2nd. In it all kinds of *curved* surfaces can be made as strong and as easily as plane ones.

3rd. It is more suited to fret work on a large scale, because as there is no grain there is no danger of splitting. Hence very large curves may be fearlessly cut in it with the bow saw.

It can, moreover, when required, be made equal, if not superior, to wood in a solid mass; as, for instance, say, in the pillar of a table. The shell formed by moulding, or by gluing panel together, can be filled up with pulp; so much strength as would be thus attained is, however, rarely needed.

As regards *pulp.*—The Swedish wood-fibre pulp is now much used. Paper pulp is made by beating up scrap paper with water till it is thoroughly disintegrated; then squeezing out the superfluous water and mixing it up with strong glue-paste to the consistency of mortar. This can be pressed in moulds, or built up and shaped with a spatula to any desired form; but in the latter case a little only can be done at a time between repeated dryings. When only a small quantity of pulp is wanted, a mixture of glue-paste with the paper-dust formed in rasping, sawing, and otherwise working the papier-mâché, will suffice. In Fig. 6 is shown the spatula, or small trowel used for working in pulp.

The *bracket* (of which Fig. 7 is a front, Fig. 8 a side elevation, and Fig. 9 a plan of shelf) may most easily be made in two pieces, exclusive of the acorn pendant, which will form a third. The back is sawn from panel, say, two ¼ in. thicknesses glued together. The trefoil may eventually be fitted with mirror, or left open, as preferred. The projecting portion is pasted in one piece on a model, but some little after-dressing is required to bring up the mouldings clearly and well. The back in the lower part passes within the mouldings, which are a comparatively thin shell, to give the necessary strength. The acorn pendant will be most readily turned in wood, and formed with a little stalk to its cup, to be glued into a hole made to receive it. Possibly this bracket, especially in its lower part, may give the impression of being somewhat heavy, but this will not appear when after enrichments of gold and pearl have been added.

Figs. 10 and 11 give front and end views of a "Davenport" writing table. Of this article the most important and elaborate parts as regards our present business—construction—are the legs. These should be an inch in thickness—that is, they should consist of four thicknesses of ¼-in. panel glued together. These are cut out to pattern with the bow saw, and finished with rasp, sand paper, etc., as if in wood. At *a*, Fig. 11, is indicated a groove cut on the inner side of each leg, a quarter of an inch deep, to receive the end of the ornamental cross rail which connects them.

This ornamental rail, shown in the front elevation, will be seen to be of fret work, designed with a lightness and boldness which the danger of splitting would render impracticable in wood. A less stout panel is used for this, say $\frac{3}{4}$ in. thick.

Still thinner panel will be used above in the desk portion, of which it needs only to be said that it is made in precisely the same way as if the material were wood. In the interior fittings of drawers and compartments, some economy of space may be effected by the use of papier-mâché, as very thin panel, say $\frac{1}{8}$ in. thick, will suffice. The desk will be screwed down upon the legs after both it and they have been decorated.

In making such an article as the present, a considerable quantity of panel will have to be planed. This can only be properly done with a toothed plane, as the tendency of an ordinary smooth plane is to tear up the sheets of paper in flakes, rather than to reduce the surface to a true level.

Where there is a considerable amount of joinery work, as in many parts of the article before us, it is well, previous to gluing together, to give the material a coat of the black japan varnish (of which more presently), which, after drying, should to a great extent be scraped off again with a chisel worked backwards. This last operation removes any glossiness of surface which might have interfered with gluing; and the varnish hardens the papier-mâché, and prepares it for future treatment. After this, the little compartments within the desk will need only one coat of the varnish subsequent to putting together, and that will have in some measure to be scraped off as above, in case they are finished, as they will most likely be, by papering with some kind of ornamental paper. When also silk or velvet is used to line or mount, the surface of the varnish has in the same way to be scraped off before it is glued down.

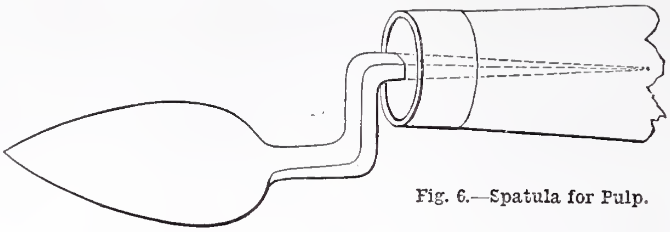

Fig. 6.—Spatula for Pulp.

All joinery work should, however, be done before the final coat of japan varnish is given to any outer part, since it is next to impossible to cut the hard and highly polished japanned work without chipping the edges.

The ball feet and the acorn pendants are, of course, made separately. Such things are usually turned from wood—American birch wood by preference. It is true that in wood it is not possible to get a surface equal to papier-mâché, but the ball feet are much below the eye, and not being highly ornamental, they will escape any particular scrutiny; whilst the small size and rounded form of the pendants will also, to some extent, exempt them from close observation. The inferior material is held to be sufficient; though there is no reason why the pendants, if of no great size, should not be turned from paper; or if large, why they should not be pasted on models. The ball feet are fixed in place with screws; the acorns end above in little stalks, which are glued into holes bored to receive them.

To the worker of artistic tastes all these instructions for the merely constructive part of the art will doubtless seem tedious; for the effect of the work in the articles hitherto spoken of almost wholly depends on the after decoration, about which we have not as yet touched, but which will be fully dealt with farther on.

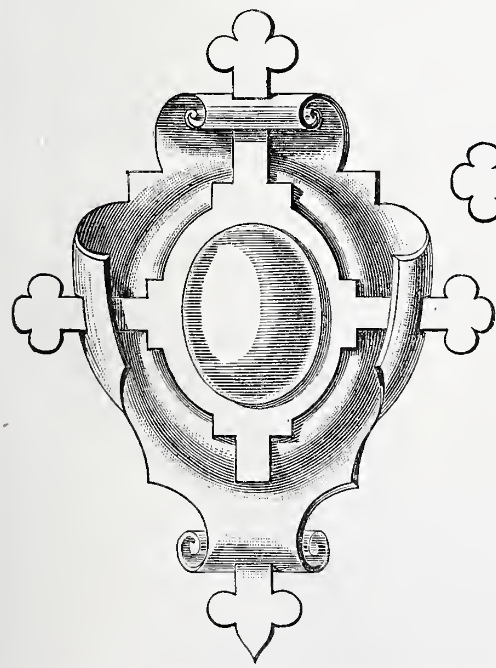

Fig. 12.—Elizabethan Centre Ornament in Papier-Mâché.

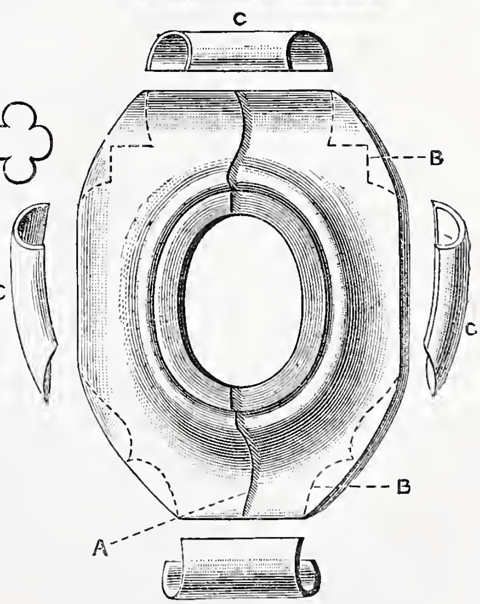

Fig. 13.—Parts of which Fig. 12 is composed.

There are, of course, ways in which papier-mâché is made decorative by form alone. Many architectural ornaments for interior work are now made of pulp (shaped in moulds) instead of plaster of Paris, over which this material has an advantage as being less liable to break or chip. Such things scarcely come into our province; but something in the way of ornament is to be done by modelling pulp with the spatula, as well as by pasting on the model. For house decoration papier-mâché may be made to serve as a cheap and easy substitute for wood carving, especially in the production of the style of ornament known as Elizabethan.

The chief characteristic of this style is the manner in which the extremities of its shields or cartouches are bent, rolled up, pierced, and interlaced with other members of the composition, to an extent which induces the conclusion that they must have had their origin in ornaments cut in leather, or some such pliant material, and afterwards curled and arranged in this fantastic fashion. Yet by whatever it may have been suggested, there is no question but that such ornament, when carved in wood or stone, is highly pleasing from its richness and variety.

But to carve it is laborious and costly, as must have been felt even in the Elizabethan age; for in an elaborate house of the period with which the writer is acquainted, the decorator has formed his shields, scrolls, etc., of sheet lead, rolled and interlaced in the usual manner. These are nailed to the oaken panels, and painted so as to make them look, as far as possible, a part of them.

A later decorator, having a like object in view, would have made his ornaments of plaster, which would speedily have chipped and exposed the deception. The lead has not chipped, but it has bent, and become indented wherever it has received a blow, and thus betrays itself; besides, there is a certain thinness and meagreness about it which to a practised eye at once distinguishes it from wood carving.

Yet the idea of producing a rich effect by inexpensive means was a good one; and had the decorator been acquainted with papier-mâché he might have made a complete and enduring success. His enrichments would then have been strong and rigid; they would neither have chipped like plaster, nor bent like lead, and would have been less liable to suffer from accidents than oak itself.

Fig. 12 is an Elizabethan enrichment which might serve as the centre of a panel, either on a large scale in a panelled room, or on a smaller one in cabinet work. The models for pasting once made, it can be reproduced to any desired extent.

It will be seen that it consists of three members—the cartouch, the cross, and the carbuncle or rounded centre. Each of these will have to be made separately. For the cartouch the models are drawn in Fig. 13. The comparative projection of its parts is shown by the sectional line, A. The main portion is first pasted, cut from the model, and sawn to shape as at the dotted lines, B, B, and partly dressed. The curved portion, C, C, pasted on separate models, can be glued on; and the rolls at top and bottom completed by gluing on additional strips of panel and giving the little shaping necessary with chisel and gouge. The cartouch can then be dressed altogether as described above.

Fig. 14 shows the cross, which is cut from flat panel. The dotted lines at D, D, indicate where parts of the limbs are cut out, and it is so fitted to the projections of the cartouch as to give the effect of piercing through them. Pieces of thicker panel will need gluing behind the ends to bring their backs level with the general plane of the back of the cartouch; and between the cross and the cartouch, where it does not touch, the spaces can be filled in with the paper-dust mixture.

The carbuncle requires a separate model. This is turned simply to an oval. The paper shell is sawn, when pasted, down the longest diameter of this oval, and thus two carbuncles are formed at a time. The carbuncle is, like the cross, glued into its place.

When finished, this piece of ornament may be fixed to the panel either simply by gluing, or better, by fancy-headed screws, or by common screws the heads of which are sunk and concealed. It should not, like papier-mâché in general, be coated with the ordinary black japan varnish, but should be painted with the panel so that both may appear one piece.

The above examples have rather been chosen as showing how for certain purposes papier-mâché possesses advantages over wood; and as also showing how the difficulties which may arise in working it are best to be overcome. But the variety of articles suited to, and ordinarily made in, papier-mâché, in which the construction is so simple as to need little or no explanation, is very considerable; and on some of these the beginner may, perhaps, rather choose to exercise his skill. Instance, for example, all the variations of what we may call the saucer-form: trays for smokers, for pins, for pens, for pools at round games, etc. etc., which can be made of many shapes, more or less ornate, by pasting on one model only, as may be seen in Figs. 15, 16, 17, and 18 (15 and 16 are two different views of the same tray). Or such articles as are made by a simple combination of pieces of panel—flat brackets, pipe racks, card and letter racks, etc. Figs. 19 and 20 show a card rack thus made.

Whilst speaking of such simple matters some mention ought to be made of a class of articles for which, perhaps, more than for any others, papier-mâché has been employed, namely, for tea and other flat trays. In making a tea-tray the rim is pasted, in a single piece, on a model which, if large, is necessarily somewhat cumbrous, since it has to be a sort of wooden frame, strengthened with cross pieces. The bottom of the tray is of flat panel, glued to this rim.

Almost all articles of furniture may be, and in the days when papier-mâché was a fashion have been, made of this material; and these admit of an amount of surface enrichment which would not be attempted on wood. Perhaps it has been most successfully used in small tables; chess tables especially. The alternating squares in pearl and black, tastefully ornamented, may often be works in papier-mâché that leave nothing to be desired.

While I am writing of furniture made of papier-mâché I may as well take the opportunity to point out that many things much in request in the present day may be easily and successfully made in this material. For example, nothing is easier and more simple than with a core of wood, on which to paste the sheets of paper, to imitate one of the Japanese umbrella stands, as a counterfeit of which many are content to use earthenware drain pipes, painted and otherwise ornamented to suit their fancy. The paper stand, to my mind, would be infinitely preferable.

Fig. 21 gives a form of rasp very useful in papier-mâché for working in hollows.

(*To be continued.*)

"TIPS" FOR TYROS.

BY OPIFEX.

5.—FIXING TRANSFERS FOR CARBON PAPER.

THOSE who use carbon paper for transferring designs, and for the other various uses to which it is put, often find that when freshly made the transfers, etc., are very liable to get "smudged" and spoiled. This evil may be avoided by sprinkling French chalk upon the transfer, rubbing over with the hand, and then dusting off the chalk.

Transfers upon brass for *repoussé* work treated thus will even stand the process of "pitching" without being obliterated.

6.—MUZZLE FOR FERRETS.

Should any of our mechanical friends be of a sporting tendency, it may be useful to them to know how the best kind of ferret muzzle may be made.

Chuck a piece of beech, 3 in. diameter by 4 in.; turn it into a conical shape, and then turn off the point right across, until the diameter of the face is an inch. Now take a piece of sheet brass No. 22 gauge, B. W. G., or about $\frac{1}{32}$ in. thick, and mark out with a compass a disc 2 in. diameter. Place and centre it upon the face of the chuck, fastening it thereto securely with strong tacks, or by a screw arrangement; when perfectly secure spin it rapidly and, using oil freely, apply a smooth, blunt tool to the brass, commencing at the shoulder of the cone, and applying considerable pressure. Work out gradually to the circumference of the disc; in this way the metal will assume the shape of the chuck, and when it is sufficiently bent, a band about $\frac{3}{16}$ in. wide may be cut with a sharp-pointed, graver-shaped tool.

This band constitutes the muzzle, and the size will, of course, depend upon the size of the animal for which it is intended.

Having smoothed the edges of the brass with file and emery cloth, drill two holes at the opposite sides, so that the line between the holes shall divide the diameter of the circle one-third of its length from the circumference. Between these holes a small rod of iron wire is to pass; this rod has an "eye" turned upon one end, while the other is passed through a small screw plate. Next "tap" one hole to suit this screw, and rime out the other so that the wire may pass through it.

When the muzzle is placed upon the ferret, this wire rod is inserted behind its long canine teeth, and screwed up, which effectually prevents the animal laying hold of its prey, while it does not otherwise interfere with its comfort in the slightest.

LATHES AND TURNING APPLIANCES.

BY F. A. M.

III.—THE OVERHEAD MOTION.

OVERHEADS—AMBITION OF AMATEUR WORKMEN—OBJECT OF PRESENT PAPER—ADDITIONS TO PLAIN LATHE—RESULT OF WORK DONE IN PLAIN LATHE—REVOLVING TOOL IN SLIDE REST—ITS ACTION—DRILLING SPINDLES IN PLAIN LATHE—CYLINDRICAL WORK—FACE WORK—FACE PLATE—HOLTZAPFFEL'S OVERHEAD—MILNES' OVERHEAD—EVANS'S OVERHEAD—BIRCH AND COMPANY'S OVERHEAD.

HAVING considered with my readers the most desirable mode of procedure to be followed, both in choosing a lathe and testing a lathe, we may now pass on to consider some of the appliances that have been added to the ordinary plain lathe, in order to enable the turner to produce turned work of an ornamental character.

In the present paper I propose to give some account of several of the best forms of "overheads," as the overhead motions of turning lathes are often called, to point out their advantages and disadvantages, and to conclude by giving drawings and description of a simple form of overhead which our readers will probably be able to make, in part at any rate, and add to their lathes.

Amateur workmen take much more pleasure in contriving and inventing an arrangement for themselves which they fondly suppose will surpass those contrivances which are the result of the accumulated experience of many workmen and designers who make a life study of their work. If professional workmen proceeded in the same way, they, too, would meet with almost as many failures as the amateur. Instead of doing this, the professional will set before him some tried scheme known to answer its purpose well; and, copying that, will not deviate from it until he finds by experience that it has defects which he sees he can remedy.

While not desiring that our readers should follow in a slavish way what has been done by others, even though it might be by far the safer road to success, yet we may at any rate press upon them the necessity for making themselves acquainted with what has been done by others, before attempting to strike out an independent path for themselves. The following descriptions are intended to help them to do this, and to form a foundation on which they can build constructions less likely to prove disappointing, and also to enable them to choose which of the several plans to be described will be most likely to suit their own particular circumstances.

The first addition to the plain lathe will be the slide rest; then comes the division plate and index; and then the overhead motion. Leaving the division plate for a future paper, let us now consider the overhead, an extremely useful addition for metal and ornamental work, and one which an amateur may make, in great part, for himself.

When the work is revolved in the plain lathe and cut by fixed tools held either in the hand or in the slide rest, the result is naturally of circular section. But if, while the work is firmly held in the lathe as before, instead of revolving the work we rotate *the tool*, and, while so rotating, we bring it up to act upon the work, we can then produce an infinite variety of different forms. Now, the revolving tool may be a drill or a single-point "flying" cutter, or it may be a serrated disc, something like a small circular saw called a milling cutter; all these are carried by "frames," in which they revolve, which frames are grasped and held and guided by the slide rest. From this explanation it will be seen why all these different appliances depend one upon another, and that the overhead is of no use without the slide rest and division plate; and only when the turner is provided with these three can he go on to add the drilling instrument, vertical, horizontal, universal, eccentric-cutting frames, and other instruments used in connection therewith. All these revolving tools being held in the slide rest, require to be set in motion from the treadle and fly wheel, and this is the peculiar office of the overhead motion; it should be noted, however, that the revolving tools do not remain in one fixed position like the mandrel, but they must be capable of being applied to their work in several positions, and must be capable of being moved whilst at work without throwing off the band or cord by which they are driven.

Let Fig. 1 be the plan of a lathe bed, with headstock and chuck in position; then *a*, *b*, *c*, and *d* are four different positions, which a drilling spindle might be required to occupy whilst its pulley is being driven by the band from the overhead. For instance, suppose Fig. 2 were placed upon the mandrel; here we have the base of a column to be fluted; we require for this a drill with a rounded end fixed in the drilling spindle, which must then be approached by one screw of the slide rest till it cuts into the work to the proper depth, and then by the other screw of the rest it must be slowly traversed to the right, as from *a* to *b*, while rapidly revolving all the while, so as to cut out each of the flutes. The band then must lead down to the pulley of the drilling spindle and drive it in position *a*, and also in position *b* about 12 in. from it; also in any intermediate position between the two; and it must allow of the driller being withdrawn from the centres backwards towards the workman at least 3 in., as would be required if it were operating upon a larger diameter. It might also be necessary to traverse the driller still further to the right, say 2 or 3 feet; this is provided for in some "overheads," but is rarely required.

Besides cylindrical work, such as is shown in Fig. 2, we require to do "face work," such as that shown at Fig. 3. Fig. 3 may represent a face plate, requiring to have a long hole made in it by slot drilling—that is, by a drill made so that it will not only bore a round hole while being pressed forwards, but also cut while it is slowly traversed sideways, much after the manner of the fluting drill in the preceding example. This necessitates positions *c* and *d* (Fig. 1), which positions, like *a* and *b*, are also liable to a variation of several inches, endways of the drilling spindle, according to the length or overhang of the work.

Many other positions may be required, but if the overhead will guide the band fairly to the pulley of a driller in these four positions, it will also act satisfactorily in any other position that is likely to be required.

Fig. 4 shows the kind of overhead which is made by Messrs. Holtzapffel, of 64, Charing Cross, who are considered the first makers of ornamental turning apparatus, as they are also the most expensive. The drawing is taken from the most excellent book on ornamental turning, which forms the fifth volume of their work, "Turning and Mechanical Manipulation;" the headstock and lathe bed have, however, been added, for clearness' sake, in their relative position beneath the overhead. The apparatus consists, first of a shaft or spindle, *s s*, about 22 in. long and $\frac{5}{8}$ in. diameter, carrying at the left-hand end a small stepped pulley, by means of which motion is communicated to the spindle from the fly wheel of the lathe by a catgut band; the rest of the spindle is occupied by a roller of about 4 in. diameter, lightly made of wood, and mounted on the spindle by means of brass ferrules, one at each end. The spindle runs on points carried by a bent bar, *b b*, which bar is hung by adjusting screws to the ends of a spring supported by its middle by a tall iron bar, *a a*, bent over at the top, and fixed to a second upright, *c c*, which is supported by the bracket, *d*, on the left end of the lathe bed, whilst the socket, *f*, holds the lower end steady. Thus the upright is formed of two pieces, *a a*, *c c*. It is grasped by the screw of the bracket, *d*, so that while it can turn in *d* and *f* it cannot rattle or shake. To bring the roller over the pulleys of the drilling spindle at positions *a* and *b* (Fig. 1), the top of *a a*, where it carries the spring, would be pulled forward so that the band would run straight down, being twisted one quarter round. As the drilling spindle traversed from *a* to *b* (Fig. 1) the band would travel of its own accord along the barrel or roller.

The positions *c* and *d* (Fig. 1) present no difficulty, and here the band has no quarter twist. The tension of the bands is regulated by the milled headed screws at each end of the spring. The spindle, *s s*, is adjusted fairly horizontal by regulating the length of the shorter band; and, for some of the less used instruments, it is necessary to have separate bands of slightly different lengths. This and the fact that one cannot act upon long work reaching more than a foot from the mandrel are the only and slight disadvantages of this excellent arrangement. Its chief and very important advantage is that it runs more easily than any other kind of overhead, its only friction being that at the ends of the spindle, *s s*, where it runs on points. Two lesser advantages are that the oil is not so liable to be sprinkled upon the work from the ends of the spindle, *s s*, as from the guide pulleys employed in many other forms of overhead, and that the interposition of the spring between the spindle and the upright, besides keeping up the requisite tension, absorbs any tremor that might otherwise have been communicated to the lathe bed. This form of overhead is often called "the goose-neck."

Fig. 5 shows the arrangement adopted by several makers. The illustration is copied from a woodcut of a lathe by Milnes, of Bradford. The overhead shaft carries a long roller which makes the overhead effective upon any part of the lathe bed, an advantage not possessed by the last example. The overhead shaft is not capable of being drawn up by a spring to tighten the belt, and therefore some other plan must be found for regulating the tension. Upon the stay bar, *b b*, slides a socket, *s*, which is bored through transversely so as to take a small bar, *c*. One end of this bar carries an adjustable spherical weight, and in a fork at the other end runs a small pulley. The bar swings on the stay bar so that the weight bears up the pulley against the band, giving it the proper direction and regulating the tension. The danger here is that the oil applied to the small pulley should fly upon the workman and damage the work with spots, but this is partly obviated by making the pulley with a long and very small boss. It might be still better to cause the little pulley to run on points by driving through it a small spindle, and putting small centres, in the shape of pointed screws, through each side of the fork. Mr. Milnes now prefers to make the roller 10 in. long, to slide on a feather upon the shaft wherever it may be required; also the stepped pulley to the left has been omitted, as it was not found to be of much service.

So long as the drillers, etc., are used in positions *c* and *d* (Fig. 1) this overhead works well; but with the positions *a* and *b* it will be less satisfactory, since, though the band will travel of itself along the drum, the socket, *s*, will have to be pushed by the hand if the driller traverses far.

Coming now to Fig. 6 we find another plan, which but slightly differs from the foregoing. Here the stay bar is uppermost; it carries the weighted lever above it, and the lever carries at its front end *two* pulleys which draw up *both* sides of the driving band, giving an ample allowance for those cutting frames which would have required bands of shorter lengths if driven by the two foregoing examples. But then its second pulley adds slightly to the friction. On the roller shaft is seen a speed pulley, driven from the fly wheel below, and allowing of a variation in the speed: a decided advantage which this form has over the preceding. Mr. J. H. Evans, of Wardour Street, London, makes an overhead motion of this type for his high-class lathes for ornamental turning. The two tightening pulleys are further off than the one pulley of Fig 5, yet the oil may injure work in ivory or white wood.*

Fig. 7 shows a much more elaborate arrangement, by means of which almost all the disadvantages of the former devices are avoided. Except for the extra complication and expense, very little can be said by way of criticism except that the standards are bolted to the lathe-bed and may possibly communicate to it a slight amount of disturbance. The arrangement, however, would only be applied to a rather strong lathe. The particular example illustrated is taken from a photograph of a lathe made by Messrs. G. Birch and Company, of Islington Tool Works, Salford. The lathe to which it is applied is of $5\frac{1}{2}$ in. height of centres; it is suited both for metal work and ornamental turning; it is expensive of necessity, yet not so expensive as some, and it is believed by the present writer to be the most perfect overhead motion mounted upon the best lathe that he has yet seen. This does not prove that it would suit all our readers equally well, nor that all should go to the extra expense involved; some who wish to do ornamental work only, would probably be best suited by the first example given; whilst others who could not afford to buy the overhead under consideration, and yet wished to do long work, would find the example in Fig. 6 cheaper and efficient. Looking at Fig. 7, it will be seen that the spindle, *s s*, which carries the drum is supported by lever arms, *a*, *a*, turning in the forked tops of the uprights. These arms are held up by links, supported by other levers, *b*, *b*, carrying weights, which weights serve not only to support the weight of the spindle and arms, etc., but to put the proper amount of tension upon the band which runs on the drum. The drum, then, is capable of vertical adjustment, and no tension pulleys are required. There are, however, two other centres of motion at the ends of the first motion shaft, *d d*, which shaft receives the motion from the fly wheel upon its speed pulley at the left-hand end, and communicates it to the spindle, *s s*, at its right-hand end, by means of another pair of speed pulleys, so that changes of speed can be made from the fly wheel to *d d*, and from *d d* to *s s*, giving great variety.

(*To be continued.*)

* Since the above was written, Mr. Milnes has adopted the form shown at Fig. 6.

OUR GUIDE TO GOOD THINGS.

29.—New Patent Tool-Cabinet and Work-Bench.

Viewed from a purely utilitarian and economic standpoint, it is difficult to conceive any means or to call to mind any article in which the object in view is attained so completely and thoroughly as it is in the New Patent Tool-Cabinet and Work-Bench which was thought out and patented by the head of the firm of Messrs. Richard Melhuish and Sons, 85 and 87, Fetter Lane, Holborn Circus, E.C., and is now manufactured and supplied by the firm for home use and for export.

When closed, the cabinet has the appearance of a handsome piece of furniture, which might, as far as the eye of the observer can determine, serve various purposes for which drawers are generally required. If measured in each direction as it stands, it will be found to be 3 ft. 6 in. long, 1 ft. 7 in. wide, and 3 ft. high, occupying a space of about 16 cubic feet, not to go too closely into its exact contents. When the top is lifted up, and the doors at the sides are opened, its actual purpose is at once revealed; and the observer, perhaps, will be somewhat astonished to see how much has been accomplished in so small a space.

The top of the cabinet, an illustration of which will be found in our advertisement pages in No. 2 (page 31), is recessed and of sufficient depth, not only to contain a considerable number of tools, but also to cover and hide from view, when it is shut down, the small but convenient work-bench that covers in the drawers below. Within the lid are contained a variety of the smaller tools which are frequently required, and which it is desirable to have immediately within reach. Among these are, as will be noticed, a couple of squares, rule, compasses, wrench, spokeshaves, brace, several bits, gas-pliers, gauges, bradawls, gimlets, and a few useful bits for use in the brace. The larger and heavier tools are contained in the cupboards at the sides—room being found in that on the right for a good panel-saw, tenon-saws, bow-saw, hammers, auger, mitre-box, mallet, screw-driver, rasp, and gauges; while on the other side are packed away various planes and other tools, provision being made even for a glue-pot of handy size. The work-bench, which is very nearly 3 ft. 6 in. long, and 1 ft. 6 in. wide, although not very large, is of sufficient size for all practical purposes; although, for large work, a bench of larger size would have its advantages. It is fitted with a patent bench-stop, and a small but serviceable grip vice, for which provision is made in the interior of the cabinet when it is not in use and is closed. The drawers, which are six in number, are fitted up with partitions, and are thus fitted for the reception of carving tools, and other tools necessary for the prosecution of any kind of work which the owner of the cabinet may adopt as a hobby, besides joinery and cabinet making. Thus, for example, room may be found for appliances for fret cutting, a branch of art wood work which finds favour with a great number of amateurs. Provision is made on the right of the front for a peg, on which to support any board or slip of wood, whose other end is gripped and held in the vice, to allow of its edge being planed up. The whole of the six drawers, the two cupboards, and the top, can be instantly closed up and fastened with one small lock and key; which is of great advantage when the owner, perhaps, is suddenly called away in the midst of his work, and yet wishes to leave his tools secure and in safe keeping. "Safe bind, safe find," runs an old saying; and this is as applicable to tools as to anything else which it is desired to keep out of the way of meddlesome intruders.

The tools which are supplied with the cabinet are specially selected, it should be said, as being the most suitable. All are of the best quality, fully warranted, and of full size; precisely the same, in point of fact, as are supplied to practical workmen.

The price of the cabinet, fitted with tools as shown, and made in walnut wood, is £17. It may be made in plainer material; but there is little, if any, advantage gained in using an inferior wood, especially if the cabinet occupies a conspicuous place in an amateur's own room, in which he is accustomed to do any kind of work that would not be permitted in any other room in the house. There is a special form of the cabinet, made for export, to stand hot climates, with solid brass corners, and all parts dowelled and screwed together. This is of walnut, polished, and costs £22 13s. with tools, or £10 12s. 6d. without tools.

Many officers have a fancy for carpentry and joinery, especially of an ornamental character, but occasionally are required to shift their quarters at very short notice, both at home and abroad; and even to go abroad with very little time for preparation. To such as these, the Tool-Cabinet and Work-Bench will not fail to be a most welcome means of securing the prosecution of their favourite work without much trouble or inconvenience in packing and removal. Many amateurs at home will prize it for almost identical reasons, and perhaps more for the *multum-in-parvo* characteristics of the appliance, which enables much to be done in confined space. Lastly, many a professional workman who is cramped for room at home will be pleased with it, because, although he will not dream of becoming a purchaser, it will show him how he may manage to dispose of his tools within the limits of the work-bench itself, and yet always have them close at hand. And this, I know, is a desideratum to many a workman who seeks to help his family and himself by doing an occasional odd job at home out of hours.

I may add that important modifications are being effected in the cabinet, which will render it more acceptable as a piece of furniture, and more serviceable to wood carvers, artists, draughtsmen, and others. Space forbids me to say more about these modifications at present, but they shall be described at a future time when fully matured.

The Editor.

SHOP:

A Corner for Those who Want to Talk It.

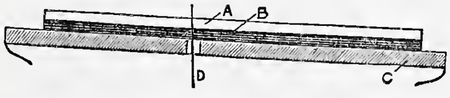
*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

Cost of a Patent.—G. B. B. (*Portsmouth*).—The preliminary expenses of taking out a patent are not very heavy, amounting only to £1 10s., if you yourself take the matter to the Patent Office. If, however, you find it necessary to seek the intervention of an agent, the outlay will be increased, as the agent must, of necessity, be paid for his services. It would not be possible or practicable for us to offer a monthly prize for the best invention out of all that might be submitted to us during each month, the prize to consist of the cost of obtaining provisional protection. Any advice I can give you with regard to your proposed patent is much at your service.

Cutting Rebates with Circular Saw.—C. C. E. writes:—"The circular-saw table should be sloped down towards the operator, about 2 in. below the horizontal, then when raised for cutting rebates, etc., it is not in an awkward position as it would be if made horizontal in its normal position."

Electro-plating and Gilding. — A. W. Y. (*Neasden*).—Instructions on these subjects will be given in Work in due course.

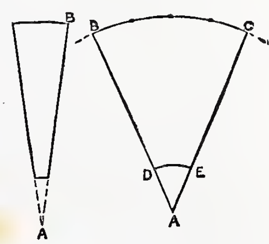
Fret Cutting.—Inlay writes:—"I think it may be useful to some of your readers who are amateur fret workers, and who have fret machines, to know another method of inlaying than the one mentioned by Mr. J. W. Gleeson-White in his article in No. 1



A, White Holly. B, Ebony. C, Tilted Cutting Board. D, Saw.

of Work on 'A Cabinet in Fret Work.' This method has the advantage of being an easy one, and is, at the same time, a sure way of getting a good result. Say that you wish to inlay a piece of white holly into a piece of ebony, the method is this:—Having your woods of the same thickness, you fasten them together by means of a paper between, gummed on both sides, the pattern being on the holly. Then you tilt your cutting table to a slight angle, and cut with a vertical saw, so that the piece to be inlaid is rather larger than the piece below it, which falls out, and the edges are not quite square, but bevelled, as in the annexed diagram. With a slight force the holly (A) can be driven into the ebony at B, and the piece is inlaid. You then divide the pieces of wood by inserting a chisel and splitting the gummed paper. This method does away with any necessity for a back-board, or of filling up with 'glue and sawdust,' and ensures a perfect fit. Neither is there any trouble about fitting the parts, as each is driven into its place before the woods are divided. It will then stand 'papering,' and even planing, if need be. At the same time, it is all done with one cut. I am sending a sample of what I have done in less than three minutes, and I think you will agree with me that the result is fairly successful. There is no glue about it, as you may ascertain by pressing the back, when the inlaid piece will come out; but, of course, glue should be used for anything permanent."—[The specimen sent was admirably cut, and fitted most accurately in every part. Yet inlayers and marquetry cutters often resort to the mode of filling up chinks and misfits as spoken of by Mr. Gleeson-White. It is a difficult matter to determine where the cutting was commenced—so good is the fit.—Ed.]

Scale for Metal Open Diapason.—Amateur.—A fair scale for a chamber organ metal open diapason would be as follows:—C, C, 5 in.; Tenor C, $2\frac{5}{8}$ in.; Middle C, $1\frac{1}{2}$ in.; 1 foot C, $\frac{7}{8}$ in.; 6 in. C, $\frac{5}{8}$ in.; Top G, $\frac{9}{16}$ in. Thickness of metal would vary according to its stiffness; but if C, C, is made of metal about $\frac{1}{16}$-in. thickness, and top, G, about as thick as a visiting card, it will be sufficient. The feet patterns can be cut out as follows: Having decided on the length of the foot—say 12 in. long—draw a section of it full size, as in diagram herewith, and continue the sloping lines down till they meet in the point A. Then take the distance A to B in the compasses, and strike an arc, B, C. The circumference of a circular pipe is $3\frac{1}{7}$ times its diameter, so with the compasses step that distance round the arc, and join the last point thus gained, C, to the point A. Then take the distance from point A to the bottom of the foot, and strike the smaller arc, D, E, and sheet, B, C, D, E, will be the sheet required to form the conical foot of the pipe. This is cut out and turned up on a conical pattern of wood, soldered down the back, and the lip formed by rubbing down on the portion of the cone which has been flattened for the purpose. The lanquid is then soldered in its place and the foot joined on to the body of the pipe.



Handrailing. — Excelsior. — You wish that "some practical reader of Work would explain the difference between the tangent system and the falling rail system of handrailing, and point out the advantages and defects of each, and also advise a young worker as to what books he should study in order to obtain a practical knowledge of this mysterious art." The tangent system was introduced by an American of the name of Riddell, who wrote two or three works on the subject, which were published in this country. To go into a thorough explanation of the method adopted by Mr. Riddell would take up considerable space, and would prove next to useless to you, because his system is faulty, and involves much waste of material. The falling line system is based on Euclid's "Elements of Geometry," which you should study in the first place in order to get a clear perception of the first principles of the art. Without this you cannot understand the method of drawing sections of solids, and unless you attain to a fair comprehension of this you cannot hope to be proficient as a handrailer. To give adequate instruction in such a subject as this, which may be regarded as being one of the most intricate and difficult branches of joinery, requires a series of papers, and I am glad to be able to say that I have obtained from a practical handrailer of nearly forty years' experience a promise to write some articles on the subject in which the falling rail system as practised by himself shall be fully explained for the benefit of yourself and all readers of Work who may be interested in the matter. This writer will prepare models one-fourth size, which may be obtained at small cost, comparatively speaking, and will show practically how handrailing may be executed in the most economical manner, and the least possible expenditure of material, time, and labour. He is prepared, further, to teach the art of handrailing as practised by himself to any young workman who might be able and willing to place himself under his tuition for a short time.

Printing and Lithography.—J. D. (*Perth*).—Both subjects will be treated in due course. Meanwhile, if you and your friends will mention any particular thing connected with either art on which you may be in doubt or difficulty, you shall be helped if it be possible to do so. Do not hesitate to write, for it is earnestly desired to afford help to all who need help.

Carpentry and Joinery. — A. H. S. L.—Arrangements are pending for a complete series of instructions on carpentry, joinery, and cabinet making. I should recommend you to wait for these.

Spots on Mirror.—W. C. T. (*Ardgowan*).—You ask how to remove spots from the back of a mirror, which, you think, have been caused by damp. These spots you describe as "circular with black centres about ¼ in. in diameter shading off to grey." Looking-glasses are silvered with quicksilver and tinfoil, which combine to form a fragile coating easily susceptible of damage. Possibly the spots on your mirror are numerous, and, if so, the best course you can adopt is to have it resilvered. It is said that damage to the silvering of a looking-glass may be repaired by first removing the amalgam from the injured part, and making a wall of beeswax round it to receive some nitrate of silver, which must be poured into the shallow receptacle thus made. The silver must then be precipitated by means of sugar or oil of cloves and spirits of wine. But to do this to every spot would be a troublesome business even if you were successful, so it would be better and easier to resilver the whole plate. Kindly give particulars of the Patent Darning Weaver you mention in your letter.

Telephone.—H. B. O.—Yes; a paper, or papers if necessary, will be given on the telephone and its construction, but it is not possible to do everything at once. If everything was done, or could be done, to-day, there would be nothing left to do to-morrow.

Working Marble and Stone.—DEAN FOREST.—I am not acquainted with any book that is devoted to an exposition of cheap sculpture likely to be useful in grave-stone making. Tools and appliances for cutting and dressing stone may be obtained of most dealers in tools and hardware. They are chiefly saws for cutting blocks into slabs, and mallets and chisels for dressing and cutting letters. If you are a novice seeking to gain some knowledge of the art, any stone mason would tell you what is required for the manipulation of the stone, and how the work is done; but for the higher branches of the art you would have to seek the assistance of the monumental mason, who devotes himself more particularly to this kind of work.

Electricity.—J. G. (*Portsmouth*).—You will find that electric lighting, bell work, and instrument making with sketches and working drawings will form a prominent feature in WORK. A contributor is now at work on a series of articles on Burglar Alarms, showing how to protect the house against the intrusion of burglars in the most simple but most effective manner.

Wire Thread Fret Saws.—B. and S.—As I explained in my notice, these saws are not yet on the market. As soon as they are on sale, the sizes in which they are made, and the prices at which they are sold, will be announced in this Magazine.

Violin Making. — B. and S.—This subject is down for treatment, but there is neither space nor opportunity for going into it immediately. If you require assistance on any special point in connection with violin making, write, and your question shall be submitted to one who is skilled in the business.

Mixing Paints.—F. A. (*Lambeth*).—This will be fully explained in articles bearing on House Painting, and possibly a paper or two may be devoted to this specially describing the mode of procedure to be followed at an earlier date than it would be possible to enter on a consideration of house painting. Moreover, it would be of assistance to many in enabling them to better understand some papers that will appear at no very distant time on a new mode of decorating surfaces with oil colours.

Sheet Metal Working.—W. H. L. (*Crewe*).—An experienced worker in sheet metal is now about to prepare a series of papers on the business in which you are engaged, and they will be commenced as soon as opportunity offers.

Joinery and Cabinet Making for Beginners.—H. D. (*Bury, Lanc.*).—You ask for a series of papers on articles that can be made with about three shillings' worth of tools, and wish me to say what tools it would be best to buy with that money. You continue:—"By small articles I mean those that can be sold at a little profit so as to get more money, and therefore more tools. If you could state what they would cost and what they would sell for, I should be very thankful." I should very much like to hear more about yourself; that is to say, how old you are, and how you are employed, for you are evidently bent on doing the best and utmost you can on a very slight amount of capital. Now, if I am not very much mistaken I think there will be help in store for you, and that some of the readers of WORK, whose eyes light on this, will send you an odd tool or two that they do not want, to help you make up a kit of the most necessary articles. But supposing that nothing of this kind were forthcoming, I should advise you to commence with fret sawing, and buy a bow saw frame and a few saws, a piece of wood, and a simple pattern of a bracket or tray, or some article that is quickly and easily made. You will want nothing in addition to the fret saw beyond a light hammer, a fine bradawl, and a few fine brads or French nails wherewith to fasten the pieces of fret work together. With regard to the price you are to ask for any article that you make, it is difficult to advise you. Things in fret work are sold in fancy goods' shops at prices ranging from sixpence upwards, and supposing at first you were to ask for each article twice as much as the materials cost you, you would get back the cost of the materials, and as much again for labour, and with this you could buy more materials, and, after a bit, more tools, as money begins to gather a little. Always bear in mind that excellent advice or rather injunction, "Despise not the day of small things." Practically you are laying this to heart and acting upon it, and although I am far from being "among the prophets," I dare venture to say that with your spirit, combined with patience and perseverance, you cannot fail to succeed, God permitting. Let me hear from you again, for I can assure you I take a deep interest in your proceedings, and the doings of all such as yourself. If it be possible to introduce a few papers describing the mode of making a few small articles that may be quickly and easily made for sale, you may rest assured that it shall be done in order to help you and all others who show so earnest a will to help themselves.

Power Loom.—J. A. A. (*Manchester*).—You ask if it be possible for me to devote a portion of WORK to the construction of the power loom with wheel calculations, etc., adding that it would be of great service to scores in Lancashire, and make WORK doubly valuable in that county. I am glad to say that I am in communication with a contributor who is prepared to write on the construction of both the hand loom and power loom, and so it will not be very long before the desire of yourself and others is satisfied. There are emigrants from the old country in Manitoba, and elsewhere in the colonies, who have plenty of the raw material, but want the means of spinning it into yarn, and then weaving it into stout homespun material for clothing, and so, you see, there is abundant reason for moving in the matter as soon as may be, in order to meet their wants and yours. Write again and explain to me how the knowledge of the *construction* of the power loom, etc., "would be of great service to scores in Lancashire." Is it sought in order to lead up to better work, or to the making of looms?

Cabinet in Fret Work.—T. F. (*Willington-on-Tyne*).—The wood is too thick to give the required effect. The thinnest veneer—2-ply if possible, or a thin 3-ply—should have been used. This, with plentiful rubbing down with sand paper, would have avoided the result in your case, which is certainly disappointing. Your kindly expressions regarding the design itself are welcome, and the designer is sorry the first worker found obstacles in the way. Whether it would be possible to fill up the spaces cut out with any composition to obtain the effect of inlay seems doubtful. Yet the honour of being the first to use No. 1 is not marred by the failure, and we shall always recall the effort, and remember the name of the first reader who recounted his experience. (J. W. G-W.)

Hand Circular-Saw Benches.—A. R. (*Scorrier*) writes:—"These machines are very useful in joinery works or saw mills, where there is motive power to drive them, as they will do work that cannot be done by frame or hand saws, such as grooving, rabbeting, etc., and will cut rafters, staves, laths, etc., with greater despatch than any other kind of saw. But how often do we see timber presented to such machines that should not be. I believe some employers think if they have a circular saw at work that it and the man that has to work it are capable of cutting almost any depth of timber with it. This is a great mistake, and one, I think, that should be looked into by our Government Inspectors. How often have we seen a man at a saw bench trying to push a piece of timber from 9 in. to 16 in. deep against a circular saw. He will push it 2 or 3 in., and then through overfeeding, or through being unable to push any farther, he has to stop. After a pause he pushes an inch or two farther, and so on, until he pushes through the cut, doing the saw no good, and himself harm. There are benches made with rope roller and rack feed to bring the timber to the saw, and all benches in which saws are being worked above 24 in. should have one of the above appliances. Again, when a man has to push a piece of timber above a certain depth he is obliged to stand behind the timber, and directly in front of the saw, and should the timber close or catch the back of the saw it is liable to be flung against the sawyer; therefore, you will at once see the man is in a dangerous position. Had the bench either of the above feed motions the man could stand by the side of his work and near the saw bench, and be near at hand to stop the saw or the feed should it be required. Shallow and short stuff, such as laths, staves, etc., requires but little power to push or feed it, therefore the sawyer may stand on one side, and not put himself in such danger as if directly in front of the saw. As WORK is a new paper, no doubt many will avail themselves of writing to it, therefore I will take up no more space in this number, but, with the Editor's permission, will write more on saws in future numbers." [The pages of WORK are always open to workmen on any subject connected with their trade, and I have much pleasure in inserting your communication, which, I trust, will lead to the adoption of the course you advocate with circular saws that are used to cut wood of considerable thickness.—ED.]

REPLIES to the following correspondents are held over for want of space:—H. D., W. J. B., J. G., F. A., J. C. (*Aberdeen*), J. D. N., E. P. W., SARA, H. T. C. (*Leytonstone*), A NOVICE, PROGRESS, MECHANIC, W. H. (*Liverpool*), F. S. (*Newcastle-on-Tyne*), C. L. (*Uxbridge*), G. E. D. (*Liverpool*), W. G. P. (*Fenny Stratford*), G. W. (*Liverpool*), A COTTAGER, H. D. (*Haverfordwest*), H. S. (*Bebington*), A. R. (*Scorrier*), W. T. (*Leyton*), H. W. (*Gateshead*), NULLI CEDO, H. S. (*Exeter*), F. F. (*Peckham*).

Trade Notes and Memoranda.

THE first Exhibition of Blacksmiths' Work, under the auspices of the Worshipful Company of Blacksmiths, was held towards the close of March, 1889, in the Hall of the Ironmongers' Company, in Fenchurch Street. The exhibition of the work of the journeymen and apprentices of London was a small one, the number of contributors not exceeding thirty.

SOME TOPICS OF THE HOUR.—The Registration of Architects.—Fireproof Floors.—The Utility of Local Museums.—Architects' Fees.—English *v.* Continental Doors.—The Shaftesbury Avenue Architecture.—Trade "Discounts," alias "Commissions."—The Restoration of Westminster Hall.

PATENTS have been applied for in fireproof wall and ceiling papers, for drawing the outlines of objects and scenes in correct perspective, brick ovens for bread baking, moulds for pressing bricks, etc., and for improvements in glazed structures.

THE Society of Arts has guaranteed £100 towards the Autumn Exhibition of the Arts and Crafts Exhibition Society.

"SECONDARY BATTERIES" will be the title of a lecture by W. H. Preece, F.R.S., before the Society of Arts on an early date.

SHIPBUILDERS continue to be well employed upon the Wear, and there are about 10,000 tons of shipping on the stocks and in the water in excess of what there was at the beginning of the year, the output for the last three months being in excess of the corresponding period of 1888.

THE iron trade of Dudley is well maintained. There is a good demand for tin plate and sheet iron, and manufacturers of boiler plates are fully employed.

ENORMOUS quantities of goods are being sent out from the Boot and Webbing warehouses of Leicester.

THE method of lighting the channels of harbours by means of electric buoys, which has been tried in New York Harbour, is likely to be adopted in this country, as it has been favourably reported on by officers appointed to examine the system.

THE following is a formula for a wash for lime walls, so as to bear washing. Mix the powder from three parts silicious rock (quartz), three parts broken marble and sandstone, also two parts of burned porcelain clay with two parts freshly-slaked lime, still warm. The four constituents mixed together give the ground colour, to which any pigment that can be used with lime is added. It is applied quite thickly to the wall or other surface, allowed to dry one day, and the next day frequently covered with water, which makes it waterproof. This wash can be cleansed with water without losing any of its colour; on the contrary, each time it gets harder, so that it can even be brushed, while its porosity makes it look soft. The wash or calcimine can be used for ordinary purposes, as well as for the finest painting. A so-called fresco surface can be prepared with it in the dry way.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

SCOTT'S EMULSION

OF

PURE COD LIVER OIL

With Hypophosphites of Lime and Soda

Is three times as efficacious as the plain oil.
It is almost as palatable as milk.
It does not nauseate or produce a loathing for food like the plain oil.
The Hypophosphites and Oil are so skilfully combined that they are much more potent in building up flesh and strength than if taken separately, and it is to-day the best remedial agent for the cure of

CONSUMPTION, CHRONIC COUGHS, BRONCHITIS, ANÆMIA, WASTING DISEASES OF CHILDREN, And GENERAL DEBILITY that exists.

Physicians universally prescribe it in preference to the plain oil, having seen its remarkable curative effects.

Scott's Emulsion of Cod Liver Oil can be bought of any Chemist at **2s. 6d.** and **4s. 6d.**

A Free Sample **4-oz.** Bottle will be sent to any one who will write for it if they will pay carriage on receipt.

EGYPTIAN TRELLIS WORK.

BY C. H. OZANNE.

Though there are occasional specimens of this work to be seen in England, it is not nearly so well known as it deserves to be. Most of the readers of Work who visited the Italian Exhibition last year will have observed some pieces of furniture decorated with very poor examples. If so, they gathered a very moderate idea of its capacities. Perhaps the illustration given in Fig. 3 may enable them to form a better idea of what can be done.

It is difficult in an engraving to give a perfect rendering of what the panel is in the solid. To indicate the colour of the various woods used is difficult. The rows of beads, separated by turned intervals which run horizontally across the panel, are of walnut; the stars are arranged in squares, alternately lemon and ebony. The series of stars forming the outer square is of lemon; the series forming the square within that is of ebony; the next, lemon; and, finally, the two stars remaining are ebony.

Of course, such elaborate patterns are only used for small ornaments—such as brackets, panels, etc. For larger work the beads are coarser, and the open spaces are of sufficient size to allow the ladies of the harem to see what is going on on the other side of the screen, which protects their beauty from exposure to the vulgar gaze.

In Oriental lands this trellis work is largely used. Of course, in England we do not sit in balconies, as everybody does in a hot climate; and we do not appreciate the advantage of allowing every breath of fresh air free circulation. It is not so rare a commodity with us. To fully value the trellis work, it is necessary to be the wife of a jealous pasha. You are as carefully guarded from every male eye as a rare tropical plant from frost. In the harem, or women's quarters, you are allowed to remove your veil, but then every care is taken to prevent your beauty from rousing the admiration of any passing Lothario. Your gorgeous cage is hot and close, and female society is apt to pall—I do not speak from a masculine point of view. Man was not born to live alone, nor was woman.

No doubt the harem ladies appreciate the trellis that allows nothing of their faces to be seen but the occasional flash of a bright eye. But that they would prefer less careful protection is manifest from the way in which they allow their veils to fall forward —by accident—as they are driven in closed carriages along the fashionable promenades, and expose the greater part of a round, somewhat vacant face, leaving the rest shrouded in a transparent film of gauze. That this accident is designed is evident from the way in which the white veil tones down the complexion, which is pasty, and throws into strong relief the large black eyes, which they know how to make the most of, in spite of the two repulsive blacks who take charge of the fair bevy.

Though it is not the custom in this enlightened land to seclude the fairer sex from male society other than that of their lords, we still desire to a certain extent to shut off the gaze of the curious from the privacy of our homes. In passing along the street the lower half of many a window is screened by a blind of muslin, wire, laths, and, occasionally, fret work. None of these is artistic, and all more or less prevent the inmate of the room from seeing the passers-by.

In Fig. 5 is shown the framework of a simple half-blind. The centre is intended to be filled in with the trellis work, shown in Fig. 3, turned to suit the design of the frame fixed upon. In Fig. 5, I have merely indicated the position of the trellis work, and leave the pattern to the taste of the worker. In Fig. 6 is shown a projection for the ends of the frame; this is to run in the brass guides (Fig. 4). The practical workman will know many ways of fastening the blind. I merely give this as a suggestion.

In Fig. 2, an example of the simplest style of work is given in section. It is composed of strips of wood squared. These are turned up, leaving square blocks alternating with the turned intervals. As many as necessary of these strips are turned, and then the pieces to connect these strips with one another. Generally a lot of these latter are run out in one length, and then cut up as required. Holes are bored in the square blocks of the strips, and the little pegs inserted in them. The whole is tied up with string, and slipped into the holes in the frame.

Fig. 1 is not quite so simple. The strips are entirely rounded in the lathe—the pattern can be varied to any extent. The star is composed of three separate pieces, as shown. To put it together when the panel is a large one requires practice, and, if fine work, a very delicate touch. A strip is placed in the hollow of the hand; the long piece of the star is inserted in its hole in the bead; the second ray of the star is put into the next bead of the same strip; then the last piece of the star is inserted in its centre. One of the little pillars, A, is put into position, then a second strip is added, and held by the fingers. The two other ends of the strips are then slightly opened to allow the second piece, A, to be inserted. The two strips are then pressed together, and will not fall apart if gently handled. The holes for the pegs should be slightly large; this makes it easier to be put together. When framed up it is very strong; more so than fret work, and the effect is richer. The solid bars should always run the shortest way of the panel.

To build up a large panel will require some practice and patience, as it frequently falls to pieces as the last bit is being put into position. The result will fully repay the little trouble necessary to attain the requisite dexterity.

In the illustrations enough is given to put any one who takes trouble into the way of producing a variety of patterns. The shape of the beads, and of the pieces forming the star, can be varied to a great extent. In a long strip one of the stars can be replaced by a little pillar, and the corresponding bead lengthened to suit.

In future papers I hope to be able to give some examples of the application of this style of ornament to ordinary pieces of furniture. Many of these are far from artistic.

I am sure that any workman who fitted up a half-blind in the style of Fig. 5, selecting his trellis work from Fig. 3, and mounted it in his window, would have his hands full for many a day.

I have several specimens of this work in my drawing-room, and every visitor with any eye for artistic furniture is at once struck with it. It is, in my opinion, one of the most effective styles of decorative wood work that I have seen; and I am sure that if any reader of Work saw the general effect he would agree with me. It has an advantage over relief carving in that it shows up well against the light, and that various coloured woods can be used in combination. It is not nearly so difficult to learn as carving.

REPOUSSÉ METAL WORK.

BY GAWTHORP.

For Illustrations of Articles in Repoussé Metal Work, see Art Supplement issued with this Number.

Before touching on the various designs embodied in the Art Supplement presented with this number, let us see what repoussé work really is. Every one knows that "repousser" means "to push again," and hence "to push back" or "away." The simplest definition of the work is pushing the metal from one side and pushing again on the other side, until it assumes a "bold relief" and "correction of redundant form;" in short, raising and modelling the metal. Here we would point out that that class of work done by many amateurs on wood or lead, and which consists simply of hammering with a nail or punch upon the groundwork of the design, until by the expansion of the metal the pattern rises up in formless lumps, is *not* repoussé work at all. We therefore strongly urge those who fondly hope to imitate the great masters, or even to produce something artistic, to give up this method at once, for though by it "bold relief" may be obtained, yet there is no beauty of form nor correct modelling.

It will therefore be seen that flat chasing, for which designs (Nos. 2, 4, and 6) are intended, is but a step in the right direction, and should almost only be employed upon those articles which, of necessity, must be kept quite flat, such as tea trays, teapot stands, etc.

But to return, it is quite evident that the metal must be solidly backed up by some plastic material which will give at just the right spot, and at the same time possess an adhesive power that shall make the metal and itself one solid but impressionable mass; one, in fact, that would keep a true impress of the work were the metal suddenly and adroitly removed. What material will answer these requirements? Some writers mention wax; and no doubt wax was used by the earlier workmen.

Many amateurs (and, unfortunately, some school teachers) choose wood or lead, but none of these fulfil all requirements. Pitch, toned down with tallow and plaster of Paris, is very largely used by professionals, and is, no doubt, well adapted for the purpose; but as many amateurs and ladies have complained of the annoyance caused by the splintering off of fine chips which adhere to hands, face, and clothes, the writer has invented a composition which avoids the unpleasantness, and has been pronounced excellent by those who strongly object to a "mess."

Pans of pitch to be put in the oven or on the fire should *never* be used.

The metal to be decorated should be brass, copper, silver, or gold, and should in all cases be properly prepared; by which, we do not mean highly polished, but carefully planished and freed (by facing) from the scarcely visible flaws that will afterwards mar the work. The metal should also be selected for its softness, for some rolled metal, especially brass, is exceedingly hard and liable to crack. The metal must now be attached to the cement. This is effected by heating the metal, warming the cement, and pressing the former upon the latter by weight or otherwise, until absolute contact is obtained all over the metal.

The choice of tools is a very difficult matter, in which many amateurs have been grossly imposed upon; and our advice is, unless the buyer is an experienced workman, never buy of mere salesmen. The tools should be light, well tempered, and carefully faced.

The hammer should consist of a light steel-faced head, as shown in Fig. 1, upon a slender but strong handle. Mallets are not suitable for striking the tools. The tracer (Fig. 2), which is gently and rapidly tapped as it is steadily drawn along the outline of the work, as shown in Fig. 3, must be a well-made tool, properly pointed, without being too sharp, or the worker will be under a great disadvantage. Next in importance are the raising tools (Fig. 4). These are used after the metal has been turned face downwards upon the cement, and are hammered into the back of the design to produce on the face the required height and form. Having once more turned the metal face upwards, any "redundant form" is corrected with the modelling tools, which are very similar to the raising tools. Before removing the metal from this position, texture, surface, and matting tools (various forms of which are represented in Fig. 5) may be used to "superadd diversity of texture and even colour," and also to mat in the background. Other useful tools are: a mallet for roughly raising large and unimportant surfaces; a drawing point, with which to mark out the design on the metal; a pair of strong shears; a spirit or other lamp, and blowpipe to fix the metal on the cement; an iron for smoothing the surface of the pitch; a sand-bag to set the work upon; and a few unimportant sundries.

The metal used should always be large enough to allow of a margin, and in the case of trays and salvers, it is advisable to purchase them ready made, especially as it is impossible to make up some forms, such as those with plain spun edges, after working, without injuring the pattern thereon.

"But to what use can I put this work?" asks the amateur. The following list of articles to which repoussé work may be adapted will perhaps satisfy such an inquirer. Tea trays, salvers, card trays, ornamental shields, plaques, candle sconces and rings, alms dishes, spectacle cases, match boxes, flat candlesticks, menu holders, teapot stands, glove and handkerchief boxes, crumb trays and scoops, photo frames,

finger plates, ash trays, brush and mirror backs, letter racks, panels for firegrates, coal boxes, cabinets, bellows, book mounts, and innumerable articles for which there is a great demand at bazaars and fancy fairs.

We will now make a few notes on the designs accompanying the present number, hoping at some future time to give more minute details of the actual working and use of the tools. The designs for flat chasing (Nos. 2, 4, and 6), should be traced, after they are drawn on the metal, with a medium tracer, not too blunt, carefully copying every line, endeavouring to produce the effect of an engraving. This done, the groundwork in Nos. 4 and 6 should be punched. That of No. 6 with a small ring tool or perloir. No. 5 may have a background put in with any fine tool. In No. 2 the ornament is to be matted or tooled over, leaving a bright background. As No. 6 is intended for a teapot stand, it should be worked on thick metal, and, when finished, have four small brass balls screwed to the back.

In Nos. 1, 3, 5, 7, 8, and 9, the outline should be traced with an ordinary tracer, moderately thick and not too sharp, tracing lightly where little relief is required, and more strongly in those parts that should be more highly raised. It must here be noted that in designs for true repoussé, no shading lines or marks to represent shading must be put in, as all effect of light and shade must be obtained by proper modelling; indeed, very little more than the mere outline should be traced. For raising, five or six modelling tools and a blunt tracer are required. Start with the bolder parts, taking them down in one surface, leaving details to be put in after general effect is obtained. Where sharp relief edges are required, use the blunt tracer just inside the outline. Having modelled the design as well as possible, turn the metal over again, thus bringing the work face uppermost; then trace round the outline with a blunt tracer. Touch up the modelling, smooth away roughness and excrescences, and then put in the background with suitable mats.

Some work is greatly enhanced by tooling over the raised design, but this requires much practice to produce a good effect, but, nevertheless, is well worth the painstaking effort necessary to learn this really difficult part of the art.

BORING SMALL CYLINDERS.

BY OLLA PODRIDA.

II.—Simple Way of Boring Cylinders in Self-acting Lathe with Saddle—Packing Up—Mounting and Setting Cylinder—Roughing Tool—Facing Flanges—Boring Bar—Wedge—Conclusion.

In the previous article on this subject, three different methods of manipulating work of the above nature were described. First, by chucking and boring in a self-acting traversing lathe with slide rest. Next, by means of hand tools, D bits, etc., in a common lathe provided with T rests only; and lastly, a makeshift, whereby the boring could be accomplished by hand without having recourse to a lathe for that purpose. All of these methods, and the last two in particular, are suitable only for small work, or where the bore is short, the difficulty of obtaining a smooth true bore with—in the case of deep works—a necessarily long and unavoidably springy tool being obvious.

The present article takes us a step further in describing a method whereby large as well as small cylinders may be treated, provided that a suitable self-acting lathe with a good saddle is at hand. The advantage of the method about to be described is that a practically parallel bore is obtained with a minimum amount of trouble. I use the term *practically*, because the wear of the tools in cutting prevents a perfectly true result being obtained in any case where a large surface has to be operated upon. This is of course unavoidable; all that can be done is to make sure that the tools used for the finishing cut are of good temper, and stand well, and this selection can only be made from experience, or rather actual experiment. When such a tool is found, carefully note it, and place it aside for such special duty only.

The process about to be described will be more clearly understood by reference to the illustrations. Fig. 4 is a front elevation of the lathe, showing the cylinder in black, mounted and fixed on the saddle ready for operation. For the sake of clearness, the cylinder is shown in section, and to economise space, part of the lathe heads and bed is omitted. The cylinder is held down to the saddle by bolts, *b*, *b* (see also Fig. 5, end elevation and cross section through boring bar and cylinder), and straps or plates, *p*, *p*. These straps bear on pieces of hard wood, *w*, *w*, fitted to cylinder body. Liners, or packing pieces, for keeping the cylinder at its proper height are interposed at *l*, *l*; these are also of hard wood. B is the boring bar, *c* its carrier, and *d* the driver. The T-shaped slots at *g*, *g*, are for the holding-down bolts, *b*, *b*. Figs. 6 and 7 give details of one method whereby the tool, *t*, is adjusted and secured in the bar, B.

Before proceeding with the details of setting and boring, it may be observed that in cases where the cylinder may appear too large for the lathe, the heads can be packed up to meet the case. This is commonly done in practice, and more especially in small shops where the choice of machines is limited, and their range small. Some engineers keep cast-iron packing pieces for this purpose, but hard wood will answer quite as well, at a pinch. The only thing to be watched is that, when the lathe feed is taken from the leading screw, the heads are not packed up beyond the reach of the change wheels; where the feed is obtained from an independent back shaft, it is only necessary to lengthen the small driving belt as required. The illustration given herewith may be taken as representing the boring of a $3\frac{1}{2}$-in. cylinder in a $4\frac{1}{2}$-in. lathe, with a boring bar $2\frac{1}{4}$ in. in diameter.

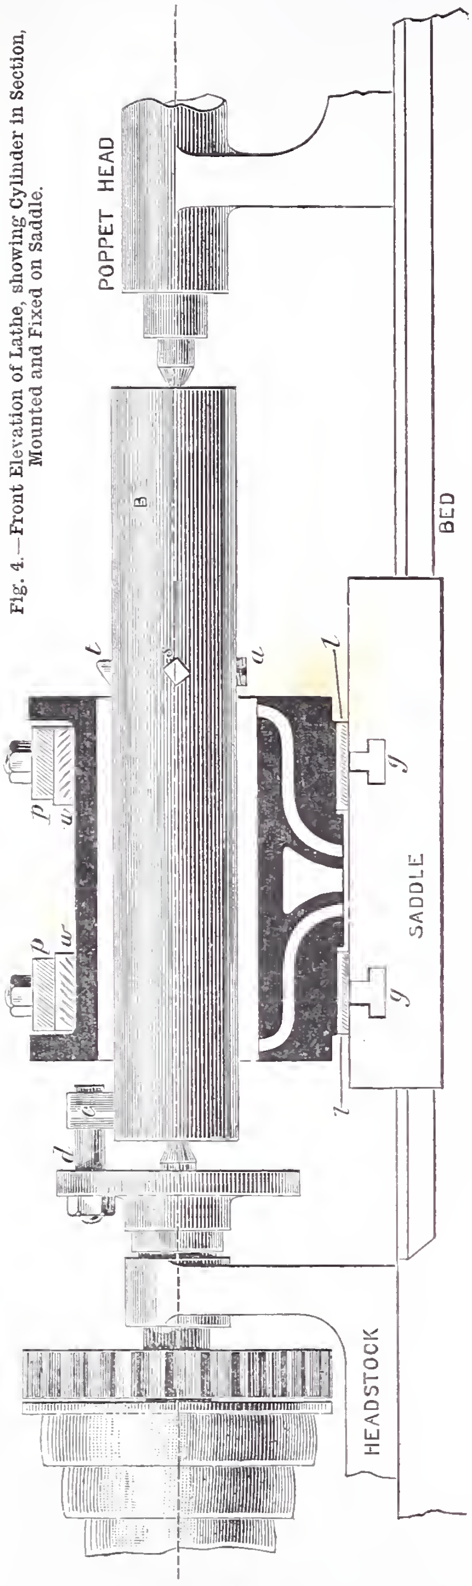
The procedure in mounting and setting the cylinder is as follows:—The slide rest having been removed, and the face of the saddle cleared, the cylinder is packed up to agree roughly with the lathe centres, and lightly bolted down by means of the straps, *p*, *p*, and bolts, *b*, *b*. The bar is then shipped in place between the centres, and the bore of cylinder set carefully to it by means of a tool stuck in temporarily for the purpose, or by the callipers or V-foot scribing block. If found too low, small alterations can be effected by strips of paper under the liners, *l*, *l*; if too high these liners must be planed down, always, and in either case, making allowance for compression of the liners. Lateral adjustment can be readily given by blows, where required, with a wooden mallet or block.

It is a good plan to check the bore with outside of cylinder, so as to ensure the thickness being equal all round. An important point to be observed is the adjustment of the saddle upon the lathe bed. If this is neglected, and it happens to be slack, an oval bore will occur, owing to side play. If too tight, undue strain will be thrown upon the self-acting gear, and a breakdown may result.

It will most likely be found that the strain on the holding-down bolts, *b*, *b*, has sprung the saddle slightly, and caused it to bind on the V's of lathe bed. This must be watched, and the wedge piece in front of bed adjusted accordingly. Everything having been set and adjusted, a fair start on the boring may be made. Two cuts, a roughing and a finishing one, will be sufficient, and the feed should not be heavy, say at the rate of forty cuts per inch. The roughing cut should be arranged so as to leave about $\frac{1}{32}$nd of an inch for the finishing one. Unless a circle has been struck on the flange for guidance, the tool will have to be set to depth by trial, a sharp look-out being kept with a pair of inside callipers set to size.

The roughing tool may be of the shape given in Figs. 6 and 7, but the finishing one must be flatter on the cutting edge, not so

Fig. 4.—Front Elevation of Lathe, showing Cylinder in Section, Mounted and Fixed on Saddle.



pointed, but thicker and bluffer, so as to guard, as far as possible, against "chattering." A slight alteration in the shape of the cutting edge of a tool often makes a wonderful difference in its performance, and, in this direction, experiment is by far the best guide.

By substituting knife or side cutting tools for the boring ones, the flanges may be faced in position, but the operation must be carefully carried out to avoid shifting the job; the whole surface of the flange should not be attacked at once; a narrow ring should first be faced commencing from the bore, then another larger one brought to the first, and so on, shifting or lengthening the tool by degrees until the whole surface has been roughed down. During these operations the feed must be given by hand, and the rough facing should be done after the rough and before the finished boring cuts. If possible, the flange of steam chest, or rather slide face, on which the cylinder is shown resting, should be secured by wedges or stops to prevent its twisting or shifting laterally upon the saddle. Before running the finishing cut through bore, the holding-down bolts must be slightly slacked off equally, so as to avoid, as far as possible, flattening or springing the cylinder; but in the case illustrated, owing to the proximity of the bolts to the flanges, and the small size of cylinder, this would not amount to any appreciable extent. It is, however, important in the case of large cylinders. I may add that where a suitable mandrel is at hand, the flanges may be faced upon it by a distinct operation, and with considerably less trouble than by the boring bar.

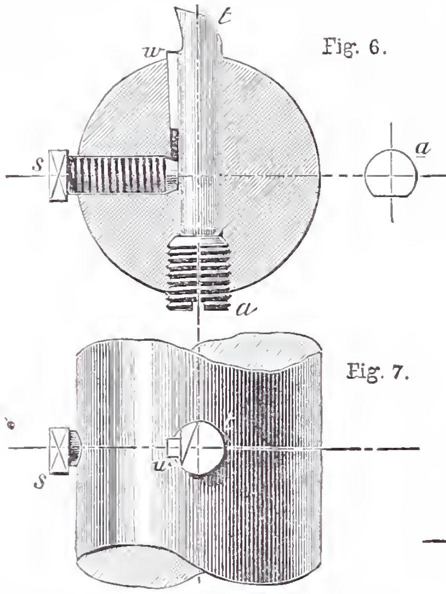


Fig. 6.—Section of Boring Bar, showing Method of Fixing Tool. Fig. 7.—Bar in Elevation.

Before concluding, a word or two about the boring bar must be added. It should always be as stiff as possible, and, therefore, as large in diameter as reasonable clearance for chips will allow. For large work, a block or head is keyed on the bar, and the cutters carried therein instead of in the bar as illustrated. The centres in ends of bar should always be carefully drilled to fit those of the lathe, and it is imperative that the one which runs on the dead centre of poppet should have a small hole drilled up a short way so as to clear the centre point, as well as to hold a small supply of lubricant; and with regard to this matter the centre must on no account be allowed to run dry or squeaky. This is important, as the finishing cut must be kept going *without the least stoppage* from start to finish. Fig. 6 gives a section of the bar, showing the method of fixing and adjusting the tool. Referring to Figs. 6 and 7, *t* is the tool adjusted vertically by the screw, *a*, and secured by the setscrew, *s*, the latter being further assisted by the wedge, *w*, which fits into a suitable slot and tightens against a flat upon the front of tool, which is shown clearly in the section at *a*, to the right hand of Fig 6. The setscrew, *s*, should be of steel, and slightly hardened at the point. The hole through bar for tool is drilled, in the first place, and then tapped at the bottom to receive the adjusting screw, *a*. The hole for setscrew is then drilled and the slot for wedge cut, after which the setscrew hole must be tapped. Both of these screws must fit well into the holes so as to guard against their working loose. The wedge, *w*, must also be of steel, but it should not be hardened. The tool should fit well into its bed, not too tight, but just a nice driving fit. It can be easily backed out when necessary by removing the adjusting screw, *a*, and using a drift. If at any time on account of limited clearance there is no room for head of setscrew, *s*, it may be taken out and the tool held only by the wedge, *w*, but this wedge must on no account be omitted, as on it depends the rigidity of the tool.

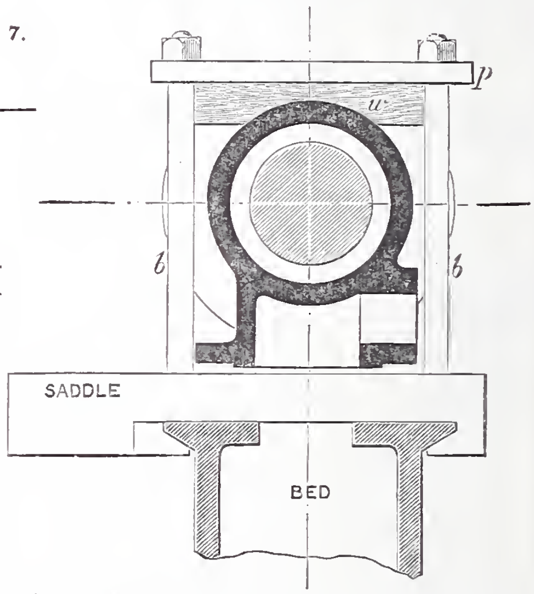

Fig. 5.—End Elevation and Cross Section of Fig. 4, showing Straps in Position.

In concluding, I venture to express a hope that the foregoing may be of assistance to some of the professional as well as amateur readers of WORK. The instructions given above are not necessarily confined to cylinders alone, but equally applicable to any form of work which may be more economically treated in the manner described. I hope to return to the subject or rather to a kindred branch again, and still further illustrate the simple extended uses to which a lathe may be put. Should there be any doubt attached through want of clearness in the above, I shall be happy to render what further assistance lies in my power through the medium of "Shop," which, I am glad to notice, is gradually growing, a proof of the interest taken in WORK by its readers, and the manifest utility of "Shop" to all who seek assistance in matters of doubt or difficulty.

THE SCRATCH OR BEADING ROUTER.

How to Make and Use it.

BY DAVID DENNING.

Utility of Scratch—Its Object—Its Action—Formation of Beading—Shapes of Cutters—Mouldings on Edge of Wood—Points to be Looked for in Scratch—Stock—Fence or Butt—Screwing Stock Together—Working with Scratch—Cutters—Combination of Beads by Simple Cutters—Moulding Curves—Stopping and Finishing Beads—Formation of Cutters—Cleaning up Work.

It is well known to those who are constantly in trade workshops that, whatever the handicraft pursued in them, there are little appliances for facilitating operations which are seldom seen by the outside public; that is, the tools are home made, and such as are not articles of sale in the ordinary tool shop. One of them is the "scratch," a tool much used by cabinet makers in forming the beads which play such an important part in modern furniture of the so-called Early English type. It is, however, not strictly correct to say that the scratch is not obtainable at tool shops, for, in a more elegant shape, it is offered for sale under the name of "bead router," or some similar title which has a better sound than plain, commonplace "scratch." However called, it is nevertheless only a modified form of the tool about to be described; and without wishing in any way to disparage the router, I do not think it can claim any advantages in practical work over the scratch. In point of economy, the latter has the best of it, for it can be made for as many pence as the other costs shillings, without any very great demands on time or skill. Another thing to be preferred about the home-made article is this: extra cutters can be prepared with the minimum of trouble as they are wanted to cut or scratch any particular form of beads or small mouldings. Still, as I have said, I do not want to decry the ready-made router of the shops; and the rougher variety, which, by the way, is the only one I have seen in use among practical workmen, may be offered as an alternative form for those who for any reason are debarred from purchasing ready-made tools.

Perhaps, however, there may be some who do not quite understand what the object of the scratch is; and as it is more than probable that some of our readers are not acquainted with it, some little explanation of the work that can be done with it may be given before describing the tool more minutely. To begin with, it may be described as a kind of cross between a plain scraper and a moulding plane. Its action is a scraping one, but the cutter is held firm in a stock, which is so contrived that the edge of the cutter, when fixed for any given piece of work, shall always act on the same place on wood being beaded. A rebate plane does the same, but the blade of a plane works by cutting, and not by scraping. By filing the scraping end of the scratch cutter to any desired outline, it will be seen that the wood brought under its influence assumes a corresponding outline. Thus, for instance, if we want to cut on the surface of a piece of wood—say, on the square rails between two drawers, on the drawer fronts, on the framing of a door—three beads as in Fig. 1, all we have to do is to shape the end of the cutter accordingly, as shown in Fig. 2, where it will be seen that the beads are replaced by hollows.

On the same principle, any desired section of beading can be formed by preparing a cutter of negative or reverse outline. An immense variety of the shapes that may be assumed by beadings is, therefore, at the disposal of any one who will take a little trouble to work them out. We are, perhaps, rather too apt to forget that the plain beading (Fig. 1) is not the only form this simple and effective means of decoration is capable of assuming, but that others are just as easy, although more complicated-looking. When the cutter is made, and of course the handle or stock to hold it in, there is no more difficulty in forming one outline than another.

A further use that may be made of the scratch, and one that will probably commend it to those wood workers who are, as yet, unacquainted with its powers, is the facility with which small mouldings or beads on the edges of wood may be made with it. Take the common one shown in Fig. 3, so useful for the edges of shelves, etc., or the more elaborate-looking beaded edge in Fig. 4. No expensive tool, nor yet much skill, is needed to work these. The scratch will do them both; or if a stop-clamper is wanted, it may still be pressed into the service. Surely, enough now has been said to show the utility of the tool, and also to give some idea of its scope; so, without more ado, let us see how it may be made. Please note that the form and general construction are only to be regarded as typical; for one peculiarity of those tools which are generally made by the user of them is that they are seldom found alike in minor details. The things, not being made by machinery, or to a given pattern, are generally modified in some way or other to suit the fancy or convenience of the workman; and if a number of them were examined, it would most likely be found that, though there might be a general resemblance, no two would be exactly the same.

In the scratch, broadly speaking, the following points would be found in all, as without them it could not be a useful working tool:—They are, firstly, a cutter of sufficient strength to cut or scratch; and, next, a stock which, while holding the cutter firmly, shall yet allow its position to be altered when desired, and of such length and shape that it can be conveniently held, and the efforts of the workman applied with the best advantage. Further, as already hinted, there must be some guide by which the bead can be worked in a uniform line. These being the requisites, all other details are merely matters of

Fig. 18.—Piece of Wood for Rubbing between Beads. Figs. 19-26.—Sections for Scratchings.

personal convenience, and for the present, at any rate, may be left out of consideration.

The stock is composed of two pieces of wood shaped as shown in Fig 5. The size is not important, but for ordinary work 8 in. to 12 in. in length will be found convenient, as it is sufficiently long to allow of being firmly held, and not so long as to be cumbersome. For the thickness, ½ in. will do very well. The width of the narrow part may be about 1 in., and of the wider part, forming the shoulder or fence, 1½in. to 2 in. The wood should be hard and strong; but, beyond this, it does not much matter what it is. Beech, ash, oak, and others of similar character, are all suitable, though, if equally convenient, the preference should perhaps be given to that first named.

It may be well at this point to say something about the width of the fence or butt end of the stock. When beading the edge of a board, this is not of much consequence, as the only difference with a deep fence will be increased friction; but if the surface is the part to be beaded, it will readily be seen that the fence should not be thicker than the board, if this is laid on a bench. With a wide board, such as a panel, the edge may overhang the bench, so that in this case the size of the fence does not much matter. As, however, rails and styles have frequently to be beaded, it will be found convenient to keep the fence narrower than the thickness of the wood it is to be worked against. Theoretically, a shallow fence is best, though, in practice, not much attention is paid to the theory. However, all that is necessary is that the fence shall be a little deeper than the projection of the cutter, in order that when this is applied to a new surface. it may be guided properly. Of course, it is necessary that the shoulder must be at a right angle with the lower edge of the stock, *i.e.*, those parts which will come in contact with the wood being beaded, will be at this angle. It does not matter whether the two parts of the stock are made separately, or are cut from one thick piece and afterwards sawn apart; but, in either case, it will be well to round off the lower surface a little, much as the stocks of cutting and marking gauges often are. In fact, if we take one of these tools as exemplifying the scratch, we shall not be far out; the essential difference being, that in a gauge the block or fence is movable with a fixed cutter, while in the scratch the cutter is movable.

The two parts of the stock are held together by screws — ordinary screw-nails, which should be stout. Three, or at most four, nails will be required for each stock, though it is quite possible to manage with only two. Still, it will be better to have one through the shoulder end. The position of the other screws is not of importance, provided they are so placed that they clamp the wood sufficiently to hold the cutter. As this may have to be moved to any part of the stock, it will be convenient to have several holes bored for screws, so that they may be used in whatever position may be most convenient for the work in hand. Fig. 6 shows the completed scratch, with the cutter fixed; and the mode of working it is as follows, though it may be almost superfluous to give this, as the manipulation must be almost self-evident:—The wood to be beaded is placed against the bench stop, or otherwise held, as if it were to be planed. The cutter (by the way, this, the stock, and the two combined are all, in workshop parlance, generally called the scratch, though, for the sake of description, I have particularised them) is placed at the same distance from the fence that the intended bead is to be from the edge of the board. Screws are tightened up — with an ordinary screwdriver—so that the cutter will not slip.

In working with the scratch, the right hand grasps the butt end, and the left the other end of the stock, which is held at a right angle to the edge of the wood to be worked on, with the shaped end of the cutter downwards. The fence is pressed against the edge of the board, and the scratch worked backwards and forwards till the beading is formed. Now, very little experience will show that the cutter should not project much below the lower edge of the stock, and that much of the appearance of the beads will depend on the way the cutter is set. Remembering that the cutter acts till the stock comes in contact with the surface, there will be no difficulty in understanding that it ought not to project much—only sufficiently, in fact, for all the members of the beading to be exposed. If it project too much, the beads, instead of being on the same surface as the level of the wood, as they generally are, will be sunk. If they are intended to be the latter, no difficulty will be experienced in making them so, by slightly projecting the cutter a little more.

Now about the formation of the cutter, to which some attention must be given, that cleanly-made beads or moulds may be the result. Steel is the best metal to use, and it goes without saying that it should be hard, such as that of which scrapers are made. The thickness is immaterial, so long as the metal is sufficiently rigid, but in excess, the difficulty of shaping the cutters will be increased. It may be said that the thickness of an ordinary scraper will do for any ordinary purpose, and, if desired, a scraper may be used for forming the cutters from. To do so, however, entails some labour, and pieces of broken band saws are generally employed for cutters—partly, no doubt, because they are little more than waste, but especially because the width is already prepared. Of course band saws vary in this respect; and to say that the width of a band saw is the proper dimension for a cutter, is much like telling one that anything is about the size of a piece of wood; so it may be said that the width of a cutter must depend on the size of the bead to be formed. This must not be too large, as the scratch, though a useful tool, is not a powerful one, depending entirely on the strength of the operator; and in unaccustomed hands, at any rate, the labour of cutting a wide series of beads, say anything over ¾ in., is not a slight one. Perhaps ½ in. would be a good limit for the novice; but so much depends on the hardness of the wood to be scratched, that no definite rule can be laid down. As this may seem a small limit, it may be suggested that any width of beading can be got by simply altering the position of the cutter, so that it scratches parallel with any that have been already made. Thus with a single narrow cutter with one recess, as in Fig. 7, a series of beads, which need not be limited to three, as in Fig. 1, may be scratched. It may, however, be said that three is a very usual number for these beads. Working on the same principle, it will be seen that almost any combination of beadings may be made by using different single cutters; thus the beading shown in section (Fig. 8), consisting of a bead between two hollows, may be made by using two cutters shaped as in Figs. 9 and 7, the former being for the hollows and the latter for the bead. Again, a beading such as Fig. 10 may be formed by simply reversing a cutter shaped like Fig. 11.

Hence it will be seen that a combination of beads to almost any extent may be made by a few simple cutters. What applies to beads on flat surfaces, it will also be seen, applies to mouldings, though these will be found more troublesome to work if the members are of large dimensions. Generally speaking, for obvious reasons it will be found that the work of shaping a moulding is much reduced by, as far as possible, preparing the wood—that is, cutting as much of the superfluous stuff away as convenient with a plane or other tool (say, a spokeshave for curved mouldings), and merely leaving the outlines of the moulding to be scratched with the bead. Thus, supposing that a length of moulding of the section given in Fig. 12 is intended to be worked from a piece of rectangular section, it will be obvious that the work of the scratch may be greatly lessened by planing the wood to the section shown in Fig. 13, leaving comparatively little waste to be removed by scratching. Though the large member of the moulding may seem a big one for the scratch to work, it must not be forgotten that the cutter may be reversed, for, the member being ¼ circle, it will be seen that a small cutter of ⅛ circle will do for it. Care will be required in cutting such mouldings, to see that the cutters are set at proper lengths, so that there may be no serious inequalities. Slight ones are of small consequence, as they can be removed with glass-paper. For such a moulding as that shown, the cutters, therefore, will only be two in number, their respective positions when in the scratch tool being as in Fig. 14, where, for the sake of explicitness, a short space is shown between each.

Perhaps, however, the chief use of the scratch—at least, where moulding planes are not available—is not so much in forming straight mouldings as in moulding curves—as, for example, that for a curved pediment like Fig. 15. When only a bead is to be scratched, or a small moulding planted on, it can be done much more easily with the scratch than by carving. In preparing curved beads or mouldings, the only special caution that need be given is that the stock should always be at right angles with the bead, in order that this may be parallel all through with the edge of the wood.

Now, when scratching a bead, or beads, these may either be extended to the end of the wood, as in a panel or the frame of a door; or they may be stopped, as they often are when they are on the front of pilasters, especially when shelves are supported by these, or when a little piece of carving is added. To discuss when a stopped bead or one extended to the end is best is out of the question here; but to "point a moral," take Fig. 16, representing the end of an upright surmounted by a turned knob. There is no special reason for taking this, beyond the circumstance that it is very often seen in modern furniture. With such a termination, there can hardly be two opinions about the desirability of the bead stopping a little below the end instead of running right up to the knob. On working the scratch, it will be found that a clean stop cannot be made, so the only thing is to scratch as far as convenient, and trim off the roughness at the end with carving tools, or, in default of them, with the next best substitute, a fine firmer chisel, taking care that the cut across the end is decided and sharp without encroaching on the flat. The beads should be neatly rounded right up to this cut. Another method of finishing the beads is simply to shave them off to meet the transverse line, as shown in Fig. 17. This entails less work of the two, but has, perhaps, hardly so sightly an appearance as the other. In beading the edges of shaped work, it will also be necessary generally to finish them off by carving; but as outlines vary so much, it is impossible to say that this will always be the case. A trial will always show whether it is necessary to cut or not; and the hint is given, more that recourse may be had to cutting tools when required than to say that they must be used.

Possibly something should be said about forming the cutters and preparing them, though most people will be able to devise means of doing so without being told how. Briefly, it may be said that they are merely filed down, small fine files of the ordinary kind being used. Too much care cannot be taken in shaping the cutters, for, whatever the outline of these, the worked beading will have the same. The action of the scratch being a scraping one, not a cutting one, the edges should be square and sharp without any "burr." As a rule, careful filing will do all that is necessary; but those who know how a scraper is sharpened need not be told that a scratch cutter may be finished in the same way. In order to ensure perfect accuracy in filing the scratch, it is not a bad plan to form a kind of mould of two pieces of thin wood, ½ in. or even less, with ends shaped as the cutter is to be. By placing this between them (using screws to clamp them together, or fastening them up in a bench vice) the cutter may be shaped with very little trouble. The wood serves as guide, not merely for shape, but by it the edges of the steel can be filed up truly square, even by those who are not skilled in the work.

When beads have been worked by the scratch, it will generally be found that they need "cleaning up" by papering. Only fine glass-paper should be used, and care be taken that the papering does not destroy the character of the beads by blunting corners or destroying rounds. To use the paper properly, it should be held over the edges of thin pieces of wood rounded off to fit the various members as nearly as possible; thus, between two plain beads a piece of wood trimmed off at the end, like Fig. 18, would be useful as a support for the paper; in the use of which, however, I must repeat, caution and discretion are required. A good bead should be clean, with a well-defined outline; and the advantage that may be taken of such a simple mode of decoration is by no means trivial.

The combinations that may be made are almost endless; so that, with a little consideration, many surfaces that it would otherwise be necessary to leave plain may be relieved from utter flatness without materially increasing the amount of labour bestowed on them. By way of showing what may be done in this direction, a few beads—or, rather, combinations—are given in Figs. 19 to 26, and from these suggestions no doubt the intelligent worker will be able to form others. He will also be able to determine the application of this kind of ornamentation to many surfaces which would otherwise be left plain and untouched, and the kind of ornaments which would be best suited to the article of furniture under treatment; there being no difficulty in preparing a cutter to carry out the style of adornment required.

"TIPS" FOR TYROS.

BY OPIFEX.

7.—Buhl Work.

Many amateurs, perhaps, do not know that what is known as "Buhl Work" is simply fret work executed in a peculiar way, and applied to the decoration of furniture, etc.

Very handsome frames and other small articles may also be produced by any one who possesses a fret-sawing machine, as this class of work cannot well be done with an ordinary fret saw.

Procure a sheet of thin sheet brass of the required size, which must be perfectly flat and free from dents; also a sheet of ebony veneer (true buhl work requires tortoise shell) of the same size and thickness as the brass; glue these securely upon the sides of a piece of cardboard, and then paste a sheet of white paper upon each side; place between two flat smooth boards, and apply good pressure. When dry, draw your design, and cut in the ordinary way with a fine saw; next damp with warm water, when the metal and veneer may be easily detached, and we now have two designs in the different materials, and the desired effect is produced by mingling the brass and ebony, the cut-out portions of the brass being inserted in the ebony background, and *vice versâ*.

This is accomplished by gluing upon a suitable foundation of some hard wood, as in veneering, again pressing, and when dry cutting out your frames, etc.

The surface should then be rubbed down with a flat pad—*i.e.*, a small piece of perfectly flat wood, round which is rolled a linen cloth; using emery flour and oil, and finishing with rottenstone.

The result will be that we have two articles, the one with brass design upon ebony, and the other ebony upon brass; a thin coat of varnish will complete the job, and prevent the brass losing colour.

8.—Artificial Marble.

A substance which shall resemble marble or alabaster, and be found useful for various purposes, may be made as follows:—

Mix fresh plaster of Paris with a strong solution of alum and water into a smooth paste, and bake in an oven till hard; when cold grind to fine powder, and mix with water. At this stage any dry colour may be mixed with the plaster in such a way that it shall run in streaks but *not* get thoroughly incorporated with the mixture. Now run into mould, and when set again bake, and when hard and cool dip in skimmed milk, dry, and polish with soft cloth and French chalk.

HINGES:

THEIR VARIETIES AND APPLICATION.

BY DAVID ADAMSON.

II.—Another Mode of Hingeing a Door.—Forms of Hinges.

Having in the preceding article named one way in which a door is hung and hinged, another method of doing so may now be instanced. Those who have paid the slightest attention to door fitting cannot have failed to notice that, instead of the door being within the ends or framing to which it is attached, it is often found covering these or outside of them. A very common example is in an ordinary wardrobe with sliding trays, and another in the small drawer pedestals on top of a "registered" writing table. In the latter the drawers are secured by a small hinged slip of wood which, for the present purpose, may be regarded as a door. Now it is obvious that were the door in such cases as these fixed as already described within the ends, the trays in the former and the drawers in the latter could not be drawn out. The hinged edge of the door would stop them. Of course, the end by the door may be, and often is, thickened up to allow of the drawers sliding, but then this naturally means that the length of the drawers is curtailed by at least the thickness of the door framing. If any doubt is felt about this explanation, a slight examination of a few articles of furniture will make it clear. It is an ordinary method of construction in sideboards of modern style. If two or three of these are examined, the pedestal containing the cellarette is almost certain in one, if not all, of them to be blocked to allow of clearance. I have said "almost certain," but I may go further and say positively certain if the door is hinged *within* the ends, so that a glance at the door will show whether the inside of the pedestal will answer the inquirer's purpose. With such a construction, however, we have nothing further to do at present, and it has only been named in order to indicate how the desired object may be attained by hingeing the doors on the end, and to make the reasons for such an arrangement clear. It must not, however, be supposed that it is only applicable when there are drawers and trays. Many reasons govern the causes why it is sometimes to be preferred, but it will be unnecessary to consider these, as it may fairly be supposed that the worker, when he understands the principles of both methods of hanging doors, will be able to decide for himself which he prefers. As a general rule it may, however, be said that doors should not be hung on the ends when it is necessary to cut away the thickness of the door frames from these, and leave an overhanging part, as, for instance, when there are drawers above the door, not behind it. Thus sideboards often—indeed, generally nowadays—have drawers above the doors, and it is for this reason the doors are within the ends. When, however, the door goes up to the top, or, as in the case of a wardrobe, runs right up to the frieze or cornice, there is no reason—at least as far as construction is concerned—why the door should not be hung on the ends. For the rest it is simply a matter of design, for no one, I imagine, would, unless from some very exceptional cause, wish to make a sham pilaster to move—that is, to form part of the door. To show more clearly when it would be right and when wrong to hinge a door on the ends, Figs. 4 and 5 are given illustrative of the foregoing hints. I trust these are made so clear that the amateur need not feel perplexed as to which construction he ought to adopt for anything he may make. Nor, I may add, will he vex the soul of the art furniture designer who knows his business by requiring him to "make up a lie in wood."

It is just as well to understand why and when to prefer one form of construction to another, so supposing we wish to hinge a door *on* the end, let us see how to do it in a workmanlike manner. Most of the work is done just as already described, the chief point of difference being that the hinge must be sunk in the end with, of course, the joint outside as before. The mode of fixing and general regulation are the same, but if anything, rather more care will be required to see that the bottom of the door does not drag. The edge of the door frame should be flush with the external surface of the end, and the hinge pin be in the same relative position as before. As an illustration has been given of the door hinged within ends, one (Fig. 6) is given in the same form for purposes of comparison, which will render any further explanation superfluous, especially as the letters refer to the same parts in each.

So far only the ordinary butt hinge has been referred to, but there are many modifications which come in useful at times, and though no detailed directions concerning the fitting of any of these need be given, a few of the varieties most commonly required may be named. It must, however, be understood that these are what may almost be called "articles de luxe," and if it is not thought worth while to avail oneself of them, they may generally be dispensed with, and the ordinary butt be substituted by a little ingenuity, though perhaps at a sacrifice of appearance. Try the effect, for example, of allowing the knuckle of the hinge to project further than stated, and it will be found, of course, that as the centre or pivot is further from the front the swing of the door is altered. Now it is easy to understand that in many instances—such as with carriage doors, where, owing to their curve, the pivot could not be fixed close up, as in the case of the doors described—a hinge which will allow of more throw must be used, by which all the centres can be got in one straight line, or when a door must swing clear of a moulding. For these purposes, therefore, there are hinges with comparatively wide flanges and screw holes bored near their edges. In addition to straight hinges of this kind, as shown in Fig. 7, they are made with the flaps bent. Figs. 8 to 12 show specimens, but there is such an immense variety of these cranked hinges, as they are called, that it is not possible to give anything like a complete list. Nor is it necessary, as they will seldom be required by the amateur. Indeed, the same may be said of almost all the fancy hinges, or those only used in special trades like the carriage hinges mentioned above. Probably, therefore, it will be sufficient just to name a few of the better known kinds, or those likely to be of more general use. Let us take first the heave-off hinge, the construction of which will be readily understood from the illustration (Fig. 13). From this it will be seen that the flaps are easily separable, and consequently a door or lid hinged with them can be removed without the necessity of unscrewing the hinges. A familiar example of their use will be found in Lancaster's original patterns of cheap cameras, which, it will be remembered, are fitted with them, one half of each hinge on the bottom board, and the other on the casing of the bellows body. Then there are the "stop butt hinges," which can only be opened half way, or to form a right angle, as in Fig. 14, instead of flat. These, of course, are very useful for fixing on box lids with, or a door which it is not intended should swing too far.

Sometimes with a heavy door it is desirable to use a hinge with one plate broader than the other, as in Fig. 15, the extra width of one flap allowing a greater "grip" to be taken on the wood than when both are narrow or only the width of the thickness of the door frame. These are known in the trade as wardrobe hinges. I think mention has been made that sometimes each

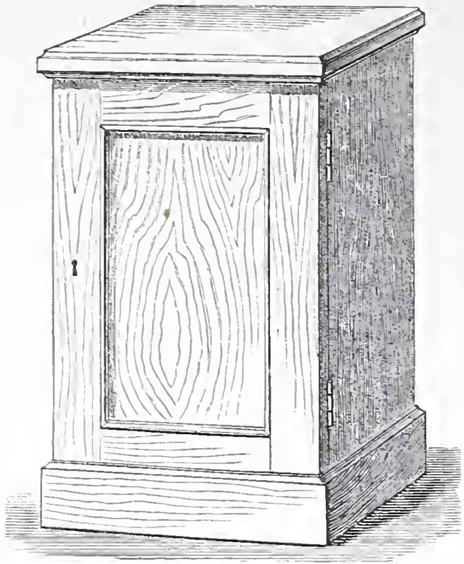

Fig. 4.—Door Hung on End: Correct Construction.

part of a hinge is sunk within the wood, and it may be said here that in furniture this is seldom done except when the weight of the door is so great that any additional support gained is required to relieve the downward drag on the screws. Both hinge plates being sunk this is reduced to the minimum. In Fig. 16, a hinge with plates

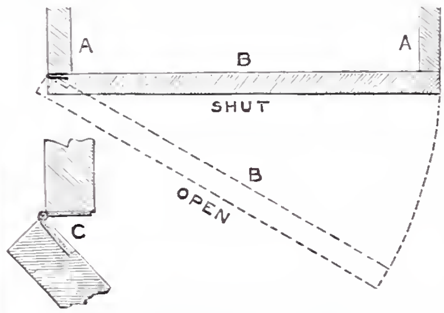

Fig. 6.—Diagram showing Door Hinged on End. A, A, Ends. B, Door. C, Enlarged View.

thickened to form a shoulder against the wood is represented; but they are seldom used, although their peculiar construction gives an appearance of great massiveness, besides other advantages in some cases. Another and more ordinary way of giving a slightly ornamental or more finished appearance to the hinge is by means of

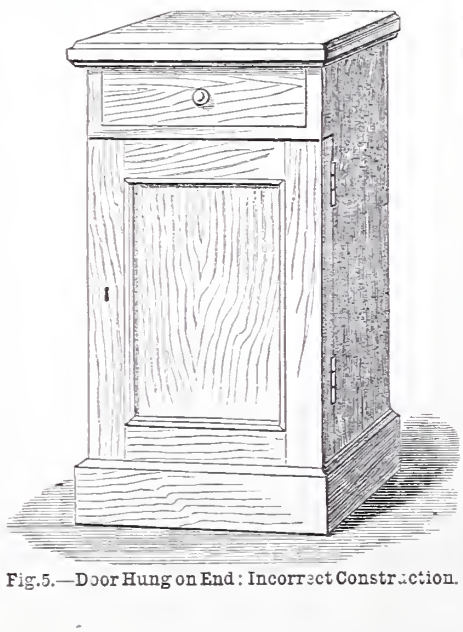

Fig. 5.—Door Hung on End: Incorrect Construction.

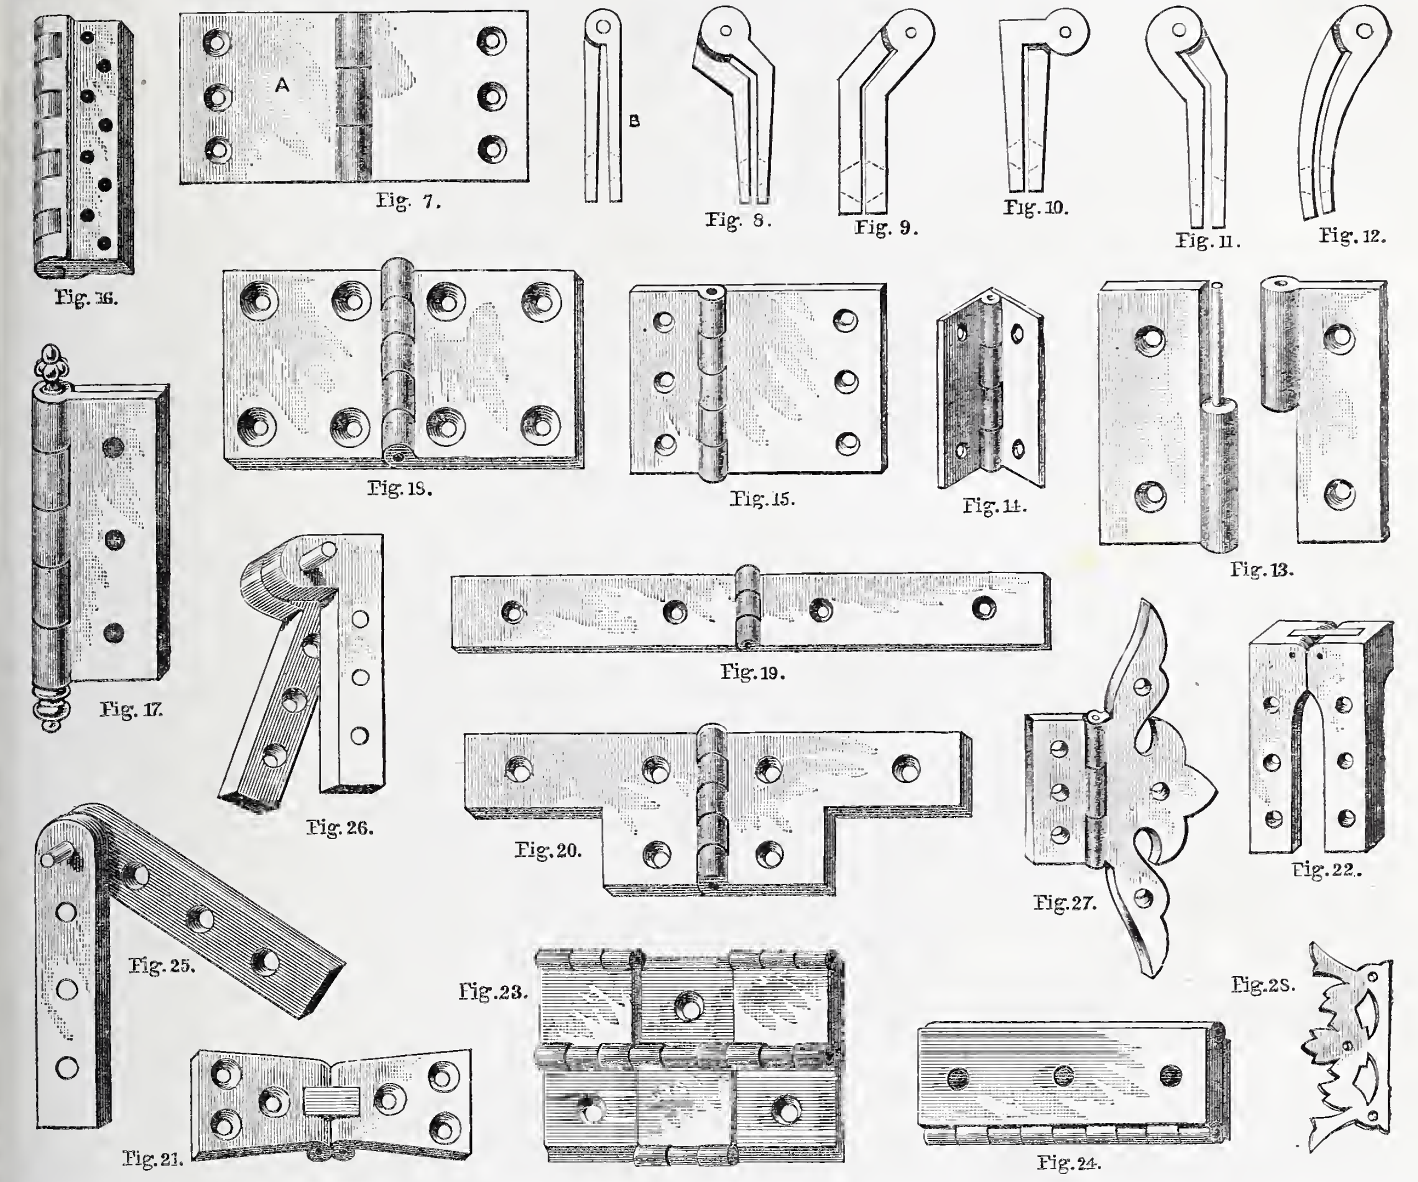
small knobs at the ends of the pins. These hinges are generally used in the better class of furniture, and should be inquired for as knob hinges or tipped butts. No difficulty will be experienced in recognising them from the illustration (Fig. 17), but it should be said that there is a large variety of patterns to which the knobs are made; for example, in a catalogue before me there are about thirty of them. As a rule it may be stated that knob hinges are generally well made and carefully finished, so that the apparently high price of hinges of this class is not caused solely by the knobs, but by the general quality.

But we must now take leave of the butt hinge for the present, and turn attention to other kinds. Perhaps next in order to it for general utility is that known as the "back flap," of which an illustration is given in Fig. 18. From this it will be seen that the proportions are quite altered, the plates instead of being long and narrow being wide and short. This indicates that their peculiar function is to connect two flat surfaces which it may be desired to hinge in such a way that they may be level when the hinge is opened out. A common use to which they are put in furniture is in the construction of flap tables, *i.e.*, tables which may be enlarged or diminished in size by raising or lowering a flap. The hinge plates are let into each piece of the table on the underside with the knuckle downwards, or the reverse way to that shown in the illustration. Another instance of their use may be seen in the old-fashioned bureau. In nearly all of these this kind of hinge is used to connect the lid or writing table part with the carcase. The hinge then is let in on top with the rounded joint upwards. From these two instances there ought to be no difficulty felt by the greatest novice in knowing in what cases to use the "back flap," and it is hardly too much to say that with either the "butt" or this, almost anything may be hinged. All others may be looked on as modifications of these. Take, for instance, the "portable desk" or "bagatelle hinge" shown in Fig. 19. It will at once be seen that this is nothing but the back flap hinge greatly narrowed in the direction of the knuckle with long, projecting plates. As I daresay is well known, and as its name indicates, this form is used for small writing desks and folding bagatelle tables, the long, narrow plates being sunk into the edges of the sides of these so that only the rounded part projects above the surface. Another variety of these hinges is shown in Fig. 20.

A distinct form of hinge is found in card-table or counter hinges, which may be used with advantage whenever it is not desirable to have any projecting knuckle. Fig. 21 is typical of them all. The flaps, it will be seen, are connected not by a pin running through them, but by a separate plate which is pivoted to each of them. As with all other hinges these vary considerably in detail, some having only one connecting piece, some two, and so on. It is, however, unnecessary to specify these, and after what has been said any remarks about fixing them are surely uncalled for. Without, however, giving numerous illustrations of these hinges, it will not do to pass over a distinct form for the same purposes, and known by the same name. This variety is shown in Fig. 22. The only special mention they require is that being fixed to the ends of the pieces they connect—not to the surfaces—they are used in pairs only. Therefore for very long joints, which, however, seldom occur in amateur work, they are not always desirable. Closely allied to the card-table hinge, among which they may be classed, are those like the one shown in Fig. 22, a form very convenient for attaching the folds of a screen or similar purposes. The plates are of course sunk in the top and bottom edges of the framing. It must not, however, be inferred that they cannot be used in other situations, or that they are suitable for screens which are intended to fold in any direction. When this is required of the hinge shown in Fig. 21. To describe their construction and fitting (a somewhat difficult job, by the way) would, however, require more space than can be spared at present, and no doubt for all practical purposes enough has been said by calling attention to the fact of there being such a hinge for those who wish to use it. While treating of fancy or special hinges omission must not be made of the butler's tray hinge, which, however, is seldom required except for the piece of furniture from which it that the hinges should not be seen, though what objection there can possibly be to a good hinge being visible may be a puzzle to which some of us can give no satisfactory answer. However, the fact remains that some prefer to use a secret hinge, or to give its more ordinary name, a centre hinge, of which a plain one is shown in Fig. 25. It does not occur to me that they are used except for hanging doors, which may either be within or on the ends. In either case their use entails more labour than the



Illustrations of Various Kinds of Hinges. Fig. 7.—Wide Flat Butt or Coach Hinge: A, Plan; B, Section. Figs. 8-12.—Sections of Bent or Cranked Hinges. Fig. 13.—Heave-off Hinge. Fig. 14.—Stop Butt Hinge. Fig. 15.—Wardrobe Hinge. Fig. 16.—Narrow Brass Projecting Butt Hinge. Fig. 17.—Knob Hinge. Fig. 18.—Back Flap Hinge. Fig. 19.—Desk or Bagatelle Hinge. Fig. 20.—Ditto: another Form. Fig. 21.—Card-Table or Counter Hinge. Fig. 22.—Ditto, for Fixing on Ends. Fig. 23.—Double-Action Screen Hinge: Open. Fig. 24.—Ditto: Closed. Fig. 25.—Centre Hinge. Fig. 26.—Cranked Centre Hinge. Fig. 27.—Ornamental Hinge. Fig. 28.—Hinge Plate.

the regular screen hinge must be used. These are perhaps the finest and most ingenious of the various kinds of hinges usually met with, and this is equivalent to saying that they are, compared with single-action hinges, expensive. To derive the full benefit from them they must also be very carefully fitted, even more so than in ordinary hinges, but beyond this caution it will be unnecessary to say more about fitting them. The ordinary double-action screen hinge is shown open and closed in Figs. 23 and 24; but there is another very important variety somewhat on the principle takes its name. It has a kind of what in default of a better term may be called a spring stop, by means of which the sides of the tray are kept upright when required. Their upper surfaces are flush with the wood, without any projecting knuckle. If, however, the tray is made with square-ended flaps, it is not necessary to have this form of hinge, as for the spring stop may be substituted a special catch let into the flaps of the tray. It is, however, advisable to use a hinge which does not, even at the joint, project above the wood.

Occasionally it is considered desirable ordinary butt hinge, for either the door must be rounded off or a shallow groove for its edge to turn in must be cut in the piece against which it works. Much might be said about this and the general fitting of centre hinges, but they are so seldom used that anything like full directions would only encroach needlessly on valuable space. Should I be mistaken in supposing that the information is not of much use to readers of this magazine, I shall be happy on some future occasion to give all necessary instructions, and the same may be said about any other kind of hinge and hinge fitting.

At present I must content myself with saying that great care must be used to get the projecting pin seen in the illustration correctly centred in the door frame. One part of the hinge, of course, is let into this, and the other into the wood above it. These centre hinges are also to be had "cranked" or bent in a variety of ways, one of which is shown in Fig. 26, in order to suit different kinds of doors and throw them back as may be desired. A few years ago these centre hinges were much used for wardrobes, and there is perhaps this to be said in their favour, that when the construction of anything seems so ashamed of itself that it wants to look like something else, or in plain English, a sham, the centre hinge is an admirable contrivance. But with all this, occasionally it may be used with advantage; all I want to impress on those who have no very definite ideas about propriety in construction is, not to make use of the centre hinge unless there is some better reason than the false notion that a hinge is an ugly thing in itself, and should be kept out of sight when possible. This leads me to say that a hinge may really be made a very ornamental adjunct to any piece of furniture by using a strap hinge, in which the flap is placed outside. Some made for this purpose are highly decorative, but the same effect may be gained by the use of hinge plates, which are merely pieces of ornamental brass. They are screwed on to, say, a door, close up against the hinge, to which they must, of course, be equal in length. If there is any other brass work, such as handles, about a piece of furniture, it is desirable that the hinge plates should correspond with these in general design. Fig. 27 gives a complete hinge with ornamental flap, and Fig. 28 shows a separate plate. Both of these are reproduced from Messrs. R. Melhuish & Sons' admirable catalogue, in which several ornamental hinges are pourtrayed.

In addition to the hinges of which mention has been made, there are a large number of others used principally by builders, or at any rate in building construction, and differing in shape as well as in size from those used in cabinet work; but space forbids for the present more than this passing notice, and any remarks about them must be deferred.

NOTES AT THE ARCHITECTURAL AND BUILDING TRADES' EXHIBITION, 1889.

It may seem to some that such a display as the above would only appeal in interest to the thoroughly practical man. The title, "Architectural and Building Trades' Exhibition," brings to the mind of many people visions of nothing but bricks, mortar, and sewer pipes, interspersed, perhaps, by way of variety, with chimney shafts and roofing tiles, and they hold aloof therefrom in consequence. It is, however, only necessary to give the matter a minute's thoughtful consideration to effectually dispel such an illusion; for, with the immense progress of modern times, there have been produced a thousand and one contrivances, in connection with our houses, which are of the greatest interest to one and all alike, indispensable as they are to their daily comfort. Our habitations are, nowadays, from the front door to the roof, fitted with innumerable inventions calculated to increase the comfort and, what is more important, the safety of the people who live therein, and to those whose desire it is to be up to date in their knowledge of such matters, a visit to the Agricultural Hall, during the period in which the Building Exhibition is held, cannot but be profitable.

For the benefit of those, however, who, by reason of time and circumstances, have been unable to go in that direction, a few notes on the most interesting and useful exhibits there may be welcome; and to that end we took an opportunity to visit the Exhibition and review the goods to be found therein.

As the most usual and generally accepted way of entering any house or building is through the door, it is fitting that inventions connected with that piece of wood work shall be considered first, and of these there were shown many possessing great practical utility.

Mr. Robert Adams, of 67, Newington Causeway, S.E., had, in his exhibit, a variety of contrivances associated with the opening and closing of doors, which showed the strides made in that direction of late years, and of these, the "Victor" spring hinges were, perhaps, the most admirable. These hinges are, of course, more adopted in public buildings than in private houses; but there are few people who have not, at one time or another, to use doors so fitted. Some forms of the "Victor" hinges are, doubtless, well known to our readers, but there is a development of the action which has been recently introduced, and which demands notice. It is styled the "New Crown Victor Silent and Non-silent Patent Double-Action Door Spring Hinge," and is certainly one of the most compact hinges of its kind. The mechanism is so contrived as to be always compensating, the result being that no slackness can arise from wear; and one of the principal objects of it rests in the fact that the weight of the door is so provided for, that it cannot possibly cause the pivot to wear, thus precluding any likelihood of the heel of the door rubbing against the hollow of the frame. The "Hurricane" spring hinge, also by the same firm, is so arranged as to resist any force of wind in exposed positions, and yet to allow of being opened by a child in an opposite direction.

Certainly, one of the greatest difficulties in the domestic routine of the household is cleaning the outside of upper windows; and it sometimes really makes one shudder to watch the acrobatic feats of servant girls on a high, narrow window sill. To provide for this, and, indeed, entirely remove all danger from the operation, the new sash gear, from the hands of the same inventor, shows what appears to be a perfect solution of the question; and were it employed more generally in extensive buildings, the number of accidents which one hears of from time to time would considerably diminish.

In the same direction, Messrs. Hill and Hodges were showing a floor spring hinge which they are putting into the market; and for bank, lobby, and other double-action spring doors, its efficacy seems indisputable. The main point with regard to the hinge in question is that, instead of having an ordinary square or pivot, it has a solid arm on its axis or pivot, which projects on end; and the advantages accruing from that arrangement certainly call for notice from those who have to do with such matters.

From the door to the hall is but a step, but in that short distance there arise new requirements and necessities, which have called forth multifarious inventions. In the entrance halls of houses of a more pretentious character, floor-cloth, linoleum, and carpeting have given way before that description of flooring known as parquetry. That such should be the case cannot for a moment be wondered at, for good parquet is characterised by a durability, evenness of surface, and beauty of appearance, which combine to make it a powerful rival to other materials of a softer description. To those anxious to discover how far the manufacturers of that particular flooring have extended their operations, the exhibit fitted up by Turpin's Parquet Floor, Joinery, and Wood Carving Company, of 22, Queen's Road, Bayswater, constituted a good index by which to judge. With some people, the one great objection against the adoption of parquet flooring has been its expense, but with the ever-increasing capabilities and improved facilities possessed by makers to-day, it is being brought more within the reach of all; and one thing is certain, housewives will be the first to welcome the advent of such a decorative and highly sanitary flooring. Of the latest of Messrs. Turpin's productions, the patent thin parquet flooring is, perhaps, as important as any. This latter quality is $\frac{5}{16}$ths of an inch thick altogether, including ornamental pattern and backing; the latter of which is made of either one, two, or three wood laminations, laid crossways of the grain of the wood at right angles. By that means, the thin parquet is rendered as strong and durable as that 1 in. in thickness, and is capable of resisting the strain of heavy bodies placed upon it, without any ill effects whatsoever. As must be apparent to those who are compelled to study economy, and yet desire to embellish their houses in that direction, this latter description appeals very strongly; and the fact that it can be removed at pleasure from the under flooring, without either sustaining any damage, is an additional commendatory qualification. In these days, when bad, "puddingy" carving is so rife, to see really good cutting is refreshing, and it is only due to say that several panels shown by Messrs. Turpin were of the highest order. Some dado panelling, also emanating from the same workshops, called up the "good old times" when wood-panelled rooms were more in vogue than they are to-day.

Mr. Henry Bassant, of 87, Charlotte Street, Fitzroy Square, further represented the parquet industry; and good workmanship, combined with artistic judgment, characterised the selection to be seen on his stand. Up to a very recent date, the patterns worked out in parquet were somewhat restricted, the difficulty of disposing the blocks of wood in free decorative schemes being no small consideration. Now, however, designs are being produced which show that the difficulty specified is giving way before modern improvements; and many patterns shown by Mr. Bassant were of a really free and artistic character.

From the floor to the walls is the next most natural step, but, strange to say, what is technically known as the "decorating" section of the building trades was left almost entirely unrepresented in the recent display. There was, however, one exhibit of great interest to those who study the development of wall decoration. It consisted of a new Cordovan leathern wall decoration, styled "Calcorion," manufactured by the "Calcorion" Decorative Company, Limited, Addison Works, Woodstock Road, Shepherd's Bush, W., and there is no uncertainty in predicting that it will be sure to find favour in the eyes of high-class decorators. The rare beauties of old Spanish leather hangings, authentic examples of which are now so scarce, have been expatiated upon by painter and poet; and when one looks at such rooms as are to be found in, for instance, the Musée Plantin in Antwerp, it is impossible not to regret, in a measure, the disappearance of that material from our walls. It is to satisfy this want that "Calcorion" has been devised; and certainly, as far as appearance goes, it seems fully qualified to do so. From an economical point of view, the new wall covering would not, perhaps, find favour everywhere, although the simpler designs are reasonable in price. Economy is not, however, quoted as a qualification thereof, and the more elaborate schemes of decoration, worked out in that material, are altogether *recherché*, and would grace the highest palaces in the land. In texture, "Calcorion" is much akin to leather, and when embossed and decorated, it would require an experienced connoisseur to detect the difference. Its natural colour is buff, but, as may be readily understood, a pattern embossed on it may be treated in any colours that may be deemed desirable, thus allowing great scope in treatment. It is manufactured in pieces of 12 yards length and 36 inches in width, and the method of affixing it to the walls is much the same as that employed with other thick materials of a like description, strong paste being the chief factor in the operation.

Further continuing the decorative line of thought, a fine ceiling in fibrous plaster was shown by the Hitchins' Fireproof Plastering Company, Limited, 1, Gresham Buildings, Basinghall Street, E.C.; which served to further substantiate the claim of that material for use in extensive schemes of decoration. Fibrous plaster is, by this time, so well known, that to lengthily describe it here is unnecessary, but there are one or two improvements introduced by the above firm to which attention must be drawn. What are termed wirework slabs, that is to say, a thickness of fibrous plaster, having through the centre, and forming a foundation, a square of wirework netting, form a new feature; and, from the method of their manufacture, are absolutely fireproof in every respect. By the use of that description of slab, the necessity for ordinary lath and plaster is avoided; and, in addition, the work can be painted, papered, and finished within a very short period of completion.

Architectural wood work, as might be surmised, played an important part in the year's show, and among those manufacturers of wood mouldings for interior decoration, Mr. Samuel Elliott, of the Albert Steam Joinery and Moulding Mills, Newbury, exhibited a choice selection. In this section, again, we find the influence of modern progress, for, whereas in days gone by a skirting board and cornice moulding were deemed sufficient, nowadays, dado and picture mouldings are indispensable, and the industry has undergone further development in consequence.

It is often the case that the beauty of an interior, especially one of a less elaborate character, depends on the sharpness and disposition of the mouldings employed in it, and for the architect to have such a selection to fall back upon as that shown by Mr. Elliott is half the battle. Mouldings in oak, walnut, and other woods served to show that manufacturer's capabilities in that direction, and also gave the uninitiated an idea as to the development of that particular branch of wood work.

Another excellent display of turnery, joinery, and interior wood work came from the Keighley Timber and Saw Mills Company, of Lawkholme, Keighley, Yorks., and the north country certainly could not have sent to town better representatives.

As a selection of high-class joinery and turning it was to the fore, and such indispensable factors as balusters, skirtings, mantels, windows, and examples of panel work were shown by that Company, and went to prove conclusively that a builder nowadays is not under the least necessity to send abroad for his wood work, as some seem inclined to think that they are.

Another stand of a similar character was that of Messrs. L. W. Ransom and Company, of the Britannia Works, Kensal Road, W. Staircases, handrails, newels, balusters, scrolls, wreaths, caps, etc., were there to be seen in abundance, and indicated that the requirements of the trade are well understood and studied by those wood workers.

The importance of the window-cleaning difficulty, already referred to, is so great that numerous inventors have made it the subject of study, and of those the "Millar's Patent Reversible Window Company" offer an admirable solution of the question. Windows fitted after the manner shown by that firm can be easily reversed—that is to say, the outside brought inside—by anybody, and any necessity to sit out on the sill is completely done away with. A more practical and admirable arrangement few would desire, and the combination of simplicity with perfect efficiency is there successfully accomplished.

When one compares the gasfitting and general domestic metal work of to-day, more particularly in the way of chandeliers, gas-brackets, etc., with that of years ago, the result is decidedly satisfactory; and people are, fortunately, beginning to appreciate the fact that metal work, in the hands of an artist, is one of the most charming materials for decorative purposes. The idea entertained by some, that to be a metal worker is lowering, is fast being dispelled, and the world-wide reputation made by Quintin Matsys at the forge is proof enough as to the absurdity of that notion. Indeed, one of those artificers in metal who exhibited (Mr. A. G. Hamilton), has called his works "The Quintin Matsys' Forge," and it was gratifying to observe that the work shown by him was of such a high class that the great master himself would not have taken exception to it. To attempt to describe all the knick-knacks on his stand would be futile, but we may briefly say that several standard lamps and hanging lanterns in wrought iron by that maker were equal to any being produced. Some gong stands in the same material constituted rather a unique speciality; and one or two decorative wrought iron kettle stands were of a character to elicit admiration from the artist and the housewife alike. There is a sturdy grace associated with wrought iron work which appeals to our English tastes, and to those who love to see the imprint of the workman's tool on artistic productions, the study of that special branch of metal work is full of enjoyment.

Electricity as applicable to the house received a full share of attention, and of those who make a special study of that branch Messrs. Verity Bros., 137, Regent Street, had fitted up a most interesting display. To those who consider the electric light inapplicable to the private house the stand in question would have been a revelation, for chandeliers, or, to speak more correctly, electroliers, side brackets, standard lamps, and others, all illuminated by electricity, were the most incontestible proof of the way in which that wondrous fluid has gained ground. A somewhat recent invention shown was a combination of gas and electric fittings, so arranged that a bracket could be used for either purpose at will, without any difficulty or alteration. Messrs. Verity also exhibited specimens of their wrought iron work, which was of the highest class, and, indeed, did space permit, their stand invites further description; but we must proceed.

One of the most important and extensive sections of the Exhibition was that devoted to machinery, and it is in that department, above all others, that the stamp of modern progress is most unmistakably affixed. Machines for this purpose and that purpose, for making bricks and executing the most delicate mouldings; mechanical contrivances from a steam engine to a fret saw, all demanded attention; but to attempt to particularise one tithe of the good qualities claimed for them would be folly. A cursory glance is the most that is possible in such a connection; and to start with motive power, Messrs. Crossley Bros'. gas engines took a high place. The "Otto" gas engines are far too well known to require comment here; and any one visiting the Exhibition who desired testimonials as to their reliability had only to glance up at the array of prize medals shown, and doubt was set at rest.

Following in the same line, Messrs. J. E. H. Andrew and Company, 80, Queen Victoria Street, London, showed several of their "Stockport" and "Bisschop" engines, and the best test of their quality was the manner in which they fulfilled the duties allotted to them.

Messrs. Dick, Kerr, and Company, 76, Queen Victoria Street, had an array of their "Griffin" engines working away, and to judge from such a collection as was there shown they fully justified the description given of them.

Of wood-working machinery the display was large and satisfactory, and whether the visitor was an amateur or artisan there was sufficient to interest him for a long time.

Messrs. J. Sagar and Company, of Stone Dam Works, Halifax, showed by their exhibit that they have a perfect grasp over the manufacture of all branches of wood-working machinery, and to adequately review their stand alone would fill a small volume. Of the machines at work there, the "Self-contained" band sawing machine, the "Premier" combined hand and roller feed panel, etc., planing machine, and the "Hand-planing and trying-up machine," were some of their latest productions, each possessing qualifications which go far to recommend them for high-class work. Fret saws, from the simplest to the most elaborate, were in active operation, and one particular machine, constructed to work with either strained or unstrained saws, at pleasure, attracted much attention. The "Variety" wood worker is the style and title of another contrivance from the Stone Dam Works, and as it successfully performs the operations of planing, sawing, moulding, grooving, jointing, rabbeting, squaring, chamfering, tenoning, mortising, and boring, the name is certainly fully justified.

Machines of a great diversity appeared in the stands adjoining, but space will, unfortunately, not permit their description on this occasion.

OUR GUIDE TO GOOD THINGS.

30.—The C. H. M. Improved Flooring Cramp.

Notice has been taken in this part of Work of some lathes, lathe chucks, and excellent tools of various kinds used for ornamental turned work and in joinery. Our attention is now turned to appliances that are different in character to those which have just been mentioned — appliances that are chiefly useful in building and carpentry strictly so called, and which may be termed the C. H. M. specialities. This, at first sight, appears a somewhat singular and quaint distinction; and many, perhaps, will be puzzled for a moment to determine what C. H. M. may mean. The difficulty, however, will vanish when they are told that all the articles to which reference is made, and which are illustrated in this page, are manufactured by Mr. C. H. Matthews, 13, Charles Street, Wolverhampton, who has utilised the initials of his name in this way as a sort of trade mark by which to distinguish goods of his own make from all other goods of a like kind and serving like purposes that may happen to be in the market.

The first of these, the C. H. M. Improved Flooring Cramp, is illustrated in Fig. 1, in which are clearly shown its construction, the manner in which it is used, and the purpose which it serves. It is serviceable in laying down flooring, and by its aid the floor boards are forced into as close contact as possible along their length before they are nailed to the joists. The ends of two floor boards are shown in position on a joist; one of them has been already nailed down, and the other is being tightly jammed against the nailed board by the machine before it is itself secured by nails. The cramp rides, so to speak, on the joist, and is gripped tightly to it by the handle and contrivance shown at the side of the joist. By turning the handle shown on the opposite a bevel cog wheel is turned, which gears into a larger wheel of the same kind, from the centre of which a deeply-cut screw proceeds, whose extremity works freely in a metal plate perpendicular to the joist. The screw works through a piece of metal with a rounded head attached to one end of the bar, which is driven by the action of the screw against the floor boards, exciting considerable pressure, and compelling a close joint between the boards. The cramp is made of malleable castings, and is furnished with wrought iron wormed pins and steel lance-blade teeth. It is light, compact, steady in its action, and serviceable, being formed to grip joists from $1\frac{1}{2}$ in. to $3\frac{1}{2}$ in. in thickness, and by reason of its construction, compressing floor boards with the greatest possible force directly applied. These cramps are sold singly at 21s. each, and in pairs at 40s. per pair.

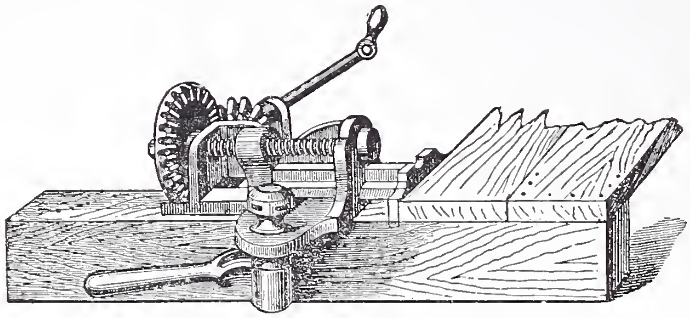


Fig. 1.—C. H. M. Improved Flooring Cramp.

31.—The C. H. M. Lever Handle, Bright Bar, Planed Wedge-Action Bench Cramp.

The Bench Cramp, whose name has just been given in full, differs in many particulars from similar contrivances in general use, but the principle on which it is made and its action are very much the same. Both parts, B and C, are movable along the bar, D; but the portion C may be rendered immovable to resist the pressure of anything impelled against it by the part B. When in work, B is moved towards C, on the bar, D, by action of the screw turned by the bar inserted in the head of the screw at A. The part C, which, as it has been said, is movable, becomes immovably tightened on the bar, D, by depressing the handle, E, and forms a line of support on the bar, D, for direct pressure transmitted from B. Under ordinary pressure, C may be rendered movable by raising the handle, E, upwards with the hand, and under severe pressure a blow in the direction indicated by the arrow will effect this without injury to the cramp. This cramp is made for setting out for joiners, cabinet makers, etc. It is made with bars from 1 in. × ¼ in. × 16 in. to 2 in. × ½ in. × 66 in.; sold respectively at prices ranging from 11s. to 50s. Couplings and lengthening bars are supplied for cramps above 48 in. in length, ranging from 48 in. to 66 in., and sold together at prices from 16s. to 24s.

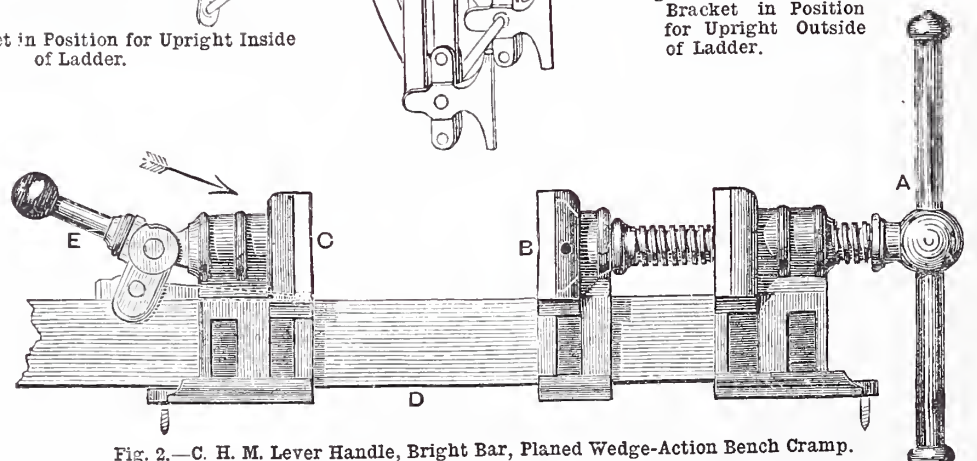

Fig. 2.—C. H. M. Lever Handle, Bright Bar, Planed Wedge-Action Bench Cramp.

32.—The C. H. M. Improved Bracket.

These brackets are made in wrought iron, and are useful for bricklayers, plasterers, painters, etc., when it may be found necessary to form a temporary scaffolding by means of planks and ladders. The brackets may be used with ladders at any incline as far as the perforations in the brackets will admit, and on either side of the ladders. In Fig. 3 the bracket is shown for use on the outside of a ladder, the ladder being upright, and the bracket being hung on it by hooks, which are placed two on one round, and two on the third round below. As the ladder's incline is greater, the bars on which the planks rest must be lowered as shown by the holes pierced on the framework of the bracket. Fig. 4 shows the mode of slinging the bracket from the inside of the ladder; it is, in fact, reversed. Fig. 5 shows the bracket closed for removal. The brackets are strong, light, portable, and safe in use. They are made in three different sizes to suit rounds $1\frac{1}{8}$ in. in diameter and 9 in. apart, and $1\frac{1}{4}$ in. in diameter and 10 in. apart. Prices range from £2 4s. per pair to £3 6s. per pair. Brackets to suit ladders are made to order.

The Editor.

A Corner for Those who Want to Talk It.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

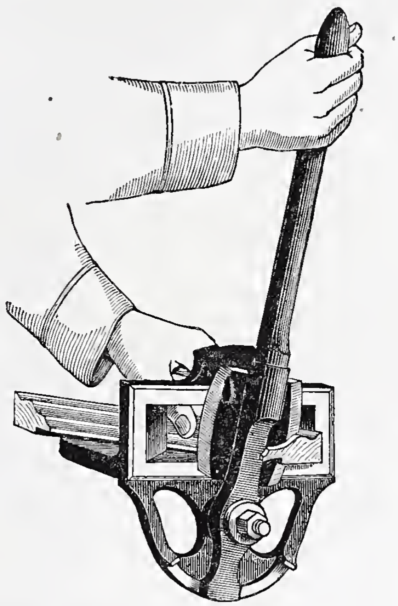
I.—Letter from a Correspondent.

A Good Word for "Work."—E. D. (*Old Kent Road*) writes:—"It was with pleasure I saw the announcement of Work in *Cassell's Saturday Journal*, about three weeks before the first number came out. I said to myself, this is the very thing that is wanted, and at once made it known to several of my acquaintances, five of whom have commenced to take it in. I shall continue to make it known as much as I can, as I am sure it will be a great boon to many like myself who are fond of making things, having been an amateur workman for more than twenty years. I am sure it was really wanted. I am also pleased with the article by David Adamson ('Artistic Furniture' in No. 2), not so much for instructing us in utilising old packing cases, which often spoil our tools (new stuff is so cheap that it is not worth while to use old), but for advocating the use of nails or screws in making up work. I have made a good many things in my spare time: tables, chairs, book-cases, cabinets, and overmantels, all of which are screwed and glued, or nailed. I never could make a proper dovetail, it being so difficult, and I am sure that inability in this respect has deterred many from making anything really useful, otherwise than mere ornaments or knick-knacks. One thing I will ask of you: that is to announce any exhibitions of mechanical work, so that myself and others can have time beforehand to send in any articles to exhibit. I wish your Journal every success, which I am sure it will have."—[Thank you for your goodwill towards Work, and your good words and deeds in its behalf. You must remember that although new stuff may be cheap enough, it is by no means well seasoned, and therefore often inferior to packing-case material, which frequently has this advantage. All mechanical exhibitions of which we may have notice shall be duly announced in Work.—Ed.]

II.—Questions Answered by Editor and Staff.

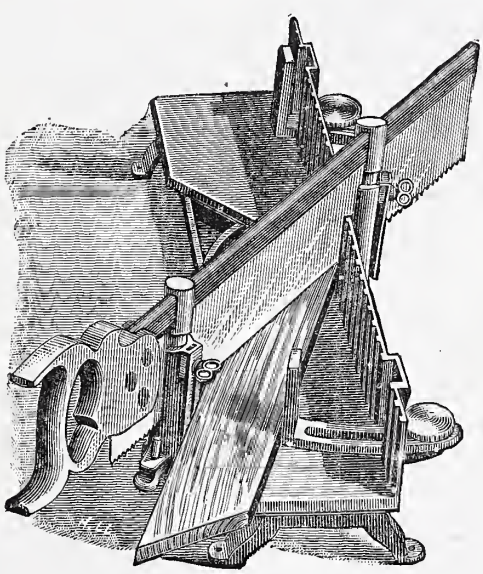
Picture-Frame Making.—W. B. W. (*Liverpool*).—You ask "that some practical illustrations be given as regards the best and easiest method for an amateur to form the right angle in sawing the pieces from the long slip of gilt or other frame, so that they may join exactly and neatly in framing a picture;" and you then proceed to describe the home-made mitre box you have put together to aid you in cutting the pieces of the frame from the moulding, and say that "although you saw it through according to the angle slit, invariably the corners will not join in an exact and neat manner." This, I must first remark, shows that the "angle slit," as you call it, in your mitre box, otherwise the transverse saw cut or saw kerf through the upright sides of the box, is not truly made at an angle of 45°. Were it so, the joints at the corners of the frame could not fail to be made exactly and neatly, to use your own words, because when two pieces correctly cut at an angle of 45° are put together, edge to edge, one piece being cut in one direction and the other in a direction precisely opposite, they cannot fail to make a true right angle or angle of 90°. You will find a mitre box correctly illustrated and described in Mr. Adamson's paper on "Artistic Furniture" in No. 3 (page 35), the illustrations being Figs. 10 and 11 in page 37, the former showing a perspective view of the box, and the latter the box in plan, or as viewed from above, exhibiting clearly the directions of the transverse cuts that must be made downwards through the sides. I venture to recommend you to have a mitre box made for your own use by a skilled mechanic, and you will then find no difficulty in cutting your mouldings properly, because you will have a true and reliable guide to cut them by. If you are disposed to lay out a few shillings in providing yourself with a machine for cutting mouldings, I have given here an illustration of an "Improved Mitre-Cutting Machine" made by Messrs. Booth Brothers, Dublin, and sold by all dealers in tools, etc. The price of this machine to cut 2-in. mouldings is 12s. 6d., and an extra cutter may be had for 2s. 3d. There was an American mitre box in the market some years ago, with which a tenon saw or a panel saw could be used equally well; but this seems to have been superseded by the "Improved New Langdon Mitre Box," of which an illustration is appended. Ordinary mitre boxes cut from right angles to angles of 45° inclusive, but this mitre box cuts, by using the circular arm or guides, from right angles to 73° on 2½-in. wood. In addition to this, it is claimed for the Improved Langdon that it is the only box adjustable for mitring circular work in patterns, emery wheels, and segments of various kinds. The prices for the four sizes in which it is made range from 24s. without saw, and 34s. with saw, to 70s. and 84s., without and with saw respectively. The first size will cut 3½ in. at right angles, and 2¼ in. at the mitre, and the largest size 9½ in. at right angles, and 6½ in. at the mitre. You are now in possession of the best existing means for cutting mitres correctly. Thank you for your efforts in making Work known to your friends.

Electro-magnet.—A. G. (*Croydon*).—Your query, relative to an electro-magnet required "to lift the greatest weight with two quart Bunsen cells," cannot be exactly answered, unless we know the conditions under which the magnet will be worked. For instance, a magnet working at some distance from a battery through a line of wire will not develop as much magnetic power as the same magnet worked up close to the battery. In planning a



Booth's Improved Mitre-Cutting Machine.

magnet to develop the greatest capabilities of a battery, we must take into consideration the resistance of the whole circuit, and proportion the coils of wire to that resistance. Then, again, the nature of the work to be done must be considered, whether the magnet will be required to simply hold up a weight *placed to its poles*, or to *attract and lift* a weight to its poles from a distance. The power of a magnet on an armature detached from its poles varies in an inverse ratio with the square of the



Improved New Langdon Mitre Box.

distance of the armature from the poles of the magnet. The best *holding* power is secured by a horseshoe form of magnet with the cores placed close together, whilst attractive power is slightly increased by placing the cores wider apart. Assuming that you will use a magnet close up to the battery, the following instructions will enable you to utilise the full power obtainable from two cells placed in series. Use a 9-in. length of ⅝-in. best Swedish iron made soft by annealing, and bent into horseshoe form, with its legs or cores 2 in. apart. Get two ebonite or boxwood bobbins 3 in. in length by 1½ in. in diameter, and wind on them (as a reel of cotton is wound) nearly 1 lb. of cotton, or silk-covered No. 16 B. W. G. copper wire. Silk-covered is best if you can get it. Wind one bobbin from right to left, the other left to right, and join the inside end of one coil to the outside end of the other. Fill both bobbins. The bobbins may be had from Messrs. H. Dale & Co., 26, Ludgate Hill, E.C., who will also wind the wire on them if you desire them to do so. No. 18 wire may be used if the magnet is to be worked at a distance from the battery.—G. E. B.

Wood Screw Cutters or Boxes.—R. R. (*London, E.C.*).—The screw boxes and taps described in "Our Guide to Good Things" (No. 3, p. 46) may be purchased of Messrs. Richard Melhuish & Sons, 85 and 87, Fetter Lane, E.C., or direct of Messrs. Alexander von Glehn & Co., 7, Idol Lane, London, E.C., agents for Messrs. Peugeot Brothers in the United Kingdom. The specialities of this firm of French manufacturers seem well worthy of attention. Having given the information you ask for, I will append the concluding paragraph of your communication, and express my pleasure at finding that Work has been so heartily welcomed by yourself and others. You write:—"Allow me to congratulate you on the success which must attend the publication of such sterling information in such a readable form, and at such a popular price. I am sure Work will do good work."

Coloured Cement.—J. H. C. (*Bow Road, E.*).—I am not acquainted with any firm that make coloured cement, but it is possible for you to give any colour you please to cement, whether chocolate, black, or any other, by adding to the cement colouring matter which you can purchase of any oil and colourman.

Advertisements in "Work," etc.—F. T. (*Bristol*).—It is difficult, I can assure you, to locate advertisements otherwise than where they are at present. I can only submit your views to the Manager of the Advertisement Department, to whom I will also mention your wish to see a "Sale and Exchange Column" opened in the Magazine. Your newspaper cutting—*i.e.*, "Lighting by Electricity"—has been forwarded to Mr. Bonney, who will readily tell you what he thinks of the statements set forth therein. Stereotyping will be treated in Work in due season.

Slips for Wood-Carving Tools.—Tom.—You ought to be able to procure these through any dealer in tools, etc. If, however, you are unable to do so, apply to Messrs. R. Melhuish & Sons, 85 and 87, Fetter Lane, London, E.C. In reply to your query as to how these shaped slips are to be used, you will understand that as it is not possible to sharpen some varieties of carving tools, as V cutting and veining tools, on a hone or sharpening stone, as ordinary plane irons, chisels, and gouges, the sharpening must be effected by rubbing the shaped stone on the edge of the tool. In order to effect this in the most thorough manner possible, the slips are shaped to suit the conformation of the tools for which they are intended.

Marking Steel and Iron Tools.—W. L.—Put a coating of yellow soap or beeswax on the steel or iron on which you wish to write your name. Then, having written your name on the soap or wax with a bone point or quill point, taking care to mark through the soap, raise a small wall of the material used for coating the iron round the space on which the name is written, and fill with a mixture of strong acetic acid 3 oz., and sulphate of copper, sulphate of alum, and muriate of soda, each 4 drachms. Let this remain until the name is sufficiently bitten in, and then pour off acid and clean the iron.

Overmantel.—Barrington writes:—"The overmantel shown in No. 2 can be made from old tea chests. I think they are made of a kind of cedar. They can be had for threepence each—good-looking wood." [This is going to a "deeper depth" than Mr. Adamson even contemplated. Will you kindly send me a sample of the wood, as I should very much like to have a look at it? I have never been able to put tea-chest wood myself to any other use than that of lighting fires, and it will be quite a new experience to me to find that our friends the Chinese have used any material in this way worth having. It is otherwise with the lead lining.—Ed.]

Elizabethan Twist in Lathe.—C. C. E. writes:—"May I remark—as you invite remarks—upon your description of the 'Lukin' Lathe, that a spiral chuck, without the addition of a costly set of change wheels, is of no use even for a spiral; and that with them you cannot cut an *Elizabethan* twist, which has a convex contour; and that although I have *heard* of two lathes that can cut them, I do not believe there is any lathe in existence by which they can be produced. Hence the word 'Elizabethan' is misleading. They are effected by cutting a spiral groove, and then finishing approximately by rasps and files and paper, as you probably know." [If the spiral groove can be cut in the lathe, why cannot the sharp edge of the spiral groove be also removed, and the Elizabethan twist finished, without rasp or file? After receiving your letter I called on a turner, in whose shop I had seen some Elizabethan twists, and he assured me that they had been produced entirely in the lathe, and were turned, I think, at Bristol. He also showed me a double spiral that he had begun to cut himself, but which had broken through a flaw in the wood.

Further, to make sure that I was not mistaken in the matter, I put the question to another workman, who has gained his experience under one of the first, if not *the* first, lathe-makers in the United Kingdom, and he, too, said there was no difficulty whatever in *completing* an Elizabethan twist in the ornamental lathe, with proper tools. I am aware that your experience is also great, and I shall be happy to insert any communication from you *per contra* to what has been stated as to the possibility of doing what you say can only be partly done, hut not finished, in the lathe, leaving it to be taken up and answered by those who, like yourself, are skilled turners.—Ed.]

Bookbinding.—J. S. (*Moss Side, Manchester*).—Papers on this subject are being written for Work.

Violin Making.—J. S. (*Moss Side, Manchester*).—A skilled maker of violins is intrusted with the preparation of a series of thoroughly practical papers on this subject. These will be brief, and to the purpose, and will be commenced at the first convenient opportunity.

Coal Mining.—Fretwork.—You say:—"Will you kindly let me know if you intend devoting any part of your paper to the art of mining, such as coal? I hope this will not offend you. As I am a collier, it is natural I should ask such a question."—[To this I may say that no question, he it what it may, that is put with reference to any kind of work that is done by man, can give offence. On the contrary, your query, and all queries, are heartily welcomed, because they evince the wide and earnest interest that is taken hy workmen of all grades and trades in Work, which is intended hy all who are concerned in its production to he truly and honestly helpful to workmen. You may rest assured that when any opportunity offers of touching on matters connected with your calling, it will be done; and that when any invention is produced likely to lessen the perils of mining, and to be helpful to the miner, it will be described. Meanwhile do not hesitate to ask any special question bearing on your trade on which you require information.—Ed.]

Cabinet Making.—R. G. (*Birmingham*).—You will soon have detailed instructions in cahinet making to help you. It is scarcely worth while to devote a supplementary sheet to working drawings of a cahinet in fretwork large enough to keep the weekly numbers of Work in. Make a plain hox of the proper length and breadth, and 3 or 4 in. deep. Ebonise it, and cut an overlay in white wood to he attached to sides and top. You will soon find suitable patterns in fret work for overlays of this kind in Work. There are pleuty of good things of this sort in store for you.

Thin Circular Saws.—A. R. (*Scorrier*) writes:—"It is every employer's place to get as much work done with as little cost as possible; some try to do it hy having cheap tools and cheap machines, and employing men that have had little practice at low wages, which, in the long run, proves to he the dearest. A bad machine, a bad saw, and an inexperienced man is dear at any price. To work a thin saw—in the first place, there should be a good machine, a good saw, and a careful practical man to work it. I say 'careful,' because I have seen men that have had much practice very careless, and no hetter men than those that have had little practice. We often see in sawmills where there is hard and soft wood nearly all the time cutting, that the saw that has to cut the hard wood has to cut the soft wood as well; this is a mistake. A saw to cut hard wood should he stouter than for soft wood, and sharpened differently; consequently it will require more power to drive it, which means cost. Again, should saws that are stout enough for soft wood be used in cutting hard wood, they soon get crippled, and run untrue. Therefore you will see that by having saws for each class of work, thinner saws may be used in cutting soft wood to advantage. Again, how often do we see deals up to 11 in. deep, having only two cuts put in them, sawn in the deal frame, when with care and a little skill they could he sawn with a circular saw, and more than twice the amount of work turned out in a given time, and with a very little more waste than if sawn with frame-saws. As a rule, deal frame-saws are from 16th to 15th gauge. A circular saw 30 in. diameter, of 14th gauge (which is less than the 80th part of an inch stouter), could be used for cutting deals, etc., up to 11 in. deep if kept expressly for such work, and worked hy a careful man. Another advantage in cutting deals with thin circular saws, is to have a curved wedge made of steel fixed close to the teeth at the hack of the saw—the front of the wedge to be the thickness of saw-kerf, and the hack of wedge one-half thicker than saw-kerf; this will prevent a certain amount of friction on saw-plate; and on the timher leaving the saw, the teeth at the back are not so liable to catch the timber and throw it back to the sawyer, doing him, perhaps, great injury. Much more might he said in reference to thin circular saws, hut I will take up no more valuable space in this number."

Electrotyping.—J. O. A. (*Manchester*) writes:—"I shall be much obliged if you will give me a little information on electrotyping. I have been trying to make an electro for letterpress printing, but I cannot get the deposit to go into the hollow parts of the mould. The mould is $2\frac{1}{2}$ in. × $3\frac{3}{4}$ in., the anode is $4\frac{1}{2}$ in. × 7 in., and the battery is a three-cell quart Daniell coupled in series. The solution in porous cells is about 12 water to 1 acid. I have a zinc cylinder in one cell, and a cast zinc plate in each of the other cells. The mould is suspended in a solution of cupric sulphate in the usual manner, and the connections are made with No. 16 copper wire. Does a stronger solution in porous cell give a stronger current? also, do the zincs require filing smooth when they hecome pitted or eaten hy the acid? I find that I do not get as good results when I only use one or two cells, but I do not want to add to the number until I get some information as to the cause of failure." [To the above the reply is:—All your arrangements are right as far as I can see. Have you used the best hlack-lead, and brushed this carefully into the deeper parts of the mould? The deeper hollows must receive careful attention to insure success. Use a small sable pencil to hrush the lead in the hollows. Have you any acid in the cupric sulphate solution? It must have some free sulphuric acid to dissolve the anode, or the work will not go on right. A stronger solution in the porous cells would strengthen the current, but 1 of acid to 12 of water is quite strong enough for a Daniell battery. Have you amalgamated the zincs? No need to file out the pits in the zinc plates; but well hrush them, and keep them amalgamated. All that I have written on this subject in my article on the Bunsen battery applies with equal force to the Daniell. A bunch of copper wires as an anode, with the tips of the wires pointing close into the hollows, may help to start the deposit in those parts.—G. E. B.]

Proportion of Fly-wheel.—J. P. A. writes:—"I should like to know the proper rule for finding the diameters of the driving cone, when the diameters of the cone on the spindle are known. I have a small one; the diameters are $1\frac{1}{2}$ in., $2\frac{1}{4}$ in., 3 in., and $3\frac{3}{4}$ in., and I want to make the driving cone, so that the hand will be as tight on one speed as another, for turning metal."—[To this the answer is:—It would be very much less expense and trouble if J. P. A. endeavoured to find some one who has a pattern, as it is a costly one to make; hut by finding the proportion between the relative speeds, the tension of the hand may be made to coincide with each. At the same time, for such diameters as given ($3\frac{3}{4}$ heing the largest), it is not worth the trouble, as little metal-work can he done in such a lathe, except of a very small size.—J. H. H.]

Polishing Metal.—Machinist.—You ask:—"How are the finely-polished surfaces seen on the lathes and machines sent out hy such firms as the Britannia Company obtained? Especially those of the cog-wheels, where it is impossihle for an emery disc to be used, seeing that the part hetween the edge of the face and the boss is recessed. Then, again, there are the mouldings, and small hand-wheels with circular rims." [To this the reply is:—The process of polishing and finishing lathe and other work will depend a great deal upon the way in which it is manufactured. Such work as referred to is generally left from the machine, and very little time spent on it after. With regard to the finish of cog-wheels, these should not be polished in any way whatever, hut left entirely from the cutter.—J. H. H.]

III.—Questions Submitted to Correspondents.

In deference to a wish evinced hy many, that their queries should he suhmitted to correspondents and readers *en masse*, presumably in the hope that many may be induced to give their experiences on the points and questions raised, this section of "Shop" has been commenced for this purpose. Correspondents and others answering inquiries in this section are requested to head replies with the number, subject, and initials, etc., or *nom de plume*, at the commencement of each query, and append their own initials, etc., or *nom de plume*, as they may prefer.

1. Lawn-Tennis Court.—J. H. C. (*Bow Road, E.*) asks:—"Can any one tell me if there is any sand which would bind without cement, for covering a lawn-tennis court? I am told that in the south of France the lawn-tennis courts are covered in with such a sand."

2. Elastic Moulds for Electrotyping.—T. W. (*Foley Street, W.*) writes:—"Will any one give, under the preceding heading in Work, a receipt for making elastic moulds for taking impressions from metal medallions slightly *undercut?*"

3. Graduation of Hydrometer.—Barrington writes:—"Will some one tell me how to graduate a hydrometer? I have made one of tin, and I do not know how to mark the scale. I want to use it for liquids between 1010 and 1040."

4. Cheap Still.—Barrington asks:—"What is a cheap way of getting up a still to produce small quantities of distilled water, using the heat of a grate?"

5. Solidifying Petroleum Oil.—W. H. (*Liverpool*) asks:—"How can I solidify the common commercial petroleum oil, such as is sold for lighting purposes?"

Letters awaiting attention have heen received from the following correspondents:—X. Y. Z. (*Orkney*), G. M. (*Calvin*), S. A. C. (*Coventry*), W. H. D. (*Edinburgh*), W. D. (*Newcastle-on-Tyne*), W. J. W. (*Henley-on-Thames*), A. C. J. (*Regent's Park*), F. S. (*Exeter*), W. R. S. (*Croydon*), F. R. S. (*Kentish Town*), A. E. G. (*Ipswich*), R. O. (*Soho*), W. J. P. (*Portslade*), "Moulder" (*Limehouse*), J. B. (*Longfleet*), H. B. (*Glasgow*), O. H. (*London*), H. H. (*Gosport*), T. E. (*Stamford Hill*), S. H. (*Esher*), F. B. B. (*Colchester*), J. I. (*Longsight*), J. W. L. (*Sheffield*), A. E. (*Liverpool*), Amateur (*Liverpool*).

Trade Notes and Memoranda.

The Taff Vale Railway Company has introduced the electric light into its passenger trains. The power is obtained from Brush machines run off the axle of the van.

Edison's newest phonograph, comprising all his most recent improvements, is now on view at the Gainshorough Gallery, Old Bond Street, London, W.

A new patent safety lamp for miners, the invention of Mr. Clifford, was recently exhibited at a meeting of the Manchester Geological Society, and has been described as sound in principle, and eapahle of giving very good results, hoth as to safety and all-round illuminating power.

A light hammer, weighing 10 ozs. only, faced with hide, for jewellers' use, has heen designed hy W. Oliver, of Buffalo, U.S.A. It is useful for striking an elastic hlow without inflicting injury upon delicate work.

M. Chevreul, chemist, author, and centenarian, has just died. He was the last witness of the Great Revolution, having been horn on August 31, 1786. In 1813 he was a professor in the Lycée Charlemagne, an officer of the university, and Director of the Chemical Department at the Gohelins-Tapestry. It was here that he devoted himself to those studies in colours which have made his name famous. It was his researches into the composition of fatty suhstances that led to the invention of the stearine candle. He was a Fellow of the Royal Society of London, and a Commander of the Legion of Honour.

Noel Masson, who died a few days ago in Paris, was so unfortunate as to lose hoth his hands in the Franco-German War. In spite of this misfortune he became one of the most expert etchers of his time. He was hest in landscape. At the time of his death he was only in his thirty-fifth year.

Woods of British Borneo.—The principal and most useful wood found in British Borneo is "bilian," or iron wood. Its characteristics are these:—hardness, density, and the heing ant-proof. The logs run from 2 ft. 3 in. to 2 ft. 6 in. square, and, say, 40 ft. in length. It affords excellent shingle wood, and is a most valuahle timher for general purposes, heing large and plentiful. Other sinking woods are "russock," "grealing," and "mirahou," the last named heing a heavy, dark, yellow wood, valuahle for furniture, and taking a fine polish. Camphor wood also, and a red wood, "sirayah," which gives logs 5 ft. in diameter and 40 ft. long, are also found in abundance; in fact, the woods of Borneo are so various that, as yet, most of them are comparatively little known. Some of them are already in demand for Australia, and so good a customer so near to Borneo will work, it is to he hoped, for mutual benefit.

One of the largest wire ropes ever made for use in this country has been recently sent out from the works of Dixon and Corhitt, and R. S. Newall and Company, Gateshead. Its circumference is 5 in., and its length 4,560 yds. It weighs over twenty-three tons, and occupied three large railway trucks. It was made for the North British Railway Company, and is to he used for drawing their trains from the Queen Street Station, Glasgow, to Cowlairs.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS.** Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

VOL. I.—No. 8.] SATURDAY, MAY 11, 1889. [PRICE ONE PENNY.

Old Form of the Bureau.

SOME LESSONS FROM AN OLD BUREAU.

BY DAVID ADAMSON.

I.—MODERN WRITING APPLIANCES—ADVANTAGES OF BUREAU—SCAMPED WORK IN THE PAST—SPACE TAKEN UP BY BUREAU—ACCOMMODATION AFFORDED—DEPARTURES IN STYLE—COMPARATIVE CHEAPNESS OF BUREAU—VENEERING—MATERIALS—WORKING DRAWINGS—WIDTH AND THICKNESS OF PIECES—LIST OF PIECES REQUIRED.

POSSIBLY on seeing the above heading the reader may be inclined to wonder what occasion there can be to describe the construction of such an old-fashioned piece of furniture. We have now so many modern contrivances for the purpose—from the plain leg writing-table to the pedestal cylinder fall, the register, and a number of others, not forgetting several American "patents" of marvellous ingenuity and cumbersomeness (structures formed for the exemplification of the good old injunction to have a place for everything, even though the place may sometimes be forgotten)—that the bureau has somewhat fallen into disrepute, or, at any rate, neglect. It is now so seldom made that it may, perhaps, be supposed that its descendants fulfil its purpose better, or it would not have ceased to be an article of modern manufacture. The fact, however, must not be overlooked that many forms of furniture and useful varieties, in every respect equal to, and in many instances superior to, those looked on as the best, have come to be regarded as obsolete. They have, however, merely been forgotten and relegated to the shops of dealers in second-hand furniture, whence they will, no doubt, some day emerge from their temporary obscurity—in modified design, perhaps—as novelties. Let us see in what respects the old-fashioned bureau is deserving of recognition as a modern piece of furniture, and, if possible, do something to rescue it from untimely demise; for, slightly altering a well-known address to another article of domestic comfort, it may be said—

> "I love it—I love it, and who shall dare
> To chide me for loving that old 'secretaire'?"

No contention is made that the bureau

surpasses all other forms of writing-desk, for each has special advantages of its own in a greater or less degree; but that is far from saying that all of them are superior to it. Like its younger brethren, it has features peculiar to itself; and if any of these remarks may seem to imply that it is better than any of them, please bear in mind what was stated in the previous sentence. Now let us look at the bureau (Fig. 1), and, comparing it with other forms of desk or table, note what appear to be its chief characteristics, and the points wherein it may be considered superior to them. Perhaps the first that may occur to the amateur cabinet maker is its extreme simplicity; for though some of the old bureaus are complicated and elaborate, the one before us is as plain almost as it could well be. A plain honest piece of work—more agreeable to look on, perhaps, than if it were more pretentious—and it may well serve as our model. If nothing better is learned from it, at least it will show that plainly-made furniture is not necessarily ugly. Elaboration and ornamentation are pleasing only when judiciously employed. If over-done, the effect may be striking, but it soon palls, and the eye is wearied with its ostentation. To design a plain piece of furniture is not difficult, my amateur friends; but when you get ambitious and want to make a handsome thing, that's where the difficulty comes in. This old bureau, and many another old piece of woodwork, remind us that soundly-constructed furniture has a charm of its own, even when there is no pretence at ornamentation, and the finish is a little rough. It certainly is somewhat crude and rough—do not let any prejudices against modern things, as compared with those of an older date, blind us to this fact. In a few choice specimens of old furniture we may find evidences that the old workers were not a whit behind those of the present, either in artistic or technical skill; but candour compels us to admit that most of their work was not equal to the bulk of that which is now made. That much rubbish is made now, no one who knows anything about modern furniture will deny; but can anybody say that scamped work is a recent production? If there be one rash enough to make such an assertion, will he allow me just to remind him of the discoveries made during the restoration of, I think, Peterborough Cathedral, as to the plan adopted by its builders. That was a practical comment of a rather startling kind—one which should make those very enthusiastic belauders of everything that is old calm down in their affected admiration of it.

If they really appreciate good work, they will see more of it in any half-dozen first-class furniture shops than in an equal number of museums. Is it not blind, unreasoning veneration, the tribute to antiquity, which may be more or less influences us all, that calls forth so many remarks in favour of old furniture, rather than an intelligent acknowledgment of good qualities, wherever they may be found? I do not now refer to the old work stored in our treasure-houses of art, but to the every-day specimens one comes across, which is surely the fairest way of judging the class of work our forefathers made. Let any one carefully examine such things, and he cannot help acknowledging that they are mostly coarse and clumsy by comparison with modern work. The most that can be said in favour of them is that the makers made the best of their opportunities; for I fancy it is sometimes forgotten that many appliances and tools are only of recent origin. We have now better tools than ever, our workmen do not remain in one district, nor are they behindhand either in their endeavours to turn out honestly-made articles, or in intelligence. Those who delight to sneer at the British workman may not agree with these remarks, but they are nevertheless true; and the real cause of so much faulty work must be attributed, not alone nor principally to the tradesmen, but to those buyers who want to get things under their value. But what has all this to do with the bureau? Nothing directly with its construction, though indirectly we may learn to appreciate not only it but other things, and to regard them as objects for intelligent study. Hence I trust the few hints may not be amiss.

Briefly, let us imitate what is worthy of imitation in old workmanship, but do not let us fall into the error of supposing that want of finish is in itself meritorious. It cannot be anything but an indication either of carelessness or incompetence in modern work, though in the old it may have been unavoidable, and consequently is not to be found fault with. Well, having delivered my little lecture, we turn again to the bureau, and note some of its excellences. For one thing, it does not occupy much space—only 3 ft. 6 in. across by 1 ft. 8½ in. from back to front; and yet there is an available table-space of about 3 ft. 3 in. × 2 ft. 1 in. when the lid is opened. Now, suppose we compare this with any ordinary writing-desks. In these, with the exception of the cylinder fall, we find that they occupy as much space when not required for use as when being written at. The old bureau on this point clearly has the advantage. Again, look at the drawers. Where can one get such accommodation in any of the pedestal writing-desks of the ordinary "knee-hole" form? Then see how easily and quickly any writing that has to be suddenly left can be secured from prying eyes. It is only necessary to push back the papers, lift the lid, and turn the key—nothing can be simpler. What other desk is equally convenient in this respect? Inside are convenient receptacles for small documents, etc., in the form of pigeon-holes and drawers; which, however, are not singular to the bureau. In case the arrangement shown in Fig. 2 does not suit the fancy or requirements of all, those who prefer some other may be reminded, in the words of a cabinet maker (Heppelwhite), referring to the bureau (or, as he called it, simply a desk) nearly a century ago, that "the drawers and internal conveniences admit of much variation." By the way, it is not uninteresting to notice that Heppelwhite gives us the general sizes for bureaus as follows:—"Length 3 ft. 6 in., depth 22 in., height of desk (*i.e.*, overall) 3 ft. 2 in., including 10 in. for the inside of the desk." These measurements differ only slightly from those of the one under consideration. But more of some of the older cabinet makers' designs, etc., later on; for though this bureau is a very plain one, I hope to show how it may be altered in detail, or, rather, how ornamentation may be added to it to make it represent various styles—for example, Chippendale, Sheraton, etc. The general construction will, however, remain the same. But, some one may ask, has the bureau no disadvantages to counterbalance its good qualities? and the answer may fairly be in the negative, unless, indeed, some may be inclined to object to a level surface for writing on, instead of a slope. Those who think thus will have a plan suggested to them for making the desk to their liking—one which, I think, will be found practicable without seriously increasing the difficulties of construction. Perhaps the only particular in which it may be said that the bureau is not so convenient as the ordinary knee-hole pedestal table is in getting access to the drawers in the lower part when the writing-flap is down. To get anything out of them—especially out of the two top drawers—that may be wanted while writing, the flap must be raised. After all, however, one cannot have everything, and the inconvenience—if it can be called one—is so slight that it is almost unworthy of consideration. Perhaps as a set-off against this it may be said that, for the accommodation found in it, the bureau is the cheapest form of writing desk and table; though, if it is to be made properly, it will be found to cost a fair sum for materials, and I purpose giving, as nearly as possible, the specification of that from which the drawing (Fig. 1) is made. That it might be made at a less cost I do not deny, but it does not come either within the province of this journal, nor yet of my own inclination, to give instructions for the manufacture of shams. By this I do not wish to say that it must be of oak if it is to be genuine, for it may be equally well and soundly made in pine; only, if it is of pine, let it be either painted in plain colour—not grained—or simply stained and varnished. Nor would I go the length, as some do, of objecting to veneer, for experience shows that veneered work, when *properly* done on a suitable base, is not to be despised, although some critics, who know little or nothing about it, condemn it utterly. However, as veneering is hardly likely to engage the worker's attention while making the bureau, the various *pros* and *cons*, whether of a theoretical or practical kind, need not be considered here.

The only remark I will at present offer about veneering in connection with the bureau is that those who prefer making it in mahogany will be able to get finer figured wood in veneers than in the solid, and that therefore they may as well make it of some cheap mahogany—such as bay-wood or Honduras. This has very little figure, but it serves excellently as a foundation on which to lay the choicer and more beautifully-marked veneer. Those who can lay veneer need scarcely be reminded that they are not likely to get good figure in "knife-cut."

But let us suppose that we are to commence making a bureau, for which the one represented is to serve as a model. As it is of oak, it will, perhaps, simplify the instructions to assume that the one to be made is the same, and I shall, therefore, refer to oak only, whenever it is necessary to distinguish between the principal wood and the pine which enters into its construction. Those who prefer to make the thing in some other wood—say, mahogany, ash, etc.—have only to substitute it for oak whenever this is mentioned. It will be noticed that I have not mentioned that now popular wood, American or black walnut; and it may occur to some that this is an oversight. The fact is, I hardly know what to say about it for the purpose of this piece of furniture—so much depends on the maker. If his intention is to make a bureau which shall be a verisimilitude of the real old-fashioned thing, then American walnut will be decidedly wrong, for it is, comparatively speaking, only a very recent introduction, and was quite unknown, in this country at any rate, at the date when the bureau was still an every-day article. This, however, rather savours of inculcating the notion that the new bureau is to appear as if it had been made years ago—in other words, that it is to be a spurious antique. This, it is almost superfluous to say, is not a desirable ambition to be entertained; but as there may be some who, without any desire to deceive, wish to avoid an anachronism and to be strictly correct from an antiquarian point of view, the suggestion is given. Apart from this, there is no reason why American walnut should not be used. While mentioning American woods, I may just put in a caution not to use the stuff known as satin walnut. The name is taking, and almost seems to imply that the wood is a superior kind of walnut. It is, however, nothing of the sort, being in reality a very inferior timber of little or no intrinsic value as a furniture wood, for which, however, it is now being used. Possibly some good qualities may be discovered in it later on, and there is no saying that it may not become popular, for it must not be forgotten that American walnut only a few years ago was a drug in the market; but in the meantime I would strongly advise no amateur to make anything valuable in it. It is very unreliable.

Before actually beginning to make the bureau, or, indeed, any other piece of furniture, a full-sized working drawing or plan should be set out. It need not be a troublesome matter, even for those who are not draughtsmen, as all that is absolutely required is that it shall show distinctly the sizes of the various parts. When this is done, it greatly facilitates work, besides preventing mistakes in cutting up the wood. If the maker can show details and sections, well and good; but if not, he can easily supply the needed reminders by a written word or two. All that is wanted is that the drawing shall be a serviceable guide to him when working; and whether the explanation is given partly in words or altogether in lineal representation, is of little consequence. Theoretical working drawings and useful practical drawings for the workshop are by no means necessarily the same. In the present case, two drawings will suffice—one of them showing the shape of the end, and the other the plan of the front. This latter shows the arrangement of spaces for drawers, etc., and need only be drawn of one half of the bureau, as the other portion is exactly the same. Of course, in measuring from it, all horizontal lengths must be doubled and the other parts duplicated. In case the novice may be in any difficulty about this — for working drawings are too often regarded rather as a source of mystification than of elucidation — Figs. 3 and 4 are given to serve as a guide. On the former, which is a drawing of the end (without the plinth), the measurements are shown in inches. On the latter, to prevent confusion, they are omitted, but it will be understood that the full-sized drawing must show them in actual measurement. The width of the various pieces from back to front, such as the divisions between the drawers, may be stated on them. Thickness will show itself. One rather important matter may be mentioned here, viz., to show the thicknesses as they will be when the wood is planed and cleaned up, not as it nominally is. Thus the said rails are of 1 in. stuff, but as this will be, when finished up, only some ¾ in., or at the most ⅞ in. thick, it will easily be perceived that the working drawing would be misleading if the full nominal thickness were shown. The same principle applies generally to all wood, and it is important when mentioning thickness to understand whether the measurement is given of the finished or rough stuff. To prevent any confusion arising to the reader in the present instance, I may say that all *thicknesses* that will be given must be taken as indicating the nominal measurements of the rough stuff, so that due allowance must be made for waste and finishing. As this method may seem strange to the inexperienced wood worker, I may explain, for his benefit, how it comes about, and it will then be seen to be perfectly natural. A log of, say, 12 in. thick, has to be cut into twelve planks of 1 in. each. If these could be, so to say, sliced off, they would be actually 1 in. thick, but as they are cut with the saw, which forms a passage of its own thickness and removes a certain amount of material in the form of sawdust, it needs no great discernment to recognise the fact that the twelve (nominal) 1-in. boards will not be equal in bulk to the original log. Besides the saw-cut—or kerf, as it is technically called—a further deduction must be allowed for roughness to be removed by planing, etc., so that altogether a fair margin must be allowed for finishing. Sometimes, it is true, planks will be found which are fully up to their nominal thickness, but so seldom that it would be unsafe to rely on meeting with them just when they are wanted. Indeed, they may almost be said to come under a separate standard of measurement, though not exactly a recognised one, in which they are described as "full" ½ in. or "full" 1 in., or whatever the thickness may be.

When the working drawing is prepared, it will be found to be a very convenient plan to make out a list of all pieces required. Much time is thereby saved, and uncertainty avoided in fitting the parts, which, as they are got out, should be numbered to correspond with the list. So far as I know, this method is not adopted generally in either trade or amateur workshops, but its advantages will be manifest to, and not readily relinquished by, those who have tried it. It is well to have the list legibly made out and placed so that it can easily be referred to as the job progresses. The precise arrangement of the list, of course, does not matter very much—some preferring one, and some another, for reasons which, though, perhaps, important in a large factory, are scarcely likely to be of much importance in small shops or to the amateur. All things considered, the tabulation adopted in this case is probably, at least, as convenient as any other. In it some of the smaller pieces, such as drawer stops, are omitted, as they can be made from waste or short ends, and their enumeration would only encumber the list with needless details. It will be seen that the wood is classified according to thickness, not according to the position it is to occupy in the bureau, as some might prefer. This, if one may judge from some remarks that have lately appeared in an important technical contemporary, is a point on which opinions differ, as each plan has its own peculiar advantages, and it is one that cannot be fully discussed here. The choice must be left for each individual to decide for himself, and he may extend it, as some do, by specifying the small bits left out if he thinks it necessary. The annexed Table gives a list of the timber required to construct a bureau measuring 3 ft. 6 in. wide × 3 ft. 4½ in. high × 1 ft. 8½ in. back to front; unless, indeed, any one wishes for special reasons to use other thicknesses, etc. Perhaps, instead of saying that they are required to be as stated, it will be better to understand them as reliable thicknesses, given as suggestions in case of doubt, though I would not advise any departure from them unless by an experienced worker.

In addition, there will be required about 7 ft. of moulding for plinth; the material for the plinth itself; blocks,

List of Pieces of Timber required in Construction of Bureau.

No.	Pieces.	Length.	Width.	Thick.	For	Remarks.

The exact measurements will, of course, be taken from the maker's working drawing, and, if necessary, be altered accordingly.

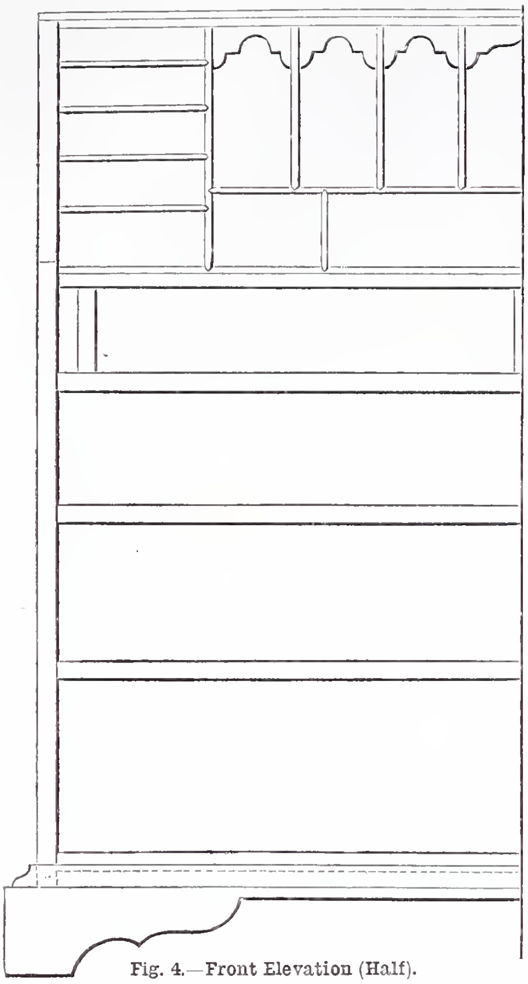

Fig. 4.—Front Elevation (Half).

without incurring, on the one hand, needless waste, and, on the other, allowing sufficient for trimming and fitting. If there is any doubt, it is better to cut the pieces rather over than under the sizes, for these can always be reduced by a shaving or two being removed. It will be noticed that in one or two instances $\frac{1}{8}$th of an inch is given, and this may seem to imply that absolute exactness has been studied in such cases. It has to a certain extent, but the principal reason they are given is to show the approximate proportions these pieces bear to the corresponding parts to which they are to be attached, but they must not be taken as exact when finished. It is in making them fit each other accurately and correctly that the skill of the maker shows itself. Measurements are all very well in their way, and indeed necessary, but no measurement will overcome the need of fitting and adjusting the various parts to each other. The list may seem a somewhat formidable one, and its preparation is not accomplished without an expenditure of time; an expenditure which is more than repaid by the increased speed and facility of working. Before going any further, it may be stated that all the

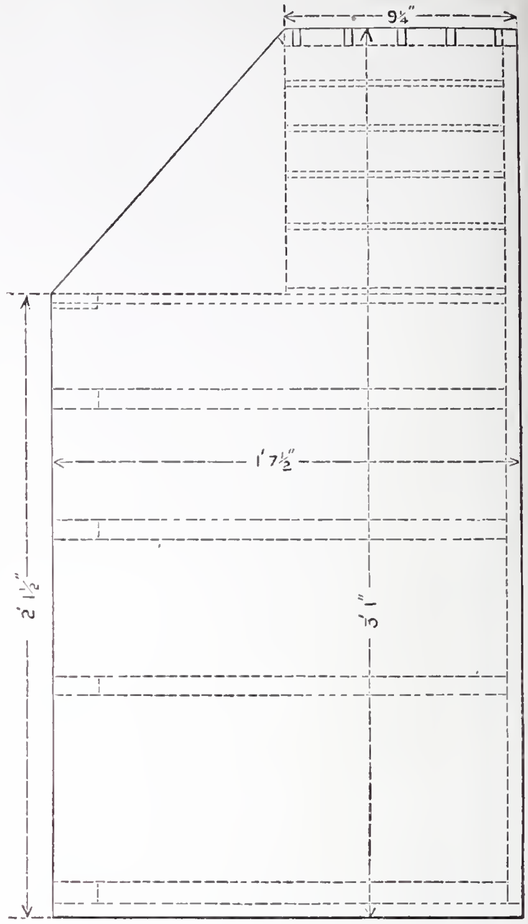

Fig. 3.—End of Old Bureau.

drawer-stops, and beads, which will be dealt with later on, as well as the back of the bureau, when referring to the parts with which they are connected. The sizes given are taken as nearly as possible, but they do not all include small fractions of an inch. They give approximately the measurements to which the material may be cut in the rough parts to No. 29 inclusive are of oak. The remainder may be pine, or any wood that may be preferred to it. Pine is named, as those portions of the bureau from which this description is given are of it, and they do very well. The only alteration that I would suggest with regard to them, were I asked to improve on the material, is that the insides of the lower drawers, *i.e.*, the large ones in the body or "carcase" of the bureau, would be better in something else.

But here I must stop, trusting I have given every reader who may make up his mind to construct a bureau something to do in getting out the timber required.

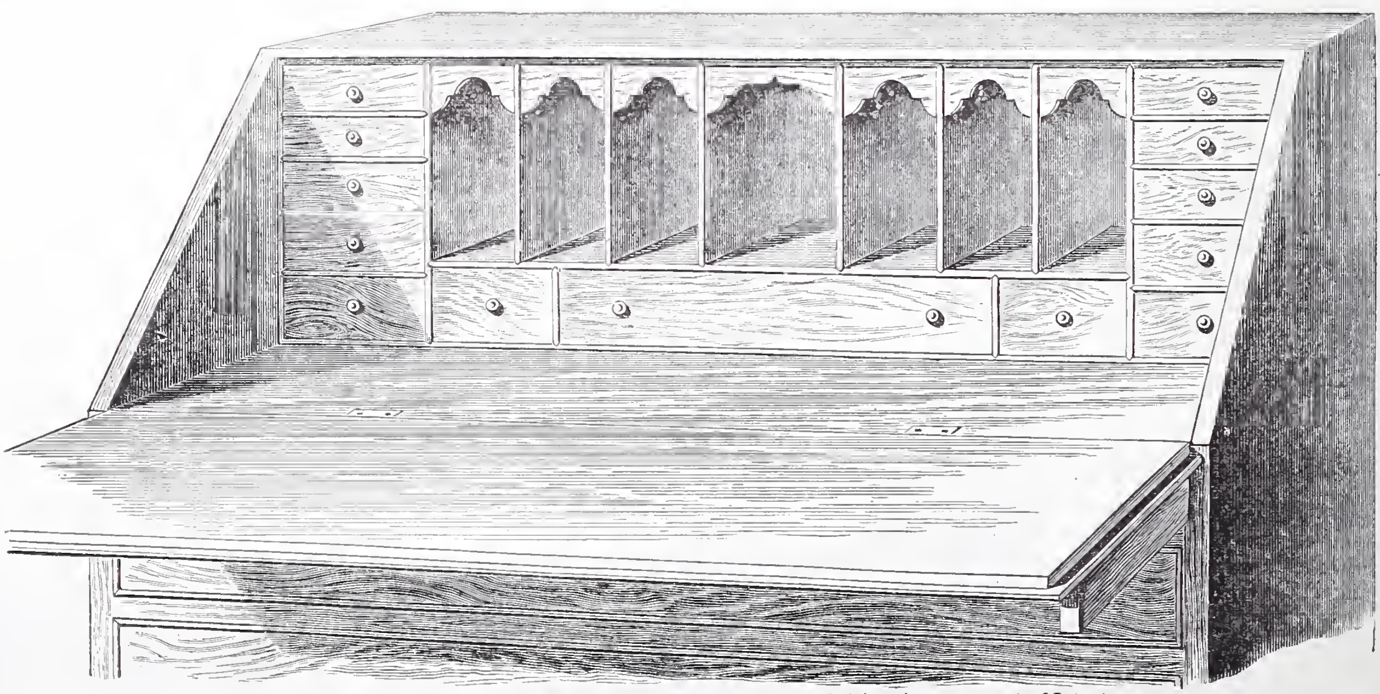

Fig. 2.—Upper Part of Old Bureau or Secretaire, Open and Exhibiting Arrangement of Interior.

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

I.—Iron Lists—Templates—Marking.

In the present article I purpose dealing with the construction of girder work in the iron yard, starting from the completion of the general drawings, and when, therefore, all the purely theoretical calculations have been made and the manufacturing or practical stage is reached.

It sometimes happens in preparing the designs for works of novel or intricate character that points affecting the manufacture of the work are overlooked, and it is, therefore, incumbent on the leading hands in the shops to examine the drawings very carefully in the first instance, in order to avoid subsequent hitches during the progress of construction.

The mechanical processes commence with the rolling of the iron or steel plates, bars, and other sections required for the job, and the preparation of templates for marking the positions of the rivet holes.

All flat pieces over 12 in. wide must be rolled as *plates*, and this will involve some unevenness of the edges, the plates being rolled between plain cylinders, and their edges subsequently sheared to the sizes ordered; this shearing cannot be effected with the accuracy necessary for neat work. The narrower *bars* being rolled in grooved cylinders will have their edges as well as their surfaces smooth; but all the parts on leaving the rolling mill require some amount of straightening before being built up into the structures of which they are destined to form parts.

If two or more thicknesses of plates are to be riveted together, it is evident that they should be of exactly equal widths, and have truly-formed edges; and in such cases, even when they are less than 12 in. wide, they should be rolled as plates and planed to the required dimensions.

On the iron lists sent to the rolling-mills, the dimensions marked must be sufficient to allow for the reduction by planing. On the amount of allowance to be made on this account there exist differences of opinion, and it will be affected by the accuracy observed in the particular mill to which the order may be sent; but the practice I have found most satisfactory is to allow a quarter-inch on all edges and ends of plates for working. This allowance is, of course, so much waste; and some small firms, after tendering at very low prices, have kept it down to as little as one-eighth of an inch; but this is very risky, and I have known cases of whole plates having to be thrown aside through the insufficiency of the margin to cover the irregularities of the edges.

While the iron is being rolled, the templates for marking the rivet holes may be proceeded with. These will be made of strips of wood formed into frames to suit the shapes of the plates and bars, and perforated with holes corresponding to the intended positions of the rivets.

It is necessary before proceeding further to make some observations upon the different methods of making the rivet holes, as upon that adopted the arrangement of the templates will depend in some measure. There are three ways in which the holes may be made: by punching simply, by drilling out of the solid, and by punching small holes and drilling or rymering them out to the required size. Formerly punching was universal, or almost so, but in recent years, with the advent of improved machinery, drilling has been gradually superseding it for large and important works, the magnitude of which justifies the construction of special machines for their execution. In the old style, punches with flat ends and a good deal of taper were commonly used, and the holes made by them were not of equal diameter throughout. To mark the plates, stumps dipped in white paint were used. The perforated templates were clamped on to the plates and bars, and the stump passed through the perforations, and their positions thus marked by white rings upon the material to be punched, which, the templates having been removed, was then ready for the puncher. The marked work being passed under the punch by hand, it is evident that the quality of the result is dependent upon the accuracy of eye and steadiness of hand of the workman attending the machine; hence it is almost impossible that the punched holes can be exactly in the position marked; and in work done by an inferior hand, their eccentricity may become very appreciable; then when the plates are laid together to be riveted up, the holes will not coincide, and either the rivet will be distorted in closing, or the holes must be broached out to a larger diameter to make them concentric, and thus the plates are weakened by losing more of their substance than would be necessary with more exact work.

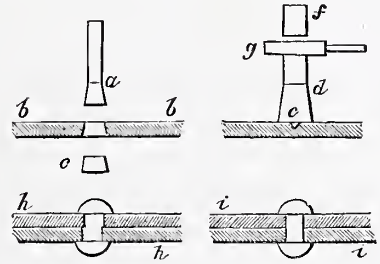

Fig. 1.—Punching and Riveting Plates.

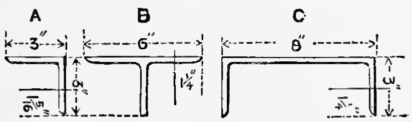

Fig. 2.—Position of Rivets in Angle Sections.

In ordinary punching, the material is partly cut and partly burst out of the solid, and therefore around the edges of the holes some injury must be caused, and the strength of the plate for some distance—probably about one-tenth of the diameter—deteriorated. This difficulty is, however, overcome by punching the holes smaller than the finished size, and drilling or rymering out the damaged part; thus for the finished diameter of $\frac{3}{4}$ in. the holes may be punched $\frac{5}{8}$ in. and then drilled out to $\frac{3}{4}$ in. Here also we are in the hands of the puncher as to accuracy of position; therefore, to ensure accuracy, recourse is had to the process of "nipple" punching, which is slightly more costly, but much more satisfactory. There is no difficulty whatever in correctly making the templates, as the centres of the rivet holes are set out by dividers, and the perforations made by an accurately formed centrebit; and lest there should be the slightest deviation from the vertical direction during the drilling of the wood, the template when used is turned over, and that face upon which the holes were set out placed in contact with the metallic surface to be marked.

If the work is to be "nipple" punched the plates are marked with a centre punch instead of a stump dipped in paint, and thus the centre of each intended hole is indicated by a conical depression, into which the "nipple" of the punch falls, thus securing the proper adjustment of the plate to the punch.

In the accompanying Fig. 1, *a* is the working end of an ordinary punch, and *b b*, is a section of a plate from which the distorted "burr," *c*, has been punched out. The more nearly cylindrical the punch, *a*, can be kept, the better will be the work executed by it. Great care is required in grinding these punches, in order that they may take their bearing fairly, otherwise constant breakages will result. At *d* is shown a "nipple" punch, of which *e* is the "nipple," and beneath this is shown a section of a plate with a countersink, into which the nipple falls. *f* is a rising and falling block, by which the punch is driven through the plate; between this block and the head of the punch is a wedge, *g*, so arranged that by drawing it back the block, *f*, can make its stroke without acting on the punch, thus allowing time for the plate to be fairly adjusted to the nipple, when the wedge, *g*, being pushed in the hole, is punched. This operation for each hole takes some time to describe, but in practice it is fairly rapid, and it is certainly a very great advance upon the older method. *h*, *h*, shows a section of two plates, in which the rivet is distorted through bad punching; and *i*, *i*, a section in which the rivet is properly formed.

Multiple punching machines have been made to punch a number of holes at one stroke, the plate being automatically moved forward after each stroke, and the punches acting at each stroke being determined by templates working on the principle of the Jacquard loom. These contrivances have, however, been found very costly to construct, and are very rarely used; hence I shall not occupy the space allotted to me with a description of them.

If holes are to be drilled under a single drill, the same marking as that used for the nipple punch will be suitable; but girder work is generally drilled in a multiple drilling machine, and in this case the centres of the holes do not require marking throughout, as the drills themselves are adjusted to the required "pitch" or distance from centre to centre of rivet holes, and templates only will be necessary for marking the positions at joints and connections of rivet holes which are out of the general run of the work, and such as have to be drilled by hand or small portable machines after the girder has been built up.

If every department fully and faithfully performs its duties, the *working* drawings when they reach the yard should have *every dimension* clearly marked upon them; but experience shows that this does not always happen. The reasons for this might be discussed, but they would not be edifying. It is therefore highly necessary that the template maker should know just what is required for the practical execution of the work, as any mistake which escapes him will appear in the work itself.

Some very awkward places often occur in making joints in bridge girders, especially where several members meet together; and here may be a temptation to overcrowd the rivets in order to avoid clumsy-looking joint plates, but it is important that this be not done to the detriment of structural strength; and the most carefully made general calculations will be frustrated if even the smallest details are improperly arranged.

The distances of rivets from each other, and especially from the edges and ends of plates and bars, is a matter of great importance, as if they are reduced below their proper limits there is danger of the material bursting out. Under no circumstances should the centre of a rivet be closer to the edge of a plate or bar than one and a half diameters, and that only when the strain on the rivet does not act towards the edge of the plate, but parallel to it; this would give $1\frac{1}{8}$ in. for the distance of a $\frac{3}{4}$-in. diameter rivet; and although a great amount of work has been done to this proportion, it is, in my opinion, very little. Similarly three diameters will be the very least distance allowable between two rivet centres in girder work; this would be $2\frac{1}{4}$-in. for $\frac{3}{4}$-in. rivets. This close packing of rivets cannot but cut up the grain of the plate, especially when they are irregularly placed, as in some joint plates; and it must be remembered that the strength of a plate across the grain is less than that in its direction—in the ratio of about 6 to 7.

In joining angle and other sections together, the space allowed for the rivets is often very limited, in which case the rivets should be placed in the centre of the width. In Fig. 2 are shown three sections of iron or steel; A is angle; B is tee; and C is channel section. The distance of the rivet centre from the edge of any limb is found by deducting from its width the thickness of the adjoining limb and halving the remainder. Thus, if the angle iron is 3 in. by 3 in. by $\frac{3}{8}$ in. thick, the distance of rivet centre from the edge should be $3-\frac{3}{8}$ divided by 2 equals $2\frac{5}{8}$ in. divided by 2 or $1\frac{5}{16}$ in. The 6 in. by 3 in. by $\frac{1}{2}$-in. thick tee iron, and the 8 in. by 3 in. by $\frac{1}{2}$-in. thick channel iron, will each have their rivet centres $1\frac{1}{4}$ in. from their edges.

When the strain on the rivet is towards the nearest edge, tending, therefore, to tear it out, it must be much further in, two diameters being the least to be allowed between the rivet centre and the edge of the plate or bar. Should distances less than those I have here given appear upon the drawings, they should certainly be referred back to the drawing office for verification before being worked to.

The templates having been properly prepared, and being ready for use, we have to take in hand the material supplied from the rolling mills. All this, as it is delivered to the girder yard, should be put under cover to protect it from rusting; then as soon as the inspecting engineers have made such tests as may be specified, and passed the iron or steel, work may be begun on it.

It will generally be found that the plates require more or less straightening, as in cooling they will take on some twist; this may be removed by hammering, but that method is very rough, and it is altogether better to straighten them in machines made for that purpose, consisting usually of three rollers.

(*To be continued.*)

"TIPS" FOR TYROS.

BY OPIFEX.

Moulded Corners for Picture Frames.

Picture-frame making is a very favourite amusement with many amateurs, and from its nature is likely to continue so always; yet there are few things more difficult to do well, notwithstanding the helps which have of late years been invented, such as mitre-cutting machines, corner clamps, etc.

Picture-frame moulding being covered with a white composition, it is hard to carry out the various operations of sawing or even cutting with mitre machines, "shooting" or planing the surface of the mitres, gluing, and nailing, without chipping off some of this composition; and besides this difficulty, there is oftener the other, and greater one, of cutting exact angles, so that, from some of these causes, the result too often is that we make a "mess of the job." Now although we strongly recommend the reader to overcome these difficulties by patient painstaking and practice, yet before this desirable end is attained many amateurs become tired of trying, and we therefore suggest a remedy for spoiled corners which will not only hide the evil, but if well done will be an improvement to almost any ordinary picture frame.

Procure a small piece of good basil leather, say about 5 or 6 in. square, and soak it in lukewarm water in which some glue has been melted—about a wine-glassful of melted glue to half a pint of water. Next select a leaf, which is about the length of the joint at your mitres; the kind of leaf is of course a matter of taste, but a narrow, pointed leaf will suit best for a beginner. Now, having rubbed your leather as free from water as possible, wiping it on both sides with a cloth, flatten it out smooth, and lay the leaf upon it, mark the shape exactly, including a short stalk, and then cut out cleanly with a very sharp penknife. Now with a blunt, smooth, pointed instrument—*e.g.*, a small paper knife—mark out clearly the veins as upon the natural leaf, and otherwise model it as faithfully as possible. Repeat the operation for the number required, and lay aside to dry thoroughly in the sun, or other warm place; when dry, give each leaf a coat of gold size, and when it is dry give another. When this second coat is almost dry apply gold leaf, gilding the leather leaves all over on right side and edges. Glue these securely to the corners of your frame, being careful to place them exactly at the proper angle, and most picture frames of ordinary moulding will be improved by this addition.

Gold Leaf: How to Use It.

Gold leaf is a thing which is impossible to manage unless one knows how, and yet we often have occasion to repair gilt articles of various kinds, or "touch up" a picture frame, etc. The usual practice is to apply some of the many gold paints, and the invariable result is a nasty patch, which, to a critical eye, is worse than the original flaw.

But besides patching and mending, gold leaf is highly effective in combination with black for the ornamentation of various articles of furniture which amateurs often construct for themselves. A book of "gold leaf" which is quite good enough for such uses may now be bought for sixpence; indeed, this German gold is quite as good for inside work as the "real thing."

Having procured a book, lay it flat upon a table, and carefully open the first leaf, when the metal foil will lie before you; with a pair of sharp scissors cut off the paper leaf you have just raised; lay it flat upon your open hand, and rub it on your hair; whether you use pomatum or not, there will be quite sufficient grease to answer the end in view. Now lay the paper upon the foil in its original position and press firmly with the hand; lift carefully, and the gold will be found adhering; this paper leaf with foil attached will now bear to be carried about, and may be cut up with scissors to size and shape required. The same process may next be carried out for as many leaves as we need for the job in hand.

Having said so much about gold leaf, we add a hint as to the method of laying it on, in case the reader does not know.

Paint the part you wish to gild with gold size, and be very accurate, as the leaf will stick to every spot touched; this size will dry rapidly, and when it is just *not dry*, or "tacky," *i.e.*, sticky, cut a piece of your leaf a little larger every way than your design, etc., press it firmly, and then lift the paper; do not touch it again till quite dry, when you may remove the surplus foil with a large, soft, camel's-hair brush, or "dabber."

For illuminations, etc., gum arabic may be used instead of gold size, and may be allowed to dry, breathing upon it for a few seconds when you wish to apply the gold.

LATHES AND TURNING APPLIANCES.

BY F. A. M.

IV.—The Overhead Motion (*continued*).

Another Arrangement of Overhead—Its Defects—High Speed for Drills and Cutters—Construction—Crossway or Fourway—Horizontal Bar—Ball—Castings and Forgings—Guide Pulleys and Sliders—Assistance Rendered by Overhead—New Overhead of London Lathe and Tool Company.

We come now to an entirely different arrangement, which is simpler than any yet described. It is also very fairly efficient. It has its advantages and disadvantages which will be stated, and then detailed drawings will be given so as to enable those who wish to make it for themselves. At Fig. 8 will be seen the general arrangement of the overhead. Here there is but one long band which is quickly adjusted for use, and, when not required, is not removed, but simply slipped off the large wheel to the right with the left hand, while with the right hand the slack loop is pulled so as to draw up the lower end which embraced the large wheel close up to the crank shaft; then the slack loop can be turned back and wound round the horizontal bar out of the way, leaving the fly wheel free for the ordinary band. Since the bands for the mandrel and for the drillers and cutters have to be frequently changed, it is a matter of some importance to be able to do this quickly.

We will now confess the defects of the arrangement. One is that since there is only one band, no variations in speed can be made but those due to the different diameters of the grooves of the fly wheel and those upon the pulleys of the various instruments employed. The greatest speed then will be determined by the ratio between the largest groove on the fly wheel and the smallest on the pulleys. Now these latter cannot be less than $\frac{3}{4}$ in. in diameter, because, if so, the hooks of the $\frac{1}{4}$-in. band, used for overhead motions, could not go round them without too severe a jerk; the utmost speed will therefore depend upon the size of the largest groove on the fly wheel. If the lathe is provided with a 24-in. wheel, the speed will be sufficient, but if the lathe be a small one, having a fly wheel of 20 in. or thereabouts, it would be better to adopt the plan shown at Fig. 4, or some other, which enables more speed to be obtained.

Here it may be well to draw attention to the great advantage of a high speed for the small cutters and drills: they *must* run fast if they are to work well. When they run at a proper speed and are kept sharp, it is astonishing how much hard wood they will remove, and how smooth a surface they will leave. A ratio, then, of 24 to ¾ will do very well; that makes the cutters revolve 32 times as fast as the foot wheel. Now the speed of the foot wheel may vary from 30 to 160 revolutions per minute, but we may consider 100 revolutions per minute of the fly wheel as pretty fast treadling to keep up continuously; let us, therefore, take 3,000 revolutions per minute as about the correct speed for the drilling spindle and small cutting frames for ornamental turning. A band ⅛ in. in diameter is quite strong enough, and much better than a thicker one, since it must bend easily round the small ¾-in. pulleys. If it be of catgut it may be joined with the usual hooks and eyes, sold at the tool shops; or it might be of Binn's endless blind cord, if a piece could be obtained of a suitable length; if not, it might be of whipcord or string, long spliced. It is a great advantage to avoid the jerk caused by the hook and eye as they pass over the small pulleys; this is sure to leave a slight mark on the work.

Proceeding now with our description of the overhead illustrated in Fig. 8, it will be seen to consist of a piece of iron gaspipe, 1¼ in. bore and 1⅝ in. external diameter, extending from floor to ceiling, and fixed so as not to touch the lathe at all. If, however, the ceiling cannot be utilised there must be a bracket as at B, and the upright pipe would end about 6 in. above the cross bar. There is, however, a considerable advantage in the first plan, since, when the overhead motion is fixed to the lathe, a slight amount of tremor is communicated to it, which interferes with the perfection of the work. Let it be understood, then, that the bracket, B, would not be used except when the upper end of the standard could not be supported from ceiling or wall. The top and bottom of the upright pipe are screwed into 1¼-in. flange plates. The lower of these is screwed to the floor, and the upper one to a board about ¾ in. thick, which board is fixed by long screws passing through the plaster of the ceiling into the joists above. This arrangement fixes the pipe firmly in a vertical position, yet allows of its turning on its own axis in the two flange plates, so that the horizontal bar may swing partly round in a horizontal plane. About 6 ft. high up the pipe from the ground is what gasfitters call a "cross" or "fourway," shown quarter size in Fig. 10. This cross is not screwed to the pipe in the usual way, but is bored out so as to remove the thread in such a way that it can slide up and down, the pipe from flange to flange being in one piece, and the cross slipped upon it and secured by the screw, A. This screw is obtainable from the gasfitter like the rest of the fittings. It is called a plug, and it serves here to fix the cross upon the pipe at the height most convenient for the band, a piece of wood being fitted into the arm of the cross to enable the screw to press upon the pipe.

We come now to the horizontal bar shown at Figs. 8, 9, and 11. This may also be of gaspipe of about ¾ in. bore, and it will require to be from 4 to 5 feet long. Its length should be such that a perpendicular dropped from its right-hand extremity would fall from 15 to 18 in. in front of the headstock. This bar should be smooth, because at one end there slides on it a heavy ball, and at the other two small sockets carrying a pair of pulleys each. To make a good job it should be turned up (though gaspipe is not nice to turn), and probably it would be better to employ for this purpose a piece of smooth steel tube of about ⅞ in. external diameter and ⅛ in. thick. We have now to connect the horizontal bar with the vertical so that it may swing or rock, like a see-saw, or like the beam of a steam engine, in a vertical plane: this we can do by means of the remaining arm of the cross. At B, B, Figs. 10 and 11, is shown a diminished T piece, one branch being the same size as the branches of the cross—*i.e.*, that for 1¼-in. pipe—and the other two branches being suitable for ¾-in. pipe. A rymer would be put through those two arms to remove the thread so as to make a thoroughfare hole to fit the turned gaspipe or the steel tube chosen to suit it, which would then be driven through half its length. At C, Fig. 10, is shown another way of fixing the bar. Here a piece of solid bar iron is screwed with the proper thread to suit the cross, and bored across with a hole of about 1 in. diameter to fit the bar, which is then driven in, and, if necessary, may be held by a pinching screw. Both these plans, while holding the bar, allow of the required see-saw motion. The second is the best, as it brings the bars a little closer together. Also it may be difficult to meet with the requisite T for the other plan. The ball is 5 in. diameter of solid iron; it may be obtained finished, with screw fitted, for about eight shillings. On the end of the bar, at D, is seen a stop screw tapped into the pipe, intended to prevent any possibility of the slipping off of the ball.

All this work the amateur is advised to order from the foundry; it requires tools which he has not got, and whatever overhead he undertakes he must of necessity spend something in castings and forgings. The main standard, being of 1¼-in. gas "barrel," can be bought in 14-ft. lengths at sixpence per foot. Let the height of the workroom be measured, and give that measure to the workman after subtracting ¾ in. for the thickness of the board for the ceiling. Order the two flange plates fitted so that they can be turned round by the hand; they cost 9d. each. Order the cross (at 1s. 9d.) bored out so that it will slide upon the pipe; the screw plug costs 4½d. Then comes the ¾-in. pipe: that costs 3½d. per foot; the T and stop screw about 1s. 3d. Allowing 3s. for boring the cross, 3s. for turning the ¾-in. pipe, and 8s. for the ball, we come to about 27s. Fix the standard yourself, using a plumb line, then you will not be charged for journeys, fetching tools, etc.

We come now to the four guide pulleys and their sliders, which the amateur is to make himself; a very nice little job, which should be well within the powers of any amateur turner in metal. In Fig. 11 the bar is seen in plan looking down upon the sliders, to which are attached the stirrups of the pulleys; Figs. 12 and 12A show the side elevation; Fig. 13 the end view of the left-hand slider and pulleys, and Fig. 14 the end view of the right-hand slider with its pulleys. The stirrups are to prevent the possibility of the bands flying off the pulleys. The shape of the left-hand slider is clearly seen in Figs. 11, 12, and 13. It is made in that way to enable the workman to incline the pulleys, as seen in Fig. 13, to suit the slant of the band as it descends to the different speeds on the fly wheel. The right-hand slider need not be made in that way, but as Fig. 14; however, it might be made like the other to save a second pattern. At Fig. 14 is seen between the stirrups an eye-hole cast in one with the slider. This is intended for the attachment of a small cord or chain, best seen in Fig. 8, which is looped round the upright, so that if the band were to come off the pulleys or wheel, the weight would be checked before it could fall far; the loop would be slid up or down to suit the position of the right-hand slider upon the bar. As to the construction of these sliders, they are made from castings of brass or gun metal; patterns must be made, or one pattern will do if preferred. When received, the castings would be chucked and bored out to fit and slide upon the bar, and the flat wings filed flat and drilled to receive the stirrups; these stirrups may also be of gun metal together with the pulleys. The pulleys are shown 3 in. in diameter, and they should not be less. They should be chucked and bored first, and bushed with hard steel, driven firmly in, and then driven on to a mandrel and turned true with the hole. The pins on which they run must also be of hard steel, as if not, owing to the great speed at which they run, they will soon wear loose and make a disagreeable noise. Here we have then four guide pulleys, each with its centre requiring oil and liable to sprinkle that oil on the work; also the friction of our apparatus will about equal that of Fig. 5 and Fig. 6. To prevent the dispersion of the oil and diminish the friction we may, however, adopt the form of stirrup shown at Fig 15, which is but little more trouble to make. Instead of a steel bush inserted in the pulley we have a small steel spindle with both ends hardened, running on two small pointed screws, also hardened; these screws have heads which are screwed hard up to the sides of the stirrup, but wear can easily be taken up by lightly tapping with a hammer upon the bow of the stirrup so as to condense the metal and close slightly the arch upon the little spindle within. These little pulleys, so mounted, will not disperse the oil unless too much is applied, and they will run without noise or rattle. The little centres of the spindles should be carefully coned, and then a small hole drilled up for ¼ in. to contain oil, then when properly hardened they will wear very well.

Made as above described the overhead represented at Fig. 8 will be very cheap, will run lightly, will not disperse the oil, will be quickly and easily adjusted for work, and will therefore, in spite of its simplicity, bear comparison with any of the foregoing examples. To shorten the band it is only necessary to unfix the screw at the hinder arm of the cross and to raise and fix it a little higher on the upright; to lengthen the band so as to reach further from the mandrel the cross is lowered in a similar way.

To complete the subject it should perhaps be stated that it is possible not only to drive revolving cutters, etc., from an overhead, but also to give a regular feed to the slide-rest screw by connecting it with the mandrel, so that whilst one part of the overhead is driving a cutter or drill, another part is feeding along the cutting instrument to produce a screw or spiral. Fixed tools, both for wood and metal, have been guided in this way, and screws have been cut even in steel as coarse as 8 threads to the inch, and fairly accurate in pitch for 3 or 4 in. in length, by Mr. Haydon, the inventor of the system, which system would prove very useful to those who possess neither slide lathe nor spiral apparatus. Special precautions, however, have to be taken against slip of the band.

Since the above was written, yet another form of overhead has been brought out by The London Lathe and Tool Company, of 37, Pomeroy Street, London, S.E. It is a very good one, and of an interesting description. In this, as in some other forms, there is a long horizontal shaft, raised above the lathe bed, which runs in bearings and is supported by tubular stays. This shaft is driven from the fly wheel as usual, and upon it are two large and light pulleys, one of which is fitted with a key which slides in a long groove, or key way, cut in the shaft; so that though it may be pushed along by the hand to any part of the shaft, yet it must turn with it; this is the driving pulley. The second, or companion pulley, also slides freely along the shaft, but it is not keyed in any way, but acts merely as a guide pulley. The overhead band passes round a pulley which forms part of a weight, then over the two pulleys on the horizontal shaft and down to the driller, cutter, or grinder, or whatever it be required to drive, fixed in the slide rest; thus the tension of the band will remain constant, and yet its length may vary as the driller, etc., is moved by the slide rest. The guide pulley revolves in the opposite direction to the drive pulley, whilst the shaft which carries it is turning within it in a contrary direction. The size of these pulleys will diminish friction by allowing of a slower motion of the overhead shaft. The weight hangs just above the lathe board, so that in case of accident it would not have far to fall. The pulley in the weight can be taken out to put the band round it, and therefore the band may be without any hook and eye to jerk the spindle of the cutters, and injure the perfection of the work. The whole arrangement appears to be very convenient, and capable of giving a high speed, so important for ornamental turning. If there is an objection, it is that the pulleys would require to be pushed along the shaft by the hand if the length of the flute or cut exceeded 4 or 5 inches. The guide pulley being loose would follow of itself, but the driving pulley will not follow so easily, owing to the extra friction caused by the key. [The lathe to which the overhead just described is fitted, namely, the "Five-inch Geometric Lathe," of the London Lathe and Tool Company, will be noticed, and an engraving of it given in an early number.—Ed.]

A COAL BOX IN CARVED OAK.

BY HIRAM PRICE.

CARVING—MATERIALS—SCALE AND DIMENSIONS—JOINTS—SIDES—BACK—TOP—HANDLE—SUPPORTS—FEET—IMITATION OF OLD OAK.

IN designing any household article in carved oak, and more especially if the article is intended to be in keeping with real old carved oak furniture, the designer naturally looks to the remains of the seventeenth century for guidance. But when that article happens to be a coal box—a matter not less necessary in oak-furnished rooms than nobler things—there is, so far as the writer is aware, no authority to which reference can be made. Our ancestors of the early Stuart Period burned logs, and had no need for coal scuttles. The consequence has been that, in devising such a convenience (originally for his own particular sanctum), the writer has had little to guide him, beyond his own sense of the fitness of things. As, however, he has succeeded in making a scuttle which, whilst serviceable, harmonises well with its genuinely old surroundings, he has pleasure in offering its design to others.

It will be observed that the carving on the sides and top, though original in its arrangement, is in a style frequently met

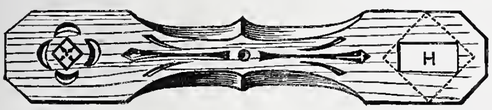

Fig. 7.—Support of Handle.

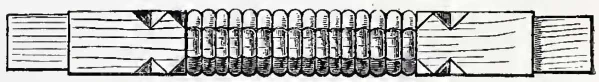

Fig. 6.—Handle.

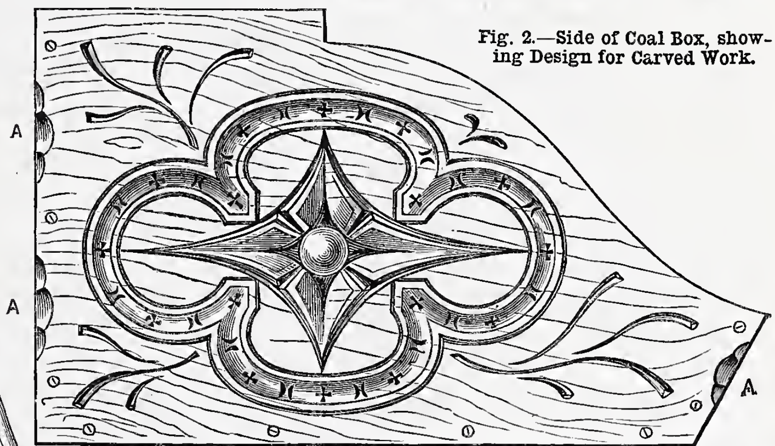

Fig. 2.—Side of Coal Box, showing Design for Carved Work.

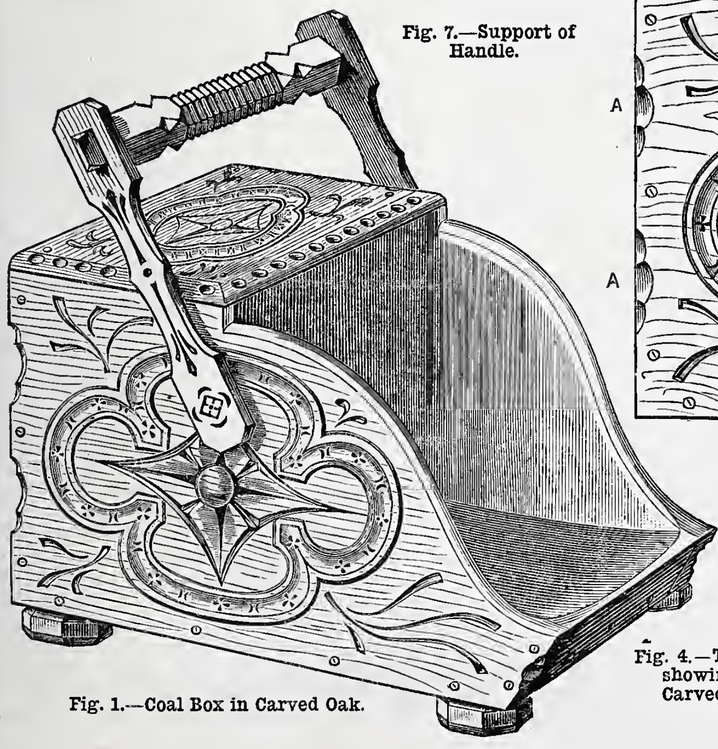

Fig. 1.—Coal Box in Carved Oak.

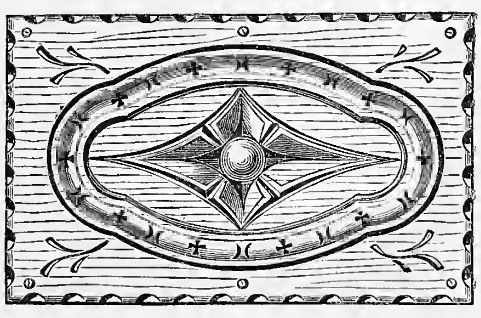

Fig. 4.—Top of Coal Box, showing Design for Carved Work.

with on seventeenth century panels; and it is one which, with a very moderate amount of labour, produces a rich and artistic effect. Whilst sufficiently deep to give a pleasing play of light and shadow, it is not of a kind liable to weaken the wood work of an article in which strength is a first essential.

The sides, top, front, and supports of handle, are in oak of about $\frac{5}{8}$ in. thick, after planing down. The back also is of oak, and is, for obvious reasons, somewhat stouter, about $\frac{3}{4}$ in. The bottom is of similar thickness, but in this place elm is preferable, as being more tough, and better fitted to withstand the rough usage to which it must be subjected. It can readily be stained to match the colour of the oak, though this will matter little, since a few days' use will make it black enough for anything.

It will be seen from the illustrations that the joints are not dovetailed, but merely screwed together, the position of the screws being, in most instances, indicated. Dovetailing would interfere much with the effect of the carving, whereas the black, round-headed screws employed are rather ornamental than otherwise; and with sound oak of the thickness specified, and $1\frac{1}{4}$-in. screws, there will be abundant strength; whilst to many home workers, the simpler mode of construction will be an advantage. If glue is not used in putting together—and there will be no necessity for using it—a mere streak of soft putty along the middle of each joint before screwing will effectually prevent any possibility of coal-dust working its way through.

Fig. 1 gives a rough sketch of the scuttle as a whole in perspective; this is not to scale. The remaining illustrations, 8 and 9 only excepted, are on a $\frac{1}{4}$ scale. The box has an internal measurement of about 14 in. by $8\frac{1}{4}$ in., and $8\frac{1}{2}$ in. high.

Fig. 2 shows one of the sides—dimensions, $15\frac{1}{4}$ in. by 9 in. A reference to the transverse section (Fig. 3) will give some additional idea as to the character and depth of the carving which ornaments it. Even in the deepest cuts — the veins, namely, which meet round the central boss—the wood is only penetrated about $\frac{1}{4}$ in. In those bands which form the quatrefoil the middle will be seen to be hollowed out by a single draft of the gouge, and this hollow bears an enrichment which may be given entirely with grounding punches (it often is so, as we see these bands in old work), but in the illustration, double nicks with a gouge are shown alternating with punched crosses. The back and front edges at A, A, A (Fig. 2), are seen to be scooped out with triple drafts of the gouge between the screws; this gives a little diversity to the straight lines, and does not weaken the joints. The manner in which the exposed lip is rounded off, somewhat more on the inner than the outer edge, is shown at B, B, Fig. 3. This piece is screwed to the bottom, back, aud front.

The back (seen at C in the longitudinal section, Fig. 5) is nearly square, being $8\frac{1}{2}$ in. by $8\frac{1}{4}$ in. As before mentioned, it should, if practicable, be a trifle stouter than the sides, etc. The front, marked D in the same figure, measures $8\frac{1}{2}$ in. by 3 in. Except at the ends, where against the joints the edge is left square (as seen in Fig. 1), its lip is rounded off as shown in section, in Fig. 5. The bottom, G, Fig. 5, is 13 in. by $8\frac{1}{2}$ in.

The top, of which the dimensions are $9\frac{3}{4}$ in. by 6 in., appears in Fig. 4; its front is also seen at E, Fig. 3, aud its shorter section at F, Fig. 5. It is like the sides, carved, but its smaller size renders a somewhat smaller and simpler design desirable, the character of the carving being, of course, precisely the same. The upper edge is taken off all round, and relieved with hollows made by single strokes of the gouge, as shown. This piece is screwed down to the back and sides.

The handle and one of its supports are shown in Figs. 6 and 7; in Fig. 3 also, which should properly be a section merely, a front elevation of handle and supports mortised together has been introduced for economy of space. In Fig. 1, the handle appears turned back at an angle of about 55°, as it generally will be when the coal box is standing at rest; but in Fig. 3, that it may explain its construction more clearly, it is directly upright. The supports, Fig. 7, are of similar board to the sides, etc., and are 10 in. by 2 in. Through the upper end of each is a mortise, H, cut to receive the tenon of the handle. The handle itself (Fig. 6), and of which the centre appears in section in Fig. 5, is $12\frac{1}{4}$ in. long by $1\frac{1}{4}$ in. square. How its central part is brought to an octagon, and made better for grasping firmly, as well as more ornamental by incised bands, may be seen in Figs. 1, 3, and 6. A dotted line surrounding H, Fig. 7, indicates how it is mortised diagonally into the supports, beyond which its tenons project some half inch, and are then rounded off. A small screw through the *back* edge of each support secures the tenon. The supports are fixed to the sides of the box by a small screw bolt and nut, as shown at K, Figs. 3 and 5. If an ornamental bolt is not to be bought, any one can, with a hand-saw file, in a few minutes alter an ordinary bolt-head to the form seen in Fig. 7.

The appearance of this handle and its supports in Fig. 3 may possibly raise a doubt as to whether it is not somewhat heavy for the box, but no such question is suggested by the actual thing. In Fig. 3 we get but a mere skeleton of the lower parts, and thus the handle, the whole of which is seen, looks unduly large. Its bolt-upright position also causes it to appear full high, but it is not felt to be too high when pushed a little back, as in Fig. 1.

In Figs. 8 and 9 is shown one of the octagonal feet, which are only indicated by dotted lines at L, L, in Figs. 3 and 5. These are merely sawn from inch board and the edges rounded off; if preferred, there is no reason why they should not, instead, be turned round; they could be made more quickly in the lathe than by hand. They are $2\frac{1}{2}$ in. in diameter, and are fastened to the bottom, as shown, by stout screws. These last two diagrams, 8 and 9, are drawn to $\frac{1}{2}$ scale.

In carrying out these plans in a scuttle for his own use, the writer has employed *old* oak, and this, when it is desired to make one's work have the appearance of real old carved work, is much to be preferred. No process of colouring with which the writer is familiar will give to altogether new wood the rich and mellow tone of ancient oak; and though in course of working-up much of the colour of old wood is apparently destroyed, it is easily restored by treatment, and the surface will become undistinguishable from one which has weathered a couple of centuries. To restore old oak after working up, nothing more is necessary than to make a solution of iron, by putting old nails, etc., in a bottle with vinegar; and this for use must be weakened with water, or it may make the wood too dark. Except when very thin, as in panel, the old wood will always show comparatively light where deeply cut into, and such light places it is safer to go over two or three times with a hot weak solution, and so gradually bring all to one uniform tone: then rub with boiled oil, and polish with beeswax and turpentine.

HOW TO DRY NEGATIVES QUICKLY.

BY L. IVOR POOLE.

There is an old saying "Curiosity is woman's curse, but in a man 'tis ten times worse." Surely when it originated photography was unknown, or an exception would have been made in favour of the mau who happens to be a photographer, for most of us are anxious to see how the print will look without unnecessary delay. Of course, heat can only be used to a very limited extent in drying a negative, so, in the long and tedious interval after the washing, till the negative is ready for printing from, there is nothing for it but to sit down and wait, or get on with something else in the meantime. Any way, we must exercise our patience, for drying in the ordinary way cannot be hastened. Sometimes, however, there are other reasons besides curiosity for wanting a print as soon as possible after exposure, and then the necessity for quick drying of the negative is important. It can be managed so rapidly, that more than once I have had a negative in the printing frame within a quarter of an hour from the exposure of the plate. True, when treated so hurriedly as this, the hypo. has not been thoroughly washed out, but this can be done afterwards, without any harm apparently to the negative. After fixing it, just rinse under the tap for a minute or two, after which it is dipped in methylated spirits, where it is allowed to remain for a few minutes. Before placing it in the spirits, however, much of the water on the surface should be removed from the film either by "dabbing" the film with a soft silk handkerchief, or with a piece of blotting paper. The glass side of the negative may be rubbed, but, of course, to do so on the gelatine side would simply be to destroy it. By taking care, a soft handkerchief may be used with impunity. Blotting paper sometimes leaves a fluff adhering to the film. After the negative has soaked a sufficient time, say from three to five minutes in the spirit, it is taken out, and the spirit allowed to drain from it or mopped up with the handkerchief. If the negative is then placed in a strong current of air it will be ready for printing from on the ordinary albuminised paper. A sufficient draught of air may be got by blowing with the mouth, or a pair of bellows may be substituted for the human blower. As often as not, I simply flog the film with my handkerchief loosely spread, and though it is the roughest way, I think it is as good as any.

The drying may be still further hastened by immersing the plate, after it has been in the spirit, in ordinary sulphuric ether, but as this is so very volatile, its use is somewhat expensive, and the time gained is hardly commensurate.

The action of the spirit is no doubt this: it unites with the water, of which there is only a very small quantity in the film, and disperses it. The spirit which soaks into the film quickly evaporates, and leaves the negative free from moisture. Ether evaporates more quickly still, so may be used as a final dryer if necessary. As the spirit every time it is used takes up some water, it loses its quick-drying powers, hence the reason for removing as much of the moisture as possible before putting it in the spirit. I find it more economical to use a small quantity of spirit at a time, renewing it frequently, than to have a large quantity constantly going. Though methylated spirit has been mentioned, it does not follow that it and no other alcoholic preparation would do, for anything that will mix readily with water and evaporate quickly will answer the purpose. For instance, two table-spoonfuls of any kind of spirit from gin upwards would be ample for an ordinary quarter plate, with the advantage that it—the preparation—could still be used —medicinally—afterwards.

NOTES FOR ELECTRO-PLATERS.

BY GEORGE EDWINSON BONNEY.

IV.—Analysis—Anion—Anode—Gold Anodes.

Analysis.—A correct quantitative and qualitative analysis of all the substances and solutions used by electro-platers can only be made by a chemist trained in this special work, and with the aid of apparatus only found in a well-appointed laboratory. But it is most desirable that operators in this art should be well acquainted with the nature and quality of the materials used by them in the make-up of solutions; be able to detect impurities and adulterations; and determine in a short time by a mode of rough analysis the identification of a salt or a solution. Some substances can be easily recognised by some characteristic colour, form of crystal, odour, flavour, or general appearance, and thus adulterants may be easily detected. With others it would not be safe to use the senses of smell and taste in their detection; in fact, those senses should always be warily employed in the detection of any chemical, and the practice of smelling indiscriminately at bottles, and tasting of salts, cannot be too strongly deprecated. Nearly all substances and solutions give characteristic results when treated with certain other substances or solutions, or when heated over a gas-stove, or in the blow-pipe flame. For instance, the presence of silver in a solution may be indicated by adding to the solution some hydrochloric acid, or some chloride of sodium, or any other soluble chloride, when the silver present will combine with the chlorine of the added chloride, and fall down as a white curdy precipitate. This precipitate is insoluble in hot water and in nitric acid. The only precipitate nearly like it is chloride of lead; but this is *soluble* in hot water, and so can be detected and separated from chloride of silver. Compounds of sodium can be detected by the yellow colour of the flame in which they are burnt, potassium, by a violet tint, and copper, by a green tint. The presence of copper in an acid solution of this metal can be shown by immersing therein a piece of bright iron, when some of the iron will be dissolved by the acid, and copper be deposited on the iron to take the place of the dissolved iron. In a similar manner a piece of bright zinc will reveal the presence of gold; and a piece of bright copper, that of silver or mercury. The analysis of gilding and plating solutions, to determine the quantity of metal contained in them, and also the quantity of free solvent present, should be understood by every electro-plater. The apparatus is not very costly, nor is the task a difficult one when the method of doing it is understood. The same may be said of the analysis of potassium cyanide. Full directions will be given for the analysis of each in the article or note under their respective headings. See *Gilding Solutions, Analysis of; Silver-plating Solutions, Cyanide of Potassium, Free Cyanide*, etc.

Anion.—This term was invented by Dr. Faraday to indicate the radical of an acid, or the portion of a salt set free at the anode during electrolysis. It is defined by Mr. J. T. Sprague as "the electro-negative, or chlorous radical of the acid or salt decomposed." For instance, suppose we are using a solution of the double cyanide of silver and potassium in the work of electro-plating. The salt of silver in this solution is combined with a salt of potassium, and three distinct substances are present, apart from the water which holds them all in solution; these are—silver, potassium, and cyanogen. When the electric current is passing through the solution in the process of plating, silver and potassium are set free at the goods being plated, and cyanogen is set free at the silver anode. The salt is thus broken up or decomposed, and cyanogen is the anion of this salt. The following is a list

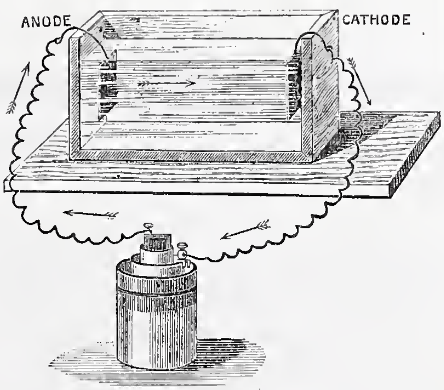

Fig. 1.—Diagram showing position of Anode and Cathode.

of anions given by Mr. Gore:—"Oxygen, fluorine, chlorine, bromine, iodine, and cyanogen; probably, also, sulpho-cyanogen, and also the various mineral acids. See also, *Anode, Cathode, Cations*, etc.

Anode.—A name given by Dr. Faraday to the positive plate or wire in a solution undergoing electrolysis. It is derived from two Greek words: *ana*, meaning "upwards;" and *odos*, "a way"—the way in which the sun rises. This term, applied to the action of the electric current, as used in electrolysis, signifies the way by which the current rises from the battery to enter the bath, or vat containing the solution to be electrolysed. This way is *from* the negative element of the battery *to* the positive element in the solution to be electrolysed. To make matters still plainer, let me say that the negative element of a battery is that part which receives the electric current and transmits it to the anode; this element is, therefore, the positive pole, and, by virtue of its connection to the anode by a wire, makes this also the positive pole or element in the solution. By way of illustration: the carbon element in a Bunsen battery is the negative element, because it receives the electric current generated by the positive, or zinc, element of the battery; but it is also the positive *pole*, because, through it and its metal connections, the current is transmitted to work outside the battery. The accompanying illustration will show this to the eye of the reader at a glance. See, also, notes under heads *Positive, Negative, Battery, Cathode, Current*, etc. Anodes may be soluble or insoluble in an electrolyte, as may be required to suit the nature of the work in hand. Insoluble anodes are used when we wish to decompose an electrolyte, and break it up into its several component parts without adding another element to it; as when acidulated water is decomposed by the electric current to form oxygen and hydrogen—in which case a platinum anode is used, because platinum is not soluble in the acidulated solution. Insoluble anodes are also used when we wish to extract all the metal from its solution, and deposit it in a pure condition on the cathode. Anodes are said to be insoluble when they are made of elements which are neither soluble in the solution to be electrolysed, nor can be made soluble therein under the influence of the electric current. Some solutions of the acids and alkalis will act very feebly, or not at all, on an element, even when heated to boiling point, but will dissolve it freely when a current of electricity is passed from it through the intractable solutions. For instance, gold is only feebly soluble in a strong solution of potassium cyanide when exposed to air, even when the solution is heated; but it is freely soluble in the same solution when only a feeble current of electricity is passed from it through the solution. Insoluble anodes are generally made of platinum or carbon. Soluble anodes are used when we wish to maintain an electrolyte at its original strength—that is, to contain the same quantity of metal in the solution after it has been worked as it had when first made up. To do this, the anode must be only soluble in the solution whilst the current is passing, and must then be dissolved therein to an extent equal with the rate of metal deposited. Unless an equivalent of metal is dissolved from the anode for each equivalent of metal deposited at the cathode, the original composition of the solution cannot be maintained during the process of electrolysis.

Gold Anodes should be made of pure gold plate or ribbon, not less than $\frac{1}{16}$ in. in thickness. Thin gold leaf or sheet is apt to become ragged at the edges as the anode gets worn; these ragged edges drop tiny pieces of gold to the bottom of the bath, and thus the solution, or the gilded goods, gets credited with an undue portion of the wasted anode. Plates of pure gold $\frac{1}{16}$ in. in thickness can be easily bent over a platinum wire, and this forms the best support for the anode, since it is not acted upon at all by the gilding solution or the fumes arising therefrom. Copper, silver, or brass wires dissolve and contaminate the solution with an alloy. Alloyed gold may be used as anodes, but the deposited metal will soon become an alloy of gold instead of pure gold; and the alloy is as likely to be as variable in composition as most deposited alloys are, and thus give trouble to the gilder. If gold anodes have been hardened by hammering, they should be annealed before being used. As a rule, the surface of anode presented to the solution should be slightly in excess of the surface to be coated with gold. As anodes are more quickly worn away at the surface of the air on them, they should be lifted out when not in work, and their position frequently changed.

(*To be continued.*)

OUR GUIDE TO GOOD THINGS.

33.—Winn's New Patent Water Director.

The New Patent Water Director is, as its name implies, an appliance for throwing water, so to speak, in the form either of a jet or spray, on anything on which it may be desirable to cause water to impinge. It is not a syringe, in which water is first drawn in by the withdrawal of the piston within from nozzle to top, and then driven out by pushing the piston back again from top to nozzle; but it is simply a contrivance to take the place of the ordinary nozzle or tube, which is usually fitted to the end of the flexible tube that is attached to all garden engines and pumps, as a means, with the nozzle, for the direction of the water which is ejected from such machines by the operation of pumping. This, at all events, is the inference to be drawn from the annexed illustrations of the New Patent Water Director to be found in this page. Illustrations of this kind are most helpful to the comprehension of the description of any article; but it is by no means an easy matter to give a really good and intelligible description of anything, especially if it be a machine of any kind, from an engraving. To help me, therefore, in writing such descriptions, I shall always take it as a personal favour if manufacturers, patentees, and dealers will send me a specimen of the appliance to be described, that I may be enabled to thoroughly understand its construction myself before I attempt to describe it for others. I shall be glad, also, if they will name retail prices, for I have always held it to be neither of advantage to the reader, nor helpful to the maker, to say nothing about price; for many a man who will readily buy an article if the price suits his pocket, will take no trouble to make even inquiries about the thing if he be kept in the dark on this most important of all points. Apparently the Water Director under consideration is a useful and desirable contrivance for the purpose for which it is intended, more especially as the jet of water may be turned to spray, or the water entirely shut off by simply sliding the upper part or outer case upon the inner pipe or stalk, which terminates in a piece of metal twisted into a spiral form. There is no cock of any kind, and the movement is effected easily and smoothly, without concussion. That it is made and supplied by Messrs. Charles Winn, brassfounders, St. Thomas's Works, Granville Street, Birmingham, is, I think, a sufficient guarantee for its goodness, as far as make is concerned, and its utility. Messrs. Winn and Company state it to be "the simplest and most effective thing yet offered for the purpose." It is sold in three sizes—namely, $\frac{1}{2}$ in., $\frac{5}{8}$ in., and $\frac{3}{4}$ in., which, I presume, is the diameter of the inner pipe; but whether externally or internally, I am unable to say, for the reason stated above. The prices are 35s., 45s., and 60s. per dozen, respectively, according to size; or 45s., 60s., and 75s. if supplied with union.

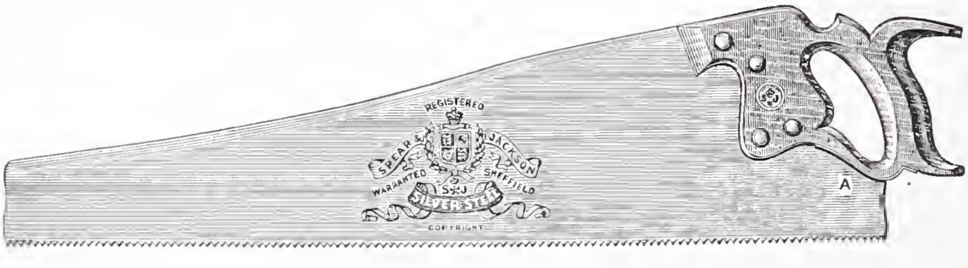
34.—Spear and Jackson's Improved Pattern Silver-Steel Handsaw.

This excellent saw, described in Messrs. Spear and Jackson's price list as No. 1887—a number which, perhaps, it will be well to quote in giving orders—is in every respect a nice tool to look at, and a capital tool to handle and work with. An old professional to whom I showed it, one of the best handrailers in the United Kingdom, fairly smiled with pleasure as he took the specimen saw sent to me into his hands, and examined it from handle to point with the utmost interest. "Yes, that's something like a saw," he said, as he handed it back to me with a lingering touch, and then asked the price, as though he would have liked to have made it his own. I could not tell him then, as I can tell my readers now, that this particular saw of silver-steel, full polished, with apple-wood handle, fitted with registered brass heel supporting and protecting plate, raised brass screws, and highly-finished blade, costs 120s. per dozen 26 in. long, and 130s. per dozen 28 in. long. And his approval was in no way diminished when, taking the saw in both hands, I brought point and handle together in pretty close proximity, and, letting go the point, allowed the blade to spring back smartly and sharply to its original position. The appearance of the blade is very good, being well-nigh as bright as silver; all the dirt, if I may so call it, being taken out of the metal—probably, by the Bessemer process and hammering combined. This saw, as well as all other best saws manufactured by Messrs. Spear and Jackson, Ætna Works, Sheffield, is tempered and ground by patented machinery, and is accurately tapered from the tooth to the back, and from the heel to the point, the teeth remaining the same thickness throughout, so that the saws work clean and sweet, with the least possible set. The reinforce plate of polished brass, attached to the outer edge of the handle at A in the accompanying illustration, and extending on both sides of the blade the entire width of the handle, not only supports and stiffens the heel of the blade, but protects and strengthens the handle at its weakest place. The handle, moreover, being carried well forward on the blade, as shown by the illustration, the weight of the saw is brought nearer the wrist of the operator, who has thus greater control over it, and the feeling of weight at the point is avoided. The blade also is materially stiffened by this arrangement, and may therefore be thinner than is usual in saws of the ordinary pattern, and still, at the same time, as rigid. I do not think that any workman, whether professional or amateur, would regret becoming the possessor of one of these saws. It may appear to be somewhat expensive when the price is contrasted with the cost of other saws of the same size. Its form is similar to that of the handsaws made by Henry Disston, an American manufacturer; more especially in the curved line of the back, which will only be regretted by those who are in the habit of using the back of the saw sometimes as a straightedge.



Spear and Jackson's Improved Pattern Silver-Steel Handsaw (No. 1887).

35.—How to Select Wood-Working Machinery.

This is a handy little volume, forming No. 3 of the "Timber Trade Handbooks," published by Messrs. William Rider and Son, *Timber Trades' Journal* Office, 14, Bartholomew Close, E.C., and written by Mr. J. Stafford Ransome, Associated Member of the Institution of Civil Engineers. It is devoted to a consideration more especially of the larger machines used in felling and preparing timber for the various purposes to which it is applied; reviewing in order the machines themselves, as regards power, construction, and purpose, and the various motive powers in use for actuating them. There is much to be learnt from its pages on the points already stated, as well as on purchasing machines. Some chapters are devoted to tree felling, the handling of logs after felling, and handling and cross cutting logs in the yard.

36.—Practical Iron-founding.

This useful and well-illustrated work is from the pen of "A Foreman Pattern-maker," one of the contributors to Work, as its readers will recognise. It is published by Messrs. Whitaker and Company, 2, White Hart Street, Paternoster Square, E.C. It is, to use the author's own words, "an attempt to give a condensed account of the principles and practice of iron-founding"—an attempt in which the writer has been entirely successful. It further contains the most recent practice with regard to machine moulding and the working of iron. It may be said to be replete with information on sands; on moulding both in green and dry sand, loam-work, etc.; and on the mode of going to work in moulding, and the tools that are used. The book is well illustrated with various diagrams and engravings, most of which are apparently from the pencil of the writer of the work.

37.—Barry's Patent Model Apparatus for Teaching Applied Mechanics.

This is the title of a small pamphlet in which an account is given of an apparatus devised and constructed by Mr. E. Barry, 75, St. Donatt's Road, New Cross, London, S.E., for the purpose of "making youths conversant with mechanics and with what are called the mechanical powers, and induce in them habits of scientific reasoning." In the apparatus the whole of the mechanical powers and their action are clearly exhibited, and practical illustrations are afforded of simple machines used in raising weights, moving heavy bodies, horizontally, vertically, and on inclines, and overcoming resistances by the aid of the working models. It contains, in fact, thirty-six distinct machines with accessories, with which endless experiments and combinations can be made. Its cost, complete in case, is £5 5s., no great sum when its practical value as a means of teaching mechanics by ocular demonstration is considered. The Editor.

A Corner for Those who Want to Talk It.

**** All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters From Correspondents.

Plans, etc., for Building.—A Subscriber who wants to Build writes:—"Having entered my name as a subscriber from the time I first received your circular giving a description of your new publication entitled Work, I have, with pleasure, perused its pages, and derived therefrom much valuable and useful information. I venture to suggest and ask you from time to time to favour us with a sketch and specification for building neat two-storied dwelling-houses at a moderate price. I am sure it would add additional interest and instruction to numbers of your subscribers. I know a few who would be delighted to receive such valuable information, and would myself gladly embrace the favourable opportunity of turning to good account the plans and information which, I am sure (judging from other suggestions and plans), would be worthy of carrying into effect. I hope ere loug to be favoured with such when time and space permit."—[I insert your letter with pleasure as a means of ascertaining the views of readers on this subject. The difficulty would be to please all who may want to build, and to meet their wants in every particular. To my mind, the better way would be to begin with pairs of cottages of four or five rooms, giving types of two kinds—one suitable for towns, and the other for the country—and then to proceed onwards and upwards to what are usually known as villa residences. This mode of treatment would give an opportunity of describing new materials, modes, and appliances used in building; and readers who required any departure from the types given could be told how they might best effect their purpose in "Shop." I shall be glad to have a full expression of general opinion on this subject.—Ed.]

Our "Cabinet in Fretwork."—Samuel Cosgrove (*Macclesfield*) writes:—"I beg to say that I have prepared, and am exhibiting at the Town Hall, Macclesfield (April 9), a cabinet from your drawing issued with No. 1 of Work."—[I am obliged to you for the programme of the Exhibition sent with your letter. I am glad to find you have cut and made up the design, and trust that you may be successful in securing the first prize. Let me hear the result.—Ed.]

II.—Questions answered by Editor and Staff.

Plumbing, Joint Wiping, etc.—Plumber.—You will, I hope, soon see papers on these subjects.

Lithography in all its Branches.—W. R. S. (*Croydon*).—Lithography will be taken up in due season.

Etching on Steel.—Excelsior wishes to know the composition of a powder used for etching on steel. The powder is strewed over the tracing made in soap, and moistened with water, then allowed to penetrate the steel. I have bought such a powder in the streets of London, but do not know its composition. I have tried a mixture of common salt and saltpetre crushed to a fine powder and spread over the tracing, then moistened with water. This bit into the steel, but it had not made much progress in two hours. When moistened with a drop of nitric acid its action is more rapid. Common salt spread on the tracing, and then moistened with very dilute nitric acid, has a rapid action on steel. Perhaps a brother etcher will oblige by sending a few hints for publication in "Shop."—G. E. B.

Batteries for Electric Lighting.—F. T. (*Bristol*).—I have not tried the Lalande battery for electric lighting; but others not connected with their manufacture and sale have done so, and have printed their experience. This is what one says:—"I had two years' practical work at lighting by the Lalande-Chaperon oxide of copper battery. The batteries used comprised large cells $1\frac{1}{3}$ ft. deep, 2 ft. long, and 1 ft. broad; these were very heavy, as each cell, when complete and charged, weighed 384 lb. We used 10 c. p. lamps of 20 volts, and as the electro-motive force of each cell was ·6, we required about 35 of these cells to obtain the necessary voltage." Finding the labour and cost of maintaining such a battery so great as to render their use impracticable, he next used only six cells during the day to charge 10 accumulators, using the current from these at night. He then gives results. "The quantity of current from each cell being large, it was possible to light ten 10 c. p. lamps of 20 volts for thirty hours, or six days of five hours; but not being able to regenerate the potash of battery and recover the zinc, this became impracticable on account of cost." Place these practical remarks side by side with the glowing account of the battery in the newspaper cutting sent, and draw your own conclusions. During the last ten years many of these so-called regenerative batteries have been invented and placed on the market. They are will-o'-the-wisps among batteries, for they only beguile persons from the right path by their flashy claim to inexpensiveness. A few moments' thought will serve to convince any unbiassed mind of the hollowness of the claim. The electric current required to regenerate them costs as much, or more, to produce than the current obtained from a charged battery. The principle can be applied to the Daniell battery, but not economically. You cannot get any of these batteries to retrace their action and work backward. I propose writing a short paper on the Daniell battery at some future time. The subject of electrotyping will also be taken up at some time by myself or one of my colleagues. Stereotyping will also receive attention from one of us. To sum up: all that is of interest to workmen in their work will be treated of in the pages of Work. The remaining suggestions in your kind and interesting letter have been handed on to the publishers, whose business it is to arrange the advertisements.—G. E. B.

Electro-gilding.—Nemo (*Norwich*).—Work your gilding solution with current from one quart Daniell cell, or one Bunsen weakly charged. The solution must be worked hot (160° Fahr.), and may be heated in an enamelled saucepan. Iron or any other metal vessel will not do for the purpose. Use an anode of pure gold attached to the wire leading from the copper or carbon of the battery. If the solution does not work freely, add a small piece of cyanide of potassium to it. If you want any further advice, please write again, and I will gladly help you. Look out for my forthcoming articles on "Notes for Electro-platers."—G. E. B.

Brass Casting.—Brassworker writes:—"Will you say how antimony acts upon usual pig brass, and how much should he added to pot of metal of, say, 40 lbs., and if any beneficial result is obtained from using same in brass? Others advise a little lead to soften brass. Will this do, and, if so, how much should be added to pot of metal of, say, 40 lbs? Should the softening be correct, does it at the same time become more breakable or 'short,' as metal is called that breaks readily?"—To the above the reply is:—Antimony acts by facilitating the combination of the mixture called "pot metal" (copper and lead). 1 of antimony to 7 of lead and 16 of copper, mix well, and give a harder alloy than the lead and copper alone. There is a red brass composed of copper, 160 lbs.; zinc, 50 lbs.; lead, 10 lbs.; antimony, 44 oz. The metal is not short, but soft. The effect of lead upon common yellow brass (copper and zinc), when added to the extent of $\frac{1}{4}$ oz. or $\frac{1}{2}$ oz. to the pound, is to render it more malleable, and to make it cast more sharply. The lead must be added last, and stirred just before pouring. If excess of lead is put in, it will ooze out, and partially separate in cooling.—J. H.

Building Model Locomotive.—Amateur writes:—"I intend building a model locomotive 3 ft. long. Now, what I want to know is—(1) Can I get a casting of the bed-plate in iron 35 in. × 9 in. and $\frac{1}{8}$ in. thick? My impression is that I cannot. I would prefer a casting, as it is such a lot of trouble cutting out the various dimensions. (2) Where can I get the boiler tubes brazed in? There does not seem to be a brazier about here (*i.e.*, Wimbledon). Can you recommend me one in London?"—To these queries the following replies are given:—(1) It is quite possible to make a casting of a "bed-plate" (frame-plate) for a model locomotive in iron, measuring 35 in. × 9 in. × $\frac{1}{8}$ in., but then it would be of no use when done. Wrought iron or steel plate is the proper material. (2) Any of the model-makers would braze your boiler tubes. Batemau & Lee, High Holborn, do plenty of this kind of work.—J. H.

Scrolls and Designs for Monumental Work.—J. C. (*Aberdeen*).—No branch of manual work will be neglected in Work, but as I have already said, to touch on every trade at once is not possible. I can only say that papers on the art of the stone mason will be given as soon as it is practicable with designs for the special work to which you allude. Meanwhile, you will not fail to find in every number of the Magazine some hint, suggestion, or piece of information that will be well worth its price to you for home adoption and use.

Pit Frame for Wheel Making.—E. J. E. (*Abingdon*).—Your inquiry for the method of "making a good frame for wheel making" requires a longer reply than can be given conveniently in "Shop." I have much pleasure, therefore, in saying that provision shall be made to meet your requirement in the form of a paper with illustrative diagrams, which, I hope, you will find helpful to you.

Plasterers' Work.—C. L. (*Uxbridge*).—This subject, in commou with the work of other trades, will receive mention at any and every opportunity.

Violin Scroll.—T. D. N.—The instructions for making violin scroll would require much more space than could be devoted here, but articles on violin making are in progress, when the subject will be fully dealt with.—B.

Violin Cramps.—E. P. W.—Please accept latter part of answer to T. D. N. on "Violin Scroll" in reply to your queries on violin making. A joiner would not be likely to have wood screwing tackle small enough ($\frac{3}{8}$ or $\frac{1}{2}$ in.) for making violin cramps. These can be bought from either Lafleur & Son, Green Street, Leicester Square, London, or J. Scheerer, Covered Market, Leeds.—B.

Treatment of Gold Rings after Soldering.—Dean Forest.—After soldering wedding rings and keepers, drop them into a mixture of sulphuric acid 1 part, water, 10 parts, and leave till the borax is dissolved. They must then either be gilt or polished; wedding rings would do scratch-brushed and burnished, but keepers would require to be gilt, and if required to look as new, also lapped.—Aurolectric.

Model Beam Engine.—W. J. P. (*Fenny Stratford*).—I do not know of any book that will tell you how to make a model beam engine. It is a thing amateurs seldom think of attempting. But there is a very clear sectional view of a beam engine in "Stationary Engine Driving," by Michael Reynolds, p. 42. It is a folding plate, and can very well be worked from by scale. It is published by Crosby, Lockwood, & Co. Any information you may require as to the details of work of this kind can be had for the asking.—J. H.

Mounting Tracing Linen.—Lara asks:—(1) "How to mount drawings made on tracing linen. I have tried it a few times without success. It always becomes *baggy*, and loses its polish. (2) Can tracing linen being damped be restored its original gloss, and how?"—Your query is not sufficiently defined. I may assume, tracing cloth being in itself sufficiently durable, that it is not intended to mount on canvas. If for an ordinary picture strainer or board, the simplest way is to glue the outer edge of the strainer on one of its longest sides, turn the tracing cloth down, say, $\frac{3}{8}$ths of an inch, and fix. Allow time for this to set. Next glue opposite edge of strainer, and pull the tracing tightly down, pressing firmly to the glued edge, repeating the process for the other two sides; cut out the corners of the cloth to prevent creases. On most tracings you will find one or more selvage edges; these should be cut off before mounting, otherwise the cloth will give when tightened more in other parts than on these edges. If objection is taken to the cloth showing on outer edges, glue $\frac{3}{8}$ths of an inch on flat surface of strainer, and proceed as above. Use Le Page's glue or transparent cement, cold; hot glue will affect surface; indeed, any glue or cement used is sure to show through even if the surface is otherwise unaffected. If the tracing is for show, put a strip of coloured paper over the part affected by the glue, and so form a border. A sheet of white paper under the tracing shows it up to advantage. Above all things avoid damping or wetting. Tracing cloth wet is practically spoilt, and I believe any solution you might try to regain the lost gloss would only add to the mischief. The Aladdin remedy, new lamps for old, is about the only way to effect a satisfactory issue.—Joachim Miller.

Bunsen Batteries.—H. D. (*Haverfordwest*).—(1) Porous cells for quart Bunsens, 6d. each. (2) Zinc cylinders, amalgamated, 1s. 3d. per lb. Both procurable of any dealers in electric sundries. Here in London, of Messrs. H. Dale & Co., 26, Ludgate Hill, E.C. (3) One cell for electro-plating and gilding on a small scale, or working a small shocking coil, or small magneto-motor. Two cells in series for working larger coils, magnets, or motors. Three cells in series for electro-coppering and nickelling and lighting a small lamp. Four cells in series will light two small incandescent lamps. (4) Although I mentioned electric lighting as one of the kinds of work suitable to the Bunsen battery, I am not favourable to this system of lighting by means of a battery. There is too much trouble, and mess, and expense attached to it, to make it pleasant. See reply to H. S. on this subject. (5) The cost of a Bunsen battery will be about 3s. per quart cell, complete. Acids will be extra cost, of course. That is about the cost here in London.—G. E. B.

Internal Resistance of Battery.—G. W. (*Liverpool*).—All conductors of electricity offer a resistance to the passage of this force. This differs with different conductors. Its nearest equivalent in mechanics is friction. The internal resistance of a battery is the total resistance of the conducting fluids and elements within the cells. This is ascertained by balancing against it the known resistance of certain coils of wire and instruments. The coils are known as resistance coils, and are equivalent to electric weights. The balance beam, so to speak, is named a "Wheatstone Bridge," and the indicating instrument is named a "Galvanometer." The resistance of wires is ascertained by the same method. Electrical measurements and measuring instruments will receive our attention, and be treated of in future numbers of Work.—G. E. B.

Glazier's Diamond.—N. T. (*Leyton*).—Superior diamonds will cost about 30s.; from this price downwards for a good tool to 21s. You may get a fairly good one second-hand at a pawnbroker's shop for 10s. 6d.; but second-hand diamonds may he damaged or out of set. To use a diamond, place the sheet of glass on a cloth-covered level board, measure off the dimensions, lay a straightedge along the intended line to be cut, hold the tool in the right hand, with the steel holder close to the straightedge, find out by trial the cutting edge of the diamond, then draw the tool along in this position to the end of the line. You can feel and hear when the diamond is *cutting* the glass, then keep the tool in the cutting position all along the line to the edge of the glass, but not over it. The pressure on the tool should he only enough to keep it in cut, but must be uniform throughout. Of course the tool will wear out, but will last a lifetime with good care. If the diamond spark is injured or torn out of its setting, it must be reset. Tool vendors will get this done.—G. E. B.

Electric Lighting by Battery.—H. S. (*Bebington*).—Four quart Bunsen cells in series will light up two small incandescent electric lamps. These lamps are small glass globes fitted with platinum wires attached to a thin filament or string of carbon. The globes are exhausted of air, and sealed

One wire of the battery is hooked on to one of the platinum wires on the globe, and the other battery wire to the other bit of platinum, then the carbon filament gets white hot and glows, emitting a soft, white light. Proper holders for the lamps are supplied by those who sell the lamps. Having tried lighting by batteries on a small scale, and experienced the cost and trouble, I do not advise any other person to follow my example, save only as an experiment to see what can be done this way. —G. E. B.

Small Dynamo.—A COTTAGER.—Small dynamos are preferable to batteries for lighting up small electric lamps. I am trying to arrange for a few papers on dynamo building. Before you decide on electric lighting for your cottage, you must arrange for power to drive the dynamo. Have you a gas engine, steam engine, or water motor?—G. E. B.

Circular Saws.—A READER.—You ask for a "simple rule to calculate the power, not nominal, it would take to drive a circular saw of any diameter up to 60 in. to cut, both soft and hard wood the depth it will reach."—For every square foot of hard wood with a 60-in. saw and ¼-in. kerf 2-horse power —actual, not nominal—is required to drive saw only. To this must be added, say, 1-horse power for shafting, etc., and the result doubled to provide for contingences. You would, therefore, require about 6-horse power actual. It is always best to provide a good margin of power, so that when the saw is working at its full capacity, the engine shall only exert at most about three-fourths of its full power.—OLLA PODRIDA.

Power of Engine.—A READER.—You ask what would be the real horse power of a "semiportable engine with two 11-in. cylinders, 24-in. stroke, and from 90 to 100 strokes per minute;" and "what pressure of steam should steam gauge indicate to get full power; and how to calculate the power of the above, or of an engine with one cylinder."—In finding the horse power of an engine, each cylinder —when there are more than one—is treated and calculated from separately. To do this in any case, the mean pressure of the steam in the cylinder during a revolution must be known. In practice this is ascertained from indicator diagrams. You do not give the boiler pressure, nor do you state the cut off of slide valve, both of which govern the power also. This information being absent, I cannot give much more than the method by which the horse power is worked, and in doing this will assume that the boiler pressure is 40 lbs. per square inch, and the slide valve cuts off at three-quarter stroke. This will give approximately and practically a mean pressure of 30 lbs. per square in. on the piston. The actual horse power of an engine is found by multiplying the area of the piston in square inches, the mean pressure in lbs. during the stroke, the length of stroke in feet, and the number of revolutions per minute together, and the result by two; which total, divided by 33,000, will give the horse power. Taking your case, for example, where the diameter of piston is 11 in., stroke 2 ft., and number of revolutions 100, the mean pressure being 30 lbs., we have as follows:—

$$\frac{(95 \times 30 \times 2 \times 100) \times 2}{33{,}000} = 17{\cdot}27 \text{ Horse power.}$$

for one cylinder, and 34·5 for the two cylinders. As to the pressure which steam gauge must indicate to get full power, I can give no information, not knowing what boiler and engine were designed to work at. If you do not know what pressure to work your boiler at, get it surveyed at once by a competent authority. If you neglect this, and go on working in the dark, as you evidently are, something serious may happen. If you will describe your boiler, giving its age, situation, method of seating, length, diameter, thickness of plates in each part, and general construction, I may be able to give you some idea of working pressure.—OLLA PODRIDA.

Standard for Porous Pots.—BATTERY.—The question of the suitability of porous pots need not cause you any trouble. In practice, the eye alone guides one in the choice of pots. The only tests are those mentioned in my article on the Bunsen battery. These were given as aids to those who wished to put up a perfect series of cells, all having the same resistance. Any cell may be used, whether hard or soft; but the best are, of course, those of medium porosity.—G. E. B.

Organ and Harmonium Building.—H. B. (*Glasgow*).—In reply to your letter, arrangements for papers on the construction of the instrument known as the American organ are now in progress.

Circular Saw.—J. B. (*Poole*).—I do not see how I can well add to the description of the circular saw noticed in WORK, No. 4 (page 61). You ask, "Can you give some idea of its capabilities? Will it saw inch boards lengthways and across? Is it properly finished, and will it saw mitres true? Has it 'continuity' of action?" As to capabilities, the amount of work that can be done by and with the saw is indicated by what was said of it in the description. It will certainly saw wood one inch thick both with the grain and across the grain. It is well finished, and will saw mitres true, provided you keep the edge of the wood you are cutting well against the fence, so that the saw may enter it at the right angle. As to "continuity of action," I can only say that the saw will keep going as long as motive power is applied to it. It is intended for small work; but with somebody to help you, and trestles whereon to support the board, you might rip up boards of any length. The fly-wheel is heavy enough for the saw. Rapidity of motion, of course, depends on the amount of power applied. You will find it a useful little saw for all ordinary purposes and light work; and by following the principle of construction and adding means of working the saw by hand power, and using an 8-in. saw instead of a 6-in. saw, you might easily construct a bench saw as an adjunct to your carpenter's bench, which would do heavier work than you can get out of the saw in question. You cannot expect a boy to do the work that a full-grown, able-bodied man will get through, and it is pretty much the same with large and small machines of the same class.

Casting in Plaster.—MOULDER.—I know of no good work on casting in plaster; but I may say that in time the fullest and clearest instructions on this subject will be given in WORK. Meanwhile, you shall have brief instructions for taking a plaster cast from the figures you have modelled in clay.

New Invention.—W. J. P.—The cost of obtaining provisional protection for nine months if you go to the Patent Office direct is only 30s. If you will send me a sketch of your invention, or, better still, a working model, I will submit it to a man in the trade to which your invention applies, on whom I can rely implicitly, and he will advise you as to its merits and value. That being settled, I will see what can be done towards helping you to secure the benefit of your invention, if you cannot help yourself to the extent first required. You see I have given no clue in my reply to the nature of your invention. I might have answered you direct by letter, but I have replied through "Shop," as you requested, on much the same principle that Admiral Byng was said to have been shot—namely, "to encourage the others"—the "others" in the present case being those who may happen to be in the same predicament as yourself. I hope and trust, by God's blessing, that WORK will prove the means of bringing help to many a man who may have inventive and creative brain power, but lacking the means to turn the products of his thought to good account.

Wood and Machinery for Fret Sawing.—A. E. G. (*Ipswich*).—You ask me to tell you "the best firm for all kinds of wood for fretwork, saws, and designs, etc." To begin with: every firm of dealers in these articles consider themselves to constitute the "best firm." Suppose you were asked to declare whom you might think to be the prettiest and most charming of a dozen young ladies, and you were rash enough to do so. You would certainly offend eleven, and, perhaps, not make any decided advance in the good graces of the twelfth. Now, unwittingly, of course, you seek to place me in precisely the same predicament with the firms. I will tell you some *good* firms from whom you may get wood for fret sawing, and apologise to all who may be omitted, on the plea that I am either not acquainted with their names and addresses, or have forgotten them in a brief spell of temporary insanity, induced by your question. In London, wood may be bought of R. Melhuish and Sons, 85 and 87, Fetter Lane, E.C.; Henry Zilles, 23 and 24, Wilson Street, Finsbury; and Charles Churchill and Co., 21, Cross Street, Finsbury. In Liverpool, of G. Busschotts, Park Lane. In Bath, of Fritz Collins. In Settle, Yorkshire, of Harger Bros. In East Dereham, Norfolk (which is about the nearest to you, failing any dealer in Ipswich), of J. H. Skinner and Co. In Dublin, of Booth Bros. Of saws, there is a good German make with a thin rounded back and narrow blade to be had of Mr. H. Zilles; and there is an equally good kind of saw imported from Italy to be had of Mr. G. Busschotts. The Griffin saws, and the Star or Hibernia saws, are also good. Of fret machines, the best undoubtedly is the Britannia Company's No. 8 fret saw.

Advertisements in "Work."—AN AMATEUR.—As I have said before, the appearance of advertisements in WORK does not interfere with the utility of the magazine. You must try to persuade yourself that the value of the information you derive from WORK outweighs considerably that which may possibly appear to yourself and others to be a detriment and disfigurement. At all events, your suggestion shall be taken to the proper quarter for its consideration.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

6. Steam Siren or Fog-Horn.—H. T. C. (*Leytonstone*) wishes to know "how to make a steam siren or fog-horn. Working drawings required."

7. Old Coloured Print.—W. H. (*Liverpool*) asks for "instructions how to remove old smoke-dried varnish from a coloured print, 'The Farm Yard,' by Bowles & Carver, 69, St. Paul's Churchyard, London." He adds:—"Can you give me an idea of the date, or tell me how I can get it? The size is 34 in. × 22 in., and it is printed on two pieces of paper joined down the centre."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Cutting and Polishing Stones, etc. (See No. 2, p. 30).—J. H. writes:—"Mr. Bear will find a great deal of information on polishing processes in the third volume of Holtzapffel's 'Turning and Mechanical Manipulation.'"

Address Wanted.—CHARLES S. WHITING (*Dublin*) will oblige by sending his full address to the Editor of WORK.

THE Westinghouse automatic brake is in future to be the standard brake upon the trunk lines of Switzerland.

AN American writer recommends red ink in which gum arabic and washing soda have been dissolved, as a suitable solution for making legible alterations on blue prints. The action of the soda is to decompose the blue matter of the print, leaving the white paper exposed. The gum arabic is added as a thickening solution to prevent the ink from flowing too freely from the pen and spreading on the paper. Red ink is simply used as a colouring agent. If the soda alone is used, the lines show white. Caustic soda is recommended as being better than washing soda.

TIMBER in Guatemala is abundant. There are forests of mahogany and pine with a great variety of other woods which are capable of being used for manufacturing purposes. The balsam tree grows wild. There are forests of the indiarubber tree, beside the textile plants, such as the maguey, the saltwort, the soft rush, the soft aloe, all capable of becoming the bases for remunerative industry. Resins, gums, and balsams are met with, such as the liquid amber, the copal tree, the turpentine fir, vegetable wax, etc.

AT the Central Institution of the City and Guilds of London Institute, Mr. T. Bolas is delivering a course of six lectures on photography, on Wednesday evenings, at 7.30. Lectures I. and II. will deal with the use of artificial light in photography; lectures III. and IV. with photo-mechanical printing methods; and lectures V. and VI. with direct contact printing methods.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

*Prospectus, Pamphlet and Sample, post free on application to the **Inventor and Manufacturer,***

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

WHELPTON'S VEGETABLE PURIFYING PILLS

Are one of those pure Medicines which for their extraordinary properties have gained an almost **UNIVERSAL REPUTATION.** Recommended for Disorders of the **Head, Chest, Bowels, Liver** and **Kidneys**; also in **Rheumatism, Ulcers, Sores,** and all **Skin Diseases**—these Pills being a **direct purifier of the Blood.**

ESTABLISHED
1835.

WHELPTON'S PILLS AND OINTMENT.

WHELPTON'S HEALING OINTMENT

Stands unrivalled for the Cure of **Cuts, Burns, Bruises, Ulcers, Sores,** and all kinds of **Skin Diseases.** A Specific for **Eczema.** *Burns, Scalds, Cuts, etc., happen when least expected—Be Prepared!*

Both Pills and Ointment are sold in Boxes, price **7½d., 1s. 1½d.,** and **2s. 9d.,** by G. WHELPTON & SON, 3, Crane Court, Fleet Street, London, and all Medicine Vendors at home and abroad. Sent free by Post in the United Kingdom for 8, 14, or 33 stamps.

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

VOL. I.—No. 9.] SATURDAY, MAY 18, 1889. [PRICE ONE PENNY.

A SUMMER FITMENT FOR THE FIREPLACE.

THE time has now come when means and methods will be sought by which the black, comfortless, unused fireplace may be embellished or hidden, and our shops will soon display the latest novelties to meet this demand. Amongst the many patterns and designs which will be shown, will be the new screens or fitments which are intended to entirely enclose the fireplace: they will be of more substantial make than the printed cards, etc., generally used, being made of wood, with shelves for plants or china, and panels of Japanese matting, paper, plush, and other materials; the wood work being enamelled in various light tints, such as cream, salmon, bird's-egg blue, etc. The construction of these fitments being simple renders them a very suitable article for the amateur cabinet maker to try his hand upon, and when made there would be a place for them, not as is the case with most amateurs' goods, there being no use for them. Thinking it may be an acceptable novelty for some, I propose to briefly describe how one may be made quickly and effectively.

Pine or American white wood is the wood required: packing cases some might suggest, but that depends upon the amateur being a "glutton" for work and desirous of spending his energy on working out dents and bruises, rough knots, nails, etc., but, as a rule, I think the amateur likes to see the result of his work as quickly as possible, so the quickest way is to get from a timber yard the wood required, which in this case is not much.

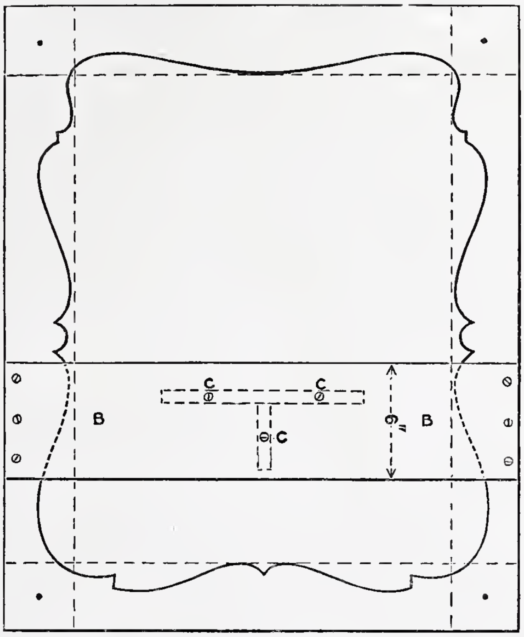

Fig. 2.—Shaped Frame for Fitment, as seen from the Back, showing Strip to support Bracket.

Fig. 1 gives an idea of the fitment about to be described. It consists of a shaped frame of enamelled wood surrounding a surface of Japanese matting, from which projects a shelf supported by a bracket. The width and height of frame must of course depend upon the space to be covered in, and should be measured exactly so that the frame may fit tightly and be self-supporting.

Having ascertained the size, cut two strips the full height and two strips the full width from a so-called 1 in. board 4 in. wide, one strip 6 in. wide the full width, and a piece for the shelf 14 in. long by 6 in. wide, whilst the bracket will require a piece 4 in. each way; this is the wood required. The four 4 in. strips are to form the shaped frame, and the 6 in. piece is to fasten at back to carry the shelf. To make the frame it requires the corners to be halved, as shown in Fig. 4; before that is done the wood should be planed and edges squared. The wood being thus prepared, lay one end across the other, as in Fig. 3, at right angle, and mark underneath the board from B to C; repeat this to the eight ends. Then with a gauge draw a line, A, at exactly half the thickness of the wood, so that when the half of each end is cut away, the two ends being placed together will form the exact thickness of the board, as shown in Fig. 4.

Having carefully marked the ends as

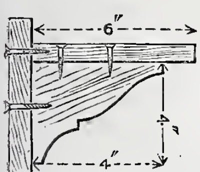

Fig. 5.

Fig. 4.—Halved Joint set out, completed.

directed, place the board in bench screw upright and cut down as far as the cross line, taking care that the saw does not deviate from the pencil line, then saw on the cross line till the half comes away, and then with a chisel remove inequalities and saw marks, that the two halved pieces may bed exactly. Now fit the frame together, and secure at each corner by a brad just sufficient to hold the pieces together; rub a little whiting or chalk on face, which will enable the line to be more plainly seen, and also allow alterations in drawing, and set out the shaped line to be cut as in Fig. 2. It is better to fix the frame in position, and then trace out the shaped outline, than to draw on each piece separately, as it will better be seen where the line will pass from one slip to another, and thus enable the workman to avoid the chance of the line not exactly following on. When the setting out is completed, the pieces may be knocked apart for convenience of handling whilst cutting. After the cutting out of the shapes is finished, well glass-paper the edges, keeping the face-edge sharp; the frame can then be glued together and a few brads driven through corners, avoiding bruising the wood with the hammer. Whilst the glue is setting clean up the shelf, the top edge of which can be rounded or bevelled to take off the thickness; also cut out the bracket and fix it to shelf by two screws passing through shelf into bracket, Figs. 5 or 6, well sinking the heads. The curved lines at top of frame in Fig. 1 are cut out with a V chisel.

When the frame is fit for handling, give a final clean with fine paper, and stop cracks that may show in joints with wax; also cover screw heads in shelf with the same; it is then ready for enamelling. Three thin coats should be given to obtain an equally flat and glossy surface. The Japanese matting, or other material that may have been chosen, is then to be tacked on at the back. The 6 in. strip of wood is then to be secured to the frame over the matting, at the height that may be thought best according to the proportion of frame, as in Fig. 2, and long thin screws passed through that into shelf and brackets, Figs. 5 or 6, and C, Fig. 2. The summer fireplace fitment is then completed.

NOTES FOR ELECTRO-PLATERS.

BY GEORGE EDWINSON BONNEY.

V.—Silver Anodes—Nickel Anodes—Copper Anodes—Brass and German Silver Anodes—Antimony—Ampère—Ammeter or Ampère-meter.

Silver Anodes should be made of pure silver, sheet or ribbon, ⅛ in. in thickness, well annealed. All that has been written respecting gold anodes in the preceding paragraph may be applied to silver anodes. The anode-plates may be suspended from the anode-rod by wires of pure silver, or hooks of the same metal. Alloyed anodes, even to a small extent, contaminate the bath with copper, and the alloyed deposit presents a dark tint, instead of the beautiful whiteness so much admired in electro-deposited pure silver. The deposit is also hard and intractable under the burnisher.

Nickel Anodes should be made of pure rolled nickel plates, of a thickness suitable to the work in hand. Small anodes for small operations should be thin, the thickness increasing with the superficial size of anode required. Plates of cast nickel are always clumsy, because heavy and thick; they are also brittle and porous, whilst the pores are apt to contain impurities. Mr. A. Watt, author of "Electro-deposition: A Practical Treatise on the Electrolysis of Metals," states that he has found "a considerable percentage of loose carbon—graphite—interspersed with badly-cast nickel. The advantages claimed for rolled-nickel anodes over the cast metal are:—The constant and steady way in which they give off the metal; they never become soft or fall to pieces while in the bath, as cast-nickel anodes do; they may be light and thin to begin with (of course, being far less costly in consequence), and they last a very long time." The firm of Messrs. H. Wiggin and Company, Birmingham, has a good reputation for best rolled-nickel anodes. Anodes of nickel may be suspended from strong hooks of copper, inserted in holes punched or drilled in the nickel plates.

Copper Anodes should be made of electro-deposited pure copper, well annealed. The cast-off plates or cylinders from a Daniell battery will do fairly well for anodes.

Brass and German Silver Anodes should be made of an alloy corresponding with the composition of the solution in which they are used, and the desired deposit of metal. They should be well annealed before being used, and may be suspended from the anode-rods by hooks, as directed for nickel anodes. For information on the working of anodes, see *Free Cyanide*, *Free Acids*, etc.

Antimony.—French, *antimoine*; Latin, *stibium.* Chemical symbol, Sb.; specific gravity, 6·71; combining weight, 122; melting point, 800° Fahr.; electric conductivity, 3·88. Electro-negative to all the well-known, and most of the rare, metals; electro-positive to carbon, boron, tungsten, molybdenum, vanadium, chromium, arsenic, phosphorus, selenium, iodine, bromine, chlorine, fluorine, nitrogen, sulphur, and oxygen. Antimony is a bright, bluish-white metal, so brittle that it may be powdered in a mortar, and is easily fusible. "It melts at 450° (C.); rapidly oxidises if exposed to air when melted; and if heated more strongly, it takes fire and burns with a white flame, giving off fumes of antimony trioxide. Antimony is not attacked by dilute hydrochloric or sulphuric acids." (Roscoe.) It may be slowly dissolved in hot strong hydrochloric acid, and in hot concentrated sulphuric acid. Strong nitric acid attacks it and forms a white substance (insoluble in acids or water), to which has been given the name of antimonic acid—a pale, straw-coloured powder, soluble in solutions of potash or of ammonia. Aqua regia dissolves antimony readily, and forms antimony trichloride, otherwise known as butter of antimony. Antimony is a valuable metal, because it forms with some other metals a number of useful alloys. With bismuth, copper, and tin, in certain proportions, it forms Britannia metal, best pewter, and Queen's metal; with lead and bismuth it forms stereotype metal; and with lead it forms type metal. It is also an ingredient in a recipe for fusible metal. See *Fusible Metal*, etc. The electro-deposition of antimony has received the attention of Mr. Gore, who has obtained a series of most interesting results from his experiments. An account of these will be found in his treatise on "Electro-deposition" (*Circle of Science Series*). I am not aware that the deposition of this metal has been put to any useful purpose.

Ampère.—An ampère is an electrical unit of measurement, generally accepted by English-speaking peoples. It is the unit of current strength, or volume of force given by any electrical generator. Its meaning may be learned by comparison with other units of measurement. For instance, in trades where the foot rule is used, the inch is a unit of measurement of surfaces. Where steam engines are used, we speak of pounds as a unit in estimating the pressure of steam; and horse-power as a unit in estimating the work done by steam working through a steam engine. Where water is used as a motive power, we speak of its pressure or "head" as measured by foot-tons; and its volume by square inches, or gallons per minute. In dealing with the measurement of electric force, neither the foot-rule nor the spring-pressure gauge can be used as instruments of measurement, so electricians have had to invent a new set of instruments, and new names for the units or divisions marked on them. The ampère is a work unit, telling of work done, and is calculated on the known power of electric force to do the chemical work of decomposition; that is, the work of breaking up chemical compounds when the current is passed through their solutions. "An ampère is that quantity of electric force which liberates ·000158 of a grain of hydrogen in one second. This is equal to one grain in 6,338 seconds." In the same *time* it will liberate the grain-equivalent of any other element—that is to say, of zinc, 32·5; of copper, 31·7; or of silver, 108 grains. "For all practical purposes, this means 18·5 grains of zinc per hour." Professor Thompson estimates the following deposits of metal to be done by one ampère in one hour:—Nickel, 1·099 grammes; copper, 1·1739 grammes; gold, 2·441 grammes; silver, 4·025 grammes. These figures will represent nearly in English grains:—Nickel, 16·958; copper, 18·115; gold, 37·669; silver, 62·106. The "grain-equivalent" on which these calculations are based is the *electrical equivalent* of each metal; and this differs in some instances from the chemical equivalent, or atomic weight of the same metal. For further information on this subject, see notes on *Atomic Weight*, *Combining Weight*, *Equivalents*, *Valency*, etc.

The ampère is also defined as "that quantity of electricity obtained from an electro-motive force of one volt passing through a resistance of one ohm." If we can determine by measurements the electro-motive force of an electrical generator, and also the total resistances of the electrical circuit, then by dividing the total electro-motive force of the current by the total resistances of the circuit, we obtain the value or strength of the current in ampères. See note on *Ohm's Law.*

Ammeter or *Ampère-meter.*—An instrument for measuring the strength of an electric current in ampères. Various forms of these instruments are made and sold. In one form, the instrument is like a galvanometer furnished with a coil of thick wire surrounding a steel permanent magnet. In all other particulars it is made like a galvanometer, but the divisions on the dial are graduated and marked to represent ampères. In another form, the instrument is made to work out the principle or law that a permanent magnet, being free to move, will place itself across the path of an electric current passing through a conductor near to the magnet. The conductor in this instrument is a broad strip of sheet copper. A magnetised steel needle is suspended vertically on a nicely-adjusted axis close to the conductor, and a pointer of aluminium, or some light substance, is also fastened to the needle, or on its axis. The needle is deflected out of its vertical position by the influence of the current passing through the conductor, and these deflections are governed by the strength of the current passing through the instrument. These two forms of ammeter cannot be relied upon to give exact readings for any length of time, because of the tendency on the part of so-called permanent magnets to lose a part of their magnetism, and thus be less influenced by the electric current passing through the instrument. It is therefore necessary to frequently readjust and calibrate the readings by an electrolytic ammeter.

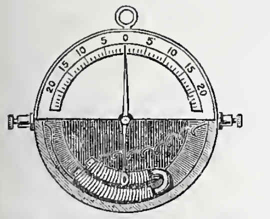

Fig. 2.—Small Electro-Magnetic Pendulum Ammeter: Lower half of Dial removed to show Magnet and Pendulum.

Another form of ammeter is constructed to make use of the well-known property of soft pure iron to become an electro-magnet when wound with an insulated conductor carrying a current of electricity. A piece of soft bar iron is bent to horse-shoe form, and wound with thick copper wire, insulated or covered with silk or cotton. A small pendulum of soft iron is suspended between the poles of the magnet, and a pointer is connected to the staff or axis. The bob of the pendulum is drawn toward the ends of the magnet poles in proportion to the strength of the current passing through the magnet coils; and the pointer shows on a dial the movements of the pendulum. The main objection to this form is found in the fact that much of the current must be absorbed in doing electro-magnetic work and in heating the coils, thus increasing the total resistance of the circuit. The same may be said of those instruments in which solenoids (*i.e.*, hollow electro-magnetic cores) are employed to draw in a movable iron core attached to multiplying gear.

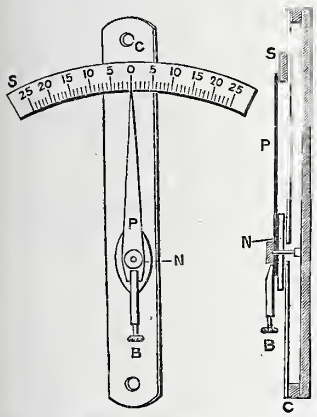

Fig. 3.—Working Parts of Vertical Magnetic Needle Ammeter: B, Balancing Screw; C, Copper Strip; P, Pointer; N, Magnetic Needle; S, Scale.

Electrolytic ammeters, or measurers of electric current, are constructed to make use of the law already given in the note on *Ampères*—*i. e.*, the known ability of the current to do a certain quantity of chemical work in a given time. In some forms of this instrument, two metal plates are suspended from a delicately-balanced beam in a standard solution of the metal composing the plates. The current to be measured, or a known part of it, is made to pass through this solution, and do electrolytic work by dissolving the metal off one plate and depositing it on the other. As one plate gets light and the other heavy, the balance of the beam is disturbed, and it tilts toward the heavy plate, just when a certain quantity of current has passed and done its quota of work. This tilting action of the beam is made to reverse the direction of the current at the same time as it moves gear to register its action; and in this way the work goes on in the opposite direction until the light plate has been weighted by deposited metal. The total work done in a given time can therefore be reckoned up and calculated, and the calculation will show the number of ampères employed during that time. The imperfections found in this instrument are due to friction of gearing, not always constant, and to alteration of the electrolyte, consequent upon changes of temperature and evaporation of solution. There are not, therefore, any perfect ammeters made; but perhaps the best of the electrolytic ammeters may be regarded, after all, more perfect measurers of electricity than the best gas-meters are measurers of gas.

All ammeters have to be calibrated, and their marks adjusted by reference to electrolytic work done in a depositing cell. The method advocated by Mr. S. Bottone, in his book on "Electrical Instrument Making," is as follows:—Procure a generator of electric current calculated to furnish the necessary strength of current; then prepare a strong solution of sulphate of copper, slightly acidulated with sulphuric acid; also two plates of thin sheet copper, at least six inches square. Weigh the copper plate intended to receive the deposit in a balance capable of weighing to the 100th of a grain, and note down the exact weight. Place the two plates in the depositing solution, with the instrument to be graded in circuit with the work and generator. Allow the work to go on for exactly an hour; then take out the weighed copper plate, wash it in hot water, and dry perfectly without rubbing; again weigh the plate, and note exactly how much copper it has gained. If it has gained 18·35 grains, then the current passing through the solution and ammeter measured exactly one ampère, and the plates must be restored to exactly their former position. If the plate has *not* gained this weight of copper, the two plates must be put closer together; if *more*, they must be placed further apart, and the experiment repeated until the right quantity of copper has been deposited in the hour. Then the instrument must be disconnected, and the pointer of the instrument must be allowed to fall back to a zero-mark on the indicating dial. Again connect all up, and mark the part of the dial to which the pointer points as one ampère. The greatest care must be taken to maintain all the conditions of the room and apparatus as they are at the end of this first test. Then increase the current so as to deposit 36·70 grains in an hour, and mark the deflection of the pointer two ampères. All the other degrees required on the dial may be got in a similar manner. Daniell cells of quart capacity will furnish a constant generator, and the number of cells will depend upon the required strength of current, each cell being connected in parallel with the work, not in series.

(*To be continued.*)

BY J. H. MOODY.

Introduction—Peculiarities of Chair—Probable Date of Type—Conversion and Adaptation of Form—Material—Pieces Required—Cutting Mortised Bars—Putting Frames Together—First Frame—Second Frame—Seat and Seat Pieces—Back Piece—Knobs—Finishing.

The several kinds of folding seat to be met with nowadays are all so good that it is a difficult matter to pronounce any one among them to be the best, and in submitting the accompanying design I am somewhat exercised, because I do not feel assurance enough to proclaim the chair which is the subject of my article to be a better one than those rendered familiar to us by the dealer in cheap furniture; but if I do not assert that all others are failures, or if I do not say that to obtain a better one than ours were beyond the bounds of possibility, I am still confident in declaring that the one I describe is distinguished by a simplicity of construction that will attract the worker, whoever he may be.

Very frequently it so happens that we come in contact with persons who feel disinclined to exert their mental faculties in giving shape to original ideas, and there are also many who are too cautious to tread out of the beaten track. There are, however, a few who bravely venture on notions of their own, and to those I would say that they will find it a good plan to make mental notes of every worthy suggestion that passes within range of their observation. A store of information thus accumulated is worth a great deal when occasion arises for its application, and the assistance that may be extracted from that source is of such practical value, that I make no doubt it was never rejected by our most eminent inventors. For the cautious ones, however, whose faltering progress is like an infant's tottering footsteps, I desire to provide every assistance; their trepidation will not allow them to quit leading-strings, and it is for their guidance I have written this article. These prefatory remarks are patent to all as they acquire experience, and the argument I wish to advance is simply that the so-called spontaneity of invention is neither more nor less than the outcome of a system of observation such as we advocate co-operating with ingenuity. Amidst all this theorising, I fancy that I hear someone say—"Why not buy the seat that is wanted? Surely, from among the many that are to be met with in shops, one could be found wherein reposed all the virtues a folding chair should possess; all labour would thereby be spared." But I who aspire to proficiency in the mystery of carpentry, give answer that "I will have none of them." My aspirations accordingly tend toward making for myself the seat I require, and I direct my energies to devise one, both strong and steady, to be useful alike in the studio or in the garden, yet withal so tractable as to readily fold up into a small compass.

It is true I could find the comfort I desire were I to borrow a chair from the house, but my hardihood would experience a check if confronted by an indignant housewife objecting to the denudation, or perhaps fearful for her furniture, lest adverse weather should arise; consequently I hesitate to adopt those means for securing my ease, for never shall it be said that I at any time deserved the displeasure of the good lady of the household. No! perish the thought. My aim is, and always shall be, to conciliate and not to vex that mind which is so severely adjusted to ideas of neatness and order. Moreover, I have my own "den" to repair to, from whence have issued so many dainty brackets and imposing overmantels, beside other articles for ornament or utility, every one of which was especially intended to gladden the good dame's eyes; there I indulge in litter to my heart's content, for the offence is condoned; there, in solitude, I am accustomed to arrange my plans for work. Perhaps I am often reminded of the story which tells of a certain clever youth, of whom no doubt every one has heard, and who, when questioned respecting the originality of a bit of carpentry which he had successfully completed, replied that he had "made it all out of his own head." On the present occasion I, like him, must summon from out of the chaos and lumber of my thoughts the image of my subject, and from another wooden source must evolve the substance : then, presto ! I shall have the folding seat that I require.

Not exactly in fact, however, will my conjurations proceed with this juggling rapidity. Oh, dear no ! in these matter-of-fact times our sleight-of-hand must be governed by deliberation in order to ensure the magic of success. In strict observance of those canons I, in the first place, give my ideas colour and tangibility upon paper, or, in other words, I make working drawings of the article I am about to manufacture, and having accomplished that, I may then consider the stuff of which it shall be composed.

I will mention that the chair I am about to describe has a peculiarity which distinguishes it from many others that I have seen, insomuch that neither webbing, canvas, or carpet are used in its construction; even the bottom is composed of wood, although its collapsibility is unimpaired thereby, for it will obediently fold up simultaneously with the closing frame, and how all that is accomplished will be made evident as the description advances. This departure, I imagine, will obtain the approval of a great many.

In the absence of authorities bearing upon antique furniture, I am unable to make reference for the precise origin of this form of chair; but the principle of construction seems to have been pretty freely used in Italy in the sixteenth century; and, at the present moment, there are in the South Kensington Museum several specimens which fold up in a like manner ; the labels of these pronounce them as derived from an Italian source, and also fixes the period that I have quoted. I have given a drawing of one of these chairs (Fig. 1) for the benefit of any one who may desire to make a similar one, but I am afraid the bent work will be a barrier to success; let us see, therefore, whether we can adapt the principle to straight stuff.

We find there are certain difficulties besetting the conversion; for instance, curved supports such as are shown in the drawing of the old Italian chair admit of a wide and safe base when the chair is in use, but straight stuff necessitates the placing of the centre, upon which the two frames are connected, rather low, in order to obtain a proper width for the seat at a suitable distance from the floor ; the base of our chair, therefore, is narrower, and the top is wider than we would wish them to be, but the lack of stability is not, in fact, so great as it appears to be. See Figs. 2 and 3.

Either beech, mahogany, or oak may be employed in making, but the choice will depend upon the embellishment hereafter to be put on the finished work. If we mean to polish, perhaps one of the two

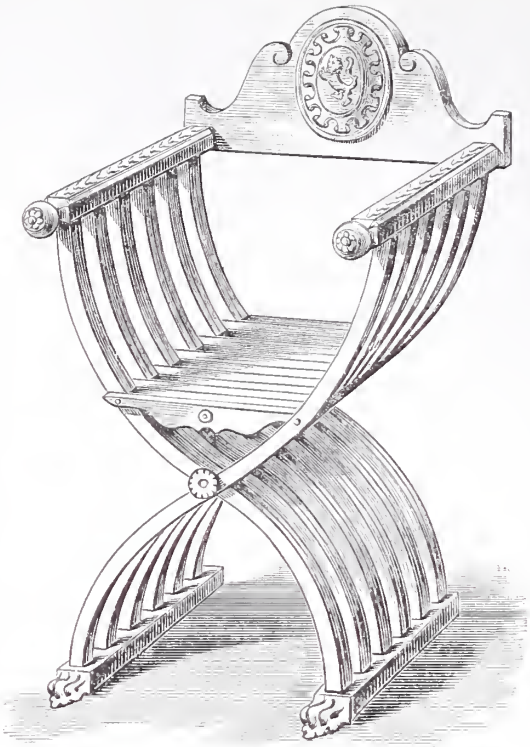

Fig. 1.—Folding Chair in South Kensington Museum. Italian, 1550.

latter kinds of wood is to be preferred ; but altogether beech will, I think, be adapted to receive any kind of finish that we shall employ, and whilst it is procured with little trouble, it will render our work of satisfactory and enduring quality, and that I imagine is a result in perfect consonance with the highest ideal of completed work.

Having procured our stuff, we get out four pieces, each 12 in. long and 2 in. square, and dress one side of them down to an angle, as shown at Fig. 4. These pieces will maintain their severity of shape until the mortise cutting is accomplished ; in fact, all items of ornament were best left alone until the rougher work is completed.

The first necessary operation, after the four pieces are cut to the desired shape, will be to set them out in preparation for mortising in the following way : Taking each piece in succession we gauge for $\frac{1}{2}$-in. mortises right along its angular face, then to indicate the exact position of the mortise, we place the pieces in pairs, side by side (Fig. 5), blocked up to level them, and whilst they are in that position, we will rule upon them 11 lines intersecting the gauged lines. These cross lines must be at intervals of 1 in., the first of them being $\frac{3}{4}$ in. from the front ends of all four pieces as they lie together upon the bench. It will be necessary to mark these front ends to be kept as such, and if we number the division on each piece 1 to 10, our description will be clearer, and annoying mistakes be avoided.

I have said that the divisions will show where mortises are to be cut, but further explanation is necessary as to the manner of doing it. In the first place, we will select the pieces in pairs, respectively, arm or bottom pieces, and mark them individually for right or left, taking note that the mortised face is inwards when the chair is completed. We then take the left arm piece and the right bottom piece, and cut mortises upon divisions 1, 3, 5, 7, 9 ; next taking the right arm piece and the left bottom piece, we cut mortises on divisions 2, 4, 6, 8, 10. These mortises will be cut at right angles with the angular planed surface of each piece, and they should not be a full inch long, but with a slight rebate in length, in consideration of a shoulder of the tenon at the end of the upright bars. These arm and bottom pieces, now that mortises are cut upon them, may be dressed into shape (Fig 4); the half-round moulding on bottom pieces is extraneous, and is added last.

The preparation of the bars does not necessitate a very profuse description. They are 10 in number, each being a trifle less than 1 in. square, with a tenon cut at either end to fit a mortise ; they are 32 in. long between the shoulders of the tenons. Holes are bored in them, from front to back, through each bar with a $\frac{3}{16}$ bit, respectively, at $12\frac{1}{2}$ in. and $23\frac{1}{2}$ in. from its bottom end, that is to say, from the shoulder of the tenon.

We now have before us the necessary number of each of the parts that are required to build up the two frames constituting the supports of the seat proper, and we will put one frame together first, thus : Taking the arm and bottom pieces, whereon the mortises bear odd numbers, and taking also six of the bars, we insert the tenons in their proper places, and use glue to fasten them there ; that done, we will put the frame aside to dry. Meanwhile, we provide ourselves with four iron rods $\frac{3}{16}$ in. diameter ; these rods will be 10 in. in length, and their ends will be prepared accordingly as tools are available — that is, they may be tapped and fitted with nuts, or they may be filed off taper ready for riveting, and provided with washers.

The first frame being made we may fix up the second one. In doing this, however, the insertion of the bar in top and bottom pieces will not be done at one and the same

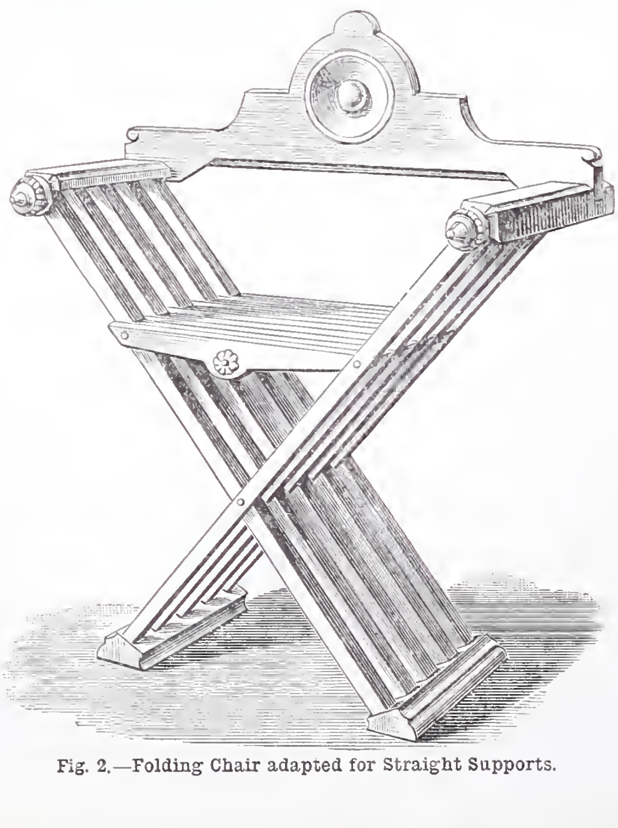

Fig. 2.—Folding Chair adapted for Straight Supports.

time, or at least we had better proceed systematically, and fit the lower piece with bars first; then occurs the interlacing or crossing of the bars which engages the two frames, and that being accomplished we may attach the top piece and glue all up. I will just mention that unless the interlacing is done with deliberation the amateur will be in an awkward muddle. The proper relative positions of bars and also of arm and bottom pieces must be rigidly preserved; for instance, the first bar of the frame we last made will be inserted behind the first bar of the other frame, and if I repeat that the top piece of the frame we first constructed will be the left arm of the completed chair, it will go a long way to prevent confusion.

get out ten pieces, and cut them at both ends to agree with the angle that the opened frames present. Each piece must be bored with a couple of holes from side to side, and the places for these can be best indicated by ruling lines at $\frac{3}{4}$ in. to right of centre, and also at $\frac{3}{4}$ in. from their left-hand edges, across their faces as they lie.

We will suppose that the boring of the seat pieces is completed, and that we have maintained intact their arrangement, but they must be altered in order to get the seat ready to fix. To that end, therefore, we will reverse the position of piece No. 2, but still keep the hole near its centre in a line behind the corresponding hole of No. 1; No. 3 will not be disturbed, but No. 4 will be reversed, so

the seat in order to ease the projecting ends that hinder; we may then replace the seat and secure the rods, of course not forgetting the countersinking.

The back piece of necessity is separate, and is of inch stuff; it may be plain or carved according to the design that is chosen. It is cut away in two places to slip on to the back ends of the arm pieces, which are also cut with laps to receive it. (Fig. 7.)

There are now certain items of extraneous ornaments (see Fig. 4) to provide for in the larger knobs which form the terminals attached to the arm pieces, and the smaller knobs or plugs, which serve to hide the ends of the rods at the junction of the seat and

Fig. 6.—Arrangement of Seat Pieces in readiness for Fixing.

Fig. 7.—Method of Attaching Seat to Arm Pieces.

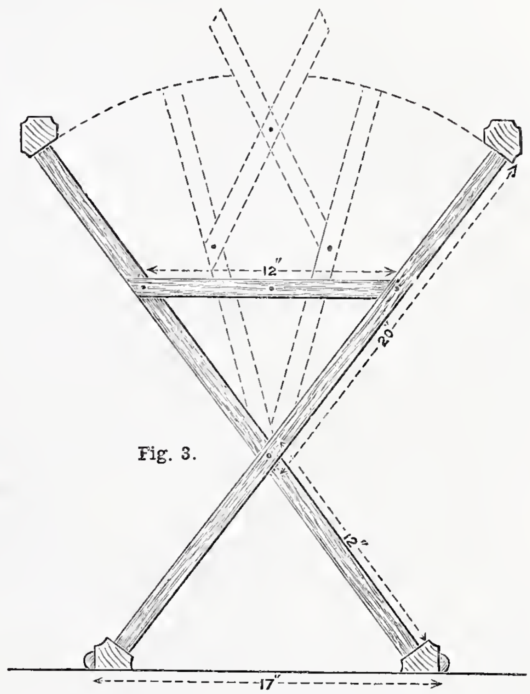

Fig. 3.

The holes in the bars at Fig. 3 are provided as a centre to connect the two frames, therefore these holes when placed in a continuous line will allow the passage of a rod right through the whole of the ten bars; the two end bars may, with advantage, be countersunk rather deeply for the reception of nuts or washers for screwing or riveting, as the case may be.

The frames being ready for the seat, the pieces which comprise it may be prepared. They are to be the same thickness as the bars, and their length may be arrived at by standing the frames open at the required distance, and maintaining their position by tying the top pieces together. I have arranged the drawing, Fig. 3, for a 12-in. seat—it should not be less—therefore, the span across the bars from the top hole on one side to the top hole on the other should be set accordingly. We shall find that our seat pieces must be cut 13¼ in. by 20 in. We

also will Nos. 6, 8, and 10. The seat pieces will then be arranged as Fig. 6, and while they are in that condition we will pass one of the iron rods through the centre holes. We must not omit to countersink the two end pieces before we rivet or screw on nuts.

If the work has been properly done we shall find the projecting ends of the seat will drop easily and exactly into the intervals in either frame; the holes in seat pieces and bars will also agree and be continuous. We prove all this by placing the seat with the bored end of its first piece in front of the first bar supporting the right arm, and with the other end resting on the first bar of the opposite frame. We ought now to be able to slip our two remaining rods right through the holes in seat pieces and bars on either side, and before we fasten them we will test whether the opening and closing of the seat are effected with facility; if not we must take out the rods again, and remove

bars; these last are to fix into the countersinking; there is also a piece of ¼-in. stuff to form a finish for the front, and which is fixed to the first seat piece.

Lastly, we will deliberate upon the quality of treatment which is to qualify the crudeness of white wood, and which will be the conclusion of our labours. We are offered two methods to choose from: first we have heard of wonders achieved with the enamel paint to be obtained of various makers, severally, and all of which are proclaimed as the best by their proprietors, and there comes to our mind's eye a presentment of how handsome our chair would look if covered with a coat of one of those paints mixed to a neutral tint, say salmon, green grey, or blue grey; but this hint is only thrown out on the supposition that we have worked to a plain design. If, however, the design we have adopted is in any way florid, there are sundry clever combinations of stain and polish which may be used and which likewise will contribute greatly to the good appearance of our work.

In conclusion, I would observe that the procedure of manufacture is identical in both the curved and the strength designs; but those who are unprepared with bending appliances had better adopt the straight work unless they like to undertake the labour of sawing out. However, our chair-maker must measure well his resources before commencing, for when precipitancy lands one in failure, the position is quite as ridiculous to my mind as when hesitancy deposits one "between two stools."

"TIPS" FOR TYROS.

BY OPIFEX.

Useful Indiarubber Cement.

Old tobacco pouches, etc., if made of non-vulcanised indiarubber, may be dissolved in chloroform, benzine, etc. Cut the rubber into thin strips, and put into a stoppered bottle, then add the solvent; let it stand till the rubber swells, add a little more solvent, and shake up well; the strength may be regulated by adding either ingredient; the proper consistency is like that of thick treacle.

This is a most useful cement for many purposes, and will join leather straps, fasten on soles on tennis shoes, etc.; it is also a capital cement for paper, cardboard, cloth, mending books, etc., and one of its chief recommendations is cleanliness, as it will cleanse by being smeared upon the most delicate paper and rubbed off when dry.

Cement for Lathe Work.

The cement used for fastening on the rubber tires on cycles is a most useful article in the workshop, especially for lathe work; the writer has often joined two flat surfaces with the cement when making special wood chucks, etc., and finds that a perfect joint which will stand "anything" is the result.

Heat and coat both surfaces with the cement, and allow it to cool under considerable pressure.

Imitation of Ground Glass.

It is often desirable to muff a window in order, either to shut out an objectionable view, or to prevent outsiders seeing into a room.

The usual way is to "dab" the glass with the end of a paint brush and white paint; this is certainly effectual, but not artistic.

We recommend the following: Make a lump of ordinary putty, *i.e.*, whiting and linseed oil, about the size of an egg, mix it rather drier than for glazing; then add half the bulk of fresh white lead, and about a teaspoonful of gold size. If it is too wet, *i.e.*, if it sticks to the fingers, add a little more whiting, and work the whole well, until it is perfectly "smooth."

Roll into a ball and apply by pressing upon the glass, which should be thoroughly cleaned first. In this way a good imitation of ground glass is procured, which may be ornamented when dry by using a stencil made of strong paper, in which any simple pattern is cut, *e.g.*, a fleur de lis, or other device according to taste; or a line may be taken out about an eighth of an inch wide, and an inch from the edge of each pane, with a device at the corners, the centre portions being "powdered" with the fleur de lis, etc.; a thin coat of very clear varnish will then protect the muffing from becoming scratched.

If it is desired to imitate tinted ground glass, use any of Aspinall's enamels instead of gold size, as above.

JAPANESE MOTIVES FOR FRET CUTTING, STENCILS, AND SIMILAR PURPOSES.

Illustrated from Native Books.

BY J. W. GLEESON-WHITE.

I.—Of Bird Forms.

To all who are familiar with the silk-sewn flexible volumes of Japanese origin, that when opened reveal such a marvellous wealth of suggestions for decoration, the first surprise at the fecundity of invention, and almost limitless variety of ideas displayed by those born decorators, in no way diminishes with increased knowledge. The more thoroughly one investigates even the popular volumes (that have been obtainable in England for trifling sums, at the principal Oriental warehouses, for the past few years), the more the wonder grows, first, that such novel discoveries in decoration could be possible at this stage of our art-history, and still more that so little of this splendid material has been welcomed by our designers.

That Japanese art has been the fashionable tendency in decoration of recent years, that hundreds of designs purporting to be based upon it have flooded our markets, is patent enough; but to those who really try to grasp the principles of its construction, who realise how thoroughly the instinct of the native artist adapted his ideas, with subtle changes according to the mood of the worker or the object he was decorating; the entirely mechanical imitation of a few details hardly proves that a paraphrase of the real art of the Oriental artist has been even attempted, but that just a few evidently characteristic touches of the lowest class of ornament have caught the popular taste, and satisfied both those who produce and those who buy.

The Japanese books more usually met with in England are reprints of Hokusai's sketches and Battei's bird and flower decorations, with similar volumes of pictorial designs; and a few volumes that, like Owen Jones' "Grammar of Ornament," are composed of patterns rather than pictures. The latter class are especially valuable to all decorators, whether those who design, or those whose handiwork carries the idea into execution. Not only do these volumes reveal thousands of beautiful patterns to be copied literally for borderings, diapers, and panels, they are teeming with suggestiveness for all who can take a hint. It is a simple fact to say that one of these pamphlets, studied carefully, might supply a designer with motives year after year, and yet fail to be exhausted. I myself know of a case where one single page of ornament from, perhaps, the most superb specimen of their skill that is to be found at South Kensington, has supplied a clever decorative artist with ideas for years past. But it is not given to all to take a hint, and there are excellent workmen who may be trusted to carry out a given design accurately and faithfully, but give them an inch of design for motive, and ask them to evolve from it a consistent plan for the decoration of the whole thing to be ornamented, whether a six-inch tile or the interior of a theatre, and they would be at a loss at once.

One of the comic papers started a joke of a certain architect who said he could reconstruct a whole cathedral from a broken piece of its floor tiling, and this pleasantry has been often repeated. Yet it is certain that a design based upon one definite piece of work, and consistently evolved in keeping, would probably yield a more satisfactory result than a medley of accurately copied details from a hundred sources dovetailed and fitted together.

Too often in modern English decoration—supposed to be of true Japanese character—the only idea the decorator has grasped appears to be the half-truth, that Japanese ornament is not symmetrical. That it does not rigidly repeat on one-half of its design the facsimile of the other is, of course, true, but symmetry is not always a merely precise balance of parts. Gothic architects showed that a harmonious whole could be obtained by other ways than the classic repetition of each detail, where, as in an Italian façade, one side of its centre was a perfect counterpart of the other.

Starting with this idea of the Japanese hatred of symmetry—an entirely erroneous one—any haphazard of odds and ends of ornament, always provided it was diagonal or one-sided, has been called Japanese, and the name has become hopelessly vulgarised, and made certain of its achievements marvels of decorative depravity, monstrosities of ornamental crime.

This symmetry of unequal parts is one of the triumphs of Japanese design; if you study a panel by a good artist (for be it humbly said, all Japan was not decorated by *one* artist, and bad taste, although rarer than in England, has occasionally found utterance in Japan), one who is master of his craft, you will find that, although the disposition of the parts is not always upon a geometrical basis, that not a few of the wildest and most unfettered designs resolve themselves into certain regular patterns, on the skeleton of which the ornament has been elaborated.

But of those quite contrary to the spirit which governs European symmetrical ornament, you will find a balance of parts—a mass of design on one side is set against a small group or a few dots of ornament on the other. The Japanese appear to have studied nature thoroughly, for in it, although details are frequently of exact symmetry, yet the disposition of groups of them is rarely, if ever, so, and this apparently unconscious arrangement is no mere illustration of what has been quaintly termed the glorious gospel of haphazard, but the result of a higher sense of beauty than mere arithmetical balance can yield.

Better mechanical imitation of another nation's art than such folly as attempting to modify it before even the rudiments of its laws are known; but if, on the other hand, you patiently study and follow out the Japanese artist's line of thought, and realise his very systematic method, that produces results as free and unfettered as Nature's own decoration, then the foolish absurdities—such as the cheap fire-stove ornaments, the hideous dinner services, and advertising placards that pretend to be in Japanese style, and cause the name to be a synonym for vulgarity and worthlessness—will quickly be replaced by better things.

But as the pages of Work, wide though its programme be, can hardly be devoted to the discussion of Japanese art in the abstract, I propose here to reproduce a few suggestive designs for everyday ornament that are original Japanese. Among a hundred volumes I have collected from time to time, as opportunity offered, there are only two that appear to be designed actually for fret cutting; but in others—especially a series of designs reproduced (by order of the Japanese Government) from existing examples of old embroideries—there are not a few that are from *appliqué* work, and the difference between sewing on a self-coloured ground portions of another coloured material to form the pattern, and cutting holes out of a piece of wood for the same purpose, is not very great, for of these designs there are many that, without modification of their detail, may be used for fret cutting or stencilling.

Of the enormous mass of suggestive material in this century of volumes, it is curious to observe how few bear adapting. For the purpose they were designed they are supremely fit, but once attempt to modify them for foreign purposes, and you lose half their charm. By this feature the native artist proves his knowledge of one of the most important principles of true design, if indeed it be not the very first, namely, the perfect grasp of the properties and limits of the material, so that he thinks out his idea in stone, metal, woven fabric, whatever it may be; emphasising the peculiar qualities of his material; knowing that stone is brittle in delicate open traceries; that iron is capable of infinite curves and slender projections; that the threads of a fabric will display themselves, however you try to hide them, and so on. Thus he misses a fatal fault of inartistic modern ornament, where wrought iron is parodied by cast, where fabrics try to look like painted decoration, and where one material apes another instead of being employed in the most natural way to obtain the result.

For if a pattern can be used on stone carving, textile fabric, and applied painting with equal effect, it must needs be either of extreme simplicity, or at best only a passable substitute in each of its applications for a more genuine design, whereby the material itself would be really decorated.

Probably this failure to realise the perfect unity of design and material is responsible for many a failure in the attempts at "ornament in the Japanese style." As one who has often tried and failed, I can speak knowingly and feelingly of the unsatisfactory effect of a beautiful idea, expressed in substances that compel a modification of its details. For example: a lacquer pattern does not come well if cut in fret work, a textile pattern is poor on the flat rigidity of a tile. But apart from this, even when the material to be embellished is similar, the European craftsman often betrays himself in carefully precise finish of some little niggling bit of detail, left with the careless suggestiveness of a sketch in the native original; or else by adding European features that ill accord with the spirit of the Eastern art.

In these papers, therefore, I propose to let Japan speak for itself, and offer not *my* idea of the art of the Rising Sun, but the designs themselves, traced roughly, but correctly, from the actual books. The volumes at my side teem with (doubtless) pregnant sentences of advice and description, but my knowledge of the Japanese language is limited to painfully and pilulously minute acquaintance with a few odd words; so all the comment of the Eastern artist must be left untouched. But the designs speak plainly and unmistakably to all who care to hear, in the universal language understanded of all peoples, the picture tongue, that which, before Volapuk raised its hideous standard, was an open secret to all the world, and united again the tribes dispersed at the Tower of Babel.

Fortunately for the accomplishment of my purpose it is that so few of the tens of thousands of suggestions here close at hand are related to either of the subjects that head this paper; or, to put it more correctly, are capable of use untouched as they stand in those branches of workmanship. The gorgeous wealth of subjects in one of these little tomes makes Owen Jones' "Grammar of Ornament" a poor thing in comparison, and the richest museums of European art mere hackneyed repetitions of a few wearied motives, when set against the immense fertility of these Eastern fancies. For they hold not only the splendour of the East, but at least the prototypes of all the West regard dear. Here is the Greek fret, the Gothic diaper, the Celtic knotwork, and the Renaissance arabesque. If I piled up all the flattering adjectives of Murray's stupendous dictionary itself in praise of these things, they would be hardly exaggerated. For conventional ornament and natural devices modified within decorative limits, those who do not hold Japan the most fecund and wealthy, simply thereby prove their ignorance of her stores. To any lover of æsthetic design (and æstheticism, remember, is pure beauty in its first significance), the contrast between the wearisome iteration of the few forms that the West borrowed so early from the East, that we style them European, and the source of these fancies—be it India, Persia, or, last and greatest, Japan—is like comparing an illustrated encyclopædia with the book of nature itself.

It must, in justice, be said, that only a portion of all this store is available for adaptation to English needs; once modified to suit our conventional shapes, it has a knack of losing no small part of its charm. Reproduced exactly, it is sumptuous and perfect, harmonising well with many schools of art, but distorted to come nearer the canons of the other school, it resents the attempt, and hopeless vulgarity is too often the result. For example: at a recent exhibition there was a mantelpiece of marble and stonework, in Gothic style, evidently a commission to a Japanese artist, who had patiently endeavoured to grasp the main features of English Gothic and infuse Japanese spirit into the details. The pointed arch lost its mouldings, natural branches of bamboo replacing them; panels of peach blossom tried to go well under Gothic canopies, but it is needless to recall each detail, as the well-meant attempt was a failure. Yet it is almost certain that Japanese panels, or rich native stuffs, could be employed *without alteration* in the choir of an English cathedral with much less sense of unfitness than the Brummagem metal work and floor-cloth-looking tiles of the most "correct" church furnishers.

But I have said too much in theory, let us go on to practice. Out of the books I named above are two intended, beyond doubt, for pierced-wood work; and here for the first time the Japanese fertility seems to fail. There are about a dozen good ones which I have copied here, but in fairness it must be said the others are comparatively poor. This is owing chiefly, I take it, to the fact that, as a rule, in Japan fret work receives the final labour of carving; and also that these two happen to be the only books of wood design I have been able to secure. The details of the cut-out panels used in the lattice-work screens now freely imported, show that this paucity of material for fret-work pattern is a mere accident of my collection, and not the result of poverty in that school of design. But in the embroidery books are so many designs, intended, no doubt, for cut-out pieces of cloth, that are so perfectly of the character of fret work, that they cannot, I feel sure, be picked out amongst those given by any but an expert in fret design. Having a certain claim to that title myself, I own at once they are precisely the same to me, and when my memory of the actual source from which I traced them fails, I shall be unable without reference to the volumes to pick out the wood from the cut-out cloth designs.

This appears to be against the theory of design advanced in the opening paragraphs, but only appears to conflict with that view. It shows to me, rather, how clear to the artist was the true likeness between art and material, whether it be with a saw leaving the holes to supply the pattern, or with scissors, putting the pieces cut out to a new ground to form the design.

And this leads the way directly to the question of fret design, viewed from an abstract standpoint, singularly disregarded by modern publishers, designers (*mea culpa*), and fret workers generally.

A great authority—Mr. Ruskin—has said, that all fret-work ornament should show the design by *the parts cut away*, not by the part left after cutting. Whether this is an inflexible rule of good taste in fret work I should not care to decide; because, if it be indeed a fundamental axiom, at one fell swoop the million designs in the market are condemned. For, of the great army, not one in a hundred thousand is designed upon that principle.

However the verdict may be, there is no doubt that Mr. Ruskin's advice is sound, and worth following. We nineteenth century people have a power of holding diametrically opposite opinions with a bland severity that would paralyse the strict partisans of earlier epochs. The gospel according to Darwin *and* Genesis (as the author of "Obiter Dicta" wittily puts it), Socialism *and* Toryism, Wagner *and* the Savoy operas, with dozens of other parallel cases, come at once to mind in support of this argument. Consequently, let us believe Mr. Ruskin, and if we cannot discard the more popular faith, let us remember that even the great critic himself is fallible, and can be quoted with contradictory force by those who delight in seeking the flaws of a great man, and love his failings, since they are then in touch with him, rather than his merits, which are transcendentally above them.

The common-sense reasons for the pattern itself being cut out are easy to see. Other things being equal, this style of design is likely to be stronger by leaving wider spaces of uncut wood to add to its rigidity. Again, the stencil-like character of such a design is much more decorative at a distance. And here, it may be said in passing, there are two classes of ornament: one that needs close view, since from afar it fades to an inchoate mass—this is the right style for all background decoration; the other, where the lesser details are so grouped that the bold design, unseen close to hand, is made up by groups of the details, and tells with a new force at a distance. This feature may be best exemplified by quoting its abuse—where, in wall papers, owing to

unskilful placing, the main features of the design form themselves into diamonds or lines, only noticeable when a large part of the surface is seen at some distance from it. But this applies not only to repeated designs. A small panel painted in all-over fashion like a piece of cretonne, to choose a familiar example, may be very decorative near, but one with just a few shapes, a conventional primrose or star dotted over it, may be more telling at a distance. It is hard to explain these things curtly, but quite needful to keep them in mind, when we come to apply the motives, and vary the theme in its actual working out.

Of the designs illustrated, those numbered Figs. 1 and 2 are distinctly Japanese, the peculiarly conventional treatment of seascape and birds being all their own. If any one doubts which form of art is higher, let him compare these two patterns for fret cutting with those of one of the popular publishers, where ships, and animals, even portraits figure, in horrors enough to scare away gods and men. The depth of bad taste, in some of these terrible instances, is enough to condemn the art of fret cutting for ever.

Fortunately, *all* modern designs are not so bad; even the commonplace German pattern, consisting of capital C's and S's writhing in mortal agonies together, is comparatively harmless by the side of fret-work pictures in English or American fashion. The Japanese artist boldly seizes upon the prominent lines in a rolling sea, suggests a moon rising from it, the toss of the spray, and a bird poised above; without one bit of actual imitation of nature, he yet gives a suggestion of real objects in a way that is both true and good art; and, *in its own way*, as good as the design of the frieze of the Parthenon. "There are bests and best so many," but we may as well have the best of each; good fret cutting is better than bad statuary. There is more real art in a few inches of Japanese wood work, a rough bit of Indian pottery, or a bit of old English wrought iron work, than in the white marble atrocities of the modern Italian school of sculpture.

These two designs (Figs. 1 and 2) would need enlargement for all but very skilful workmen. The usual plan of ruling squares to one scale all over the design and copying on a much larger set of squares may be resorted to with ease and success. There is a sectional tracing pattern, covered with pencil-lined squares, sold in various sizes that simplifies this process, and avoids disfiguring the printed copy.

More of these conventional ornaments derived from bird forms are to be seen in Figs. 3 to 13. Some are most pictorial in their scheme, others merely symbols of the prominent features, in the shape of a bird. Take Fig. 9, for example, a wholly delightful thing, although simplicity itself, yet full of humour. It is so marvellously like a bird, and yet so utterly wanting in all the accepted details. Perhaps no one ever expressed bird-form at once so simply and yet so truly. It is a concentrated joke, a petrified pun, a kind of Japanese witty epigram that once having found

Fig. 1. Japanese Wave Forms, Fig. 2. Sun, Moon, and Birds, Conventionally treated, showing effect in Stencil.

Figs. 3-13.—Japanese Bird Forms. Fig. 14.—Insect Form conventionally treated for Fret Sawing and Stencilling.

voice, said, the only wonder is, that so evident a truth was not uttered ages ago. Yet this little bird is an excellent decorative spot in itself; whether used at irregular intervals or repeated in regularly designed order over the whole pattern, it is fit and proper, aiming at nothing more than it amply performs; a verdict that would not disgrace all that can be said of the highest art.

Fig. 14 and others to appear are insects treated in like fashion. Birds again form the motive of Figs. 3, 4, 5, 6. These, if worked on a small scale, might, perhaps, be still more simplified; but if enlarged to about five or six inches, the details will not be so minute as to afford special anxiety on that account.

Figs. 7, 8, 10, 11, 12, 13, are excellent specimens of what I have tried to explain in the former part of this paper. They are decorations good and adequate, if looked at by themselves; when seen at a distance, the circular (or diamond) shape they offer tells us a distinct ornamental effect. To grasp this fully, notice how unshapely a blot the average fret-work bracket is when viewed from across a room, whence it appears a nondescript outline, no more truly adorning the wall on which it hangs than would a damp duster hung on the same nail.

Some of these designs may be used even in the small scale for which space is found here, but most will bear a certain amount of enlarging without loss. There is a limit, however, to this alteration of scale, and rather than lose the design by too great an increase in its size, it is best to choose a plan that will admit of two or more repetitions of a more handy size.

(*To be continued.*)

BINDING MADE EASY.

A CHEAP, STRONG, AND TASTEFUL METHOD OF TREATING PAMPHLETS, MUSIC, ETC.

With a Few Words on Portfolios and Blotting Books.

BY E. BONNEY STEYNE.

(*Continued from page* 83.)

COLLECTORS know how very rare many of these ephemeral publications become, especially in a perfect state; for, while well-bound books get cared for by all sorts of owners, purely out of respect to their outsides, the mass of ephemeral literature and fragmentary publications—such as reports of learned societies, pamphlets of all sorts, some of them of no slight value in after years—gradually, but surely, disappear. The original of one rare Dickens, already mentioned, I myself bought for threepence, kept it many years, and sold it for ten pounds easily in the open market. In fact, a single advertisement in a literary journal brought me three telegrams from would-be purchasers within an hour of the time the issue was on sale. But that pamphlet had chanced to escape free and scatheless from all mischief; yet this personal instance will show that a careful preservation of much comparatively worthless material may be at the same time guarding treasures for the future profit of the possessor.

In the method still under consideration, the stitches visible at the back demand a covering, but the covering need not be applied all over like the parchment. It often answers the purpose to put a second strip of buckram (or even white paper) over the stitched back, mounted so as to adhere to each cover only and be free from the back itself. If this is used, any sort of paper (a dull blue or grey wrapping paper looks excellent with a white back) may be used for the sides, cut as in Fig. 7; if it is desired to simulate corners, the way they should be cut out and mounted previously to using the paper for the sides is explained by Fig. 9.

The side papers being pasted, an inner piece of plain paper with a flyleaf—in other words, a piece like a whole sheet of note paper—the size of the pamphlets themselves should be pasted inside each cover; pieces of tin should be placed between the cover and the unpasted leaf, and the back left awhile in a press or under a few heavy weights.

There is another method I have used with success, more particularly for sheet music and larger periodicals—such as two or three numbers of the *Magazine of Art*, or the Christmas numbers of the illustrated papers; also for books already bound, after a way such as Cassell's National Library, the Pictures at Play, Shilling Shockers, and other railway literature. In this case I fold a piece of stiff cartridge paper the size of the music or magazine, as the case may be, and paste it at the inner margin on the top and bottom of the little pile of numbers or single volumes to be bound. Then I paste a piece of buckram over the backs as though they were one solid book. When this is dry, the several pieces (or the series of numbers that compose a volume) are stitched to this buckram back, exactly as described in the other method. Having made a portfolio the precise size (in the way about to be explained), I glue the buckram and insert it in the portfolio when the glue is quite dry, pasting the leaf of cartridge paper to the cover at either end. This method has been entirely successful. I have books of music that have been in constant use for the last ten years, and are practically as good as the day they were finished. For music, noting the increased comfort in its use when the volume opens easily and keeps open without the need of employing a catch on the desk to prevent the pages turning over of their own accord, I candidly prefer this way of binding to any I know. A cheap and nasty way the professional binder would call it, beyond doubt; the clever amateur (and there are many such) who binds his own books in the proper way, would laugh to scorn these feebler attempts, but in the one quality quoted, they will beat any but the very best work. Those who have known how few books will keep open where you leave them, unless they are old and with broken backs—to use the slang of the book trade—will agree that it is no slight gain to have secured this one feature.

Some books are improved by the addition of ribbons to tie, and keep the volume closed. Especially is this the case with MSS., quarto, or folio volumes, such as we use for the offspring of one's own invention, or the transcription of other people's efforts.

Besides the usual way of securing ribbon or tape for this purpose, there is another, probably of Japanese origin, that is still easier to apply, and much more effective when applied. But first to the orthodox method. At a point about an inch inside the cover, and midway in its height, you make a slit with a sharp penknife, the width of the tape or ribbon, after the paper for the sides is pasted on, and before the inner flyleaf is pasted down; then the tape is inserted, leaving an inch or so to be pasted to the inside of the cover, when the flyleaf secures it there, so that the ribbon itself, or the cover, will yield before it quits its place.

In the other plan, the ribbon, in one length, is carried all round the back (as shown in Fig. 10), showing over the back, disappearing for a short distance on either side, and coming out again at a suitable place to tie the volume and its contents.

This form of cover makes admirable blotting books, which sell well at bazaars, and make most useful and acceptable presents. When covered with the gold Japanese paper, or some pretty brocaded material, and tied with a wide ribbon of suitable colour, they are really delightful adjuncts to a writing-table.* The way they are made is exactly like the portfolio, with a narrow band of ribbon or elastic sewn inside, to refill with blotting paper at pleasure. The usual shape is to cut the ordinary sheet of blotting paper down the back and divide the half sheets. But I have made many, cutting the whole sheets once across, thus giving an oblong quarto in place of the usual upright quarto. This is at once more novel, more suitable for decoration, and more convenient, as the lesser height goes better on a writing-table, and yet opens out a wider surface for use when writing letters. This subject comes so naturally into home methods of binding that the digression must be forgiven.

But to hark back to materials suitable for our covers. There is a thin whity-brown material, a sort of canvas, that music-sellers use for the portfolios in which they keep their stock, that is pleasant to touch, cheap, and durable. Also a grey calico or linen that looks sober and quiet. But after all, the best thing is for each to adapt the nearest material to his purpose. Given a little natural ingenuity, it is surprising what good notions are arrived at by sheer force of circumstances. Then, again, the subject matter has much to do with a fitting binding. A privately-printed poem, of a few pages, sumptuously produced on rough hand-made paper, may fitly be adorned with a regal brocade, or a certain amount of finery that befits the subject; but what adorns an Oxford Prize Poem would be absurd upon a blue book or a sheaf of scientific tracts. I have seen a Bible bound in cretonne cornered with a lily of the valley pattern, but I cannot conscientiously recommend the innovation.

To make a portfolio strongly and neatly is—or ought to be—within the limit of every one's skill. Few things are more homely in any household with musical, literary, or artistic tastes, than a sufficiency of portfolios of various sizes. The usual music folio is excellent for sheet music, but to hold part-songs on the one hand, or etchings and drawings too large for it on the other, it becomes an untidy makeshift. The materials for a portfolio are cheap, the process is simple, and the cost slight. With very little practice a good portfolio, equal in every way to the best that are on sale, may be made for a few pence.

The cheap German millboards are retailed at fourpence a sheet in small towns, perhaps as low as twopence in large ones. This stuff is rather nasty to cut, but a sharp penknife and a straightedge of wood soon accomplish the severance. Beware of trying scissors or even shears, unless they be of the bookbinder's gigantic variety, upon this material. There is a quiet

* I made one recently of a white and gold-tinsel brocade, sold at Liberty's at 4s. the yard, tied with a wide yellow ribbon, that was really a thing of beauty.

obstinacy about millboard that beats the best scissors. Anything more hopeless than to see a well-meaning female trying to cut a complicated shape in thick cardboard with a pair of embroidery scissors, is hard to parallel. With a T-square mark out the needed size in pencil. Then placing the millboard on a flat surface—the kitchen floor, if no table that will be allowed to receive a chance cut is available—place a straight piece of wood up to the line, and press the left hand firmly on the wood. First pass the knife lightly down the line, and then, in a succession of quick sweeping strokes, persevere until the millboard is parted asunder. The straightedge may slip; if so, woe betide unwary fingers. A pin tack on the left-hand side of the edge, top and bottom, if it be a long cut, will help the inexperienced to accomplish their purpose, by keeping the ruler firmly in its proper place. There is only this one way to cut a clean straightedge to cardboard; it is worth practice, for all scissor cuts are abominable, and must be ruthlessly condemned. Having cut the millboard to the required shape and size, or procured some of the thrown-aside advertising cards so freely bestowed on every tradesmen, or even the tops and bottoms of the cardboard boxes such as linendrapers use, the next thing is to decide upon the covering. If old cardboard is used, it often happens that paper pasted on it raises blisters on the already existing paper, which defy any efforts to disperse them; once having risen, there they stay; whether it would be possible by cutting each one, laying it back, and pasting it, to press it down again, I cannot say; but even if so, it really is not worth the labour, for new millboard is very cheap. For use under chintz, cretonne, canvas, or any woven material, or under thick Japanese gold leather paper, any roughness of surface is of small account; but for marbled paper, or still more if smooth self-coloured paper is to be used, it is extremely important to have the millboard itself smooth to ensure a good finish.

Although embroidery is lavished in its various forms upon all sorts of purposes, I do not ever remember seeing it used for portfolio covers. I have noticed it in German illustrations of fancy work, but there is always a latent suspicion that many of those fantastic electrotypes that do duty in the fashion books and illustrated magazines for lady readers all over Europe are creations of the inventive genius who produced them, and destined never to take tangible form, but to appear in rotation in all the civilised countries of Europe, in one fashion paper after another, and then go to the end of all their kind, the waste-paper basket.

Yet embroidery might well be pressed into the service, but as that art is most probably outside the scope of this magazine, it is enough to have mentioned it, and to pass on to practicable materials. First, of course, comes leather, but I hesitate to recommend its use, for the reasons before named—that so good a material is worthy of being treated with technical skill. Next comes bookbinders' cloth, cheap, and fairly satisfactory, not very easy to work neatly, and in certain localities difficult to procure in small quantities. Then American cloth may be noticed; but this is clumsy to use, and, speaking personally, not pleasant in its appearance when used; still, it is cheap, strong, and serviceable, and amongst its varieties there is one sort with a dull morocco-like grain, that is not quite so cheap and nasty in its effect.

Cretonne, so rarely used, is often very happy for this purpose. I have made many such for my own music, for the immense variety of patterns available makes it easy to keep all one's portfolios of different design. To those who have fifty or a hundred portfolios in use, it is a distinct gain to remember that such a pattern denotes the particular composer whose works are kept therein. When I hunt for Grieg, I recall a red butterfly design. For Scharwenka, a blue and white; for Moskowski, a red and white; Bach, a sombre green; and so on. To any collector who employs portfolios, whether they hold music, engravings, sketches, botanical specimens, or what not, this grouping of species in distinct coverings is a great assistance to methodical classification. Besides, cretonne wears very well, better than any other cheap material, and I speak from a long experimental trial of various substances. Chintz and printed dress materials answer equally well.

Plain canvas is useful, but gets dirty very soon; buckram, recommended for books, is also too delicate for the rougher use of a portfolio, and soils very soon.

On the whole, for hard work, next to a dark-patterned cretonne, marbled paper is probably the best for wear. Plain paper is neater in appearance, and allows a list of contents to be written on the outside, but it looks shabby long before a patterned one. But it is needless to say more of the materials available; they are legion, and vary in every household.

To begin with the work itself—we may suppose the cardboard to be cut to the size, perfectly square and true, as the T square will ensure, if you use it properly. If cretonne is used, a piece sufficient to cover the sides and back should be cut out; if cloth or leather, it will suffice to cut enough for back and corners. For the back, cut a slip, say, an inch wider each way than the thickness you wish to devote to the back; let this slip also be an inch, more or less, longer each way. For the corners, cut out pieces the shape shown in Fig. 12, and paste these first on each corner, in the way indicated therein. Then paste the strip for the back, lay it on a clean table, and place the boards on it, parallel with each other, and at exactly the same height as the strip, and turn over the ends. See that your corners come with the joints of their covering uppermost; this is a trifle easy to overlook, and worrying in its after effect. Now paste the inner strip to the back; this should be as wide as the back strip, but not so long, being a quarter of an inch shorter than the height of the cover; paste this in its place, and with a bone paper-knife, work it on each edge of the cover, so that it sinks between them, forming a shallow gutter, so to speak, with edges, and leaving the back itself uncreased flat on the table. Now cut your side papers in the shape shown, Fig. 12, measuring them so as to overlap the already affixed cloth, by a quarter-inch or so, both at the back and the corners. Have ready two pieces of lining paper, just a shade smaller than the covers themselves, and having put in the ribbon or tape to tie, as explained earlier in this paper, paste them inside the covers. As the cardboard is certain to warp with the applied moisture of the paste (even although that be the thick bookbinders' paste, proper for such work), it is best to go through these processes as quickly as consistent with neat finish, and then leave the whole under pressure. Where it is practicable to put a block of wood with a rounded back, or a worthless volume the right size for such purpose (I keep a few condemned books for this purpose), the portfolio dries nicely with the back curved to a good shape. If such be not handy, place it to dry between sheets of dry paper, under a board, with the heaviest weights at hand, say bricks, old volumes of sermons, or speeches on the Irish question.

For covering with a material that is used for the whole surface, the process is even more simple; since then it is practically the back slip enlarged to do duty for sides and corners. It is not needful to reiterate the instruction, since the advice for the other will apply to each stage of this also.

Cretonne being curiously hard to paste at times, some sorts taking it as freely as buckram, and others with a fluffy texture that repels the adhesive matter, it is as well, in such a case, to give the boards themselves a good pasting, and thus merely reverse the usual order. For a way to affix label, on which to write name, see Fig. 14.

To add flaps to the portfolios is a rather tedious process; but after all, each flap is but another cover with another back; so that having done one, similar care will overcome the increased labour, and turn out a workmanlike article.

For railway novels in good condition, bound in stiff boards, and all such volumes, a sightly covering may be easily secured by pasting ordinary white note paper over the back, in imitation of half vellum, and covering the sides with a dull blue, sage green, or grey paper. There is usually a loose page of advertisements that may be pasted down inside. Thus treated, and neatly lettered in black (Fig. 15, p. 81), such a volume may take its place among well-bound books, without the degradation that a "yellow back" offers to a well-chosen case of books, decently and quietly bound.

As far as memory of my own failures helps me, I have tried to anticipate the hindrances and obstacles that occur at each stage of the work; but if there be any unforeseen that I can explain, a letter to the Editor in "Shop" will be read, and every effort made to offer a solution of the difficulty.

As the proud possessor of several hundred folios and volumes of my own making, I know the advantage they yield, and appreciate their aid to order, being of an unmethodical character by nature. If, therefore, one who is not precise and accurate praises their use, how much more should such methodical tidy persons—as all readers of WORK must be—be glad to avail themselves of my trivial suggestions.

OUR GUIDE TO GOOD THINGS.

38.—London Lathe and Tool Company's Improved Front Slide Lathe.

In this number of Work I am enabled to place before its readers an illustration and description of a Five-inch Geometric Lathe, constructed by the London Lathe and Tool Company, 37, Pomeroy Street, New Cross, S.E. The lathe presents many features of novelty, the front slide rest being one of the most important. Fig. 1 shows the lathe as used for ordinary wood and metal turning, but it is also supplied with overhead gear, as in Fig. 2, when required for ornamental work. The slide can be moved past the poppet head out of the way when the hand rest is being used, and this will be found very convenient at times. Another advantage of the front slide is that, the face being vertical, chips and grit are not likely to insinuate themselves between the working parts, and the saddle being clear of the bed, the lathe will take in larger work than ordinary lathes. Notwithstanding the necessary overhang of the front slide, it is perfectly rigid. The hand traverse of the saddle is effected by means of the handle shown in front. This turns a spiral pinion which gears into another spiral pinion of twice the size, forming a nut on the leading screw. The leading screw is of steel, having four threads per inch; one revolution of the handle, therefore, moves the saddle one-eighth of an inch. There is also a division plate on the front of the saddle, by means of which a movement of $\frac{1}{500}$th of an inch may be determined. This capacity for minute adjustment makes it unnecessary to have a compound slide rest. The absence of a rack is partly compensated for by the rapidity with which the handle can be rotated, and the bed being short, there is no practical loss of time in the movement of the saddle by this method. The tool box, shown in the illustration, is clamped in a socket bolted down on the top of the surfacing slide, which is actuated by means of a handle turning a screw of ten threads per inch. The head is divided into ten divisions, each of which denote a movement of the surfacing slide of $\frac{1}{100}$th of an inch. These minute adjustments give the slide rest all the advantages of a compound slide without its multiplication of parts. The socket which takes the tool box and other fittings is divided down one side and provided with a clamp which gives a better grip than a set screw. The hand rest is made the same way.

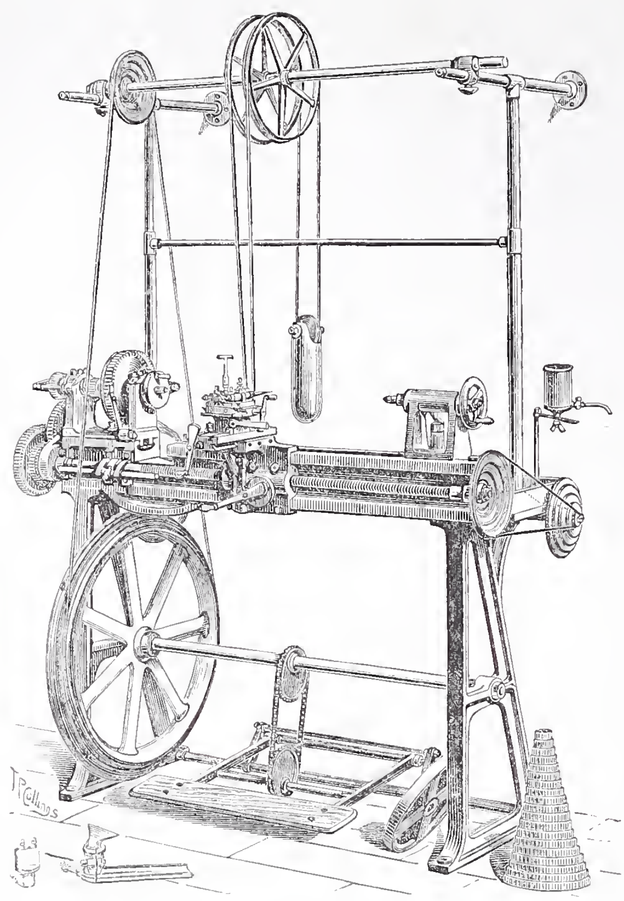

Fig. 2.—The Lathe, with Overhead for Ornamental Turning.

The headstock is back geared, the wheels being of gun metal, with machine-cut teeth. The construction is modified so that the front gear wheel is utilised as a division plate. To effect this the common locking nut, which in ordinary lathes passes through a slot, in this wheel is dispensed with, leaving the face of the wheel quite plain, and free for the holes drilled for the index pointer. The clamping is effected at the back, or smaller end of the cone, by means of a nut on the mandrel, which is screwed hard against the cone by means of a "tommy," the pressure being sufficient to lock the gear wheel and cone, and make them revolve together. A great point in favour of this arrangement is that it is evenly balanced, whereas, by the old method of using a nut near the rim of the wheel, it is impossible to properly counterweight it, as its position is different when in and out of gear, consequently, at high speeds the machine is subject to constant vibrations. The index peg is capable of being moved on its stem and adjusted, and this allows of its being shifted from one circle of holes to another, without affecting the accuracy of the work, and without the necessity of arranging the peg holes on an arc struck from the pivot on which the index arm moves. The index pointer is not shown in the engraving, which only shows the boss on which the pointer is fitted.

The circles on the division plate are divided into 192, 180, 160, 120, and 100 holes respectively, giving the following divisions:—

96, 64, 48, 32, 24, 16, 12, 8, 6, 4, 3, 2.

90, 60, 45, 36, 30, 20, 18, 15, 12, 10, 9, 5, 4, 3.

80, 40, 32, 20, 16, 10, 5.

60, 40, 30, 24, 20, 15, 12, 10, 6, 5, 3.

50, 25, 20, 10, 5.

Another feature of this lathe is an ingenious arrangement of mechanism, by means of which the motion of the saddle obtained from the leading screws may be instantly arrested at any given point; or the lathe may be used for plain turning, without disarranging any combination of change wheels which may be on the headstock at any time. This arrangement is shown on the left hand of the engraving. It consists of a rod sliding in two lugs on the front of the bed, a small fork being fitted on the rod by means of a set screw, which fork actuates a sliding clutch. The clutch, when in gear, establishes a connection between the leading screw to the right and the change wheel train to the left. The rod may be set in any position required within certain limits, so that when the saddle comes to the position where a thread should finish, or the work is to be stopped, it comes in contact with the rod, and the clutch is thus thrown out of gear. This motion is quite automatic when once set, and saves the close attention which the turner would otherwise have to give to his work when cutting screws or cutting up to a shoulder. It will be understood that to set this mechanism, the saddle must be put in a position where the work or thread is to be stopped, and the rod brought against it whilst the leading screw is in connection with the wheel train. The rod is then clamped in position by means of the small set screw on the back of the fork. There is also a provision for driving the leading screw from the right-hand side by means of a small cone pulley, which fits on the end of the screw, and is driven by another pulley on a shaft which runs along under the tool board at the back of the lathe. This is very handy for some purposes, as the clutch may be thrown out of gear, and the leading screw worked for turning without interfering with the arrangement of the change wheels.

The poppet head mandrel is provided with a screw of ten threads per inch, so that a complete turn of the hand wheel advances the mandrel one-tenth of an inch. The body is marked with inches and eighths; thus, an advance of the mandrel of eighths or tenths of an inch can be noted. The headstock mandrel is hollow, to receive rods for turning, screwing, and cutting off short pins or studs in quantities; the back screw being, in this case, removed to allow the rods to pass through. There is a change wheel stud for reversing the direction of the leading screw for cutting left-handed threads. It may be noticed that the holding-down bolt for the poppet head has a deep boss to fit into, and is turned to fit, so that the poppet head will slide without jerking when the nut is slackened out. The lathe is so designed, that the usual bridge or gap piece in the bed is not required.

The gearing between the treadle and the main or fly-wheel shaft is also arranged in a novel manner, which has several advantages over the ordinary method of driving. There is a chain wheel keyed on the main shaft, and another wheel of the same size loose on a spindle carried by the frame of the treadle, as seen in the engraving. The chain transmits the motion and takes the place of a connecting link, with this advantage, that the stroke of the treadle can be varied by slacking off the chain and shifting the position of the lower wheel, in relation to that on the main shaft, both wheels being eccentric on their respective

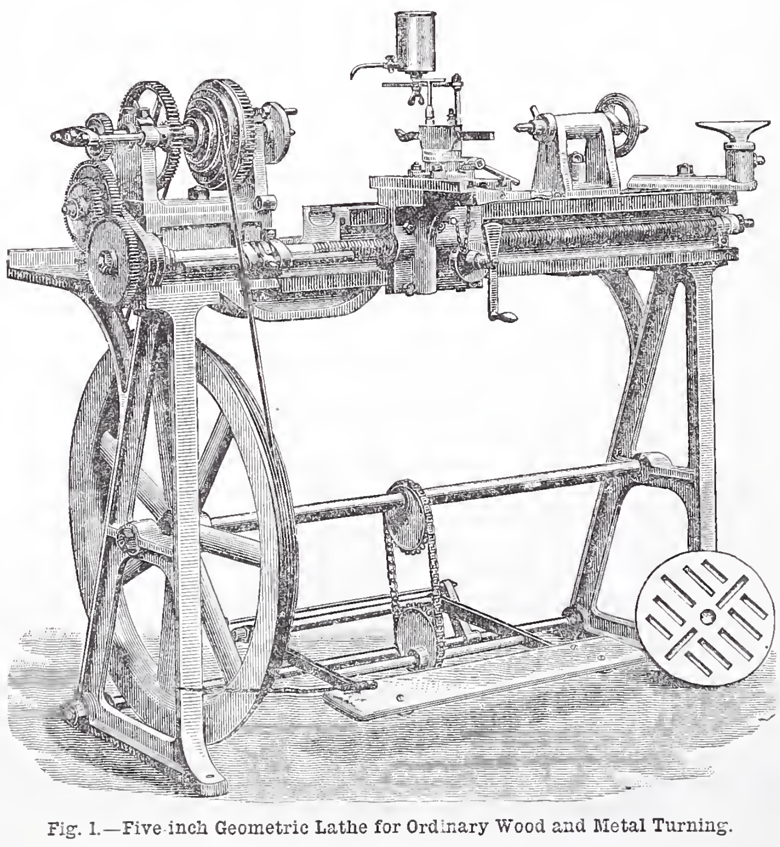

Fig. 1.—Five-inch Geometric Lathe for Ordinary Wood and Metal Turning.

shafts. There is also an arrangement by which the pivots on which the treadle moves may be raised or lowered, or its position altered, by moving the arms shown at the back. The treadle may also have a quick return, or a quick descent, by altering the position of the eccentric wheels in relation to one another.

There is also a neat arrangement for retaining the oil poured on the bearings, instead of letting it run on to the floor, and returning it again to the pivots. This consists of a little brass cup, fitting over the ends of the main shaft, and so constructed as to retain any oil which runs off the centres. The recess of the cups projects over the end of the shaft, and the cups can be moved back out of the way when required. The fly-wheel is fairly heavy, and has five speeds.

There are a variety of fittings designed for this lathe; amongst others there is a vertical slide, a very useful appliance for many kinds of work. Altogether, the lathe is well designed and neatly finished off, the workmanship being of the best all through. For description of overhead shown in Fig. 2, see No. 8, page 120.

One of the Company's lathes is on view in the Science and Art Department of the South Kensington Museum.

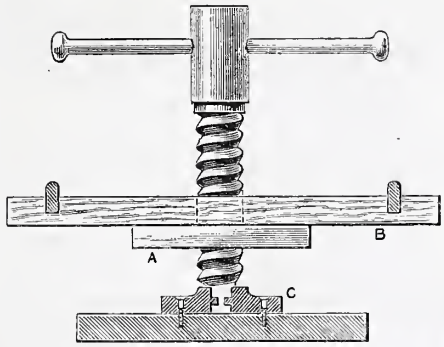
I.—Letters From Correspondents.

Preservation of Pianos.—Progress writes:—"I notice in your second issue of Work, a cutting from a contemporary on the subject of the 'Preservation of Pianos.' As you invite criticism, and I consider the information misleading to your readers, I need hardly apologise further for writing to you. In the first place I venture to remark that it was not written by a practical man; I will go further, and say, or by a man who had seen a piano constructed. The sound board is not forced into the case so tightly that it bulges in the centre, nor is it forced in at all, but is fitted to the back of the piano before the case is made. The mode of construction of the sound board is thus:—Some selected Swiss pine boards ⅜ in. in thickness, and about 6 in. wide, are jointed together, edge to edge, until the required width is obtained, after thoroughly drying, and being gauged to the requisite thickness. Bars of spruce wood from eight to twelve in number are glued in a vertical direction across the back. To give the sound board rotundity on the front, the edges of the bars are planed round in their length. These bars are placed on after the bridges. It is then thoroughly cleaned with scraper and glass paper, and varnished on both sides to protect it from damp, and make it resonant. I have never heard of a sound board splitting for want of moisture, but often when the wood has not been dry it has shrunk, and so caused the splitting. As to placing a vase with a wet sponge in it under the piano, it is simply absurd. I have before me a catalogue of Chickerings', who claim to be the largest piano makers in America. In it there are some hints on the care of pianos, but I see nothing about a wet sponge or a growing plant. I should say keep the sponge as far away from the piano as possible, because if placed in close proximity to the piano, the damp would be drawn to it, and rust all the strings, and do other damage. If your readers wish to preserve their pianos, I would advise that the piano be placed in a dry room, standing by an inside wall, as a rule behind a door, so that it does not stand in the draught from door to fireplace, as draughts often carry damp air, and cause rust. In sweeping the carpet do not wet the floor near the piano, as the damp rises. See that a fire is lit occasionally in the room in winter time. A piano always sounds brightest when it is kept dry. Keep it well dusted, and do not load the top with books, vases, etc., as these deaden the tone, and often cause noises in the piano by their vibrations. Have your piano tuned at least four times in the year, when it is new; after the first year, three times in the year will probably be sufficient, as the strings would have got settled to their bearing."

Wooden Copying Press.—W. H. D. writes:—"In the second number of yours, which promises to be one of the valuable assistants to all tool users—amateur or professional—I was struck, or, shall I say amazed (Scottice, amused), at or by the long description and perfect draughtsmanship of the amateur's wooden copying press. I have had in use 'another of the same,' which, while being slightly less mechanical in construction, is still as perfect in action, and has the advantage of having the stand ready made, or, at least, handy in most domiciles. Although hailing from the modern Athens, we children of the northern regions of the British Islands are not so far left out in the cold as not to have, as a rule, in the kitchen, a strong wooden-bottom armchair; that forms the stand I use, while Mr. D. Denning is evolving from the depths of his inventive consciousness the more elegant or shapely one to stand in the corner designed for it. The press itself, with its wooden screw, resolves itself into the screw and pressure board. The bar, B, in the illustration, in this case is a bit of birch, tapped to fit the screw, as shown—22 in. long by 3 in. thick and 3 in. wide; two might be strong enough, but that is my size. A strong pin is inserted at the points marking the centres of the arms of the chair, and on the under sides of those a hole is made to receive the two pins. These pins are simply to prevent lateral slipping or sliding, and in this case are of boxwood, but anything will do. The pressure board for the quarto copying-book, in my case, is a flush framed 1½ in. thick, which I happened to have, but any strong piece of timber which will not twist, bend, or give, will do. The attachment of this to the screw is where, I think, this home-made press has the advantage. It is well known that screw nails do not hold well in wood, so to overcome this difficulty, I got a collar turned with a notch made in the screw to receive it, allowing it (the screw) to



Wooden Copying Press.

A, Nut, or Female Screw. B, Bar. C, Circular Catch cut through before being screwed to pressure board.

revolve loosely while working up and down in its nut. Of course, to get it to catch and work, the collar was sawn through before being screwed to the pressure board, as shown in the accompanying tracing from your own woodcut with the necessary alterations."—[You have certainly shown the utmost economy in the construction of your press, but I think Mr. Denning's has a little advantage over yours, although he uses up more material. One slight difficulty suggests itself to me, and that is the shape of the seat of the chair, which ought to exert a pressure on the lower sides of the copying-book precisely equal to that which is exerted by the screw through the pressure board on the upper side of the book. If the seat of your chair is perfectly flat and level, all will be right, of course; but the seat itself, though well adapted for press purposes, can scarcely be comfortable to sit on. I have a wooden armchair on which I sit daily when at work, but the seat itself is slightly hollowed—moulded, in fact, for obvious purposes, and I fear its curved depression would render it unfit for utilisation as the bottom, or *pièce de résistance*, of a copying press.—Ed.]

II.—Questions Answered by Editor and Staff.

Inlaying.—W. H. Dunley.—The Italian and, I believe, also the French mode of inlaying, which is simply fret cutting, is carried out somewhat in this way. Suppose the material is ivory and ebony, two thicknesses of the veneers of each are glued together with paper between; this when dry receives the drawing, which is cut in the usual way; these are separated. The ivory inlaid into the ebony is called *primo*, the ebony into the ivory *secundo*, the latter being considered much inferior. The same principle prevailed, or prevails, with buhl work, in every case a light and a dark material let into each other, so that nothing is lost.

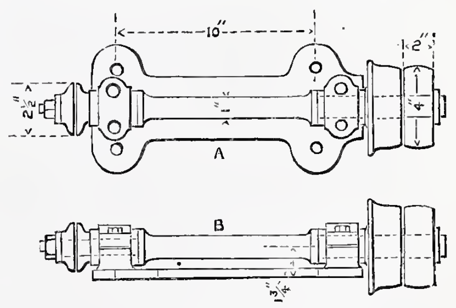
Cupboard Doors.—C. H. J. (*Chelsea*) writes:—"With reference to Mr. David Adamson's article on 'Artistic Furniture,' which appears in Work, in which he gives instructions for making the doors of the overmantel, by halving the styles and rails together and rabbeting the panel in the back, may I suggest the following method, which seems easier for amateurs?—Cut a piece of ½-in. board the length and width of cupboard. Then cut your styles and rails out of ½-in. stuff. Screw the styles on the sides of the board, cut the top and bottom rails in tightly between them, and fix them. Should it be a long cupboard, a middle rail can also be fixed, at the maker's discretion, making it a two-panelled door."—[This mode of making doors is one that is known as "mocking," that is to say, when the effect of panelling is produced by the use of slips of wood, and even mouldings, as you have described.—Ed.]

Wire Thread Fret Saw.—O. F. (*London, N.*) writes:—"The wire fret saw was illustrated in the *Scientific American*—an American paper—some years ago, I think about twelve years."—[Will you kindly try to fix the year in which the article to which you refer appears? Or will any reader who has access to a file of the *Scientific American* take the trouble to make a search for me, and let me know number and date?—Ed.]

Bunsen Battery for Incandescent Lamp.—Electric.—To light up your room of 10 ft. square you should have at least 30 candle-power. This you might get from three 10 c. p. incandescent lamps worked with current from ten quart Bunsen cells arranged in series, the lamps being placed in parallel circuit. The probable cost of each cell would be about 3s. 6d., and the cost of lamps the same, but one can scarcely venture to quote prices here to suit all districts. I do not suppose, however, that you could safely reckon on less than £3 to cover cost of installation. Working expenses extra, for which no estimate can be made. Mr. S. Bottone, Carshalton, Surrey, will give you an exact estimate, and supply you with all necessary materials if you apply to him.—G. E. B.

Leclanché Cells for Incandescent Lamp.—Nulli Cedo.—The thing proposed by you is entirely impracticable. The E. M. F. of a Leclanché cell is 1·40 volts, and it will take at least 50 volts to light your 20 c. p. lamp. You get no advantage in coupling the cells in multiple arc. Even if you used the largest size Leclanché cell for the purpose, it would take at least 36 cells in series to make the lamp glow, and this faint glimmer would only last a few minutes, because the cells so rapidly polarise on constant work. To employ this battery at all on electric light work is like using a tack hammer to forge a ship's anchor. 20 c. p. lamps are also unsuited to electric lighting with current from a battery. Nothing higher than a 10 c. p. lamp should be used. Lamps are easily switched on and off a battery. Cotton-covered copper wire for leads. The cells are charged, then connected to the switch. There is no danger. No danger at all to persons from current generated by batteries used in electric lighting. See replies to other correspondents on electric lighting.—G. E. B.

Sewing Machine Treadle for Circular Saw.—H. W. (*Gateshead*).—You cannot get sufficient power from an ordinary sewing machine treadle and fly-wheel to drive a circular saw through a 1-in. deal. One inch is too thick to be cut without extreme labour, even in a 5-in. lathe with a heavy fly-wheel. Could you not manage to pick up an old treadle and fly-wheel second-hand and rig up a little circular-saw bench? That would be much cheaper than purchasing a saw bench properly fitted. You can buy a saw spindle of any tool maker, price varying with size. A spindle with carriage and bearings for a 15-in. saw costs £6. But you can, if you can work a bit in metal, and get the loan of a lathe, make a spindle for yourself. I enclose a drawing of such a spindle in plan and elevation, with a few leading dimensions suitable for a saw of from 10 in. to 12 in. diameter. The smaller dimensions you can measure from the drawing, as it is to scale. You can make a bench by framing quartering together, and screwing a table upon it. Almost any design will answer the purpose. If you manage to pick up a crank and heavy wheel (it



Spindle for Saw Bench. A, Plan. B, Elevation.

must be as heavy as a 5-in. lathe wheel), and will then give dimensions of it, I will show you how to adapt a table thereto.—J. H.

Steel Straight-edge.—Mechanic.—To make a steel straight-edge 4 ft. long, you must obtain the use of a true surface plate, or true straight-edge, or else you must make two other similar straight-edges in order to get one true. Whatever plan you adopt, you must first rough cut and file your bar of steel to width, and then, before attempting to finish, take out all wind, curvature, or inequality of surface by careful hammering. When this is done, and the faces clean and polished, get one edge as true as possible by filing. If you can test by another straight-edge, or surface plate, well and good. But I judge from your letter that you are dependent on your own resources. Then, in this case, get two strips of dry mahogany to make two other straight-edges, the counterparts of your metal one. I suggest mahogany because it is so much easier to work than metal. If you can get a sale for steel straight-edges, make the two supplementary ones in steel. Take then the strips, and file or plane one edge of each as true as possible. In the absence of a true surface to check by, lay the straight-edges upon a plane face, scribe a fine line by the edge you have filed, then turn the straight-edge over, and try that edge again by the line just scribed. Half the amount of non-coincidence of edge and line measures the amount of inaccuracy present in your straight-edge. This you will reduce, and when, by repeated trial, you think it is true, gauge or scribe the second edge parallel with the first, and file that. Serve all three alike. Now, when you try edge to edge you will certainly find that though two may possibly appear to coincide, they will not coincide with the third, when tried edge to edge. By removing material, therefore, carefully, until all six edges of the three straight-edges are mutually coincident, each to each, you will ensure perfect accuracy, and this without extraneous aid. If you do not require absolute perfection, then two straight-edges will suffice instead of three, provided they are not only tried edge to edge, but end for end. Do not spoil the value of a straight-edge as a parallel strip for purposes of levelling by making one edge rounding, as was shown in the sketch accompanying your letter. No true mechanic would be guilty of such barbarism. All straight-edges should be perfectly parallel.—J. H.

How to Distinguish Steel and Iron.—W. L. W. (*Dublin*).—You ask for "a safe and ready method of knowing good steel from iron or bad steel," because you "find it difficult when buying tools to know that the articles are of good quality." To this I may say that iron emits a comparatively dull sound when struck with a hammer; steel gives forth a very sonorous and musical ring. Polished steel has a much more lustrous appearance than polished iron. These are broad distinctions. But when you ask a "safe and ready method of knowing good steel from bad steel," I can only say that this is entirely a matter for experience, practice, and test. You cannot judge of the temper of steel tools by inspection only; you must make trial of them. For this reason all tools by good makers are "warranted," and will be exchanged if found unsatisfactory. You might expect that a tool which shows a high polish is good, but the best guarantee of quality is the name of a maker of recognised repute, and the paying a good price.—J. H.

Riding Tricycle up Hill.—A NOVICE.—You ask for "information as to the best means to assist rider in ascending hills." Kindly give me the following particulars, and I will endeavour to assist you:—Type of machine; size of driving wheels, and to what speed are they geared; length of crank throw.—C. I.

Wire Thread Fret Saw.—C. R. B. (*Edgbaston*).—This fret saw is not yet in the market, to the best of my knowledge. When it is so, and when I am in possession of sizes and prices in and at which it is made and sold, I will mention both in these pages. I am obliged to you for your good opinion of WORK.

Valuation by Cubical Contents.—READER asks how the above can be obtained in all classes of house property. The answer is simple. To obtain the answer considerably less so—*Experience*. When it is taken into consideration that a house occupying the most space may be of the least cubical value, or that two houses built from the same plans may be so varied in the interior that the value of one shall be 3d. per cube foot and the other 4d., what established rule can decide the difference? House property worth 2½d. per cube foot, when several houses are built together, might cost 3d. if built singly. To obtain these varying prices it is necessary, either from plans or from a building of similar structure, of which the cost is known, to take the cubical contents, and so from one to price the other. The information thus obtained is of little value except for that special class of work. Other class property must be treated in a similar manner. But it may not be possible to compare property in this manner. Just so; there lies a difficulty which experience alone can overcome. Comparison gives a clue, but considerable judgment is necessary before one can properly compare one class of work to another. It is easy to find buildings ranging in value from 2d. to 6d. per cube foot, the different prices depending more on quality than quantity. It is an unsafe method of valuing, and I could quote instances in which mistakes have been made by builders of as much as three hundred in the thousand pounds by using cubical measurement. As well guess at the total value at once as guess at the value per cube foot, and I maintain that cubical valuation is more or less of a guess.—JOACHIM MILLER.

Peripheral Speed of Breast Water Wheels.—X. Y. Z. (*Orkney*).—The peripheral speed of breast water wheels is settled on practical considerations, and is usually set at 6 ft. per second—it should not fall below 4½ ft. or exceed 8 ft. per second. For economical working, the velocity of the feed water entering the wheel should be twice the peripheral velocity, or usually 12 ft. per second. This will require a head of 2¼ ft., therefore the outlet from the penstock should be 2¼ ft. below the surface of the supply. To find the gross power, multiply the number of cubic feet of water passing per second by 62½, and by the vertical height of fall of the water, and divide the product by 550; the quotient will be the gross horse-power, and the available or effective power will be from 6½ to $\frac{8}{10}$ of the gross, according to the design of the wheel. The height of the fall is the vertical distance between the level of the head-water in the penstock and the level at which the buckets of the wheel empty themselves.—F. C.

Taking a Cast after Death.—A. E. (*Liverpool*) will find this a simple matter as compared with casting the face of a living person. The features should be rubbed over with a very little oil. The beard, moustaches, etc. (if any), should be plastered down with soap, and carefully, as any stray hair which may become entangled in the mould will probably be pulled out. Cloths should be tucked under the chin and all round the face as far as the mask is to extend, and closely, that plaster may not run between them and the skin. These, going along the line of the hair, will protect it; or should it be desired to extend the east over any part of the hair, that part must be plastered down with soap. The nostrils should be plugged with a bit of oiled cotton wool. The plaster should be put on carefully with a spoon, not poured on in quantity, or it will overflow the cloths and make a mess. It is better to make the mould in two layers, colouring the inner one as in ordinary waste-moulding. No difficulty will be found in removing the mould if no hairs are left loose to become entangled in it.—N.B. In this place it would be impossible to give full directions for all the processes of ordinary plaster casting, but I have articles on the subject in preparation which may, I trust, by the courtesy of the editor, appear before long in these pages.—M. M.

Printing Estimates.—S. A. C.—I know of no English work which treats of this subject. The Russell and Morgan Printing Company of Cincinnati have compiled a series of tables showing the principles upon which estimates should be based. These tables, which are being reproduced at intervals in the *British and Colonial Printer and Stationer* (Office, 58, Shoe Lane, London), would give you all the information you require.

Smiths' Work.—VULCAN.—I am glad to receive so sensible and so practical a letter as yours, and will do all in my power to aid yourself and all young workers at the forge by suitable papers in WORK. Before this can meet your eye you will have read the first of a series of papers on "Wrought Iron and Steel Girder Work," and I have the first of another series on "Smiths' Work" in type and ready for publication. Much beautiful work is now being done in wrought iron, and I have recently seen candlesticks, ornamental brackets, lecterns, and other articles in hammered iron that afforded abundant proof that the ornamental ironwork of mediæval times is on the eve of revival. I saw also a spray consisting of a full-blown rose and leaves wrought in iron, to look on which was to me a genuine pleasure. I hope one day to follow the Sheet of Repoussé Metal Work given with No. 7 with a sheet of Hammered Iron Ornamental Work.

Hat Making.—W. G. H. (*Stockport*).—You ask for "a course of papers on the manufacture of hats," adding that "it is a trade of which little is known theoretically. If you could see your way to give papers on the preparation and blowing of fur, forming, planking, blocking, curling, finishing, dyeing, trimming, etc., you would convey a boon on the neglected hatters." I must confess that I cannot see my way to do what you ask at present, for there is so much to the front to be dealt with already. Meanwhile, hatters will find much in WORK that will benefit them indirectly at home, if not directly in connection with their trade. If a hatter takes up WORK and studies it from week to week it may be instrumental in giving him many a hint and affording many a suggestion that may be of use to him in his trade.

Printers' Lead Castings.—To judge from your sketches and the description you give of your mould for casting printers' leads, you appear to be on the right track as far as this is concerned. Your trouble is that the metal will not run in the mould. The fault, in all probability, is in your metal; try 24 parts lead, 4 parts antimony, and 1 part tin.

Our Advertising Pages.—E. C. (*North Brixton*).—Suggestions are always welcome; no apology is necessary for them at any time, for they are nearly always of service, and we are always glad to have them. I can only say that if it ever be found possible to meet your wish it will be met.

Comment and Criticism.—P. C. (*Leyton*).—I will not give your letter at length, but will content myself with assuring you that nothing will ever appear in the pages of WORK that will be irrelevant and touching on subjects that are best left alone. I sympathise with you in all you say about—but here I must stop, for obvious reasons. No one can detest flippant dealings with sacred subjects, or "profane and vain babblings, and oppositions of science, falsely so called," more thoroughly than I do.—ED.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Cement Roofing.—X. Y. Z. (*Orkney*) asks:—"Can any practical builder inform me whether cement plaster would do for a roofing material? I mean to nail laths on the rafters, as in inside house plastering, and cover with a coat of cement plaster. Would there be a danger of the plaster cracking or peeling in a storm; and if so, is there no known way of preventing? If practical, this would make a very cheap light roof, and when lined and painted would be very pretty and very suitable for, say, farm steadings. I should much like to know whether it has been tried, and with what success.

Coating for Damp Walls.—R. A. P. wishes to know "the requisite proportions of shellac and methylated spirits on wood naphtha to make a waterproof solution for inside damp walls. How much naphtha to 1 lb. of shellac."

Trade Notes and Memoranda.

AN Heraldic Exhibition is opened at Ghent. The armorial bearings of the early Knights of the Order of the Golden Fleece will form a prominent feature of the show.

THE bridge erected by Lord Burton over the River Trent is 240 ft. long. For the ferry rights at the site a sum of £12,950 had to be paid.

A PUBLIC studio is about to be established in London, under the personal direction of Sir James Linton, P.R.I.

THE piers of the Tay Bridge are founded on silty sand, and consist of two iron cylinders, which are sunk deep, joined together, and filled with concrete masonry. The maximum load is 3 to 3½ tons per square foot. The Paris Exhibition buildings rest on a substratum of stiff clay. Where the gravel was 10 ft. thick, 6,140 lb. per foot was the maximum load allowed; when between 10 ft. and 5 ft. deep, 4,550 lb. was allowed, and the thickness of concrete was increased. When below this depth, piles were driven.

SHEET metal is applied by the Americans to a large number of purposes. One of the more recent adaptations are sheet metal ceiling centre pieces, which can be painted to imitate plaster, or decorated to suit any taste. Lightness and durability are claimed for it.

LECTURING on "Some Newer Modes of Working Sheet Metal," Mr. D. W. Kemp, of Edinburgh, explained recently to the members of the Association of Science and Art that the invention consists in taking advantage to the full of the well-known properties in all ductile metals to flow or stretch under gradual pressure. The improvement claimed over the ordinary methods of hammering, cressing, or spinning might be called flowing, and consists in employing fluid pressure and heat in combination with suitable moulds, the pressure being applied on the sheet metal in such a manner as will force it gradually into the concave or hollow part of a mould, shaped internally to fit the external shape intended to be given.

THE Argentine Republic has a very large foreign trade in proportion to the number of its inhabitants, for the reason that it produces large quantities of raw material, and has, at the same time, very few manufactures. In 1887 the exports and imports amounted to £42,349,840, being equivalent to £9 13s. per inhabitant, against £8 8s. in France, £6 7s. in Germany, £6 in the United States, and £2 4s. in Russia.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

VOL. I.—No. 10.] SATURDAY, MAY 25, 1889. [PRICE ONE PENNY.

STUDIES IN WOOD CARVING.

BY FRED MILLER.

I.—TWO CORNERS FOR PICTURE FRAMES.

SINCE the introduction of *carton-pierre*, carved frames have become almost works of the past; but seeing the scope the craftsman has to exhibit his skill in a carved frame, the tyro should certainly try his hand at something of the kind. The two designs given with this number of WORK are very simple in character, and present no difficulties to even beginners in the craft. Fig. A is an adaptation of a tolerably familiar pattern, used in the "bosses" of Gothic wooden roofs. The corner consists of two double leaflets interwoven, and forming the termination of the twisted stem that occupies the rest of the frame. It would be easier when the frame is mitred and glued up to glue an extra piece, say, $\frac{1}{4}$ of an inch or $\frac{3}{8}$ of an inch deep, at each corner, so that the corners are in higher relief than the stems running along the four sides. The four bosses can then be carved out of the pieces glued on, the "grounding out" being taken to the depth of the pieces glued on, and *not* to the depth of the flat upon which the twisted stems lie. The corner is given full size for working, and a tracing should be made, and the four corners might have a little Chinese white brushed over them, and when this is dry, transfer the design of the bosses by means of a hard point and black carbonised transfer paper, to be obtained of any artist's colourman or stationer. Having "grounded out," carve away the leaves as they approach the edges of the bosses, so that the centre is the highest part of the corners, and the edges of the leaves only slightly higher than the thickness of the four pieces you glued on. Let the veining be simple and in the direction of the way of the leaf. Get the contour of the leaves sharp and angular, and let the carving be crisp and executed in a broad, free manner.

The stem running along the sides of the frame should be about $\frac{1}{8}$ of an inch in relief. The length and height must be divided up so that the twist or knob comes at regular intervals. The stem should not be smooth, but have a sort of bark-like surface running the lengthway of the stems. The background would look well if worked over with a punch instead of being left plain.

A

B

Two Corners for Picture Frames. Fig. A.—Adaptation of Gothic Boss. Fig. B.—Hispano-Moresque Arabesque.

Fig. B is adapted from a Hispano-Moresque piece of carving, and is only intended to be like a fret upon the flat. Consequently the grounding out should not be taken deeper than $\frac{1}{8}$ of an inch. Some portions of the design should be lower than the others. Be very careful to get the curves correct, and not broken, as the beauty of these designs is their flowing, interwoven character. The rest of the frame can have the double arabesque running the whole length of the frame, and terminating at each corner.

Such designs as these Moorish arabesques would make good fret work designs, and, in fact, a frame might be decorated in this way by cutting the design out as a fret, and gluing it on the flat. Those who have not yet tried their hand at carving out of the solid, but may have ventured to relieve fret work, which they have executed by a few touches put in here and there, by aid of gouge or chisel, may be led on to wood carving by working in the manner suggested, and venturing to impart a little more relief and variety to their work by means of carving tools proper, without which it is impossible to carry out the simplest carving effectively.

SMITHS' WORK.

BY J. H.

I.—Development of Art of Metal Working—Twofold Division of Subject—Ancient Hammer Work—Copper Work—Bronze Castings—Celts—Ancient Riveting—Iron Working among the Ancient Greeks, Romans, etc.—Iron Manufacture in the Middle Ages—Smelting in Sussex—Casting—Fagoting and Welding—Hot Blast—Processes of Heath, Bessemer, and Siemens.

Having undertaken to write a succession of articles for this magazine upon the work of the smith and of the boiler maker, I propose to preface those articles by a compendious sketch of the general lines of development of the art of metal working. I shall then proceed with my first series on smiths' work, to be followed by a second series on plating and boiler making.

All metal work is readily divisible into two broad classes — cast and hammered. This distinction is sufficient for our purpose, although it does not entirely cover the field, because nearly all malleable iron made by modern processes and all mild steel are cast before they are puddled, hammered, or rolled. Neither does this take account of the method of electrotyping. Both casting and hammering were employed in prehistoric ages, and both methods have continued in use until the present time. It is comparatively easy to produce intricate forms by casting, but the forging of such forms taxes the very highest skill and patience of the craftsman. Most of the specimens of prehistoric art which have been preserved to us are in the form of castings, but the more delicate hammered works are mostly of historic dates, or belong to periods immediately antecedent thereto.

The work of the blacksmith is of comparatively recent origin in human history. Skill in the working of iron dates only from a few centuries before the Christian era. In the Homeric period, iron was a rare metal of great value. One of the prizes at the funeral games of Patroclus was a self-fused mass of iron and iron fit for making arrows. — (Iliad xxiii.) Previous to the introduction of iron, bronze was the metal employed for weapons of war and defence, and for articles of ornament and domestic service. The ancients had acquired very great skill in the composition and use of this alloy, as is attested by the vast number of cutting tools and utensils which have rewarded the researches of archæologists. The origin of the age of bronze is lost in remote antiquity. No hard and fast chronological line separates it from the preceding neolithic or new stone age, when men polished their celts and implements of flint and chert. But the discovery of the use of the metals copper and tin marked a most distinct advance in the history of civilisation; and in this broad sense we are justified in regarding the bronze-using period as a very important age or era in the history of the race. It is considered probable, and in some isolated districts it is a fact, that there was also a period when pure copper, unalloyed with tin, was employed. But as a rule the advantages in increased hardness which were gained by alloying tin with copper were so evident, that in most cases bronze, and not pure copper, was used.

The evidences of a copper age are chiefly found about the Lake Superior district, in North America. Here native copper occurs in great abundance; and here the metal has, in most cases, been hammered, and not cast, though there are exceptions. In the State of Wisconsin alone, upwards of a hundred axes, and spear-heads, and knives formed of pure copper have been found. In Central India, at Gungeria, copper instruments have been found. But it is doubtful if either of these remains is of great antiquity, and they are only instanced as illustrative of the probability of a copper age having, in some cases at least, preceded that of bronze in countries where no direct evidence of such has been discovered. As a matter of fact, nearly all the primitive implements of metal as yet found in the old world are made of alloys of copper and tin.

The composition of the prehistoric bronzes varied extremely. A good bronze mixture, as used by engineers, contains about 88 or 89 of copper to 12 or 11 of tin respectively. Many of the ancient bronzes contained proportions approximating to these, but some contained a much less, some also a much greater proportion of copper. Very considerable traces of lead, nickel, silver, and iron also occur in the early bronzes, the modern art of the purification of copper from the foreign ingredients present in the ores being, of course, unknown to the early smelters.

These castings were made in regular foundries, the remains of which have been found in many districts in England. Moulds, lumps of rough copper in cakes and ingots, worn out and broken implements intended for remelting, gates or runners, cores, etc.—all these have been found in large quantities, so that there is no mystery at all about the method of manufacture of the early implements.

It is, to some extent, matter of conjecture how the metals were cast, but crucibles of clay must have been employed. At Robenhausen, in the old Lake dwellings, such crucibles have been found with small lumps of bronze still sticking in them. The moulds used were made in various materials—loam, sand, stone, and metal. In some moulds the upper portion was left open, in others, closed moulds were used, and hollowed parts of the castings were made of cores of sand or of metal. Spear-heads and celts—chisel-like implements—were cast in divided moulds, whose halves were guided into coincidence by means of dowels on the joint faces, the halves being bound together during casting with thongs, pins for the encircling cords being cast upon the outside of the mould. The metal was poured through holes in the joints.

In the case of socketed chisels, the interior core was formed sometimes of loam, sometimes of metal. This would fit into the upper portion of the mould; and the founders did not always get their cores central any more than they do now, as is evidenced by the thick and thin metal on opposite sides in specimens of castings still in existence.

In no essential did the methods of moulding and casting differ from those carried on at the present day. Yet these relics date from a period long anterior to the Christian era, how long, none can say even approximately; probably, almost certainly, many are from 2,000 to 4,000 years old. Dr. Evans thinks the bronze age began in England some 1,200 or 1,400 years B.C., and that it lasted about a thousand years, but he believes that the knowledge of copper and tin may have much antedated this.

Among the articles fabricated by the early bronze founders were the celts, or typical cutting tools, whose uses were probably multitudinous: long narrow chisels and gouges, sickles, knives, razors, daggers, swords, spear-heads, lance-heads, hammers, shields, helmets, trumpets, bells, pins, bracelets, rings, ear-rings, buttons, caldrons, etc. Some of these were riveted to their handles, and in the case of caldrons and other vessels, the plates of which they were composed, were also united with rivets.

The introduction of iron brought about a revolution in the art of metal working whose ultimate developments are but dimly foreseen, even in our own age. The date of its discovery is lost in obscurity. But we may venture to affirm that it was a metal which was little known at the period of the Homeric poems, and that it was in common use by the second or third century before the Christian era.

The significance of the passage in the "Odyssey" is unmistakable—"As the smith plunges the loud hissing axe into cold water to temper it, for hence is the strength of iron" (ix. 393). The metal was known in ancient Assyria, a few iron articles found by Mr. Layard being quite sufficient to prove that the use of iron was not unknown. A few remains have been exhumed by Mr. Schliemann from the site of ancient Troy. There are abundant evidences of its use in Egypt, probably seven centuries or more before the Christian era. Mr. Fergusson even gives cogent reasons for believing that iron was known in Egypt fifteen centuries before our era, and in the Mediterranean shortly afterwards. And it is certain that the metal has been smelted in the rude Indian furnaces from time immemorial. This summarises nearly all our knowledge of the early use of iron. But when we come to within five or six centuries of our era, the evidences of the age of iron become more abundant.

In the days of Hesiod iron had become very common. The poet gives to Hercules a helmet of steel and a sword of iron; and to Saturn, a steel reaping hook. Some centuries before the time of Herodotus, the manufacture of iron had been practised by the Chalybes, on the shores of the Euxine. Their country was full of iron ore, and covered with forests, from which the charcoal for smelting was obtained. The steel of Sinope was reputed for smiths' and carpenters' tools; that of Laconia for files, drills, and masons' tools; and that of Lydia for files, swords, razors, and knives.

Two or three centuries before the Christian era, iron was in abundant use. The Isumbrian Gauls who fought with Flaminius were discomfited because of the softness of their iron swords, which bent in action. The swords of Noricum, in great repute during the Augustan age, were of iron. Iron is mentioned by Strabo as being among the products of Britain. The Veneti, in the Morbihan, when attacked by Cæsar, had their galleys fastened with nails of iron and moored with chain cables of iron.

The knowledge of steel must have been contemporaneous with that of iron. It is impossible that it should have been otherwise, because in the primitive smelting furnaces, which must have been practically identical with those which are in use in India, Burmah, Africa, and Catalonia, at the present day, the conditions of the reduction of the metal are such that iron or steel is produced almost at the will of the smelter. The nature of the resulting product depends on the temperature, the quantity of charcoal present, and the period of time during which the metal remains in contact with the fuel. Any given grade of malleable iron, steel, or steely iron, can thus be usually produced at the will of the smelter by the regulation of these matters. But it often happens that the product is other than that desired. Or, as in the Catalonian furnaces, every grade will be produced during one and the same smelting, so that the various qualities of metal have to be sorted according to the appearance of their fractured surfaces.

Although the art of casting in bronze was practised in a remote antiquity, yet the majority of the early work in iron appears to have been wrought under the hammer. The making of huge castings is a comparatively modern branch of metal work. The only distinctions made by the ancient and the early mediæval iron workers were those into malleable iron, and steel. Cast iron, though produced in the furnace, was an abnormal product, for which no use could be found. And the malleable iron they made was superior to our best, because it was smelted only with charcoal. Small quantities only were produced at one time, just as in the Hindoo, Burmese, African, and Catalonian furnaces; but the quality was admirably adapted for the best and most delicate smiths' work. Probably the early smiths could not have produced such excellent work as they did if they had been compelled to use our inferior bar iron.

During the Middle Ages, iron in small quantity was produced in England by a rude process of smelting, the ore being simply dug from a pit and transported to the localities where fuel was plentiful for smelting. The best iron was then imported from Spain and Germany. Historical documents prove that iron has been continuously smelted in the French Pyrenees from 1293 A.D.

The revival of the English iron manufacture first took place in Sussex, where the proximity of the iron-stone to the great oak woods had fixed the location of the industry, even in the time of the Roman occupation.

Iron at this time was so precious that, though cannon were cast and forged in the metal, the balls were hewn out of stone. The first cannons cast entire in England were made at Buxted in Sussex, by one Ralph Hogge, in 1543, whose assistant was Peter Baude, a Frenchman, the art of casting guns having been invented in France. Baude afterwards set up in business, and many of his guns, both in brass and iron, are preserved in the Tower. The low state of the art of casting in England at that time is illustrated by the fact that most of the early founders were Flemings and Frenchmen, who, driven by religious persecution to this country, brought their skill with them to the enrichment of England. That this was the revival, and not the creation, of an industry is clear from the fact that many of the old English andirons or fire-dogs date from a period anterior to the fourteenth century.

Toward the close of the reign of Elizabeth, the iron manufacture of Sussex was at its zenith. The fortunes of many great families had been built upon it. Ordnance was now exported. During the reign of James I., about one-half of the iron produced in the country was made in Sussex. But by-and-by the authorities became alarmed at the rapid clearing away of the forests, pit coal not having come into general use for fuel, because of the great prejudice with which it was regarded. An Act was passed in 1581 prohibiting the destruction of timber within fourteen miles of London for the purpose of iron making. New iron works were forbidden to be erected within twenty-two miles of London. These, and similar enactments, caused the emigration of many of the Sussex ironmasters to South Wales and elsewhere. About the middle of the seventeenth century, the civil wars gave another and more serious check to the iron trade in the destruction of the Royalist and royal iron works. By the latter end of the eighteenth century, the whole of the Sussex iron works were closed.

The smelting of iron, an art in which the English had now for so long excelled, was threatened with absolute extinction by the thinning of the forests, and legal restrictions imposed upon the further making of charcoal. In one locality after another the industry suffered, or became extinguished altogether; and iron again, as heretofore, had to be imported from Spain and Germany. In these circumstances the smelting of iron with pit coal occurred to many, and some patents were taken out with that object; but prejudice was strong and the practice unsuccessful. And so things continued until Dud Dudley took out a patent in his father's name, on the 22nd February, 1620, for smelting iron with fuel made from pit coal. The ironmasters of that period feeling, like the silversmiths of Ephesus, that their craft was in danger, pursued Dudley with unremitting hostility, and the civil wars subsequently swept away the fruit of his labour and reduced him to poverty.

To Abraham Darby, the Quaker, who commenced the casting of hollow ware in 1700, and who shortly afterwards opened the Coalbrookdale Works, in Shropshire, the iron trade owes much. Previous to this the hollow ware was imported from Holland. He too had experienced the difficulty of carrying on his work in consequence of the scarcity of timber, and resorted to the use of coke. The business was continued by his sons, then by Reynolds, who married a daughter of one of the Darby's. It was at Coalbrookdale that the reverberatory furnace was invented and first employed, the credit of the invention being due to two foremen, brothers, named Cranege. By its invention the operation of puddling for the making of bar iron was effected better than was possible in the old finery worked with a blast. Then there was the patent of Peter Onions, of Merthyr Tydvil, in 1783, for working the pasty mass of puddled iron about on the end of a rod, collecting it into a lump, and hammering it under the forge hammer.

Finally, Henry Cort, in 1783, patented the method of fagoting the bars of puddled iron, and welding and rolling them into one homogeneous mass. Cort introduced the practice of rolling bar sections in grooved rollers; and generally, he fixed the details of the practice of puddling and rolling as carried on in the present day.

During the period immediately preceding Cort's patents, the iron trade in this country was in such a bad way, chiefly because the ironmasters were debarred from the use of charcoal, and had not yet learnt how to adapt their processes to eliminate the impurities present in the coal and coke, that the Government would not use the wrought iron made in England, and the cast iron was considered rotten. Cort's processes have enriched thousands of ironmasters, but he, in consequence of a most unfortunate partnership, died in poverty, broken in spirit. To his inventions mainly, the Crawshays and the other great ironmasters of the present century owe their enormous fortunes.

On the first day of January, 1760, Dr. Roebuck, a Sheffield man, a physician, and the friend of Watt, opened the famed Carron Works in Stirlingshire. He was a man of large mind and of daring enterprise, but was ruined by the magnitude of his own projects, and died poor and in obscurity.

The black-band ironstone, whose use has quickened so vitally—indeed almost created the industry of iron smelting in Scotland—was discovered by David Mushet, in 1801.

In 1828, Neilson patented the application of hot blast to the smelting of iron. By its introduction a great saving in fuel has been effected, the black-band ironstone utilised, enormous fortunes made in consequence, and industries created.

About the middle of the last century, Huntsman invented the process of fusion of blister steel for the making of homogeneous cast steel, and the methods and details still pursued are, in all essentials, identical with those invented by Huntsman. It is not a little singular that although the method of fusion had long been followed in India in the production of wootz, the practice is so recent in England.

In 1839, Josiah Heath patented the addition of manganese to cast steel, by which the quality is so much improved, that inferior blister steel will yield cast steel of superior soundness and weldability. The addition of manganese is also absolutely essential to the strength and toughness of Bessemer and Siemens' mild steels.

In 1855 Bessemer patented his method of blowing air through melted iron for the production of mild steel. By this process, no less than 7,500,918 tons of steel were produced throughout the world in 1887.

A few years later Siemens invented the open hearth methods, the regenerative furnace and gaseous fuel, by which 1,672,340 tons of steel were made in 1887.

Simultaneously with the development of the Siemens' open hearth process for the manufacture of mild steel, a great revolution has been taking place in the methods of manufacture of malleable iron. The dry puddling process, perfected by Cort, is being rapidly supplanted by the wet puddling, or "pig boiling" process, in which the grey cast iron is melted on the hearth of a reverberatory furnace, in contact with substances rich in oxygen, by which operation the carbon and the foreign elements are oxidised, and the metal rendered malleable. The preliminary cost of refining the grey pig to white is thereby saved.

My summaries in this article have related to *metal*; my next will relate to *men* and their work.

(To be continued.)

ARTISTIC FURNITURE
EASILY MADE AND CHEAPLY PRODUCED.

BY DAVID ADAMSON.

II.—A Screen Secretary.

Uses—Construction—Principal Dimensions—Shaped Brackets—Writing-Flap—How to Fix It—Backboard—Shrinkage of Wood—Interior Fittings—Candle-Sconce—Shaped Bottom Pieces — Castors — Screws and Screwing — Fasteners for Lid — Lock — Lining of Writing - Flap — Mouldings — Flutes—Other Uses.

The little piece of furniture shown in Fig. 1 is distinctly a "fancy" article. It holds no recognised place among the things usually looked upon as necessary in domestic furniture, but is one of that large class of more or less useful and ornamental oddments of the "here-to-day-and-gone-to-morrow" kind. For want of a better name I have called it a screen secretary, fulfilling as it does the purposes of a writing-table and draught- or fire-screen. Perhaps a small writing-desk and shelves, self-supported, would be a better definition, for the screen is merely a necessity of its construction. Still it may be used as the latter article.

Whatever it may be called, however, it is a useful little thing, and ought to be a welcome addition to our home comforts. It occupies little floor space, very little more indeed than an ordinary fire-screen, while for writing at it is at least as handy and convenient as the common davenport. Those who require a large writing-table will, of course, not find it suited to them, though there is no reason why the same principle of construction should not be applied in much larger sizes than those named for the small one about to be described. This will be found useful enough for occasional writing, and its portability is a recommendation. In winter it can be moved near the fire, while in summer it affords a convenient table by the open window. Any amount of ornamentation can be lavished on it, but in accord with the object of these papers it is purposely shown with little or no decoration. Those who wish to add this will readily see that carving on the ends and front of the writing-slope affords a ready means of ornamenting, as does fretwork or the application of marquetry panels. However, plain as it is, and of old packing-case stuff though it may be, if cleanly made and finished with enamel paint, it will form by no means an unsuitable piece of furniture even for a drawing-room. So far as utility is concerned, it will, however, not be out of place in any room, and those who want to give something more than useless knick-knacks to bazaars will find this a very welcome change. Those who have some knowledge of joinery will hardly need any instructions for making such a simple thing, and novices need not despair of turning it out satisfactorily, if they will make good use of the square, and take their time over the work.

For the general principles of the work, I must refer to remarks in a former chapter where the construction of an overmantel is described, and proceed at once to say what may be necessary about the special features of the thing in hand. Fig. 2 shows the front of the contrivance; Fig. 3 the end with the shelves, fall, back, etc., in section, the fall, or writing-flap, being shown shut in both of them. The scale to which Figs. 1 and 2 are drawn is $1\frac{1}{2}$ in. to the foot, so that each $\frac{1}{8}$ in. of them represents one inch in actnal size, or approximately so, for very small dimensions cannot be accurately gauged from diminutive working drawings. Though large enough for illustrative purposes, I strongly once more recommend the maker, before cutting his wood, to set out a full-sized drawing. This need not give more details than are shown on Figs. 2 and 3, where any that would be likely to confuse are purposely omitted.

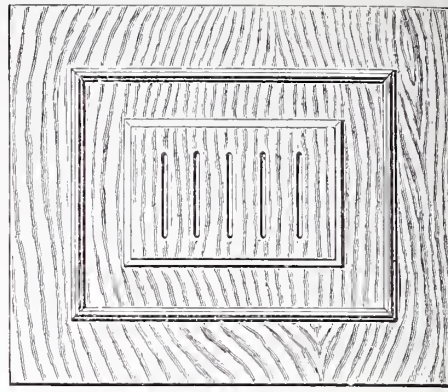

Fig. 9.—Lid with Mouldings and Fluted Panel.

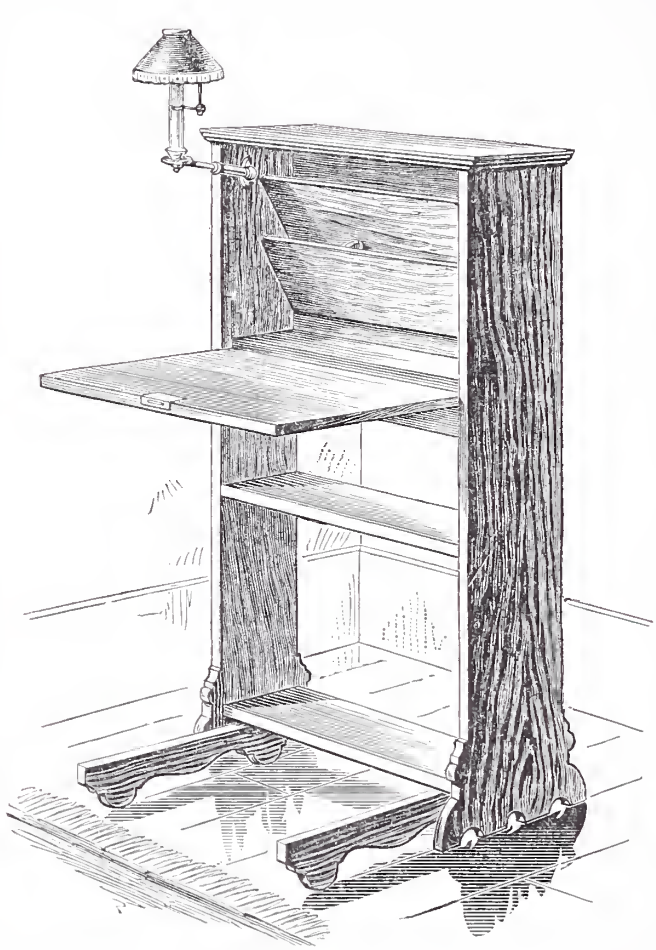

Artistic Furniture. Fig. 1.—A Screen Secretary: Perspective View.

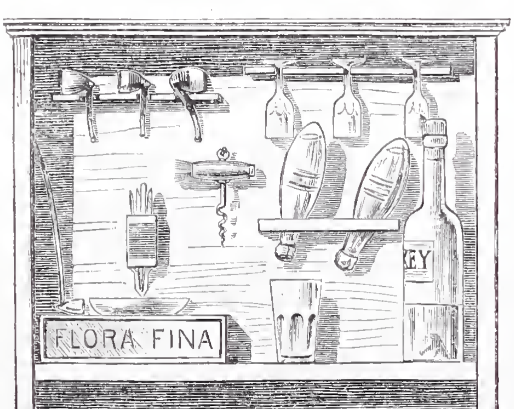

Fig. 11.—Another Arrangement for Interior.

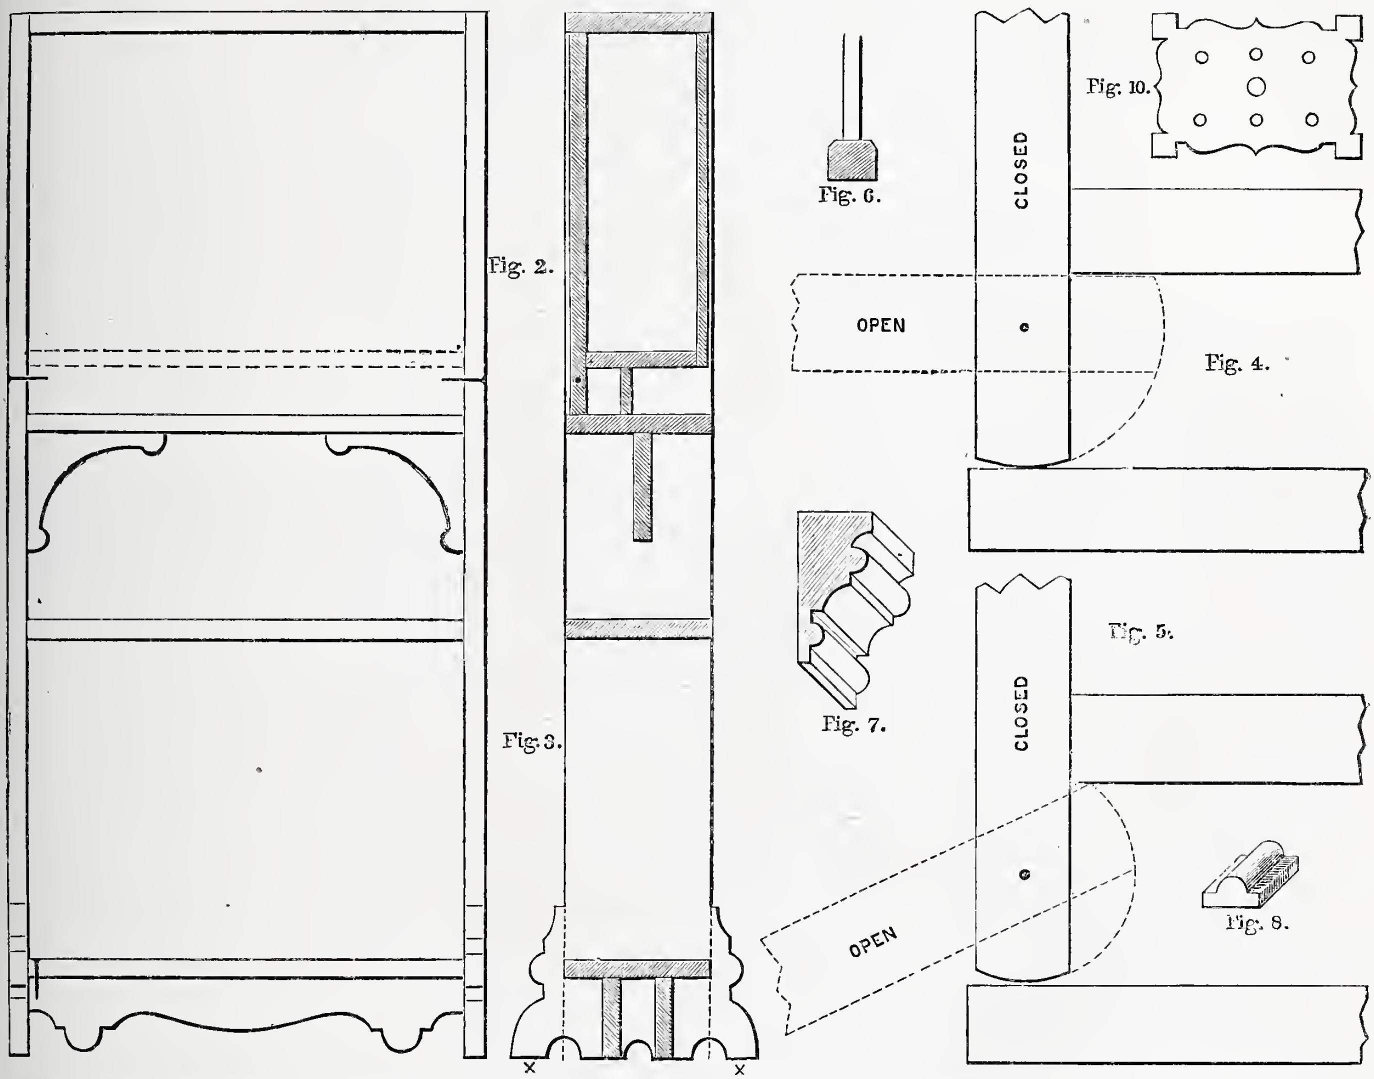
By the drawings we find that the principal dimensions are as follows:—height, 3 ft. 8 in.; width from side to side, 1 ft. 8 in.; depth from back to front, on top, 6 in., and at bottom, 12 in. Taking the thickness of the ends, and, indeed, all the rest of the material, as 1 in., the top piece will be 1 ft. 6 in. long. This, as will be seen from Fig. 2, is nailed within the ends, like the two lower shelves and the bottom of the writing part, all of which must consequently be exactly the same length as the top piece. Three nails in each end of a shelf will be sufficient to hold it.

The two shaped brackets under the shelf at the bottom of the fall will serve to stiffen the work, which, without some such contrivance, might be apt to be strained. They, therefore, not only serve to break the monotony of straight lines, but are placed for a structural object, and should not be omitted, though *on paper* they may seem superfluous.

When this part of the work has been done, the writing-flap may be made to fit accurately into its place, for, as it will have to be made of several pieces, it may be supposed that to save time it has been previously jointed up, and left rather full, so that it might be reduced afterwards to the right size exactly. Though not absolutely necessary, it will be better for the grain of the wood to be from top to bottom instead of across the flap. See that both surfaces are planed as smooth and level as possible, for one will be visible when the flap is closed, and the other is, of course, the desk side. The former must be level for appearance, the latter for comfort's sake, so that any ridges at the joints must be carefully worked down.

Now the hingeing of the front or flap will demand some attention from those who are not accustomed to this kind of work, though, like a good many other matters, it is simple enough when it is understood. In Fig. 2, just below the dotted lines, will be noticed a nail driven through each end into the flap. In Fig. 3 the nail is indicated by a dot in the corresponding part of the drawing. On these nails, or centres —for there is a special kind of hinge for similar positions, known as centre hinges—the flap works. With a flap so hung it is evident that on pulling its top forward the part below the nail swings backward and upward till it is stopped by the narrow shelf indicated by the dotted lines on Fig. 2. Were this shelf not there the flap would fall into an almost vertical position. Recognising this principle, it is merely a matter of adjustment of the relative positions of this shelf and of the centres or hinges to get the writing-flap either level or at any slope that may be most convenient. It will be understood the slope is not variable at will. When once the hinge is fixed, the angle of the board is also, so it will be well to decide on what seems likely to be suitable before fixing either the narrow shelf or the hinges. For all practical purposes, however, the shelf, which really forms the bottom of the desk, may be fixed at the distance shown in the illustrations, above the one below it—viz., about 2 in. By merely placing the hinge more or less distant from the lower edge of the flap, sufficient range of choice can be got.

To make this clearer, Fig. 4 is given, showing the position of hinge, *i.e.*, its centre or pivot when the flap is to be horizontal; and Fig. 5, with a considerable slope. These diagrams, I imagine, are more explicit than any verbal description, and will enable any one to set out the slope for himself. It is only a matter of compasses and measuring, and it will be more beneficial to exercise a little thought than simply to be told to place the hinges at such or such a distance for any particular angle that may be required. If work is to be of any value to the worker in an educational sense—and it may freely be conceded that novices' work is not worth much in any other—it is better to understand the principles than to work only to measure to definite directions. Without a knowledge of principles of his craft no man can become a competent worker, however good he may be at routine work. Hence about this hingeing no precise measurements are given now, but those who want them and cannot work them out for themselves may apply through "Shop" columns. The important matter of the position of the hinge being decided, it must suffice to say that a large screw-nail working freely in the ends and screwed into the flap will do very well as a substitute for the proper centre hinge. The head may be sunk and the hole covered with a small turned button. Those who want to know more about centre hinges may be referred to the articles on Hinges and Hingeing, in Nos. 5 and 7, pages 74 and 103.



Artistic Furniture. Fig. 2.—Front. Fig. 3.—End (Scale, 1½ inches to 1 foot). Figs. 4, 5.—Diagrams showing Mode of Hingeing. Fig. 6.—Section of End, with Block for Castor. Fig. 7.—Moulding, Elliott's Registered Design, No. 1071. Fig. 8.—Moulding, Elliott's Registered Design, No. 1001. Fig. 10.—Shaped Panel.

The board enclosing the back—and by "board" it will be understood that two or more may be jointed to get the necessary width—is fastened to the back edge of the compartment bottom, and underneath the top, through which one or two nails are driven to hold it securely, in addition to one or two through the ends. I am aware that this is not particularly good joinery work, as, unless the back is thoroughly dry, almost baked, in fact, it will, through having no opportunity for play, be apt to split. It may stand, and probably will, if the wood is quite dry. In all joinery theory is one thing and practice another; so it may be some consolation to the amateur to tell him that many thousands of articles of furniture are made every year without any allowance being made for shrinkage or expansion, and that such work, defective though it be, from a purely theoretical point of view, is quite serviceable when the wood is perfectly seasoned and dried before fixing together. All that can be done is to allow some play wherever it may be convenient, and in the present case rabbeting and precise joinery cannot be considered so. In all such circumstances the utmost that can be done is to take care to keep the direction of contraction as limited as possible, which means that the grain of the wood will run across from end to end, not from top to bottom.

I do not know whether I have already said in these articles that wood does not shrink in length, but in width; if I have, the fact being an important one will bear repetition, as the recognition of it will save many a constructive error. For this reason it will generally be found that in good cabinet making the grain of the wood is in the direction of the greatest measurement—viz., length not breadth. As will be seen from Fig. 3, this backboard may be of some thinner material than the rest of the job—½-in. stuff will do very well—and it will also be observed that it is set in a little, that is, the hinder edges of the top and ends project a little beyond its outer surface.

While we are at this part of the work it may be as well to call attention to the interior fittings, which are made of thin wood —¼-in. stuff; but even thinner than this will do. The bottom, which stops the flap, will do very well to hold ink, pens, etc., while the sloping racks will afford storage for note paper, envelopes, etc.; and as requirements will differ, it has been thought best just to indicate the method of utilising the space by a simple arrangement. The ends of the sloping boards are supported on thin slips of wood glued to the ends. The boards then rest on them, and, if necessary, are further secured by a glued block or two behind. Any partitions may be easily fixed without grooving by cutting them neatly and securing with a little glue and a few small brads or needle-points. If preferred, of course the sloping boards may be placed level as shelves, but by having them as shown, larger paper can be kept in them. Those who want something simpler even to keep their papers tidy will, no doubt, be aware that convenient little receptacles may be made by nailing tape across, leaving, of course, the spaces between the nails sufficiently loose for the purpose. The same use may be made of the ends, which are large enough for post-cards and envelopes, while a couple of cup-hooks, screwed into the back, will support a ruler. Indeed, by economising space, and with a little contrivance, it is astonishing how much in the stationery line such a little thing will hold.

The candle-sconce is another suggestion which may be welcome to some. It is merely one of the kind commonly seen on pianos, so that it can be folded inside when the lid is closed. It may occur to some that a sconce, or one at each end outside, would be not only a useful but an ornamental adjunct. If so, there is no reason why they should not gratify their tastes, only to be in harmony with the screen, the sconces should not be over elaborate in design.

Nothing so far has been said about the shaped bottom pieces, by which stability is given. They are merely small pieces cut out and glued to the edges of the ends, as indicated by the dotted lines in Fig. 3. Care must of course be taken that these shaped pieces are of exactly the same thickness as the ends, and also that they are uniform at the bottom, or otherwise the structure will not stand firmly, but rock in an unpleasant manner, when in use. It may seem ridiculous to call attention to this, but the novice, who has never tried it, will probably find the difficulty of "truing" the ends somewhat more difficult than he imagines. It may be done after a fashion, so that there may be no rocking; but this will hardly suffice to satisfy a critical eye, as, in addition, the upright surfaces must be perpendicular. Indeed, if I may so express it, squares, levels, and perpendiculars are the proper signs by which we may know that the work has been thoroughly done. If these are wanting there is something amiss.

Now, the bottom ends, widened as they are, ought to be enough for stability in the screen form, but it will be evident that some additional support will be necessary when the lid is down and being written on. Unless the shelves are loaded with books, or something heavy to counteract the leverage of pressure on the flap, there would probably be an upset. Such a catastrophe could be easily avoided by making the ends wider still at the bottom, but then look at the space they would occupy; and be it remembered, compactness is one of the chief features of this little writing screen. If it is to spread itself over the floor twenty inches or so, whenever it is wanted as much out of the way as possible, well one of its great recommendations is gone. Better have a regular writing-table instead. But we can still get the necessary stability by having hinged supports underneath the bottom board. These are shown extended in Fig. 1. Their shape is shown in Fig. 2, and their relative positions when closed in Fig. 3. They are hinged to the bottom shelf by a large screw driven through each at alternate ends, and as near the ends as convenient. If the screw is driven in from above, as indicated in Fig. 2, the hole in the board should be large enough for it to work freely, not loosely mind, but just enough to let the tighter hold of the thread in the movable piece remain undisturbed. Perhaps the appearance of the screw-head may be deemed objectionable. If so, run the screw in from below, through the thickness of the swinging bracket, and in this case the thread must bite in the shelf, therefore, the hole in the bracket must, in this case, be the larger of the two. It will be seen that the screw acts as a centre hinge, precisely as already indicated for the writing-flap. The ends of the brackets or supports will have to be rounded off to give clearance and allow them to be turned; and if they are cut to exact length, the free end will require a little bevelling off to its inner side; for it will be clear, that if a tight fit, and cut quite square on the end, it will jamb on attempting to move it. When not required for use, these hinged supports are out of the way, and rather ornamental than otherwise in appearance.

Possibly, some may prefer to have the whole thing on castors, so that it may be moved from place to place without lifting. If so, I would only say that "pin" castors should be used. These are so-called to distinguish them from the socket castor, as they have a screw or pin which can be let into the wood. Obviously, a socket into which a leg might be fitted would be unsuitable here. If castors are used—mind, I do not recommend them for this screen—they should be placed as near the ends of the bottom as possible: two to each end, as shown by the × on Fig. 3. Care must be taken that the plate of the castor is not greater in diameter than the thickness of the wood to which it is attached, if appearance be regarded. However, it may not be practicable to manage this, as the wood may be too thin to take a strong enough castor, and a weak, unserviceable one is nothing but a nuisance, whatever piece of furniture it may be on. Some of the "direct bearing" castors are good enough in their way, many of them perfect, till they are tried; but when all is said, there is nothing better for general purposes than the ordinary style, when of good quality and properly fastened, and, of course, sufficiently strong for its work.

In the round plate referred to will be seen some holes. They are for screws to support the central one, and let them be long enough. The little paltry screws, *hammered* into common furniture, are no use at all. If for any reason a castor-plate larger than indicated is advisable, this is how it may be fixed: Along the bottom, underneath the ends, fasten a rail as shown in section, on Fig. 6, and screw the castor into it. The screws will also hold better by this arrangement, as they will not be driven into end grain. Those who do not want castors on the ends may think that they will be a convenience on the hinged supports, and wish to have them there, but beyond giving the hint, any minute instructions can hardly be requisite.

Some sort of fastening will be required to keep the lid up when it is not in use for writing purposes; a spring catch may be used, or if it is desired to keep the contents of the case from prying fingers, a lock. The kind required will be a "till" lock, a space for which must be cut out where shown in Fig. 1. No difficulty should be experienced in doing this with a chisel, the principal caution I would give being, to see that the surface of the back of the lock and that of the writing-lid are equal. The part of the plate through which the bolt works will take care of itself, so far as projecting beyond the wood is concerned, for if it sticks out much, a well-fitting flap could not be closed. On the other hand, do not let it be sunk too deeply, but try and keep the surfaces uniform. A hole will have to be cut in the top for the bolt to catch in. Its exact position may be easily ascertained by smearing a little gas black, or any colour that may be handy, on the top of the bolt, shutting the lid and then turning the key. This will force the bolt against the top, and an imprint will be left just where the space must be cut. Rough and ready perhaps, but a thoroughly good "workshop" way.

But we have supposed the lock to be working without a key-hole. To form these neatly is not easy at first, and the power to do so can only be acquired by practice. The shape of a key-hole is too well known to require any description, and all I would say to the novice at present is this: Cut it as accurately as you can, and if it does not, in the end, look sightly, get a "plate" escutcheon, which is nothing but a small plate of brass, with a hole cut for the key, and screw it in position. The plate will hide any defective shaping of the hole in the wood, and be, in itself, an ornament. The thread escutcheon which is sunk into the key-hole may be used instead, but the other form is better, for the reasons given.

I am compelled for want of space to reserve my remarks on the lining of the writing-flap, mouldings and flutes in panel (Fig. 9), and other uses to which the secretary may be put. One of these is shown in Fig. 11, which I think sufficiently explains itself, and warrants us, almost, in naming the screen so fitted as the "Smoker's Companion." What's in a name? Ah, what! otherwise from appearance of the contents it might be called the teetotaler's *vade mecum*. Liquids to be partaken of medicinally—only—of course.

(*To be continued.*)

A HANDY CASKET FOR COIN COLLECTORS.

BY ONE OF THEMSELVES.

About Coin-keeping—Character of Casket—Dimensions—Joints—Carcass—Base Strips—Feet—Lid—Trays—Sweeping of Coins—How to Keep Coins in Place.

We coin collectors are accustomed to speak of our treasures in the lump as "a Cabinet of Coins," but this does not imply that every one of us keeps his collection in a cabinet, in the strict sense of the word. I for one do not. Granting that a cabinet has its advantages as being the most accessible of receptacles, it has also its objectionable points. Our hoards have an intrinsic value, and are attractive to the too-appreciative burglar; and it is, in my opinion, well to keep them in something which can, when occasion arises, be more easily removed to a place of safety than a cabinet.

My plan, therefore, is to arrange my collections in a sufficient number of handy boxes. During the years that I have made a study of numismatics, I have devised and tried many methods of disposal, and may, therefore, be able to throw out suggestions worth the consideration of my brother collectors. The box—or call it a "casket," the word sounds better, and is, indeed, more appropriate, both in respect of its ornamental shape and of the value of its contents—the casket, then, which I am about to describe is one of a series, and is the outcome of some experience. I think I may claim that three or four of such caskets, when set out to view in a room, are decidedly sightly things, and that they are easily stowed away in some secure and secret nook when safety is an object; also, they have this advantage, they enable one to arrange a greater number of coins in a given space than could well be done in any cabinet. The casket before us, with an internal measurement of only 10 in. by 6 in. by $4\frac{1}{2}$ in., holds, as fitted by me, nine trays, which give a surface of some 540 square inches. This means room for the exhibition of a very considerable number of specimens.

But before speaking of the internal arrangements, it will be well to give such a description of the box itself as will enable any one with a fair knowledge of the handling of carpenters' tools to make it for himself. My own casket, as will be seen from the illustrations, is carved, but made of some ornamental kind of wood the thing would look very well without carving.

A general view of it is given in Fig. 1, and in Fig. 2 is shown the front piece, drawn to half-size. Its dimensions are 11 in. by $4\frac{1}{2}$ in. It is of $\frac{1}{2}$-in. oak, as are also the back and the ends. The back is like the front, only it is not carved. The carving is of that simple kind which is worked almost entirely with the gouge and the dividing-tool, and which, though effective when finished, does not take long in the doing. The end pieces measure 6 in. by $4\frac{1}{2}$ in. No separate illustration of them is given, as the carving is almost identical with that on the front, the only point of difference being that in the ends the conventional foliage on each side of the half circle is a trifle wider.

At each end of the front (Fig. 2) are shown the screws, three in number, which fasten the box together. Probably a professed carpenter would not have been happy unless he had dovetailed these joints. I have enough of the craft to have dovetailed them had I been so inclined. But I knew that I could give abundant strength to my work in the more simple manner, and I chose to have the screws and to make a decorative feature of them. Dovetailing would have interfered with the ornamental character which I wished to give to my corners. The bottom of the box is merely a piece of $\frac{1}{2}$-in. deal, which is screwed to the front, back, and ends. The edges of this are completely hidden by the carved base strips (Fig. 3) which are screwed over them.

I first fitted the carcass of my box together, and having got it to my satisfaction, unscrewed it and worked the carving on front and ends; but it was not till I had put it together for the second and last time that I scolloped out the corners at front and back with a large gouge, as shown in the perspective drawing (Fig. 1), and indicated at the ends of Fig. 2. This scolloping was but the work of a few minutes; it does not weaken the casket, and it adds very much to its ornamental character.

In Fig. 3, a portion of one of the base strips which run along the bottom is drawn at full size. These strips were cut from $\frac{3}{4}$-in. stuff, but worked down so as not to be more than about $\frac{5}{8}$ in. broad and deep. The front and back strips are $12\frac{1}{4}$ in., the end strips $8\frac{1}{4}$ in.—or rather were so originally, for the finishing off at the corners, which is done after they are fixed in place, reduces their length by $\frac{1}{4}$ in. These are fixed to the edge of the bottom by slender screws. The back strip is left uncarved.

One of the feet is seen in profile at Fig. 4, and in plan at Fig. 5; both these figures are of the actual size. The feet are of $\frac{3}{4}$-in. wood, 3 in. long, and $1\frac{1}{2}$ in. wide at their widest part, but decreasing to $\frac{3}{4}$ in. at front. They project at the corners about $\frac{1}{2}$ in. beyond the base strips and 1 in. beyond the box itself, as is indicated by dotted lines in Fig. 5. Each foot is fixed by two screws, one driven upwards into the bottom of the box, and one driven downwards through it. These screws are shown in both the diagrams, and are both on the diagonal line (a, Fig. 5) drawn from the corner of the box.

The lid is cut to overhang the front and ends by $\frac{1}{2}$ in.; it therefore measures 12 in. by $7\frac{1}{2}$ in. It is of $\frac{3}{4}$-in. board, and is, for the sake of appearance, planed down at the edges to $\frac{1}{4}$ in., as seen in the section, Fig. 6. The slight enrichment cut with the gouge along its front and end edges is shown in Fig. 7. The former illustration is half-size, the latter full-size.

It has been mentioned that the internal arrangement for displaying the coins was by a series of trays. The casket is $4\frac{1}{2}$ in. deep, and as it was intended for heavy examples (chiefly tokens), the trays had to be strongly made. Half an inch was allowed for each, which gave nine trays. Had the coins been of a lighter description, as, say, a series of English silver pennies, trays of a slighter build would have sufficed; by allowing $\frac{3}{8}$ in. only for each, room might have been found for twelve trays.

In Fig. 8 is shown a section, to half-size, of one of the trays as actually made. It is of $\frac{1}{6}$-in. deal, ebonised at the edges, and secured by small screws at each end to a narrow strip of hard wood. A slip of coloured leather (b, b, Fig. 8) fixed to the under side of the hard wood by a tack, serves as a handle by which to lift the tray. This tray is strong and simple, and easily made.

My earlier attempts in this direction were not exactly as above. My first trays were made with rims running all round, and the coins were arranged loose in them. Now, if no examples came to one's hands but such as are perfectly distinct and legible, this plan might suffice. But such is not the case. Many pieces there are to which even an expert has to give close and careful study before he can decipher them, and such coins, when once made out and identified, it is desirable to keep distinct, each with its own proper description; or one may have the same work to go through again.

Therefore my later plan has been that shown in Fig. 9, and when this is adopted no sides are needed to the trays. A piece of millboard is cut to fit the tray, and through the board round holes are punched with the gouge, each to serve as a compartment for a coin. Before the millboard is fixed to the tray a sheet of writing paper is pasted over its lower side. This makes a bottom to the compartment, and prevents any danger of thin coins slipping between millboard and tray. Then the board is fastened down with a few neat brass tacks. On the paper at the bottom of the compartment one can write any short needful description of the coin that is to occupy it; and whenever, in those rearrangements which must needs occur in growing collections, a different coin has to be substituted, it is easy to cut out a circular piece of paper, write the new description on it, and paste it into the hole over the old.

It may be objected that the varying sizes of coins will render rearrangements difficult—that the new examples which we wish to place in certain situations may not fit the holes. This may happen, and if it should do so—if a larger hole is absolutely necessary—the millboard, which is only tacked down, can be detached from the tray, a larger hole punched, and a separate piece of paper pasted over it. But in arranging coins, the necessity for keeping all of one reign together, regardless of size and value, does not appear to me to be absolute. A grouping of pieces which do not greatly vary in size may frequently have as much completeness and interest.

Take, for example, our silver pennies. Of these a complete series from the days of the Heptarchy to the present reign may be disposed in compartments $\frac{8}{10}$ in. in diameter; and if the recent pieces do but indifferently fill their holes, the decreased value and importance of the coin is all the more forcibly illustrated. And a most instructive series is one of pennies ranged alone. Through Saxon times the silver penny was all but our only money; it was absolutely so through Norman times. The silver penny of those ages explains to us the now almost unmeaning terms of a "pennyweight," and of a "pound" as applied to value, for down to Edward I. the penny, by the old Tower standard, weighed 24 grains; 20 pennies made an ounce; and 240 pennies a pound of silver, alike by weight and by tale. By modern Troy weight these pennies weighed $22\frac{1}{2}$ grains, from which, by successive curtailments, they had sunk in Elizabeth's reign to the meagre proportions of the "Maundy" penny of to-day—that is, to $7\frac{1}{4}$ grains (Troy). These latter degenerate pennies will fail to fill their holes by some $\frac{3}{10}$ in., which will not, however, involve any very serious loss of space.

Or the eighteenth century tokens, the numbers of which give them an importance in every collection, might be instanced. This prolific coinage was so generally an issue of halfpence, that pieces of other denominations look out of place in it, and may well be—as they have been from some of the most comprehensive collections—culled out to find a place elsewhere. Compartments of $1\frac{1}{4}$ in. diameter will take all these halfpennies.

Similarly, the seventeenth century tokens, issued so abundantly in the few years preceding 1672, are almost exclusively of a small farthing size, and might, with few exceptions, be relegated to uniform holes $\frac{7}{8}$ in. in width.

All coins cannot, however, be made to conform in this respect; and at Fig. 9, one half of the tray given has been divided into uniform $\frac{8}{10}$ in. compartments, and the other into holes of such varying sizes as best economise space. This diagram also shows how the respective trays are numbered.

Caskets of this description have, as the writer has found to his sorrow, one weak point unknown to stationary cabinets. In careless lifting—as for dusting, etc.—coins may be jerked from their places and hopelessly mixed together. This has been remedied by fitting over each tray a second piece of millboard, which, closing upon the holes, keeps every coin in its proper place. Indeed, these shutters, being covered with writing paper, can be turned to very considerable advantage. They are numbered like the trays, and each compartment having also its number, the shutter can be converted into a register of such information about the coins beneath it as is too bulky to be written in the compartments themselves—such as where and when the example was found, how it was obtained, and from whom, the price given for it, etc. I have used one side only for this purpose; the other I have appropriated to such general numismatical memoranda as one desires to be able to refer to easily when looking through a collection—such as, for instance, the reigns in which pieces of the different denominations were first struck, or ceased to be issued, variations in weight under different kings, the rarity or abundance of this or that; and in connection with Roman coins, explanations of the abbreviations used: with other similar matter. These shutters are thus converted into a highly useful adjunct to the collection, and renders it far more valuable if any necessity arises for disposing of it.

LATHES AND TURNING APPLIANCES.

BY F. A. M.

V.—The Division Plate and Index.

Principles of Division Plate—Simple Appliance—How Powers of Lathe are Augmented—Regulation of Divisions—Material for Plates—Drilling Holes—Peg—Adjustable Index—Table of Divisions—Cost of Drilling.

Those who are acquainted only with plain turning, whether in wood or metal, may well wonder when they see the beautiful regularity with which ornaments and other enrichments are spaced round turned work. The flutes upon a column, for instance, are so correctly spaced, that no inequality can be detected by the finest measurement. The teeth of cogged wheels too—produced with such wonderful accuracy—what kind of apparatus can give so many equal divisions, ending always in a whole number, and never in a half tooth breaking two spaces into one? All this can be done by means of the division plate and index.

Let us suppose that you have turned a stand, and wish to mark the holes for the insertion of six legs or ornaments; or, that you have turned up a blank for a six-sided nut, and you wish to mark six equi-distant lines upon it, to guide you in filing it up. You can, of course, do this rather awkwardly with the dividers; it will take some time, and you will not get the work very exact, besides the trouble of repeating the process for every nut or other object requiring division. But suppose you began by dividing the pulley on the mandrel into six, making a mark at each division, and providing a fixed pointer; or, still further, if you were to drill six small holes at these six divisions, and fix a spring pointer with a little peg that would enter the holes and hold the mandrel fixed at the six angular positions; you would then have constructed a division plate and an index peg, and it could be used to divide any number of circles into six divisions.

I think my readers will understand from these simple examples the principle on which the division plate is constructed, and also be led to see that it is really an important and valuable addition to a lathe; it allows of equally spaced divisions being placed around circular work, enables us to determine and draw angles upon flat surfaces, and, by means of the index, to hold the work fixed whilst we scribe or draw lines upon it, or operate upon it with drills or revolving cutters.

As to scribing or marking lines upon the work, such, for instance, as the six lines which would be drawn upon a circular blank, to guide the workman in producing a hexagonal nut; or, again, in marking the angular divisions on a protractor, something is required to guide the scribing point; the top of the T-rest is indeed sometimes used, but only when accuracy is not required. A very simple appliance is shown at Fig. 16. This is only a flat-rimmed saucer of hard wood, about 3 in. diameter, having a round stalk or pin which fits the socket of the T-rest. If the hole in the T-rest socket be vertical, and at right angles to the lathe bed and the line of centres, then the saucer will provide a support and guide for the scriber seen lying upon it (Fig. 16), which will keep its point in one plane, and enable

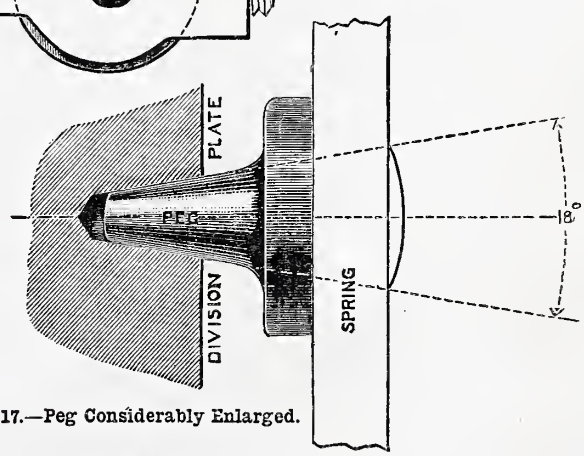

Fig. 17.—Peg Considerably Enlarged.

lines to be struck upon uneven surfaces, if only the scriber point be first adjusted to the exact height of the centres of the lathe. For this kind of work the band is simply thrown off the pulley, and the lathe is at rest. But, when drilling is to be done, or the revolving cutters are to be driven, then the treadle and wheel, not being required to drive the mandrel, are available for driving these by means of the overhead motion. We may consider the *plain* lathe as a machine for revolving work whilst it is being cut by stationary tools held either in the hand or in a slide rest. When, however, we add to a lathe the division plate and index, and the overhead motion, the lathe proper may simply hold the work stationary, whilst the cutting is done by revolving drills and cutters. By revolving the *work only*, circular and flat work can be done; by revolving the *cutting tool*, work of almost any regular shape can be accomplished, and the powers of the lathe are immensely increased. It must, however, be clearly pointed out that a division plate and index *alone* will only serve for marking out work as already explained; if fluting, slot drilling, eccentric cutting, etc., are to be attempted, not only the division plate, but also the overhead motion and the slide rest, are necessary, besides the driller, eccentric cutter, universal cutter, etc., which hold the small revolving tools, and are themselves held in the slide rest, whilst being driven from the overhead.

We will now proceed to consider how many divisions it will be convenient to have, and this will be determined partly by the class of work we intend to do, and partly by the size of the pulley, and the number of rows of holes for which we have room. The larger the pulley, the more holes we can get in; if we are going in for wheel cutting, we shall require rather larger holes than for ornamental turning; but in every case you require to choose those numbers which have the greatest number of divisors; 360 is a most useful number, having more divisors than any other not much greater than itself; and it was for this reason that it was chosen for the number of degrees in a circle. There is some difficulty in getting in so large a number, since the pulley of a 5-in. lathe will not be much more than 7 in. diameter. If we put the centres of the holes only $\frac{1}{16}$ in. apart, and allow $\frac{2}{3}$ of that distance for the hole, and $\frac{1}{3}$ for the space between the holes, we get holes of $\frac{1}{24}$th, and spaces of $\frac{1}{48}$th; then we shall require a circumference of $360 \times \frac{1}{16} = 22\frac{1}{2}$ in., eorresponding to a diameter of a little over 7 in. Such small holes are only fit for ornamental work. If you allow holes of $\frac{1}{16}$ in. and spaces of $\frac{1}{32}$ in. the holes must be $\frac{3}{32}$ in. from centre to centre, then $\frac{3}{32} \times .360 = 33\frac{3}{4}$ in. gives the required circumferenee, and corresponds to a diameter of about $10\frac{3}{4}$ in. of pulley, which would require a height of centres of 7 in. Enough has now been said to show how to reckon what number of holes ean be got into any sized pulley. Holes of $\frac{1}{24}$th are too small for any but the finest work; holes of $\frac{1}{16}$ in. will do for *small* wheel cutting; holes of $\frac{1}{12}$ in. are good for metal work, and will suffice for anything likely to be required of a division plate. In ornamental and other work, it will be necessary to divide the circle into 2, 3, 4, 5, 6, 7, 8, 9, 10, etc., parts; and, therefore, the most useful numbers of holes will be those which can be divided by as many of these numbers as possible, without leaving any remainder. Such numbers can be found by multiplying together two or more of the above numbers. For instance, we may multiply 8 and 9 to get 72 holes, a very good number, since it contains multiples of 2, 3, 4, 6, 8, 9, 12, 18, 24, 36. Here we have all the first-named numbers but 5, 7, and 10. Now 5 is already contained by 10; if then we make up another number by multiplying 7 by 10 to make 70, we get another number of holes, which will allow us to divide the circle by any number up to 10. This will suffice to show how these numbers are chosen, and also that the chief difficulty is with the prime numbers, 1, 3, 5, 7, 11, 13, 17, 19, etc., which are not divisible. The first four of these we have managed to include; the second four are seldom required, except in wheel cutting. It is possible—though probably not worth while—to include them by placing them all in one line, or circle of holes. Beginning from one zero hole, divide the circle first into 11; then beginning from the same zero, divide the *same* circle into 13, then into 14 (for 7), then into 17, and lastly, into 19. If this be done on a $6\frac{1}{2}$-in. circle, with $\frac{1}{16}$-in. holes, they will not clash. It would be well, however, to choose higher numbers than 70 and 72, and we may sometimes have a good many rows. In the ornamental turning lathes by Messrs. Holtzapffel & Company, the numbers chosen are 360, 192, 144, 120, 112, and 96; there is no necessity to have 96 as well as 192, except that it sometimes facilitates the counting; also, many of the chuck wheels are divided into ninety-six divisions, which makes it convenient to have a circle of that number on the pulley. If ornamental turning is the object in view, it is of some importance to adopt these numbers, because, in the books treating of that art, patterns are given with directions for cutting them, which directions could not well be followed upon circles having other numbers. If, therefore, they can be adopted, it is well to do so; but if there be not room for the 360 row, it might be well to substitute a row of 180 (half that number) between 192 and 140, as that would, at any rate, enable the workman to divide a circle into divisions of 2°. If there be room for only three rows of holes, 180, 144, 96, or 180, 96, 84 would do well.

Cast iron is the best material for a division plate, being the most durable, and least likely to be indented or bruised; gun metal is the most usual material, and it shows up the numbers and marks well; yellow brass is too soft for such a purpose. The point of the index peg should be carefully rounded, lest it should scratch the plate.

In many division plates the holes are simply drilled straight in, about $\frac{1}{16}$ in. deep, whilst the peg is slightly coned, so that it only bears upon the mouth or edge of the hole. The holes should be coned to an angle of about 18°, being drilled by a very short and special drill, made to cut upon its sides; the peg must then be turned to the same angle, and should be very short, so that the spring will come up close to the plate. Fig. 17 shows the peg enlarged about six times; Figs. 18 and 19 show the index spring bent round at the top for the finger, the peg being riveted in. At the bottom, a slightly tapered pin is riveted into a second hole, $4\frac{1}{2}$ in. from the first. This tapered pin fits into an iron or steel ball, which is screwed into the base of the headstock, seen dotted in Fig. 19. The shoulder of this ball would have to be gradually turned away until, when screwed up hard, the spring comes upright when the peg is in position, as at Fig. 18. The spring itself will require to be about $\frac{1}{16}$-in. thick, and this arrangement is known as the *plain* index. Its application to the pulley is illustrated in Fig. 20.

Figs. 21, 22, 23, show a very simple form of *adjustable* index. It was made from the plain one just described, by heating the top of the spring, and bending it to the form at Fig. 21. The peg of the plain one was driven out, and two holes were drilled above and two below the original hole into which the peg had been riveted; these five holes were then filed into one oblong slot, as seen at Fig. 22. The new peg, Fig. 23, was then turned and fitted with a nut (n) to bind it fast to the spring, and prevent the slightest possibility of shake. The screwed part had two flats (f) filed, one on each side, so that it would fit rather tightly into the long slot, and could be moved up and down by the screw. A thoroughfare hole was then drilled through the top of the spring, and then, with the tapping sized drill, continued through the body of Fig. 23; then the adjusting screw of steel in one piece, with its milled head, was fitted, and the small retaining collar fixed, and pinned through as close as possible, so as to avoid all looseness. The milled head has its collar divided into about ten divisions, and there is a mark on the spring to correspond, but the explanation of the uses of that addition would too much prolong the present paper. The advantage of the adjusting index as compared with the plain one is considerable. It will often enable the workman to bring his flute, or his tooth (in wheel cutting), or his pattern (in ornamental work), to correspond with a part already finished. The ball in Fig. 22 is slightly different to that at Fig. 19, the screw (s) being added. This screw being fixed when the work of dividing is begun, prevents the possibility of placing the peg in a hole in another row; it fixes the conical fitting in the ball, so that it can no longer act as a hinge.

The zero marks of the circles of holes are placed together, but they are not placed upon a radial line, because then it would be impossible to pass from one circle to another without slightly turning the pulley, or altering the adjusting screw of the index. The zero holes from which each circle counts should be placed upon an arc of a circle struck upon the pulley with the point of the division peg.

The rows of holes should be, at least, $\frac{1}{4}$ in. apart, that there may be room for figures of a visible size, and for the dots, and other marks made opposite every 5th, 4th, or 3rd hole, to assist in the counting, by enabling one to put the index peg in every 5th, 4th, or 3rd hole without making a mistake, which would very likely spoil the work, since nothing looks worse than a false cut.

The table of divisors about to follow any one can make for himself, and the present one can be continued. It would be a good plan to copy it out on a card, varnish it, and keep it by the lathe for reference; or, at any rate, that part of it which corresponds to the numbers of holes in one's own division plate. Eleven convenient numbers have been chosen and written down in the column headed "No. of Holes"; then comes, in a horizontal line, the row of "Divisors," containing every number up to 20, except the primes 11, 13, 17, 19.

Looking along the first horizontal line, underneath the divisors, we find that a circle of 360 can be divided without remainder by twelve of these numbers..

Numbers 240 and 180 come next in value, since they can be divided by eleven of the divisors; 120 by ten; 300 and 144 by nine, etc. 112 and 70 have the fewest, but they contain multiples of 7. It would, however, be necessary to continue the table to make the comparison quite fair.

TABLE OF DIVISIONS.

No. of Holes.	Divisors. 2	3	4	5	6	7	8	9	10	12	14	15	16	18	20
360	180	120	90	72	60	—	45	40	36	30	—	24	—	20	18
300	150	100	75	60	50	—	—	—	30	25	—	20	—	—	15
240	120	80	60	48	40	—	30	—	24	20	—	16	15	—	12
192	96	64	48	—	32	—	24	—	—	16	—	—	12	—	—
180	90	60	45	36	30	—	—	20	18	15	—	12	—	10	9
144	72	48	36	—	24	—	18	16	—	12	—	—	9	8	—
120	60	40	30	24	20	—	15	—	12	10	—	8	—	—	6
112	56	—	28	—	—	16	14	—	—	—	8	—	7	—	—
96	48	32	24	—	16	—	12	—	—	8	—	—	6	—	—
72	36	24	18	—	12	—	9	8	—	6	—	—	—	4	—
70	35	—	—	14	—	10	—	—	7	—	5	—	—	—	—

The cost of drilling a division plate is about six to ten shillings for each row, and a plain index and ball cost about six shillings. By beginning with a worm wheel or segment engine, the writer was able to drill his own division plate, but an account of how this was done must be reserved for another time.

(To be continued.)

NOTES AT THE ARCHITECTURAL AND BUILDING TRADES' EXHIBITION, 1889.

(Continued from page 107.)

An important exhibit, not reviewed in our previous report, was that of Messrs. E. Jacobs & Company, 105, Queen Victoria Street, London, E.C. That firm of engineers and machinists have, for some years past, shown a knowledge of the requirements of wood workers, which gives to the machines produced by them a reliability and practical value which cannot be over estimated. Among the pieces of mechanism sent to represent them at the recent exhibition, a "Panel-planing and thicknessing machine," an "Improved hand feed surface planer," and the "Newington" mortising and boring machine, were, perhaps, the most important. The first named is made in two sizes, to suit various purchasers, the larger size being capable of planing up to 15 in. wide, and from $\frac{1}{4}$ in. to 4 in. in thickness. The timber is fed up to the cutters by two geared top rollers and two bottom friction rollers, the table being easily adjustable, by hand wheel and screw, to admit the thickness of wood required. The knives, being arranged to work spirally, give a shear cut; an improvement of great importance in the execution of good work. The "Improved hand feed surface planer" is intended for use by joiners, builders, cabinet makers, packing-case makers, pattern makers, and, indeed, most other wood-working trades, and contains the latest improvements calculated to perfect the operations of taking timber out of twist, surfacing straight or taper, bevelling, chamfering, squaring up, making glue joints, and a dozen other purposes beside. Of cabinet work and furnishing items the number of exhibits was somewhat small, but, notwithstanding that, some very good things were shown by those who did put in an appearance. Messrs. S. G. Vaughan & Company, 26, Great Eastern Street, E.C., fitted up a stand thoroughly representative of modern taste in furnishing, and the freedom from any taint of the French in their goods was most gratifying to the lover of national art in handicraft. Drawing-room furniture was shown in the richest of rosewood, inlaid with ivory and decorative woods, a mode admitted to be *par excellence* for that apartment; and the free and graceful forms marked out therein, and further embellished by silk brocatelle upholstery, spoke well for the bent of modern taste.

The development of furnishing in the nocturnal apartment was illustrated by a bedroom suite in walnut, and the wardrobe being made with accommodation for writing purposes, after the manner of the old-fashioned secretaire, showed that firm's knowledge of the requirements of to-day.

Another representative of the cabinet-making trade was the firm of Messrs. W. H. Vaughan & Company, 332, 334, Old Street, E.C., who provided a good display of drawing-room, dining-room, and bedroom furniture. Such goods as there is a certain demand for in these times were shown by those makers, and as they were just selected from the ordinary stock kept by them, their capabilities in that direction could be well judged therefrom. A fine sideboard, in walnut, was particularly noticeable, and for those who still adhere to a liking for saddlebag upholstery, Messrs. Vaughan proved themselves to be in a position to suit all tastes in that direction.

Mr. Ferdinand Falet, 10 Gray's Inn Road, W.C., displayed a very attractive variety of wicker furniture; and, for the Spring season, some of their dainty little wicker chairs, dressed up as they are with dhurries and other Oriental materials, would be quite the thing.

Now that the sunny season is approaching, the matter of window blinds assumes some importance, and the variety of those articles shown at the Building Exhibition left little room for complaint. Messrs. S. Mitchell & Son, 32, St. Martin's Lane, Charing Cross, W.C., exhibited their improved "Outside Sun Blinds," and in them offered an admirable solution of the difficulty. The objection that has hitherto been advanced against the majority of outside blinds, viz., the necessity of wood framing with deep facia and side wings with wood jambs and slides, is, by the present invention, entirely removed. The blind in question requires neither wood jambs nor metal grooves, and draws up under about six inches of facia. It travels on iron rods, preserving the convenient form of the Spanish blind, and the hood portion allows of being raised or lowered to any height.

Among those little annoyances which ruffle the temper and yet have long been without remedy, is the difficulty of adjusting the laths of Venetian blinds to any required angle. Messrs. Mitchell have, however, produced an invention bearing upon that question; and, as far as it is possible to judge by a cursory inspection, we should say that it is fully calculated to answer its purpose well.

Another exhibit in the same line of things was that of Mr. Andrew Smith, 57, Ashbourne Grove, East Dulwich, S.E. The speciality which formed the chief attraction of that stand was certainly one of the greatest utility, and may be briefly described as follows:—It consisted of a patent whereby the headpiece generally used in connection with Venetian blinds is rendered unnecessary, being substituted by fittings which, when fixed, enable the blind to be removed and replaced in a few seconds, no side cords being necessary for altering the position of the laths. This is a contrivance which would greatly facilitate all such operations as spring cleaning, and would bring joy to the heart of the cleanly housewife.

Among the most attractive as well as the most sanitary of modern methods of decoration, the utilisation of glazed tiles takes a first place. When we say modern methods, it is, of course, in reference to the recent revival of the art of tile making; for, it is needless to say, tiles were among the first materials employed by the decorative artists of earliest ages. Reference to the existing records and ruins of Pompeii, the Alhambra, Granada, and other such spots, fully establishes their antique pedigree: and as antiquity is, in society, generally considered to be synonymous with respectability, no further argument on their behalf is necessary.

Messrs. E. Smith & Company, Coalville, Leicester, have done much to imbue the manufacture of modern tiles with real artistic feeling, and their display was well worth seeing and studying. Whereas, not so very long ago, it was considered a bold innovation to introduce tiles into a fireplace, now we get them in furniture of all sorts, from wash-stands to flower-stands; and their introduction constitutes a pleasing departure from old methods, forming, as they do, such a pleasant contrast with the various woods with which they are brought into connection.

The greater scope thus given to tile manufacturers has led to the production of designs, colourings, and forms, whose name is legion; and to attempt to describe such a collection as was shown by Messrs. Smith, would be almost as futile as attempting to pourtray a flower garden by mere description. Suffice it to say that terra-cotta, floor tiles, wall tiles, mosaic, hearth tiles, and decorative faïence, were fully represented in their most modern developments.

Mr. H. J. Rust, 353, Battersea Park Road, S.W., showed examples of his mosaic work, and those whose fancy inclines in the direction of that eminently durable and most antique method of decoration would do well to get particulars of his productions. There is, of course, mosaic and mosaic, but that of the maker in question bears the stamp of good workmanship, and has a peculiarly fine surface.

It would be possible, of course, to fill pages with even brief remarks on the many useful and beautiful objects that met the eye in every part of the Exhibition; but to do this would be not only unnecessary, but wearisome to the reader. We shall only encroach on his patience for a limited space in another number, and then bring our "Notes" to a close.

(To be continued.)

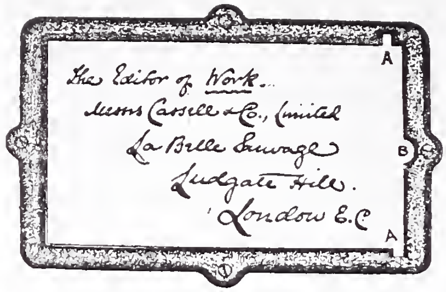
OUR GUIDE TO GOOD THINGS.

39.—Thompson's Improved Address Holder.

Address holders for portmanteaus, etc., and for the names of seat holders in church, made in brass for the most part, are common enough, but the principle has only just now been applied to business purposes in Mr. Thompson's "Improved Address Holder," an illustration of which is given in this page. Between the address holders to which allusion has just been made and Mr. Thompson's invention there is just this difference: that in the former the address card that is inserted may be withdrawn by merely sliding it out through the space left for its introduction between the frame and the wood to which the frame is attached, and may even slip out if the frame could be placed in a position convenient for its escape; but in the latter, the card, when once introduced, is so safely and securely retained that it cannot possibly fall out or work out. The frame, or address holder itself, is made of malleable cast iron neatly japanned, and is pierced with four holes countersunk, for the introduction of screws, by which it may be fixed to crates, boxes, cases, etc., for the transmission of goods and to the ends of barrels, casks, etc. If used for hampers the address holder must be screwed on to a piece of board, and the wood, in its turn, be tied to the hamper. When the frame is fixed, it will be found that its outer edge rests on the board, while there is a space of about $\frac{1}{16}$ inch between the board and the inner edge. The corners of one side of the card on which the address is written are introduced, under the nicks, A. A, in the frame, and the card is pushed on until it has been passed entirely under three sides of the frame. The edge that remains uncovered may then be easily passed under the fourth side, if the card be long enough. A semi-circular indentation will be noticed at B, at which the card may be pushed forward again, and raised by the nail if it be desired to withdraw it. The advantages of the address holder are: the security of the address card, the ease and rapidity with which it can be introduced when once the frame has been screwed on, and the preservation of barrels, boxes, etc., from injury by nails or tacks, to say nothing of its cheapness, durability, and utility. A single sample will be sent to any part of the United Kingdom, post free, for five stamps, by the agents for its sale, Messrs. W. and A. Jarvie, general ironmongers, 200, Parliamentary Road, Glasgow. Net prices, carriage paid, are: 4s. 3d. per dozen, £1 2s. 6d. per half gross, and £1 17s. 6d. per gross.

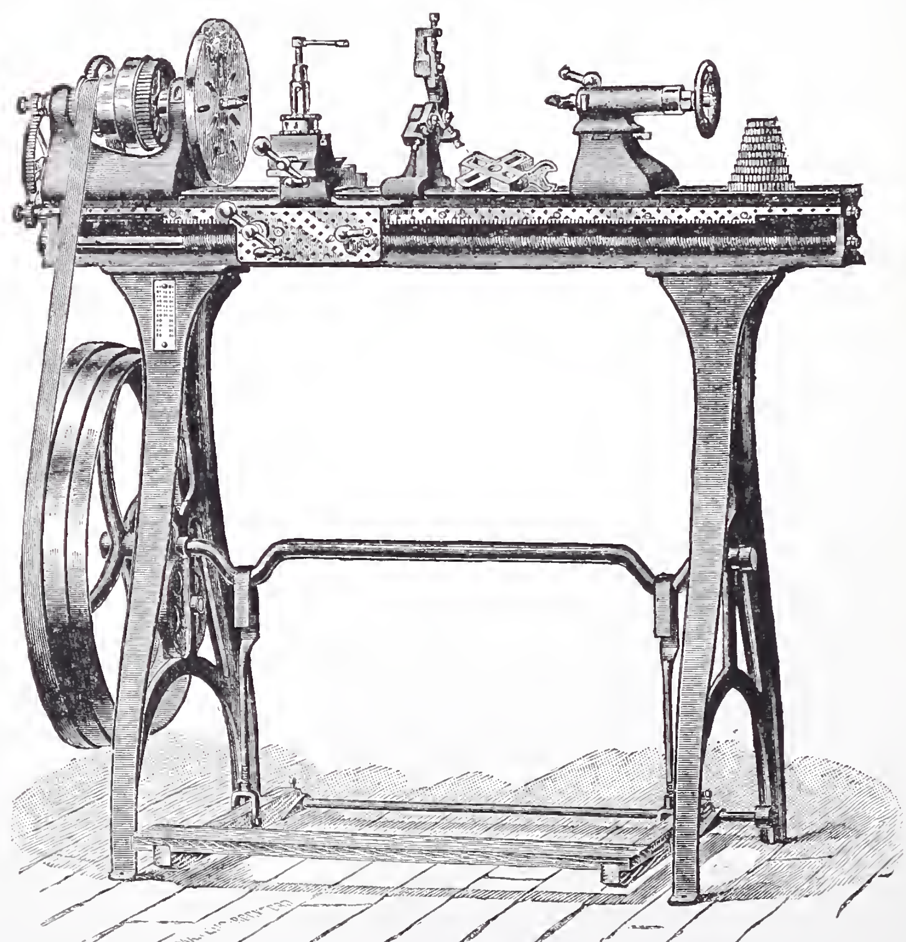
40. — Barnes' Screw-Cutting Foot Lathe, No. 5, with Foot Treadle.

The accompanying cut gives a graphic representation of Barnes' Screw-Cutting Foot Lathe, No. 5, with the ordinary treadle as found in English lathes. It is an American lathe, and is supplied by, and may be seen at the warehouse of, Messrs. Charles Churchill & Co., American importers of tools and machinery, 21, Cross Street,



Thompson's Improved Address Holder.

Finsbury, London, E.C. It differs from Barnes' usual form of lathe in being fitted with the foot treadle instead of the seat for the turner and cranked axle, by which the lathe is driven by the action of the legs in the same manner as a bicycle or tricycle. With regard to dimensions, it is a $5\frac{1}{2}$-in. centre lathe, and $3\frac{1}{4}$ in. over the tool carriage, and is just 34 in. from centre to centre. As may be judged from the illustration, the lathe is substantially built, and to this it may be added, that it is thoroughly well made in every particular. The headstock has a hollow steel spindle that will take a $\frac{7}{16}$-in. rod through its entire length. The boxes are accurately fitted to the spindle, with provision to keep them true and take up wear. The poppet, or "tail stock," as our American cousins style it, can be readily set at any desired point, or be removed altogether from the lathe bed at pleasure, thus leaving the lathe free for face-plate work or chuck work. It can also be set even for turning tapers. The spindles of both headstock and poppet are of steel, with taper holes for the reception of the centres that are positively true; moreover, the poppet centre is self-discharging. The tool carriage, which, as it may be seen, is gibbed to the bed, is a model of convenience and accuracy, and is such that the tool can be set to the work in any position, or at any angle desired, and also to bore a taper hole or turn a ball. All the works are securely protected from chips and dirt, which has the desirable effect of insuring long wear and durability to the most costly and vital parts of the lathe. The gearing that is furnished with the lathe can be combined to cut screws from 4 to 40 per inch. As a screw-cutting lathe, the maker claims that it is complete. All the gearing is cut from solid metal in the best machinery known for gear cutting, and is as true as possible, and works noiselessly. The entire weight of the lathe is 3 cwt. 29 lbs.; its price £22 10s.; a set of eight tools for metal is supplied for 12s. It is unnecessary to enter further into details of construction, for these are self-evident from the illustration.



Barnes' Screw-Cutting Foot Lathe, No. 5, with Foot Treadle.

41.—Winder's Banjos and Banjo Fittings.

Mr. J. G. Winder, Maker and Teacher of the Banjo, 16, Jeffreys Street, Camden Town, London, N.W., has asked me to call attention to his brackets for pulling banjo vellums tight, and has sent me a specimen of them, and a photograph of his "Special Banjos," which, as far as I can judge from the photograph itself, appear to be nicely made and well finished. The bracket sent is certainly well made, as the screws on the threads and nuts are deeply cut, and there is no fear of the screw threads slipping. It is of the best pattern, and is heavily nickel-plated. These are supplied at 6s. 6d. per dozen, but another pattern may be had, also plated, at 3s. 6d. per dozen, and brass brackets at 3s. per dozen. I mention Mr. Winder's specialities with pleasure, as I have reason to believe that a great many workmen like to have a turn at the banjo in leisure half hours, and even make instruments for their own use. It is not always an easy matter to get fittings in small towns and out-of-the-way places, but application to Mr. Winder will soon put an end to any difficulty that may exist.

42.—Pocket Technical Guide, etc., for the Building Trades.

Messrs. Crosby, Lockwood, & Co., 7, Stationers' Hall Court, London, E.C., have recently produced the fifth edition of Mr. A. C. Beaton's "Pocket Technical Guide, Measurer, and Estimator for Builders and Surveyors." This handy little book, which may be stowed away in the waistcoat pocket, contains technical directions for measuring work in all the building trades, with a treatise on the measurement of timber, complete specifications for houses, roads, and drains, and an easy method of estimating the various parts of a building collectively. It has been carefully revised, and prices stated according to the present value of materials and labour. It may be said to be a *multum in parvo vade mecum*, not only for those for whom it is specially intended, but for all house owners and those who are interested in house property. The information given is briefly put, and neither words nor space are wasted.—The Editor.

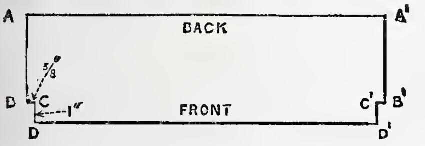
A Corner for Those who Want to Talk It.

**** All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

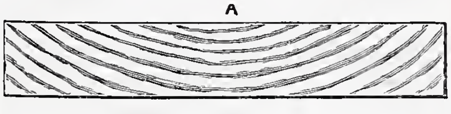
I.—Letters From Correspondents.

A First Attempt.—Kildonan writes:—"In to-day's issue of Work I observe you reply to S. (*Edinburgh*) with reference to definitions, and I think both he and also R. S. C. (*Leeds*) deserved each sharper replies even than those you gave them. You tell S. that 'those who read Work are certainly supposed to know the uses of lathes and tools.' If that is so, sir, then I must apologise for having dared to become a subscriber, for I never handled a tool in my life. Stay; yes I did. When a very little boy I used to watch for hours an old joiner at work, and one day, while the old man was outside arranging his little store of wood, I thought I would try my hand with a plane. I proceeded to *plane the bench!* Rip! went the iron over many an aged nail, and when I looked at the edge its serrated condition told even my childish brain that there would be a row. Stealing softly out, I disappeared, and for months afterwards the sight of the white apron and broad bonnet of old 'Tirly' sent me flying up the nearest cross street with winged speed. That was my apprenticeship. My next venture in the mechanical arts was when a junior telegraphist. Left alone on night duty, I proceeded to 'take down' an ordinary single wound galvanometer, so as to explore its construction, and I shall never forget the fear and trembling with which I awaited the arrival of the superintendent next morning. But this by the way. Galvanometers and more complicated pieces of apparatus have been investigated since then. But I want to tell you what Work has done for me. Lend me your ear, sir—softly—*I'm beginning to build my nest.* Well, No. 2 brought with it Mr. Adamson's overmantel. *She* approved of it. My landlady's husband, a working carpenter, has a bench and a few tools—the greater part are at his employer's yard, where the men have to provide their own kit. I bought a tenon saw, a square (9 in.), a chisel (½ in.), and a claw hammer. There were two planes (well worn) and a gauge on the bench. Having invested 4s. 6d. in nice clean yellow pine, with many misgivings I started. Being on night duty, I had the greater part of the day to myself. I wrought slowly and carefully. In Mr. Adamson's drawings and instructions the shelves and tops are simply held by nails. I was more ambitious. I cut the shelves ⅝ in. longer, and at each end cut out a piece thus (excuse freehand!):—



I made a groove in the uprights ⅜ in. deep, running from the back to within 1 in. of the front, so that the shelves are not dependent on the nails to support any weight placed on them. (B, C, and B', C',=⅜ in.; C, D, and C', D',=1 in.) Knowing that the tops would be hidden by the moulding, I thought I would venture on dovetailing! I succeeded—in nearly splitting one of my uprights!—and they fit tightly enough, though, perhaps, they are not beautiful. The result is that my overmantel will stand the proverbial three removes. Another departure from the design is in the panels of the doors. I got the 'tip' in the same No. (2), in the paper on 'Decorative Work for Panels.' My panels are of zinc, and will be prepared as there directed; when ready *somebody* will paint a floral design on them, probably a bunch of 'lilies of the valley' in the centre. Now, sir, being a very tyro, it must not be supposed that I escaped a mistake or two. *Experientia docet*, and sometimes *does it* (ahem!) with a vengeance. My mistakes have thus far been knocking two corners off the feet of the uprights, and making the groove for the shelf *on the wrong side* of the left-hand middle upright! Being concealed by the frieze, and besides being within the left-hand cupboard, I did not make a new one. There is no weight on the top shelf. With all deference to the designer, I have taken the liberty of putting a back of ⅜-in. stuff, in order the better to protect my looking-glass. For this purpose I have reduced the *shelves* behind in proportion. My back is in three portions, and flush with the edges of the uprights. Although not quite finished, I have got the worst over, and I have taken the liberty of writing you to say that Work has been of some use already to one who is an entire novice, and perhaps to encourage those who are equally ignorant of the use of tools with myself. My 'kit,' as you see, is by no means extensive—one ½-in. chisel doing the whole of the small fittings. I intended to have given you a description of the old lathe used by the old turner referred to at the beginning of my letter. It was driven by a flexible pole fixed to the rafters overhead, with a rope twisted round the object turned, but I have already trespassed too much on your time and patience. I noticed in the 'Technical Educator,' in the papers on the lathe, the writer referred to this old form, which he 'believed' was still in use in some parts of the country, but which he had never seen. I have often had *tops* made by old 'Tirly,' and I know he used the same lathe for over half a century. Should a description of it be interesting to any of your readers, I shall be very glad to try, but, unfortunately, I am no draughtsman, and so cannot give a drawing of it."—[I am glad to give publicity to your letter. You yourself certainly know the uses to which certain tools are put, and have given practical proof thereof. I meant S. (*Edinburgh*) to understand that I saw no necessity when a hammer was mentioned to explain that it is "a tool used for knocking in nails," and occasionally for other purposes into which I need not enter. You certainly need not apologise for having become a subscriber to Work; and I hope it will ever be found week by week to present fresh charms and increased utility to "She" and "Somebody" and yourself, and all others who have determined to pair and build, or rather line their own nests, for I daresay your nest has been already built for you, and you have only the lining to attend to. I will take care that a nice baby's cot is described for you when increase and multiplication begin to take place in the nest, as I trust it will. I will not trouble you for a description of old "Tirly's" pole lathe. You say you are no draughtsman, but at all events your diagram of the shelf was intelligible enough. There is one comfort—you can always fall back on "She" for illustrations to your copy when you write if you continue to distrust your own powers.—Ed.]

Cabinet in Fret Cutting.—Artist in Wood writes:—"I have the plate issued with No. 1 of Work; it is a very good design. I think the pattern proper for fret sawing will do very well for inlaying, and take less time and care than the pattern proper for inlaying, and best for amateurs to try at. The method of inlaying sent by Inlay, and put in 'Shop' in No. 6 of Work, is the one I use for inlaid panels of all kinds; the white holly and ebony should be the thickness of saw-cut veneer. When the holly is in the ebony the waste piece of holly should be taken off and placed at the back, then a piece of paper glued over the front, and the two veneers pressed between two level boards. When dry the waste veneer is taken off with a knife; the inlaid veneer should be placed paper side down on a level board, and scraped with a fine toothing plane; now a piece of ⅜-in. mahogany should be planed level on one side and then toothed. This should be sized with thin glue size and let dry before the inlaid veneer is glued on; the paper on the front side of the veneer may be scraped off with the toothing plane; the natural veins of foliage can be put in by the aid of a grainer. When white wood is used for inlay it is important that flake white be mixed with the glue to prevent it staining the wood; the glue should not be made in an iron kettle—iron will stain all light woods; it will be best to mitre a strip of ⅛-in. boxwood round the edge of the doors to prevent the veneer from being split off when closing the door. If the end grain of wood that is to be veneered on shows any curved marks it is important to know the right side to veneer. For example, supposing the annexed cut to represent the section of a piece of



wood to be veneered, veneer on the side lettered A. To inlay on the method of Mr. J. W. Gleeson-White take four veneers, say, two of dark rosewood and two of satin wood; cut square through all four at once; glue the ground veneers on piece of paper; now dip the cut-out pieces in warm water to expand them, and they fit the ground veneer, and make a good joint. This plan should not be used for a design having so many small pieces in it."

II.—Questions Answered by Editor and Staff.

To Repair Harmonium Bellows, etc.—Woodman.—To prevent a harmonium from getting out of order, it should be kept in a place that is free from damp, and not subject to sudden changes of temperature. Moths do a deal of damage sometimes by destroying the cloth and felt of the action. If there are signs of any, two or three small linen bags should be made, and a piece of camphor about the size of a walnut put into each. These can be fastened by a couple of tacks to the inside of the reed pan (which may be opened by undoing the two hooks at the back of the keys). The jerking of the wind, when playing softly, is most likely caused by the spiral spring under the reservoir being too strong; a weaker one would, probably, improve it. Should this not be the case, unscrew the covered back, and fill the bellows with wind. If there is a sound of wind escaping examine the reservoir and wind trunks for any signs of breakage in the leather. By passing a lighted paper carefully along where the escape is likely to be, it will more easily be discovered, as the flame will be blown out when it comes to it. When the hole is found, glue a piece of leather over it; a piece of old kid glove will do if the appearance is not studied. Should the escape be in the front of the reservoir, it will be necessary to take the bellows out of the case in order to get at it. But before doing this it will be better to make sure that the leak is in the bellows, and not, as is often the case, where the reed pan shuts down on the wad. To prove this, unhook the action at the back, and lift it over. Take out the spiral spring from under the reservoir, and lay some paper over the hole in the top board of the reservoir; press this down tight by means of a book or flat piece of board, so that no wind can escape; then get some one to push up the reservoir, and if the escape of wind is not heard, the leak must be looked for round the wad. This may sometimes be cured by giving a turn to the screw eyes which the hooks fasten into, or by pinching up the wad, so as to soften it. It is possible that the bellows has dropped a little; if this is so, by unhooking and lifting over the action, the bellows will be found to be loose. To remedy this turn the instrument upside down, and drive a small wedge under each end of the supports. You might get a larger bellows in if there is sufficient room, but the present one will, no doubt, be found large enough if it is made wind tight. It is not possible to give any general hints on how to construct a harmonium within the limits of this answer.—G. N.

Plaster Cast from Clay Model.—Moulder (*Limehouse*).—This must be made by the waste-moulding process. Colour the water for inner mould with a few drops of ink, and mix fine plaster to the thickness of cream. With this cover the model to ⅛ in. When hardened, brush clay water as thick as duck pool over it, then lay on outer mould, say ⅜ in. thick, of coarse plaster, embedding iron bars in its outer surface, if the model is large, to give strength. If the model is in the "round" the mould will have to be made in two (or more) pieces, to do which attach a strip of clay edgewise against the model, where the dividing line is to be, to form the limit of the first piece of mould. Cast this, then remove the strip of clay, and brush clay water along the edge of the plaster. After this cast the second piece; the clay water will prevent the pieces sticking together. Remove the clay of the model, well wash the mould with soap and water, and the sooner it is filled the better. Mix fine plaster with plain water for this, pour in, and move mould about to spread it equally. Repeat this till the cast is thick enough; coarse plaster may be used for backing up. When the cast is set the outer mould may be broken off by a few strokes of the mallet and a blunt chisel; the clay water will make it separate from the inner one. The inner mould being of a grey colour from the ink will easily be distinguished from both outer mould and cast, and must be broken off more slowly and carefully. The thorough saturation which the mould has had in cleaning will prevent the cast from sticking too closely to it.—M. M.

Electric Lamp for Bunsen Battery.—G. K.—The small glow lamps used to obtain an electric light from current supplied by the Bunsen battery cannot be made by an amateur. The glass bulb containing the carbon filament is blown by experienced workmen; the filament is inserted in the bulb, all the air is exhausted from this by means of a special air pump, and whilst thus exhausted the neck of the bulb is fused around the wires connected to the carbon filament. Such lamps are sold at 5s. each by all vendors of electrical instruments. See replies to other correspondents on this subject.—G. E. B.

Connecting Electric Bell to Clock, etc.—R. M. D.—Use No. 20 cotton-covered copper wire for the lines. Carry a wire from the bell to the clock, and connect it to the works, or metal frame of the works. Fix a bit of platinum wire to the *wood* frame of the clock close to the dial, so that it can be bent in to touch the hour hand at the hour when you wish to rise. The minute hand must clear this wire. Connect this wire to a line wire leading to the battery; then from the other terminal of the battery lead a wire to the bell. Use two Leclanché or two Gassner cells; these are best for electric bells. Have a separate line from the battery to the door, and from the door back to the bell, then from this back to battery. You will need a contact trigger to the door if you wish the bell to only ring when the door is opened. This will cost 3s. 6d. If you can wait until my articles on Electric Alarums are published, you will learn exactly how to do the job, and will be guided by illustrations. Space cannot be given here in "Shop" to fully explain how to do it, but I hope to show in my articles how to make an electric alarum clock.—G. E. B.

Magneto-Electric Machine.—H. C.—The two inside ends of the coils must be connected together. One of the outside ends is soldered to the spindle which carries the bobbins. The other outside end is soldered to the insulated brass collar outside the bobbins, which forms part of the commutator. If this part is not insulated from the bobbins and the spindle by a collar and plug of ebonite or boxwood, no current will be obtained from the machine. Other causes of failure are badly shaped and fixed commutator, allowing no break at all or a break at the wrong time. The commutator should break contact with the spring just as the ends of the bobbins are passing the poles of the magnet. The spring may be too strong or too weak, the magnet may be weak, or there may be several other causes of failure. One cannot say without seeing and testing the machine. If you do not succeed, write again and tell us how you made the machine.—G. E. B.

Crystoleum Painting.—C. G. (*Lower Edmonton*).—If C. G. S. will look carefully on page 58 he will find his question already answered. In the second paragraph from top I have said, "All this is to be painted in the transparent photo." Need I say again that the photo is pasted to the concave side of the first glass? The first painting is made on the transparent paper, then the second glass is placed in the concave of the first, and the remaining painting is worked on the concave side of this.—O. B.

Sale and Exchange Column.—BERNHARD.—If you look at the last page but two in each number of WORK, you will find that space has been reserved for special advertisements at the foot of the third column. I agree with you that it is very desirable that a "Sale and Exchange" department should be started in WORK, and if it is found that readers have a disposition to support such a department—and this disposition must be evinced by letters and advertisements sent for insertion—it would be started and developed to the very utmost. At present, however, such advertisements must find a place in the page and column indicated, until their numbers render it necessary to give them a place by themselves, and to classify them as (1) "For Purchase;" (2) "For Sale," and (3) "For Exchange."

Soldering.—F. B.—Instructions on the art of soldering will be given in these columns at some future time. The subject is far too large to be properly dealt with in "Shop;" but if you will kindly specify the class of work you wish to solder, we shall have much pleasure in instructing you how to do it.—G. E. B.

Barometer.—F. B.—I may say that some two or three methods are adopted for exhausting barometer tubes of air and filling them with mercury. The most simple is as given here. Get some *pure* mercury, place in a clean Florence flask, and warm up on a sand bath. Clean the barometer tube with a strip of split cane and a bit of wash-leather. Warm the tube gently near the flame of a spirit lamp until it is hot enough all over to be handled without scalding the hand. Then pour the warm mercury into the warm tube in a very fine, thin stream from a lipped vessel through a thin-necked glass funnel. When the tube has been filled with mercury, close the open end with a gloved thumb and shake the mercury up and down the tube until all air bubbles have been expelled, and the clear, bright column of mercury strikes the closed end with a sharp click, thus denoting that there is a perfect vacuum at that end. Warm the tube by holding its closed end *close to*, but not *in*, the flame of the spirit lamp, and turning it round and round in the hands, gradually warming it all along until the open end is reached, then back again until hot enough. Unless these precautions are taken the tube will be liable to crack. Tubes will also crack if cleaned with a *wire* brush or mop. The mercury must be quite pure. By another method the tube is first filled with warm mercury, then heated inch by inch, beginning at the closed end, until the boiling mercury has expelled all the air. This is said to be a risky method for the amateur. Another plan is to warm the tube and invert it mouth downwards in a trough filled with mercury. A small quantity of the metal ascends as the tube cools. The tube is again heated whilst still inverted, and the operation is repeated again and again until the tube is full. All remaining traces of air bubbles are shaken out, as in the method first described.—G. E. B.

Litho Retransfers from Stone.—J. D. (*Perth*). —Take Scotch transfer paper, and damp the back with a sponge. Let it lie for a minute or two, when it will be ready to take an impression from the stone without sticking sufficiently to break the composition in lifting. Roll in the work with retransfer ink (stone to stone), which is sold by dealers in litho sundries, fan the stone till it becomes quite dry, and then pull the impression on the previously damped paper. It will be found to adhere firmly to the stone, and must, therefore, be peeled off slowly. If done with care, impressions from the retransfer will compare favourably with those from the original.

Sheet Metal Working.—J. F. (*Elgin*).—Wood working naturally has had a preponderance at first, because where one man can be found who is competent and willing to write on metal working of any kind, there are at least a score who can write—and write effectively—on wood working. Many subjects in connection with metal working are in preparation, and even in course of issue, as you will have noticed. Arrangements have been made for papers on sheet metal working, and these will soon be commenced.

Picture-Frame Making.—ASHMORE.—I am glad that the instructions to which you allude were of service to you. A paper or two on the mode of making ordinary picture frames from mouldings will be given for the information of yourself and others who are interested in this subject. The article on "Frames à la Mode" was a paper on art in picture frames, and not a practical paper on frame making.

Bogus Advertisements.—It would have been better for your friend's wife to have purchased the necessary tools and materials and have obtained some instruction in the art to which you refer in your letter before she commenced operations. It is not wise to trust to such advertisements as you mention. There is no royal road to wealth; and persons who trust to specious promises—far too specious, in truth, to afford any hope of fulfilment—must expect to lose their money. I do not see how I could "bell the cat" in the matter as you suggest. Papers on the work-bench will be given. Instruction in holding saws, files, chisels, etc., is, I think, scarcely needed.

Litho Bronze Blue.—A LITHOGRAPHER (*West Bromwich*).—The introduction of a little tallow into the ink would, most probably, have overcome the difficulty.

Litho Machine Transfer.—A. C. (*New Barnet*). —The fault, no doubt, lays with your transfer paper. Procure *Scotch transfer* paper; slightly damp same by placing between damp blotting paper and warm stone before laying down transfer upon it.—J. F. W.

Toning Bath for Black Tones.—A. P. (*Stockport*).—The following toning bath will give good black tones, but it must not be used until at least twenty-four hours after mixing:—Chloride of gold, 1 grain; acetate of soda, 30 grains; water (distilled), 10 ounces. Another good one, which must be used half an hour after mixing, is—Chloride of gold, 1 grain; borax, 30 grains; distilled water (hot), 10 ounces. To obtain the best results, the paper should be sensitised by the operator.—T. C. H.

Repairing Jewellery.—J. W. (*Manchester*).—There are two ways of repairing jewellery, soft soldering and hard soldering. Soft soldering is the method employed when the article to be repaired will not stand the heat necessary for hard soldering, such as enamelled articles and rings when broken at the shoulder, and when it is not advisable to take out the stones with which the ring is set. The tools and materials for soft soldering are very simple: a blowpipe, some blowpipe solder, soldering fluid, small file, pair of pliers, and shears. To mend a ring broken at the shoulder with soft solder, cut a plate from thin gold plating or metal the size and shape to fit nicely over part or all of the inside of head and part of shank; tin one side of it, by spreading over it a drop of soldering fluid, and then working in the gas till a small piece of solder laid on it melts and spreads all over. Tin the portions of the ring that the plate is to cover in the same way, using the flame from blowpipe very cautiously; wipe off any superfluous solder from plate and ring, then adjust the plate inside in the required position, hold it there with the pliers, and gently warm with blowpipe flame till solder melts, withdraw flame, and let the ring cool; if any solder has run out at edges it must be scraped off with point of an old three-cornered file; hard soldering is more difficult, and will be dealt with next week. All materials, tools, and stones (real and imitation) for jewellers' use can be bought at King's, 13, St. John's Square, Clerkenwell, London.

Lathe Motive Power.—WOODMAN (*Newcastle-on-Tyne*).—You say you have tried to convert one of Jones's sewing machines into a saw bench, to do grooving and other similar work, but could not get sufficient speed, or enough power, and you want to know how to construct a machine to obtain power and speed for cutting, grooving, and rebating, without such labour at the treadle. Your error lies in trying to put work upon a light piece of mechanism for which it is utterly unsuited. A sewing machine treadle and fly wheel is not designed for cutting wood, therefore it will not absorb and give out sufficient power for that purpose. But you can have no simpler piece of mechanism for such work as you require than the treadle and crank, with fly wheel. The next better plan is to get a heavy driving wheel, and let some one else turn that, and so drive your lathe or saw with a belt, just as turners do in heavy cutting on large lathes. If neither of these methods will suit you, then power must be obtained from an extraneous source, using a motor, a steam engine, gas engine, or water power, as most convenient. I should recommend you to look out for a second-hand treadle and fly wheel at the marine store dealers, and then rig up a framing to suit. In this way you can obtain ample power at small cost, and the labour of driving a heavy crank axle and fly wheel, supposing they are properly pivoted, and the parts well fitted, is comparatively slight.—J. H.

Cost of a Patent.—B. D. (*High Holborn*), in reference to reply given to G. B. B. (*Portsmouth*), writes to say, "The stamp on application for provisional protection is only £1, whilst if the application is 'complete' the stamp is £4." Attention has been already drawn to the oversight in stating the cost of provisional protection to be £1 10s., so there will be no occasion to insert any further letters on this subject.

Advertisements in "Work."—J. E. G. (*Leeds*). —I note your strictures on advertisements in WORK. Your suggestions are noted, and if at any time it is found that they can be adopted, they shall be followed.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Making a Cyclorn.—BON-AMIS asks:—"Could any reader of WORK inform me how to make a cyclorn?"

Joiners' Composition.—F. B. (*Guernsey*) writes:—"The other day I was in a cabinet-maker's workshop, and noticed, after veneering, there were a few defects in the joining, which were immediately filled with a composition which was kept heated for the purpose. This hardened very quickly, and, after being sand-papered, could not be detected. Being an amateur fret worker I took particular notice of this, and I think it would be a great assistance to amateurs to know of this preparation. Will any of your readers kindly give the recipe in 'Shop?'"

Trade Notes and Memoranda.

THE new Calais mail steamer, which has been built for the London, Chatham, and Dover Company, and which will be placed in the service in May, has been named the *Calais Douvres*, after the twin ship of the same name, now to be withdrawn from the service. The new vessel is built entirely of steel, and is divided into nine watertight compartments. It is expected that she will be the fastest cross-channel steamer afloat, and will make the passage easily in an hour. She will be lighted with electricity, incandescent lamps between decks, and are lights for embarkation.

SIR JOHN FOWLER, addressing the students of the Crystal Palace School of Practical Engineering, recently, told them that England was the best place in the world for the engineer to learn his profession, and to get equipped, wheresoever his future might be. By the best equipped men, he meant, not necessarily those with certificates, although these were valuable, but those who had the best general record. He said that India, Canada, Australia, South Africa, and our other colonies and dependencies, offered vast scope for the engineer.

IT is stated in the *Revue Scientifique*, of Paris, that paper of best quality can be made from the stalk of the sugar cane; and the writer suggests introducing the industry into countries where the sugar cane is grown, and where, owing to over production of sugar, the industry is in a languishing condition.

A LARGE terrestrial globe is being constructed for the Paris Exhibition. It will be one-millionth the size of the earth, measuring about 30 metres, or nearly 100 feet in diameter. A millimetre on its surface will represent a kilometre on the surface of the earth. Paris will occupy about one centimetre, and will be a convenient unit for comparison. If this globe were revolved on its axis, a point on the equator moving at the rate of half a millimetre a second would represent the diurnal movement of the earth.

A CORRESPONDENT of the *American Machinist* relates his experience of an experimental working of steam hammers with compressed air. Water power was abundant, and the idea occurred to utilise this in compressing air for operating the hammer. Compressing apparatus and a storage tank were erected, and the air brought about 200 feet through a 2-in. pipe. He says that the hammers worked better than with steam, there was no steam blowing off, and no water dripping.

THE exhibition of the Turners' Company will be held at the Mansion House in October. The competition will be in hand turning of glass, wood and metal, with a special section for amateur turning. Particulars can be obtained of Mr. Edgar Sydney, 4, Hare Court, Temple.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

VOL. I.—No. 11.] SATURDAY, JUNE 1, 1889. [PRICE ONE PENNY.

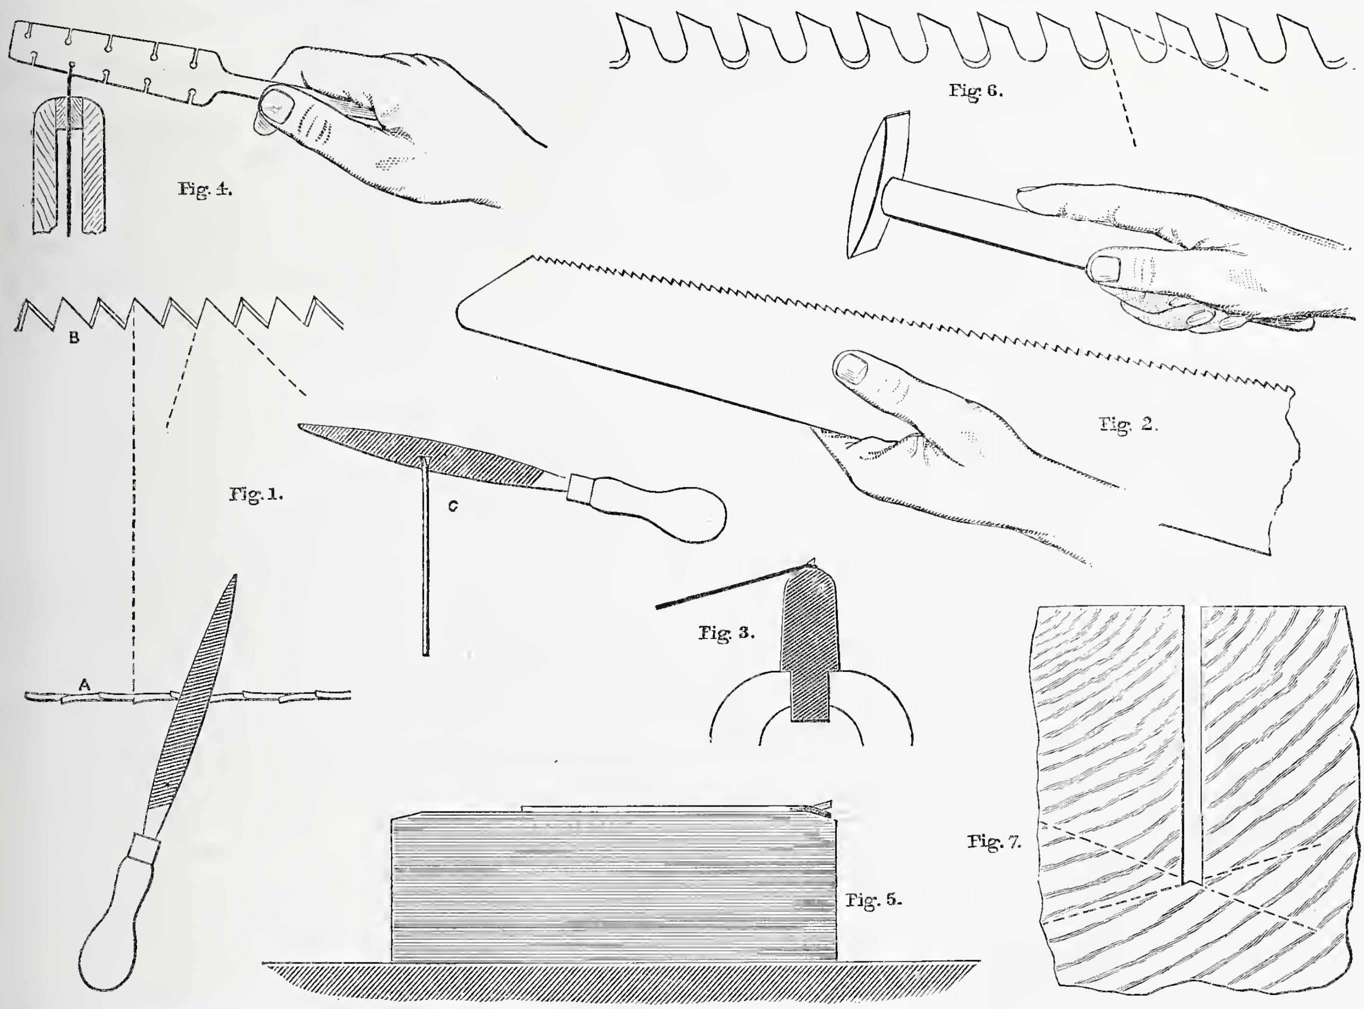

Fig. 1.—Hand-saw Teeth. Fig. 2.—Method of Setting on a Block. Fig. 3.—Section of Setting Block. Fig. 4.—Method of Using Plyer Set. Fig. 5.—Method of Setting by Chamfered Edge. Fig. 6.—Teeth with much "Rake," used for Cutting Soft Woods. Fig. 7.—Saw Kerf, Enlarged.

THE SAW: HOW TO USE IT.

BY J. H.

I.—VARIETIES OF SAW—TYPICAL HAND SAW—TEETH—GAUGE OF BLADE—SAW PLATE—STRESSING OF SAW—FORMATION OF TEETH—SETTING HAND SAW—PLYER SET—SETTING ON BLOCK—SHAPE OF HAND-SAW TEETH—TOPPING TEETH—ANGLE FOR FILE IN SHARPENING HAND SAW.

EVERYBODY uses, or tries to use, this most indispensable tool. But how different is its method of operation in the hands of a skilful or of an unskilful man; or when it is in good trim, or is out of order! So much is involved in the sweet working of saws, the minutest matters have so intimate an influence on their manner of operation, that some remarks on this subject may prove of interest and service to most of my readers.

First, as to the saw itself:—Confining our remarks to those used for wood working, there is first that general class, in its various modifications, of which the hand saw is the type, then the cross-cutting and circular, the back saws, the band and fret saws, and the various kinds used for cutting sweeped work; a whole host; all of which are used to a greater or less extent by amateurs and professional wood workers. Let us look at these *seriatim*.

Taking the hand saw type, we find this includes the hand saw proper, the ripping, half-ripping, and panel saws; all of similar outline, but differing in dimensions, and in form and size of teeth. There is no broad line of distinction between these tools, but they merge one into the other. Yet at the extreme ends it would be impossible to substitute the ripping and panel saws one for the other. The hand saw, however, which is a kind of compromise between extremes, is used indiscriminately for all purposes. What, then, are the characteristics of the typical hand saw?

Its length is from 24 in. to 28 in., being measured on the blade, which corresponds with the maximum range of thrust of which the arm is capable. Its blade is as thin as possible consistently with that amount of rigidity necessary to prevent buckling or doubling of the saw under thrust. The blade tapers in length, a form which is also best calculated to withstand thrusting stress without unduly increasing the mass of metal. The handle completely encloses the hand, so that no muscular effort is required to keep the hand from slipping away from its proper grasp. The teeth are bent to right and left alternately, while their outline is triangular—the cutting angle being very obtuse, and apparently ill-fitted for dividing fibres. Lastly, the teeth are so sharpened that their outer points first enter the wood, and the fibre is divided by a gradually incisive kind of action. Now there is not one of these points that can be neglected with impunity, for they all conduce to the proper operation of the hand saw.

The thickness or "gauge" of the blade is an important matter, because increase in thickness means additional power required to operate it, and also more material wasted in dust. As a rule, select the saw that has the thinnest blade, which will generally be found the most flexible. The Eastern nations carry out this principle to a greater extent than ourselves, by using saws so thin that they cannot be thrust, but are instead drawn towards the workman, and cut only when being thus drawn towards the operator—the rake of the teeth being placed in the reverse direction to that of ours. I do not think this is good in principle, because much greater power can be exercised in a thrusting stroke than in a pulling one, and I have not the slightest doubt that an English carpenter with his hand saw would beat by a great deal a Japanese or Indian sawyer at a trial of results.

Our best English hand saws are not only thin in the blade, but they are tapered from the cutting edge towards the back. To a slight extent, therefore, they clear themselves in the cut, and there is, in consequence, less loss by friction than in the saws of parallel thickness.

One important point in a saw plate is that it must neither show winding, nor buckle. Either defect will cause the saw to "run" in its cut, so that it will be impossible to work to a line, or only possible by exercising constant coercion on the saw in one particular direction. These evils are seldom present in new saws, but they become developed by careless usage, as forcing the saw violently through wet and harsh timber, letting it slip out of the cut, so that the point drops upon the timber while the pressure doubles or bends or otherwise stresses the saw. A saw blade once out of truth is very difficult to put right again; and if an amateur attempts by hammering to restore it to its original condition he generally contrives to indent it with hammer-marks without removing the evil. The best plan always is to take it to a saw-sharpener, who by a skilful direction of blows will generally level the plate, the process being akin to that used in operating sheet metals, the material being slightly thinned out in certain sections relatively to others. But a saw may be so badly buckled that no skill will suffice to make it what it was before buckling. Hence the reason why violent stressing of saws should be avoided.

Since this stressing is most apt to occur in wet and harsh timber in which the saw is moved with difficulty, and in timber for which the form of the saw teeth is not adapted, obviously the principal means by which a saw can be preserved in good working order is by paying particular attention to the manner of the formation of the teeth. This is really the fundamental point, attention to, or neglect of, which makes the principal difference in good or bad results.

The formation of the teeth depends on two matters—first, "set," or the amount of bending given to alternate teeth to right and left of the median line; and the method of sharpening, by which the rake and angles are imparted.

Although the blades of the best saws are thinned slightly towards the back, this by no means obviates the necessity for setting. All wood-working saws without exception have their teeth bent from side to side alternately, in order that the width of the "kerf," or groove made by the teeth, shall be slightly greater than the thickness of the plate, so that the broad surfaces of the latter shall move through the wood with the least amount of friction possible. This set is extremely variable in amount, and is necessarily so varied by reason of the wide difference in the nature of the materials which have to be divided, the extremes being, say, thick, wet, and soft wood, cut across the direction of the grain-fibres; and thin, dry, and hard wood, cut in the direction of the grain-fibres. The hand-saw tooth is not formed for so great extremes as these, but it will nevertheless embrace a very wide range of work.

Fig. 1 A represents about the average quantity of set given to a common hand saw suited for general work; that is, work within the ordinary limits of that done on the bench. This is imparted either on a setting block or by means of some form of saw-set, of which there are many. Fig. 2 shows how a saw is set on a block. The latter is a piece of iron whose section is seen in Fig. 3, and which is clamped in a vice. Upon the rounding edge the saw is held with the left hand at the particular angle required for any definite quantity of set, and the alternate teeth are struck sharply with the narrow-paned setting hammer, held in the right hand. When the alternate teeth which lean in one direction have been so treated, then the saw is reversed end for end, and the opposite alternate teeth struck.

Another common method of setting adopted is that effected by means of the "plyer" set. Here the teeth, instead of being hammered, are gradually bent over, the saw being either held in the left hand, or in the vice the while. (Fig. 4.) Of the two, I much prefer the hammer and block, because the set can be rendered more precise and uniform, and I think the risks of fracturing brittle teeth are diminished. An abrupt setting over of the teeth is also more efficient than a gradual bending from their roots; at least, that is my own opinion. The only objection to the setting block is that in unpractised hands the angle of the saw relatively thereto (see Fig. 3) may possibly be permitted to vary, and the setting, therefore, not be uniform. This, however, is a question of skill, which comes by use. But a good substitute is a block of iron, or even of hard, close-grained wood, having one edge chamfered to the quantity of set required. The saw being laid (Fig. 5) upon this, the set is imparted with the hammer, and the angle of the teeth cannot be other than that precise amount corresponding with the bevel of the edge. If hard wood is used for the block, its grain must run vertically, so that the ends of the fibres shall be opposed to the indenting force of the hammer.

In whatever manner this set is imparted, and whether it be much or little, absolute *uniformity* is of the first importance. A saw with a comparatively small amount of set, if regularly given, will operate better in wet stuff than one whose amount is greater, but given irregularly.

The shape of the hand-saw teeth is shown in Fig. 1 B. It will be noted that the rake of the teeth (*i.e.*, the amount of their leaning forward) is such that there can be no true cutting action. For the teeth to cut truly they would require to be formed with a good deal of rake, as in Fig. 6. But the quantity of rake thus represented would unfit a hand saw for general work. Actually, then, the hand-saw teeth (Fig. 1) are in principle an assemblage of scrapes, and as such they have little penetration. Wedge-like teeth having much penetration, like Fig. 6, would cause much hitching and jarring of the hand to occur, particularly in operating hard wood and in cross cutting. But there is a certain incisive action in Fig. 1 very much akin to, if not identical with, that of the wedge or chisel form, and it is due to the method of sharpening adopted. Looking at Fig. 1, A, B, C, it is seen that the teeth facets are bevelled in both directions, so that they first enter, and divide the material by their extreme outer corners only. To note what would result if such were not the case, imagine the teeth to be sharpened perfectly square across—the saw would then work extremely dead and heavy, and the labour of cutting would be vastly increased, probably more than doubled. But the teeth being bevelled, the action is such that the severance of the fibres takes place in a diagonal direction. This is seen in Fig. 7, showing a saw kerf much enlarged, from which it is evident that the action of the tool has much in common with that of the wood chisel worked diagonally, or the skew-mouthed rebate plane. The fibres are divided in series in the direction of the dotted line, and excessive stress thereby avoided.

Lastly, in order to the most perfect action, all these tooth points must be in line; if they are not, those which are below the rest will be inoperative. Hence, in sharpening, as in setting, perfect uniformity is essential to the best results. Before sharpening, therefore, the teeth are "topped"—that is, the file is run down over the points two or three times in succession, until all are level, and then the sharpening follows, until the blunted tops are just removed and no more. The angles at which the file is held for the common hand saw are shown in plan in Fig. 1 A, and in end view in Fig. 1 C.

(To be continued.)

NOTES FOR ELECTRO-PLATERS.

BY GEORGE EDWINSON BONNEY.

VI.—Anneal, Annealing—Antidotes—Aquafortis.

Anneal, Annealing.—Metals are said to be annealed when they have been heated and cooled in such a manner as to render them softer and more pliable afterwards. The temperature to which a metal must be heated and the method of cooling afterwards differ in each case, and a knowledge of this difference forms a part of the art of annealing. Iron (and all its compounds or alloys) is made hard by heating to a dull red, and cooling it rapidly, as by plunging it in cold water; but when allowed to cool slowly in hot ashes, or enclosed in a metal tube previously heated and surrounded with a bad conductor of heat, it then becomes soft. The hardest steel can thus be made soft enough to be cut with steel tools.

Gold, copper, silver, and some kinds of brass may be annealed by being heated to a dull red, and allowed to cool gradually, or they may be plunged at once into cold water without any apparent effect on the annealed metal. The art of annealing is practised by those workers in metals who draw them into wires or beat them out into thin plates. To anneal gold, silver, and copper anode plates, or strips, heat them to a dull red and cool in water. Tarnished silver plates may be cleaned by cooling them in a dilute solution of potassium cyanide, such as the cyanide dip used in nickel plating. Copper and brass plates may be cleaned by cooling them in a very dilute solution of one part sulphuric acid in forty parts of water. This should be warm to properly clean brass. Where naked wires and strips of copper are used as conductors of electricity, as between battery and bath, or in use as slinging wires, they become brittle with long use, and should, therefore, be carefully annealed occasionally to restore their softness and pliability. Pure copper may be annealed at a low heat. Fine copper wires passing from one conductor to another (as those leading from the poles of a powerful plating dynamo) will become heated by the current and annealed in passing.

It is sometimes necessary to anneal articles of jewellery in the workshop to colour them after being repaired. This should be done cautiously to avoid unsoldering any parts soldered with soft solder. Best silver-soldered goods will stand the annealing and colouring process all right. See notes on *Colouring*. It is probable that the process of annealing changes the positions of the small particles which go to make up a sheet, a bar, or a wire of a metal. What this change is cannot be demonstrated, but probably it is in the direction of an alteration from a crystalline to a fibrous form of structure. Some curious effects are observed in annealing alloys and metals coated with gold or silver. These suffer a permanent change in colour by the annealing process. German silver loses its whitish lustre, and becomes a dirty grey. The kind of brass known as gilding metal loses its gold yellow tint, and becomes coppery. Gilded copper articles lose the pure gold tint, and assume a dark coppery hue. Gilded silver articles assume a brassy yellow tint. Silver-plated copper, and alloys of this metal, are blackened by annealing. If the process of annealing is carried on too far—that is, the metal subjected to too much heat—the discoloration becomes permanent, and the gold or silver coating is said to be "sunk." If not carried too far, the colour can be restored by a judicious course of pickling. Rules, embodying a scale of safe temperature for annealing gilded and silver-plated articles, might be drawn up if we knew the exact thickness of the coatings and the composition of the metal beneath. But the safe line varies with the thickness of the coat of precious metal, and it needs a trained eye to determine by the change in colour when this line is reached. The changes of colour which take place on the surface of metals during the process of annealing are little understood. For instance, if we anneal a piece of copper coated with gold the gold coat disappears, and the surface seems to be composed of an alloy of gold and copper. Is what we see a real alloy of these two metals? If so, the alloy cannot have been obtained by fusion, for the annealing temperature has not been raised to the fusing point of either metal. Has the gold sunk into the surface of the copper? If so, the pores of the copper bar must have opened under the influence of heat and received into their mouths, so to speak, the fine particles of gold which covered them. This seems to be the only tenable explanation. In the alloyed surface the two metals are so intimately mixed in such a fine state of division, as to give it the appearance of a real alloy obtained by fusion, but the intruding grains of copper may be dissolved in an acid pickle, and leave the gold coat in its former pure condition. A similar result follows the annealing of any other plated metal.

Antidotes.—An antidote is a medicine that counteracts the influence of a poison—that is, opposes and neutralises its action. As electro-platers work with deadly poisons, they should be well acquainted with the deadly properties of those poisons and their antidotes. Under the heading of each poisonous substance mentioned in these notes, I have given cautions respecting its use, and directions respecting the selection and application of the proper antidote in case of accident. The general rule respecting the choice of an antidote is as follows:—Choose a substance that will combine at once with the poison and form a compound having no action on animal tissues. Antidotes should be promptly applied, and therefore should be kept at hand in an easily accessible position. *The antidotes to acids* are such alkalies as magnesia, soda, potash, or even chalk, mixed with lukewarm water and swallowed at once. Afterwards take a little milk, or broth, or such vegetable oil as olive oil, or oil of sweet almonds. It will also be safe to take a dose of castor oil in the course of a few hours. *The antidotes to alkalies* are such vegetable acids as vinegar, acetic acid, lime juice, lemon juice, or orange juice diluted with water and taken at once. If neither of these are at hand, ten drops of sulphuric, nitric, or muriatic acid in a wineglass of water may be used instead. After the pain has abated, take a tablespoonful of olive oil. Later on, cleanse the stomach and bowels with a dose of castor oil. *The only safe antidote to poisoning by metallic salts* is an abundance of warm water to be drunk at once so as to cause copious vomiting. If this does not succeed speedily, other means must be employed to cause vomiting, or the stomach-pump must be used. Most metallic salts may be converted into insoluble and inert sulphides by taking a strong dose of milk of sulphur, or flowers of sulphur, but it is best to get them out of the stomach as soon as possible to avoid bad after consequences. Afterwards the stomach may be relieved and comforted by a good egg beat up in a glass of milk.

The antidote to poisoning by cyanide in all its forms is a solution of iron. The common *green* vitriol or protosulphate of iron dissolved in water may be used. But as some time may be lost in preparing this remedy, it will be well to keep always handy some *steel drops*, obtainable at any chemist's shop. Give half a teaspoonful in a wineglassful of water *at once*. Then dash cold water over the head and down the spine of the sufferer. Stimulate the heart's action by giving brandy, either neat or mixed with warm water. As the action of this poison is fearfully quick, prompt action in applying the antidote will be needed to avert fatal consequences. Sal-volatile may be used where brandy is hard to get or unattainable. Liquor ammonia, six drops in a wineglassful of water, will also give relief. *The antidote to acid fumes* is the fumes of ammonia, either from ammonia carbonate or diluted liquor ammonia sprinkled on the floor. *The antidote to ammonia fumes* is the fumes of chloride of lime, or some other fuming chloride; as chlorine combines with ammonia to form sal-ammoniac, and this is simply innocuous. See also notes on *Cyanide of Potassium, Prussic Acid, Poisons, Poisoning*, etc. etc.

Aquafortis.—A name given to commercial nitric acid. It is evidently a word compounded from two Latin words meaning respectively "water" and "strong" to denote this liquid as being a strong water. For further information see note on *Nitric Acid.*

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

IV.—USE OF GUIDE LINES—THE ALPHABET IN FREEHAND — SKELETON LETTERS—NECESSITY FOR PRACTICE.

I HAVE so far merely considered freehand drawing more or less from a general point of view, but must now direct the pupil's attention as to the best course to pursue in becoming proficient in truthfully and accurately forming and drawing the letters of the alphabet without any mechanical aid whatsoever.

I will afterwards give some directions for the making of various "guide" lines, which are sometimes used as an aid by the sign writer in forming accurately and quickly some of the more difficult letters, such as C, G, S, and &. But I must impress upon the learner how absolutely desirable it is to, first of all, learn to be able to draw all the letters in a bold and workmanlike manner by freehand alone, and using his eye as his guide pure and simple. I may also add that although "guide" lines are all very well in their way, the young student, if he wishes to master this art and become a capable workman, must eschew them altogether in the preliminary stages of his practice. And, be it said, that our best "writers" never make use of these aids to correct drawing, but trust to the eye and hand alone, and that it is by this method that all the best displayed and boldest work is turned out, and which, of course, invariably bears the imprint of the master hand and an artistic eye and mind.

I will admit that occasionally it is next to impossible to construct one's letters properly and truthfully unless they are drawn or formed by mechanical means. Take, for instance, the case of the workman being confined in a very awkward and cramped position, or being up aloft on a frail platform and at a great height, in fact, sufficiently high to unsteady the nerves, and consequently the hand. Again, supposing some very large letters have to be painted on the front or side of a house, and also at a great height; in this case it is almost impossible for the workman to have sufficient room to stand far enough back to occasionally survey his work, and gauge its appearance or detect any imperfections or malformation of letters. Therefore, in such circumstances as these the use of any mechanical aid or guiding lines is perfectly legitimate.

A good many of our most dexterous and expert sign writers seldom chalk their letters out at all, but proceed offhand to write them in with the pencil and colour. And even when they do previously mark their letters out, it is merely in a rough and sketchy manner, and more with the object of properly spacing their letters and filling in the allotted space on the board evenly than anything else; and they very seldom follow their chalk lines in painting the letters, but, on the other hand, let the pencil follow its own inclination.

In commencing to practise drawing the alphabet in freehand, it is better for the learner to first of all draw simple outline letters. For this purpose, then, I here give a sheet of "skeleton" letters (Fig. 27), together with numerals.

It is, perhaps, just as well to draw these on paper with the lead pencil for a while; but, taking it for granted that the learner has been practising hard on the two previous lessons, recourse should soon be had to the blackboard, and once here, the work Therefore, at this stage of our lessons more than any other, the watchword should—in fact, *must*—be *practice*, PRACTICE, PRACTICE. It is far from my wish, of course, to dishearten the pupil; on the contrary, every inducement will be thrown out and encouragement given to the youth about starting in life to adopt and follow this educational, remunerative, and elevating art trade of sign writing, which to some, the writer included, is fascinating to a degree. It is, in fact, my enthusiasm in the subject improves in quality, so will the workman be the better able to see its imperfections, although for the life of him he cannot tell the exact points, perhaps, where the fault lies. But after a bit he will perceive and detect these also, and eventually be able to correct bad lines, and, in their place, render with precise and masterly touch those he has so long desired to obtain. Once, therefore, he has surmounted the somewhat difficult task of forming in shapely and pleasing manner the whole of the letters which our alphabet

Fig. 27.—The Alphabet and Numerals for Freehand Practice.

should proceed with both the chalk and the camel-hair pencil filled with colour.

Now, it takes but very few words to describe this method of procedure for a first attempt upon the alphabet, but as it is the whole groundwork and foundation of letter-forming and letter-painting, it is very important that the student should be very pointedly told, also, that he must completely master this lesson, or, speaking still plainer, be able to form each letter at least in a decent way before he can hope to become a creditable craftsman, and, more important still, earn money by his craft. which induces me to so strongly urge my readers to "stick to it" in this fourth lesson. Do not become disheartened at repeated failures, and "throw it up" altogether. That is not English pluck and doggedness, and failures there must and will be at the commencement, but which repeated practice will slowly but surely overcome. Some letters will be very difficult to form correctly, especially the S and the "short and"—&; but each succeeding effort on the part of the pupil will show some improvement, however slight and imperceptible it might be to the untrained eye. As the work contains, his greatest obstacle on the road to progress is passed, and the rest, it can confidently be said, will come naturally and easy to him, with one possible exception—that of colours and colouring.

Leaving the student at this point to follow the precepts I have just laid down for his guidance and success, I will seek to do no more at present than remind him that the examples given in the accompanying skeleton alphabet are to be drawn by him on a larger scale, as the other freehand exercises that have been already given in these papers.

(*To be continued.*)

HERALDIC CHASING.

BEING HINTS FOR THE ORNAMENTATION OF HARNESS, ETC.

BY OPIFEX.

HERALDIC chasing is the art by which crests, coats of arms, monograms, and various kinds of ornaments, etc., are made in gold, silver, brass, or indeed in any of the ductile metals or alloys.

The subject of this paper is not Heraldry, which is a most interesting subject in itself, and one which well repays the intelligent student, being so intimately connected with the history of our country, and having so many legends of romance and chivalry embalmed within it; but we are only indirectly concerned with it now.

Heraldic chasing presupposes some knowledge of Heraldry, or, at least, the possession of a design prepared by one who possesses it; and my object is to help my brother amateurs to produce articles in this *line*, about the manufacture of which ninety-nine per cent. of us are entirely ignorant.

We will assume, then, that some reader is anxious to have a set of crests for his harness, that he is possessed of sufficient energy to undertake the work himself, and that he is furnished with an accurate drawing of what he desires to produce.

Heraldic chasing is the near relative of repoussé work, in fact, it is its direct offspring, so that those readers who are proficient in that art will have little to learn, and will find that their knowledge has merely to be applied in a groove slightly differing from pure repoussé work.

The tools employed are of the same kind, but generally of a finer make, our subjects being, as a rule, more elaborate in detail and more highly finished than works in repoussé.

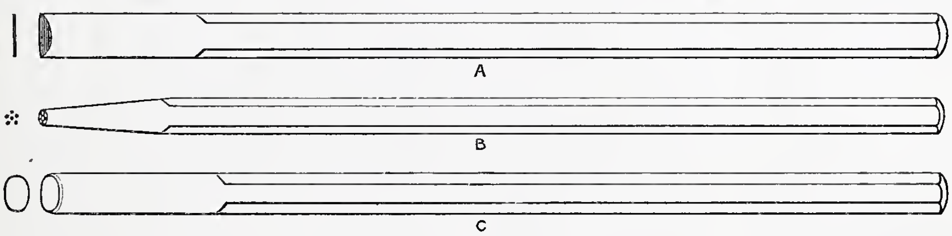

Fig. 2.—A, Tracer No. 1; B, Punch No. 5; C, Relief Punch or Beater No. 7.

Our first example given at Fig. 1 represents a falcon's wings with hooded head, and is a simple crest, easily executed, and the following directions apply to all subjects of a like nature.

There are two methods by which this work may be executed: one very simple and perhaps more suitable for beginners, but *not* the correct or professional method, and therefore not so satisfactory in its results as the other; however, I give it in hope it may induce some one to attempt the work who might shrink from the other and more complicated process.

Whichever method we follow, there are certain special tools and appliances required to make a beginning, which I shall enumerate at the outset.

The necessary tools are:—First a medium-sized chaser's hammer; any small hammer will do in an indifferent sort of way, but the reader is strongly advised to obtain a professional chaser's hammer, at a cost of about half a crown.

Next two tracers—Nos. 1 and 2, as used in repoussé work, $\frac{1}{4}$ in. and $\frac{1}{8}$ in. respectively. (See Fig. 2, A.) These tools should be flat on one side and rounded on the other, the edges being formed by grinding down the *round* side. The advantage of these over other shaped tracers is that curves and straight lines may be traced with them with equal ease, and also a greater degree of *relief* can be obtained by their use. We shall also need two straight tracers (Nos. 3 and 4), $\frac{3}{16}$ in. and $\frac{1}{8}$ in. respectively, ground on both sides; these tools should be *rather* sharp, but smooth at the edge; we also need one $\frac{1}{8}$ in. made quite sharp. These will be sufficient for the present, and I shall describe any others as occasion requires.

The following appliances, etc., are also essential:—Some flour emery and crocus powder, soft rags or cotton waste, sweet oil,

Fig. 1.—Crest: Falcon's Wings with Hooded Head.

Fig. 4.—Section of Crest taken across Centre.

steel wire scratch-brush and sheet of carbon transfer paper, an H.B. pencil, several small files of various shapes, a small soldering iron, some common solder and "killed spirit," a small block of hard wood, say about 6 or 8 in. in diameter, and the same length—a piece of this size cut from a beech bough will suit admirably if the faces are cut parallel and

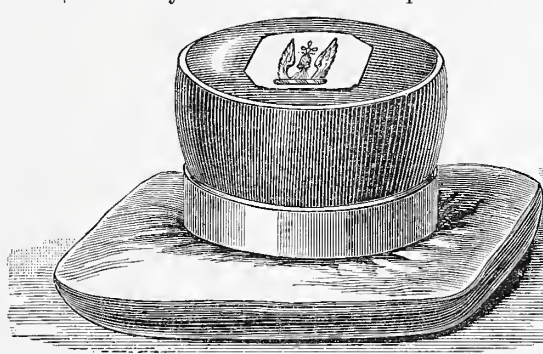

Fig. 3.—Chaser's Bowl, filled with Cement or Pitch.

made tolerably smooth—some $\frac{5}{8}$-in. "cut tacks," a fine bradawl, and last, but most important of all, we require the material to work upon; this must be thin sheet metal, brass, or silver (or gold!), but, "fiat experimentum in corpore vili," which, being interpreted freely, means, "on the present occasion let us experiment in common brass." It is cheap and *not* nasty, and for our present purpose (harness crests) is in much better taste than silver, but this, of course, must depend upon the other mountings; as to thickness, No. 25 gauge brass is what we need.

And now as to method No. 1. Cut a piece of brass about 3 in. by 5 in. or sufficient for two crests, and having made the metal quite flat proceed to cleanse and polish it on both sides, using, first emery and then crocus; or you may polish in any of the other approved methods, as in repoussé work, but the above will suit the subject in hand. Next, wash the brass well in hot water with soda and soap, to remove all grease, and rinse clean and dry. Now scratch-brush one side all over (in the absence of a scratch-brush emery cloth will serve) or scrape the surface with any sharp instrument. The object of this operation is to prepare the back of the work to receive the solder, which, as we shall see, is to be run into the reverse side of the crests.

Next lay the brass upon the block, scratched side down, and with the bradawl make a row of holes all round about an inch apart and a quarter of an inch from the edge; then tack the metal securely down.

We are now ready to transfer the heraldic device to the brass; this is effected by placing a piece of carbon paper upon it. Next place the design upon the carbon paper, and with a sharp pencil go over all the markings carefully; repeat the operation for a second copy; and we should now have two facsimile drawings in black upon the metal. Sprinkle a little French chalk upon the brass, rub gently over the drawings, and all danger of "smudging" will be obviated.

In the case of the present example the transfer may be made direct, but in dealing with crests, monograms, etc., which would be reversed by transferring (such as a lion rampant, etc.), it will, of course, be necessary to prepare a negative design.

The simplest way of doing this is to place a piece of carbon paper upon a hard, smooth surface—a piece of plate glass is best—lay the design upon it, and then go over the drawing with a hard pencil (as above), when a facsimile will appear on the *wrong side* of the design, which may then be transferred to the metal.

And now for the actual work. Taking tool No. 1 or No. 2 in the left hand and hammer in the right, proceed to indent lightly the outside of the design (*i.e.*, leaving out such markings as feathers, crossbars on the "hood," etc., in the example in hand), keeping the flat side of the tool next the design, using No. 1 for all the straighter lines and No. 2 for the smaller curves. When the whole of the outline is thus indented, go over it again, more decidedly this time, repeating the operation until all the lines are indented evenly and as deeply as possible; but this result should be arrived at by frequent rather than violent application of the tool.

Having treated both crests in this way, punch down the brass immediately surrounding the design with No. 5 (see B, Fig. 2), as this will help to raise the figure in higher relief, and also render the after process of cutting out easier.

Employing No. 6, proceed next to cut

through the whole outline as already traced. This process requires care, not striking too heavily, but with just sufficient force to go through the brass.

Of course, it may be necessary to use sharp tools of different sizes and shapes, modifications of No. 6, in cutting out. This, however, must be left to the judgment of the worker, who should always endeavour to cut out the crest, etc., as clearly as possible as regards outline. The operation of cutting out may also be performed with a fine fret saw, as used by jewellers; but this also is a matter for the worker's decision.

So far, as regards No. 1 method; but, as before stated, this is not a satisfactory process, and for this reason—we have not been able to provide for the proper *shaping* of our subject. All has depended on the fact that the untouched brass within the outline has become bulged up by the process of tracing and the use of the matting tool, and we are dependent on the after chasing for form, which in some simple cases may answer well enough; but in order that our work can possess any real artistic merit, some other method must be resorted to by which we shall be enabled to *model* our subject, leaving nothing for the after chasing but details, such as the feather markings in the example before us.

In case my readers are not repoussé workers, it will be necessary here to give directions for carrying out this alternative and more correct process.

Instead of the uncompromising block, which takes no impressions, we must provide ourselves with a chaser's "bowl," *i.e.*, a round basin of cast iron. These are of different sizes and shapes, but such a bowl as that shown at Fig. 3 will suit us best. This is filled with the substance known as chasers' cement, or, more familiarly, "pitch," which is really a mixture of pitch, resin, tallow, and Paris plaster or sand. The pitch should be melted and poured into the bowl until it just overflows, and when almost cold the brass should be heated, *unscratched* or right side rubbed lightly with oil or tallow, and placed next the pitch, pressing gently, so that it shall sink sufficiently to make sure of it adhering to the pitch. The corners of the brass may be turned down with advantage, for further security. When the pitch is almost cold—*i.e.*, when applying the hand to the brass we can feel a suspicion of warmth—the design may be transferred as above, and we are then ready to repoussé, or punch down the metal, so that when it is turned we may have our crests, etc., correctly shaped, and so have a much better subject for chasing than could possibly be obtained by the other method explained above.

The tools required for this are, in the present example, only three in number—Nos. 7, 8, and 9 (see C, Fig. 2).

No. 7 is an oval-shaped relief punch or "beater."

No. 8 an oblong, ½ in. long.

No. 9 a very small "edition" of No. 8.

Using No. 7, the broader portions of the design should be punched down, at first all over to an equal depth, and when by repeated applications the desired degree of relief is obtained, the details of form should be attended to, *e.g.*, the pinions in the present exercise.

It must also be borne in mind that crests should be beaten down to a depth considerably greater than that which would suffice to give correct form. At Fig. 4, I give a section of the crest taken across the centre of the design, which will serve to explain my meaning, by comparing the depth of relief necessary in this work with that which would be sufficient in ordinary repoussé work; the line, A B, representing the level of the metal for crests, and the dotted line, C D, indicating the relief as in repoussé. If this is not attended to, the crests will be much too thin, whilst if my directions are followed, they will stand out well upon the harness and be most effective.

Tool No. 8 will suit best to beat down the crest "wreath," and No. 9 the cord by which the hood is held; both these tools will also be brought into use for the sharper portions of the wing, feathers, etc.

When both crests are treated as above the brass should be removed from the pitch, well cleansed, and washed in hot water with soap and soda.

Next cut out with fret saw as above; or place the metal face upwards upon a block of lead, and cut out with No. 6, etc., in either case using great caution in order to preserve the correct outline of the design. And now we have reached the same point, whichever method we have employed, and the following directions are equally applicable to either.

The crests being cut out, are now placed face down and painted over on the back with "killed spirit" (spirits of salts, in which zinc is dissolved until it will dissolve no more), then with the hot soldering iron let the solder run in, until the crests are just full, care being necessary to avoid allowing the solder to overflow and stick to the right side of the articles; guard against this at first by coating with blacklead and beer, as in plumbing work.

We have now two solid crests, the edges of which are rough and jagged, and the next step is to file them out clear and sharp, using the small files of different shapes to suit the intricacies of the work.

We now arrive at the most important and interesting part of our work, namely, the chasing of the crests. To accomplish this the subject is placed upon the block—a larger one than that described above, say, about 10 in. in diameter and 6 in. deep—which should be placed upon a sand cushion upon a solid bench or table.

Having the original design placed so as to be easily seen, next proceed to indent all the lines exactly as they appear in it, using the tracers described above, and choosing those which suit the different lines, curves, etc., as occasion requires, taking great care to follow the drawing faithfully.

In this operation there is unlimited scope for artistic work, but the worker must depend almost altogether upon himself for success, as it is well-nigh impossible to give more than the most general directions as to chasing. But I may say that a safe rule will be to follow faithfully the markings in an accurately drawn pen-and-ink design, and the result will be found to be satisfactory.

The chasing being finished, the next step is to provide means of attaching the crests to the harness. This is accomplished by fixing short pieces of copper wire to the back in several places, so as to ensure that the crests shall be quite flat and secure. Take a piece of ordinary bell wire, and having made it straight by stretching, rub it well over with fine emery cloth until quite bright; next having a hot soldering iron at hand, dip the end of the wire in killed spirit, and applying it to the part of the crest where it is desired to fix it, hold it perpendicularly, and apply the point of the soldering iron to the solder; the result will be, that the solder melting, the wire will sink down to the brass, and holding it there for a few seconds until the solder sets, the wire will be found perfectly fixed. Now with wire nippers cut off at about three-quarters of an inch, and repeat the operation until a sufficient number of wires are fixed—in the present example five in each crest will be required, one at the point and base of each wing, and one in the lure. See that these wires are perpendicular to the back of the crest, and of equal length; place the crest in position upon the harness, give it a slight pressure, so that the points of the wires shall leave a mark upon the leather, then with a suitable awl pierce the leather where marked; insert the wires, press home, and clinch securely underneath the leather.

ARTISTIC FURNITURE

EASILY MADE AND CHEAPLY PRODUCED.

BY DAVID ADAMSON.

II.—A Screen Secretary.

(*Continued from page* 150. *For Diagrams, see pages* 148, 149.)

Lining of Writing-Flap—Mouldings—Flutes in Panel—Shaped Panel—Other Uses.

The writing-flap may be left plain, or, as it is technically called, unlined, *i.e.*, uncovered. It will, however, be better and more comfortable for writing on to line it either with cloth or leather. The latter is the more usual, but I must say I prefer cloth, as being softer. Leather is all very well when new, but it gets hard, and then one might as well write with nothing between the wood and the sheet of paper. Those who habitually use a blotting-pad will not be affected by either material, and except that custom requires a writing-table top to be covered, they may as well just finish the inside of the lid like the remainder of the work, either painting or staining it. If leather lining is preferred, skiver is generally used, though popularly known as morocco. Skiver, which is a split skin, does just as well, and is much cheaper. It can be got either from an upholsterer or a bookbinder, though the charge from the latter is higher than the former generally. Leather cloth must not be confounded with the real leather, though it too is often used. It is harsher to the touch, and, personally, I do not like it, except where cheapness is the prime consideration. In such a small surface, the difference in cost between any of these materials is very trifling, so the best, either leather or cloth, may as well be chosen. Any fine cloth, such as ordinary tailors' cloth, not "diagonals" or "tweeds," but the sort known, I think, as doeskins, with a smooth surface is suitable, and the colour is only a matter of taste. Dark greens and maroons are those generally used for the purpose, and most upholsterers can supply proper cloth. A "cutting" sufficiently large can easily be got for a very small sum, if the purchaser is not too particular about the colour or shade. Whatever the lining, it must be well fastened to the wood. Glue will do, but paste, strong as used by bookbinders and shoemakers, is better. Smear it on to the wood, not on the lining, rubbing it well and evenly. It may be done with a brush, but a method adopted by upholsterers is this: Wrap up some paste in a fold or two of open meshed canvas (Hessian or scrim) and rub this over the wood. The pressure causes the paste to ooze through the canvas, which retains any lumps there may be through defective mixing. When the surface is ready, the lining is laid on and pressed evenly and firmly down with the hand. Pray don't use a hot iron to expedite matters, especially if the lining is leather or leather cloth, unless its destruction is the object aimed at. If it is a very hot iron, it may be used with every reasonable prospect of perfect success in attaining this end. Properly applied, that is, with pressure of the hand or a cold iron, the paste will be dry in a few hours, when the edges of the lining may be easily trimmed off sharp to the edges of the board. Those who have bookbinders' tools will be able to roll a border, either gilt or blind, along near the edge of the lining, which, especially if leather, will be much improved in appearance thereby. It will be seen that the lining covers the whole surface of the writing-lid, instead of being surrounded by a border of veneer, as is usual in writing-desks and tables, and it is omitted as not only unnecessary, but in such furniture as the present, because, to put the matter in plain words, it is more trouble than it is worth.

So far as real utility is concerned, the thing may be considered finished, but there are certain purely decorative details which may be added; indeed, should be, if we wish to conceal the packing-case origin and crude, though serviceable, construction. It is astonishing what a few mouldings will do, and beginning at the top, let one such as that shown in Fig. 7 (see page 149) be glued and bradded all round. This is one got from Elliott, of Newbury, in whose catalogue it appears as *registered design*, No. 1071. It is very nearly the same thickness as the top board, the edges of which it should just cover, but if it comes at all below, it will not matter except in front. Were it to do so here, action of the lid would be prevented, and the moulding must be either shaved away, if only a small hindrance, or the top edge of the lid may be planed down till it clears the moulding. The bolt of the lock will, probably, still catch, but if not, a thin slip of wood glued to the top, just behind the moulding, thickening up the top equal to the moulding, will be all that is necessary. The corners of the moulding must, of course, be mitred.

Now, the surface of the lid strikes one as being too plain, and a little relief from the flat appearance will be an improvement. A small moulding glued on round the edge will make a great alteration, say Elliott's registered design, No. 1001, Fig. 8, but a more ornamental scheme is given in Fig. 9 (page 148). In it the moulding is shown glued down at a little distance from the edge. The centre is further relieved by a thin bevelled edge board on which flutes are cut. These flutes are merely hollows cut with a gouge, and the only thing it is necessary to say about them is that they should be kept clean and sharp at the edges.

Those who cannot manage to cut the flutes neatly, may not be aware of the pleasing effects which are got by merely shaping the outlines of such applied panelling (which, by-the-way, may strike the critic of art woodwork as being very shocking) and boring a few holes with a centrebit. Such a shaped and perforated panel is shown in Fig. 10, and in connection with it, the well-accepted principle that plainness is not so apt to be unpleasing as over-elaboration in design may be remarked.

What applies to the front may be said equally about the back, though there is no necessity why these two parts should be the same in appearance, *i.e.*, details may vary though some regard should be paid to harmony. It will be noticed that there is a difference in size between the two parts, and it will, undoubtedly, add to the appearance if a moulding, however small, is carried round the whole of the back panel. If desired, the small space behind may be enclosed, but made as shown, it will form a handy receptacle for various odds and ends. The upright shown in section is merely a piece of wood forming, as it were, a back to this opening, to prevent anything interfering with the free action of the lid. If this opening is not desired, of course, it can easily be closed, by bringing the back board or panel down to the bottom, so that it corresponds exactly with the lid in appearance. Both sides will then be uniform in appearance, but there will, of necessity, be some lost space. Even this might be avoided by reducing the width of the bottom till it is no more than is required as a stop for the lid, and utilising the space for a small sunk stationery rack.

This, however, would complicate the work beyond the scope of these directions, and it is hardly too much to say that, were all the ideas for alterations and modifications that may suggest themselves to be mentioned, it would, in a very short time, be found that a totally different piece of furniture, both in design and purpose, had been evolved. Still, one or two hints may not be unwelcome, and may serve to show how this screen can be converted into a still more useful thing. We have, say, a number of drawings, and we want a lock-up place for them; well, nothing easier than to enclose the lower part, that is, the space between the bottom board of all and the shelf. Let the back be fixed like the back of the writing-case, and the front fall down like the writing-flap; only, instead of it being hung with centre hinges, use a couple of ordinary butt hinges. Some may prefer a door opening in the ordinary way, when the interior may be fitted with two or three shelves and serve as a small bookcase. Again, others may like to form the space below the secretarial department into a cupboard, either with a fall-down front, or as suggested with ordinary doors. I have, however, not made the screen with either of these modifications, which are merely suggested as ideas to be worked out by those who may find them useful.

The "creature comforts" phase of utility I have already alluded to, and further reference to it is unnecessary.

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

II.—Straightening and Bending Plates and Bars.

Although wherever straightening rolls are available they will be used in preference to hand straightening, yet, as in some circumstances there is not the option, it is necessary for the operative to be acquainted with the manipulation necessary to straighten or level the surface of a plate by hammering; if a plate is merely bent in one direction it is a very simple matter to hammer it out, but if there are bulges in it the process becomes one of greater nicety. The bulge itself must not be touched, as by hammering the metal would become thinner, and therefore rise more; on the contrary, by hammering out the plate all round the bulge more room will be given superficially for the material at that place, and it will thus be drawn out level, the amount of truth of surface attained depending upon the care and ability of the men employed upon the job. Of course it is understood that the plates are straightened cold.

In Fig. 3 is shown in cross section the arrangement of rolls in a plate-bending and straightening machine, for it will serve to curve plates as well as to straighten them. The apparatus is fitted with an upper roller, A, and two lower ones, B, B. These rollers admit of adjustment in relation to the vertical distances apart of their centres, and thus the plate, C C, passing through them becomes straight, or is curved as may be required; the curvature, however, only taking place in the direction in which the plate travels. In some straightening machines a greater number of rollers are used.

There has recently been introduced a machine for levelling very thin plates which should not be overlooked, for in view of the enormously powerful machines now being constructed for various processes of mechanical manipulation, it may follow that machines of this type will be produced powerful enough to deal with ordinary bridge plates. In the apparatus referred to the plates are firmly gripped by each end in powerful jaws, which, being then forced asunder by hydraulic pressure, stretch the plates, and in

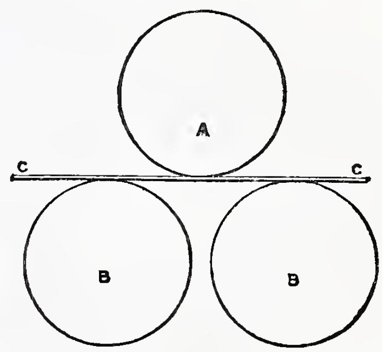

Fig. 3.—Arrangement of Rolls in Plate-Bending and Straightening Machine.

so doing take out any buckles that may have formed in them. In order to stretch the plates a force exceeding the limit of elasticity must be applied, and that for wrought iron is about eight tons to the sectional square inch, so for a plate 24 in. wide by ½ in. thick a pull of about 100 tons would be necessary. So long as no greater force is used than is necessary for the straightening it does not seem probable that the strength of the iron would be reduced by this process.

The bars of various sections, angle, tee, etc., will also require to be straightened, and this may conveniently be effected by pressure in a machine, the principle of which will be understood from the sketch plan shown at Fig. 4. A A is an angle bar, shown broken off, undergoing treatment in the machine; B, B, are properly-shaped blocks, against which the bar, A A, rests; they are solidly fixed to the bed of the machine. C C is a shaft driven by means of a belt on the pulley, D, and there is a fly wheel, H, at the other end to equalise the running. Upon the shaft, C C, is keyed a small toothed wheel or pinion, I, which works in gear with a larger wheel, K, keyed on to a second shaft, L L, upon which is fixed a strong eccentric, E. The revolution of this eccentric, which has a very small throw or stroke, drives forward the block, F, thus pressing upon the bar, A A, between the blocks, B, B; the extent of its action is regulated by raising or lowering the wedge, G, according to the degree to which the bar is bent; this adjustment is worked by hand. The action of this machine is by intermittent pressure for short periods, the bar being shifted as may be required between the

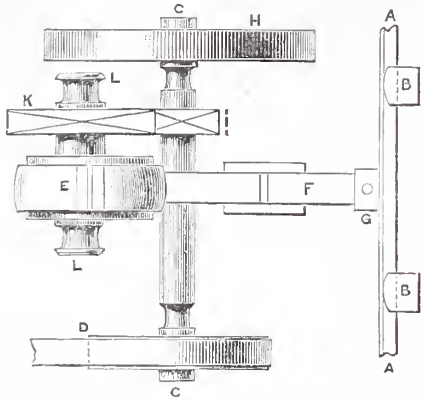

Fig. 4.—Machine for Straightening Angle Bars, T Bars, etc.

strokes. In the intervals of pressure the necessary momentum to impart it is stored up in the fly wheel, H, which gives it off when the resistance of the bar is met. From this simple form of machine much greater power is obtained, as towards the end of the forward stroke the pressure increases, until if resisted it becomes infinitely great. The bed requires to be very strongly made, its size and proportions being calculated in accordance with the strength of the largest bar it will be capable of taking, and the shafts and other parts must be in proportion, so that if anything breaks it shall be the bar and not the machine.

When angle and tee iron bars have to be curved or bent at an angle, the work must be done hot, as otherwise the normal angles of the sections would open, and in most cases the bars would crack at the root where the two limbs meet, and even when worked hot this opening will occur, and the bars must be hammered or pressed back to their original section. If the bar is made of uniform curvature throughout its length, and the curve is moderate, there will not be any special trouble from this cause, which is most noticeable in sharp bends.

If a number of angle irons are to be bent to a given curve, one is first so shaped, but to a curve so much sharper as to give the required form exactly to the others when bent hot upon it. Any slight opening of the angle can be set down by a few blows from a light hammer. In order to prepare the angle iron mould a template must be made, showing the curve it is to follow, and when of very large radius it cannot well be struck from a centre on the floor used for setting out work, but the arc required can be easily drawn by means of a bevel, the construction and use of which I will now explain. As a rule, all the curves used in girder work can be very closely followed by a series of circular arcs joined together, so if the length of each and its radius are marked upon the drawing, the foreman template maker need have no trouble in setting them out. There are a few simple properties of circles I will now point out, which will make the mode of procedure quite clear and fully explain its principles. In Fig. 5, G I H is a circular arc, of which O is the centre from which it is drawn, and I the centre of the arc. Now if from the points, G and H, two straight lines are drawn to meet each other at any point, P, in the arc, and two others are drawn to meet at some other point, P′, in the same arc, the angles, G P H and G P′ H, will be equal, no matter in what point in the arc the lines meet, so long as they are drawn from G and H respectively. If, then, we join two straight edges together so as to fit this angle, as shown at E D F, and put two pins, A and C, in the floor at a distance equal to G H, and fasten a pencil at the angle, D, then, by sliding the bevel thus made over the floor, keeping the edge, E D, against the pin, A, and the edge, D F, against the pin, C, the pencil at D will be caused to draw an arc of a circle, A B C, of the same radius as G I H. To be able to make this bevel we must know the length, G H, and the rise, Q I. These should both be marked upon the drawings, but very often they are not; then it will be necessary to calculate Q I. It will not do to scale it off the drawing, as any error so arising would be multiplied considerably in the full-sized template. The radius being known, divide it by one of the numbers in Column I. of the following table, selecting such a number as will give as a result a convenient chord length, G H, to work with. To find the rise of the arc in the centre of the chord, G H—that is, the length of Q I—multiply G H by 100, and divide the product by the number in Column II. opposite the divisor chosen from Column I. For example: let the radius be 116 ft.; take 8 as the divisor, then 116 divided by 8 equals 14 ft. 6 in., or 174 in., which is the length taken for G H; this multiplied by 100 is 17,400, and opposite 8 in the table we find the divisor 6,389; dividing 17,400 by this we get $2\frac{11}{16}$ in. for the rise, Q I, in the centre. Lay down the length 14 ft. 6 in. on the floor, putting in a pin at each end, and in its centre square up Q I $2\frac{11}{16}$ in., then G I H will be the angle to which the bevel must be made. The sides, I G, I H, must be prolonged to allow its apex, I, to approach the ends, G and H, without running off the pins. By means of this bevel the template can be made. I must now show how to shape the ends of the templates, so that the curves may be accurately joined at a change of radius. H S is an arc of shorter radius (H T, or S T), joined at H to the arc, G I H. In order that two curves may join without showing any break or distinct angle, the radii at the point of junction must coincide—that is, the shorter radius, H T, must lie upon the longer, H O. All that is required, then, is to mark the radius at each end of the template, then any two such templates being placed end to end, their curved edges will join accurately. The radius of a circular arc is drawn from any point in it as follows:—To draw a radius from the point, N, mark off on each side of it with compasses the equal distances, N K, N L, and from K and L as centres describe two arcs of equal radius, shown crossing each other at M, then a straight line drawn from N through M will be radial; and if two such lines are produced they will meet at the centre, O, of the arc. In order to allow the radial line to be drawn at the end of the arc, the curve must be carried a little further. In this case, N M would be the end of the template.

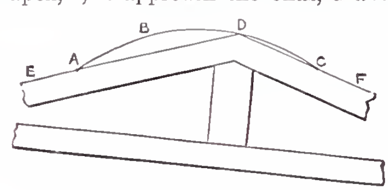

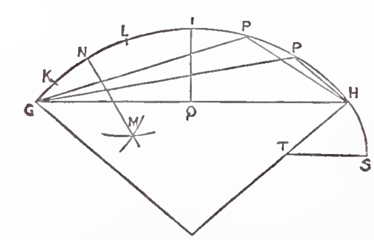

Fig. 5.—Diagram Exhibiting Properties of Circle.

(To be continued.)

THE ORDINARY CHIMNEY BREAST: ITS TASTEFUL TREATMENT AND DECORATION.

The accompanying illustration is a suggestion for the artistic treatment of an ordinary chimney breast.

Nowadays, every young lady of ordinary talent is capable of depicting floral studies accurately and with feeling; it being quite a common thing for our youthful friends to send pictures to the Royal Academy, in many cases, unhappily, without a chance of their works being exhibited. It is a pity that so much meritorious work should be wasted, and it *is* waste both of time and money in the case of most young artists.

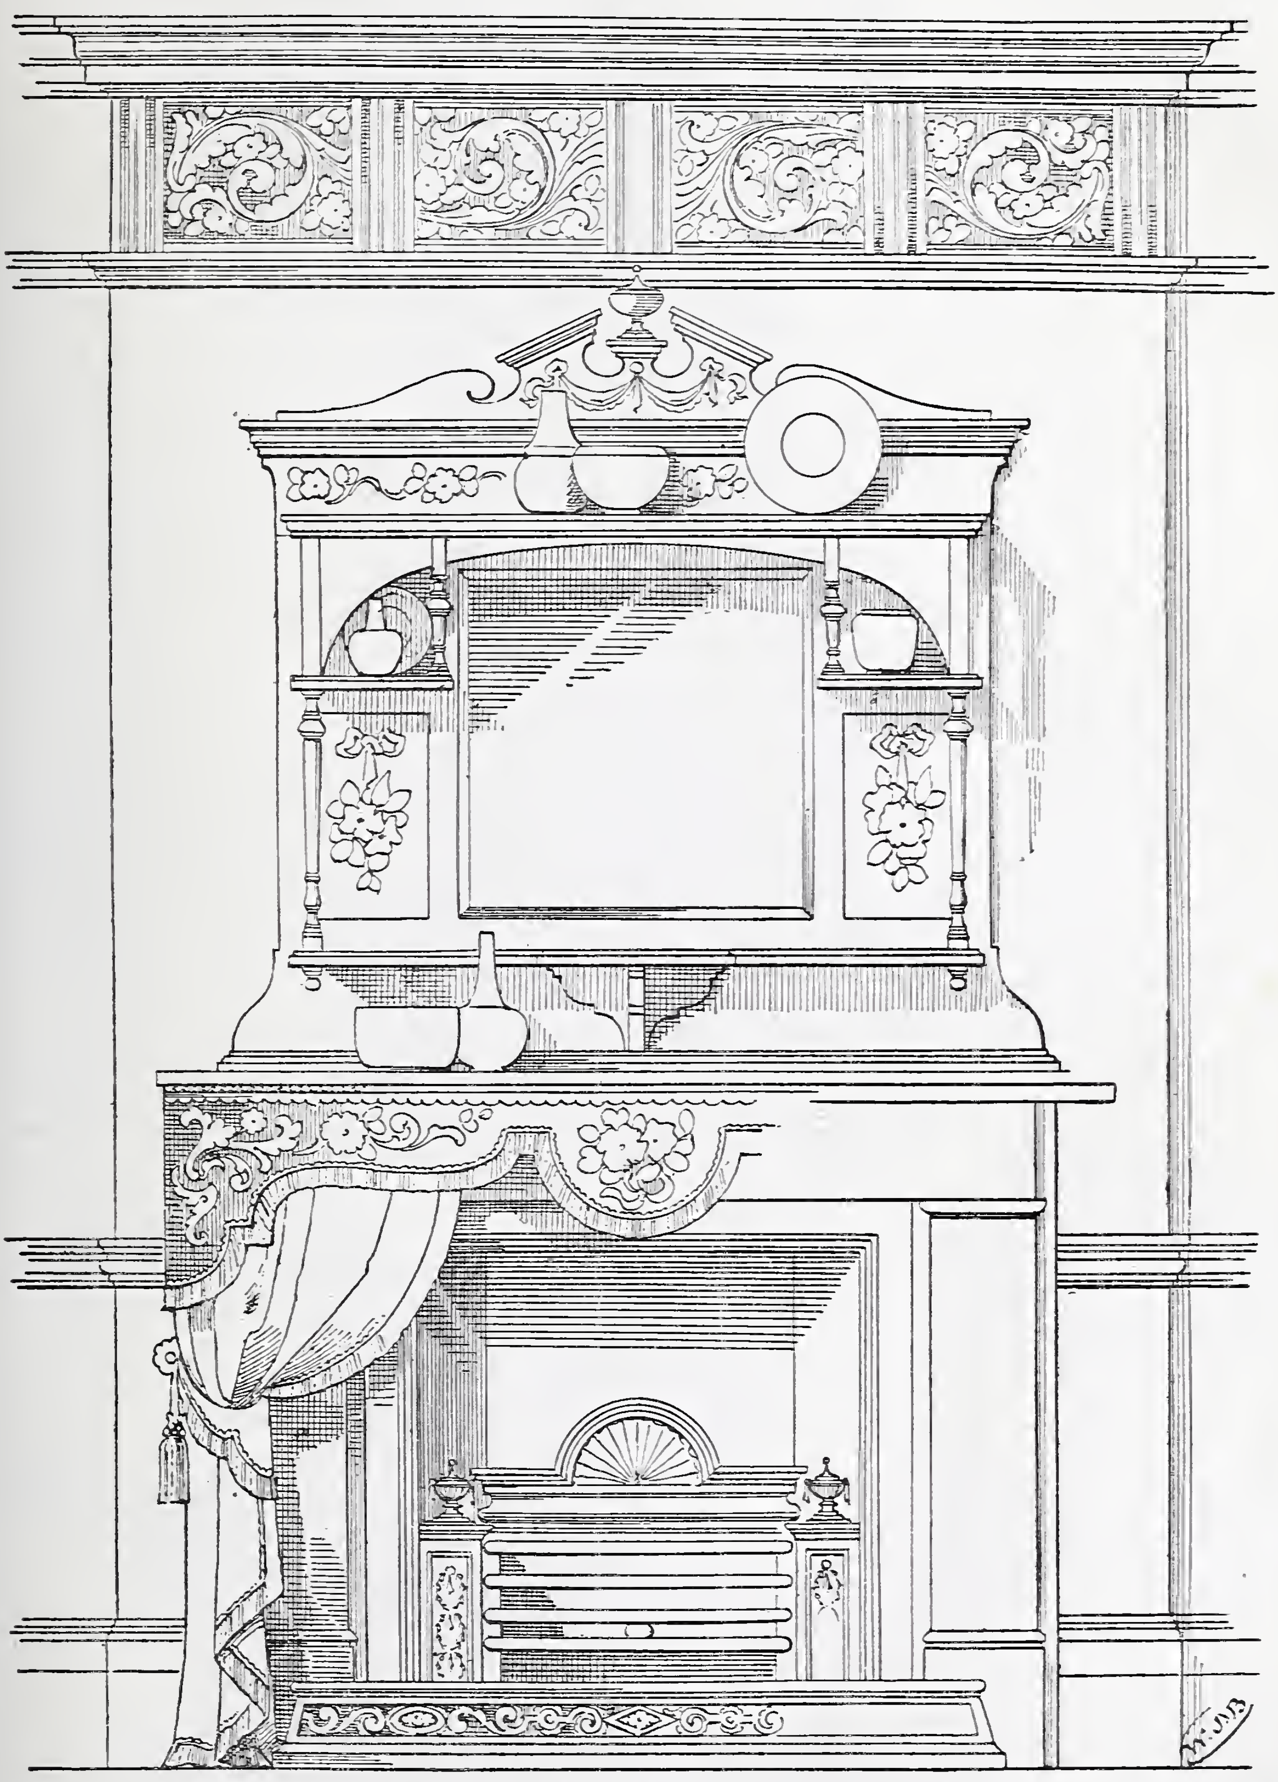
What I would propose to our young friends, as an outlet for their energy and talent, is the artistic decoration of their homes. Many of the flower paintings which are annually turned away from the Academy would form a pleasant relief to the panels of a door or window shutter.

My advice is that, instead of striving vainly for exhibition honours, they should devote a portion of their time and labour to beautifying the home. Why should they not paint the woodwork of their rooms in such delicate tints as egg-blue, terra-cotta, cream, etc., in preference to employing a man who is not an artist, and whose sympathies are not with his work?

The overmantel and chimneypiece shown in our illustration might be treated in plain tints, and then painted by hand in some tasty floral design. To begin with, the overmantel would have to be made in deal or pine, which would not be a very difficult undertaking for any moderately careful workman; then the entire woodwork of the room, including overmantel and chimneypiece, should be painted in one or more tints. A plain moulding would have to be run round the room at a distance of about 18 inches from the ceiling, to separate the frieze from the wall-paper filling, the frieze being either lincrusta-walton, hand-painted canvas, or ordinary paper.

The mantel valance is so simple that any lady could cut it to the required design, and embroider the pattern in crewels or silks. A few yards of gimp and fringe, and two small curtains sliding on a rod attached to mantel-board, complete the decoration of the mantelpiece.

The whole design admits of cheaper treatment than that illustrated; in fact, it is but a suggestion by which, I hope, some of the readers of WORK may be benefited.



Artistic Treatment of the Ordinary Chimney Breast. Frieze in Lincrusta-Walton, or Hand Painted; Wall Paper, Sage Green; Woodwork of Overmantel, Painted White or Cream, with Hand-Painted Panels.

PHOTOGRAPHIC DEVELOPERS.

ADVICE TO BEGINNERS.

BY L. IVOR POOLE.

THE tyro in the art of photography is not long in discovering that not the least of the difficulties which beset him is that of deciding on a formula for his developer. He sees so many of them given in any books to which he refers that it is no wonder he should feel perplexed. First of all he must decide whether he will use pyro, oxalate, or hydroquinone, the new claimant for favour, each of which is strongly recommended for his purpose. Then he must make up his mind on the host of minor details, and failing to do so satisfactorily, he applies to a friend who has made some progress. He will probably then have his doubts set at rest by being told more or less authoritatively that one particular developer is best. Armed with this assurance, he starts development with the formula recommended; some of his negatives turn out satisfactorily, but a good many of them do not. Some of them are flat, some thin, some too dense, and so on. The chief feature in which they exhibit some uniformity is that there is something wrong about most of them. Naturally he is enthusiastic about his hobby. He talks with others about his successes and failures, wants to know the cause of the latter, and how to avoid them in future. Some sympathetic friend is sure to be found willing to aid him and to give the benefit of his counsel. In due course the question of developer comes up. The friend probably remarks that another formula is better; he uses it himself, and perhaps brings out a photograph to show its capability of producing good work. The tyro is eager to try it, and vainly hopes by its aid to have good negatives henceforth, bright and clear, dense where required, quick printing, no stain, half tones and all the other qualities which combine to form a perfect negative. Disillusionment soon comes, for developer No. 2 is no more reliable than the other. Other friends are applied to and with like results. They get good negatives, but the beginner cannot, and so he goes on messing about without making much real progress in the art. He either becomes disgusted with photography or sends his plates to a professional to be developed. In the latter case a fair number of his negatives are satisfactory, and he will have some nice pictures to show. He will, however, know none of the true delights of amateur photography in the same way as the man who begins and finishes the photograph. His share of the work is almost limited to the exposure of the plate, a very necessary operation, but by no means the only one before the negative is finished. Such operators are rather plate exposers than photographers, and it may fairly be assumed that few beginners start with the intention of having the bulk of the work done for them.

This being so, a few words of advice to him who intends "going in for photography" this summer, or any other time, may not be unacceptable from one who *has* gone in for it for some time past. Of course, I have my own pet formulæ for different photographic processes, though they will not be named, not from any desire to withhold them, but simply because to give them might further embarrass the tyro instead of helping him to decide on formulæ for himself. The intention of these remarks is rather to indicate the general principles which should guide him, than to confine him to details.

First of all, let it be distinctly understood that there is no formula which is equally suitable for all purposes and under all circumstances; even if the ingredients admit of almost universal application, their proportions must be modified to get at all times the best results. With the chemical constituents of any developer the mental one of judgment must be largely used. Development is not a merely mechanical process, but is distinctly an art. The chemicals used are simply the tools, and their use may be very clearly demonstrable theoretically up to a certain point, beyond which the intelligence and skill of the operator must in practice carry him forward. Were it possible always to work under precisely the same conditions, such as unvarying activity of light, perfect uniformity in plates, temperature of the weather, etc., then indeed development might be reduced to a mechanical operation. As it is, it is no more so than that of an artist in painting a picture. A right comprehension of this, therefore, will save the tyro some disappointment, even if it does not help him to any great extent in producing a good negative.

Naturally, at first especially, a developer which allows of considerable latitude in time of exposure will be the most useful. A developer which cannot be modified to bring up an under exposed plate, or to restrain an over exposed one, cannot be so satisfactory as another which works fairly well, when used judiciously in either case. As a matter of fact, in the hands of experts there is no developer among those generally employed which does not admit of some latitude in exposure; but some are more easy to work with than others. That which can be most easily manipulated is of course the one which ought to commend itself to the tyro, who, however, must not make the mistake of supposing that with even the best of them in this respect the time of exposure is of no consequence. The best results possible can hardly be got unless the timing has been correct, though trifling errors, which are unavoidable, may be so far corrected that they are hardly discernible afterwards.

As the beginner is almost sure to try a pyro. developer, that is, one in which pyrogallic acid is the active agent, it may be said that he can hardly do better. If he cannot manage with it he is hardly likely to succeed with any.

Now comes the consideration of the particular pyro. developer to be used. The best advice I can give him is to choose a simple formula, consisting of nothing but the active agent, the pyro., a restrainer, usually a bromide, and an accelerator, such as ammonia. These are all that are actually necessary, and by varying their proportions it is possible to do almost anything that can be done in the way of development. Let therefore a start be made with the formula containing the fewest ingredients. By working with them, the novice not only obtains a command over the essential chemicals without them having been modified by the addition of others which, though useful in their way, are not essential, but he learns to appreciate practically the advantages offered by these. He has the rudiments of practical development on which to build his future practice, if he finds it necessary to improve his resulting negatives. He will not be long, for example, before he finds out that a pyro. developer such as described darkens and perhaps stains the negative. Of course, the stains may be removed, but that is hardly the question just now. He may wish to keep his pyro. in solution instead of weighing out and mixing it for each lot of developer, or lots of little matters may suggest themselves to him as being capable of improvement. As similar ideas of improvement have occurred to others, we get the numberless formulæ which have appeared, and however bewildering they may be to the novice, he must remember that each ingredient is advocated for a specific purpose, and in the vast majority of cases has had fair trial before it has passed the bar of photographic public opinion. It is, however, only the expert who can to the full benefit by such refinement, and no expert ever became one who could not do good work with the simplest formula. Though I have spoken of pyro., the same principles will apply to any other developer, as, for instance, the one which is causing so much stir just now in the photographic, or perhaps I should say, in the *amateur* photographic, world, viz., hydroquinone. No opinion is here expressed about the comparative merits of either or between them and other chemicals, whether used as developers, restrainers, or accelerators; but enough has been said to enable the beginner to form some notion of the kind of formula he should start with. He may be further advised not only to start with such a one, but to keep on with it till he has attained proficiency in its use, till he knows positively from experience in what direction he may reasonably require improvement on it. Stick to one developer will be a good rule for him to follow. Its peculiarities become familiar with practice, and by care he can manipulate the developer in a way to produce good results that might at first have seemed impossible. If on the contrary he chops and changes about, first trying one developer and then another, he gives himself no fair opportunity of thoroughly satisfying himself about their good or bad qualities and what they are capable of. He never gets to the bottom of them, and as no two developers require exactly the same treatment, he too hastily assumes that the fault lies in them rather than in his own inexperience. The amateur who makes progress in proficiency, and consequently in the pleasure of practical photography, is he who has learnt well one branch or mode of manipulation before proceeding to others. This, after all, is only common sense, but, as suggested in the opening remarks, the obvious advantages of beginning and continuing with a simple developer do not always occur till time has been wasted and experience gained.

But perhaps the beginner may think this rather confines him, and that were every one to act on the principle of sticking to one developer no progress would be possible. He would rather experiment for himself, and, if he can, add to the general fund of photographic information. Every one knows that the hidden mysteries of nature and art are only divulged by patient investigation, barring the usual exceptions which prove the rule, where they have been discovered by accident; and he is actually recommended to debar himself from any good which might accrue from scientific observation, or from profiting by a lucky accident. They are always possible, you know, and no one has discovered how to photograph in natural colours yet.

Such is by no means the intention of the present remarks, which are written to help the beginner, who will surely not overlook the fact that improvements in any art can hardly emanate from a novice in it. After he has emerged from his novitiate it will be quite time enough for original research to begin, and the more of it the better.

OUR GUIDE TO GOOD THINGS.

43.—Glover's Machinery for Splitting and Bundling Firewood.

Almost everything, except eating, drinking, and sleeping, is done by machinery nowadays, and machines are contrived for the performance of household operations and many kinds of manual labour which our fathers invariably carried out by hand. Even for work of so simple—I might also say, so uninteresting—a character as chopping up firewood, machinery has been devised and patented by Messrs. M. Glover & Co., Potterdale Works, Dewsbury Road, Leeds, by which the work is effected with a certainty and rapidity in every movement which cause a considerable saving of time and labour. There may be some readers possibly who doubt the utility of describing such machines as these as foreign in some degree to the nature and scope of Work, but it must be remembered that every kind of machine is possessed of interest to the mechanic in the first place; secondly, that the illustration and description of machinery are often useful in prompting some inventive brain to the production of other machines of the kind distinguished by greater simplicity, perhaps, and additional power; and, thirdly, that the industry, in aid of which such machines are contrived, must be of far greater extent and importance than would appear at first sight to any one, either to do work of the kind or to see it done by means of the ordinary hand saw and hatchet. More than this, the mention of the machinery here may cause its introduction into union houses and other places where much of this kind of labour is done by aged men, who are far better able to watch and attend to machines of this sort than to apply their fast-fading strength to the performance of the acts of sawing and chopping.

In Fig. 1, the Patent Splitting Machine is shown, which is used for dividing the wood into small pieces, instead of the hatchet or chopping knife, hinged at one extremity to the bench and having a handle at the other. The wood is first cut into pieces or blocks six inches long, as shown to the left of the machine, the grain of the blocks being vertical or running from end to end. They are carried by means of rollers into the machine, and placed under a cross head carrying a heavy chisel, which acts in the same manner as the chisel of a mortising machine, falling on the end grain of the wood, and splitting it cleanly from top to bottom, the grain of the wood being followed in the stroke by the action of an automatic side spring placed in the feeding trough opposite the knife, partly to keep the wood in place, and partly to prevent any undue resistance that might be offered if the wood were held so rigidly in position that it would be absolutely unyielding when split by the chisel. When the strap by which the machine is set in motion is thrown off, the latter is stopped by a brake applied to the wrist pin disc. The size of the pieces into which the blocks are split is regulated by the rate of feed. The sticks as they leave the chisels are carried forward on rollers towards the Bundling Machine, shown in Fig. 2, the rollers acting as a kind of sieve through which all dust and dirt that may be adhering to the sticks fall from them. The sticks, as seen on the right of Fig. 1, are placed on a travelling band in the Bundling Machine, and carried into a box, where they are shaken together and gathered and compressed into round bundles by four formers, the ends having first been brought level by a plunger, which pushes the sticks up to a diaphragm which then withdraws. After compression into bundle form, the mass is forced from the box by another plunger, actuated by a cam, and forced outwards through a tube slightly convergent, and having a spring top in the manner and position shown on the right of Fig. 2. Here they are further tightened up by a band of steel drawn up by strong toggle-joint gearing, and the bundle is then wired by wire held by a clip above, which can be released by a foot lever. The ends of the wire are then twisted by the revolution of the clip, and, the bundle being completed, is pushed out of the machine by the next in order to be wired. Figs. 1 and 2 can be worked separately or in combination. The "Excelsior" Bundling Machine, shown in Fig. 3, is worked by the foot, and is intended for smaller requirements. The lever (7), fixed at the further end by the pin (8) on which it moves, acts by means of the vertical rod (6) passing through the bed or plate (1), secured by bolts to the table on which it is placed, and the toggle joints (4) on the sliding jaw (3), which moves into the fixed jaw (2) in front of it. By these jaws the sticks are compressed into bundle form, and are then wired or tied by hand, after which the bundle is released by the spring (5) below the stand. In this machine there is nothing in the form of ropes, chains, etc., that requires renewing, and time is saved in the rapid release of the bundles, which are made round, level at the ends, and of uniform size, by the action of the machine, which makes the work easy to the operator, and obviates the necessity of close supervision.

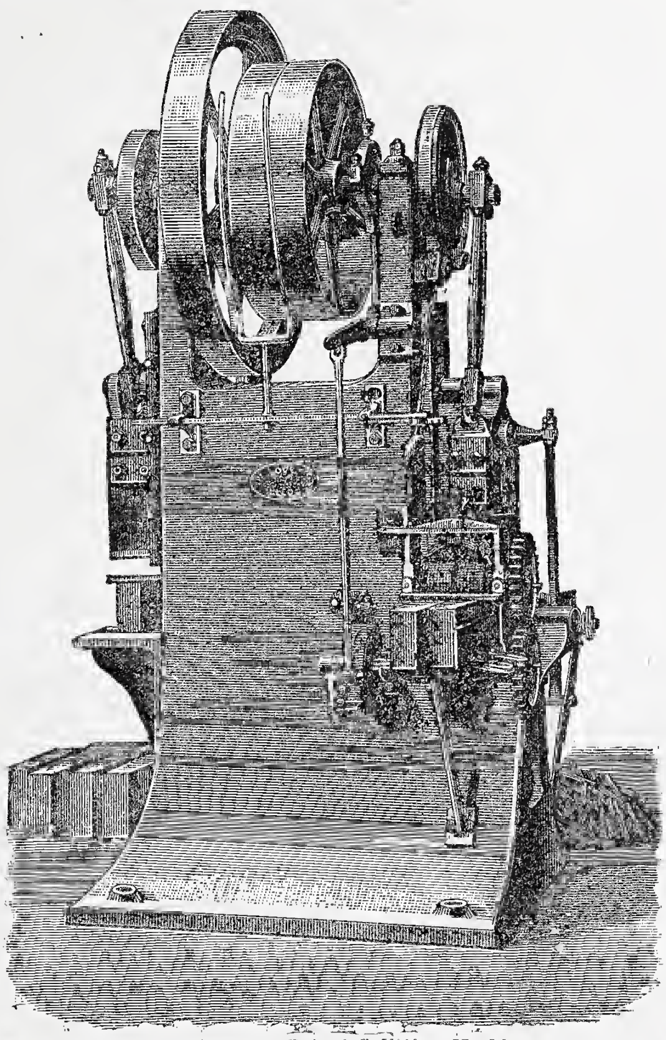


Fig. 1.—Glover's Patent Splitting Machine.

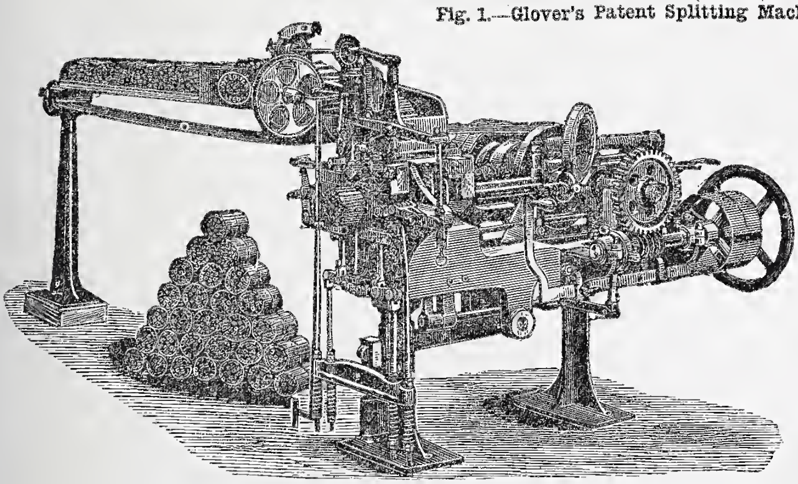

Fig. 2.—Glover's Patent Firewood Bundling Machine.

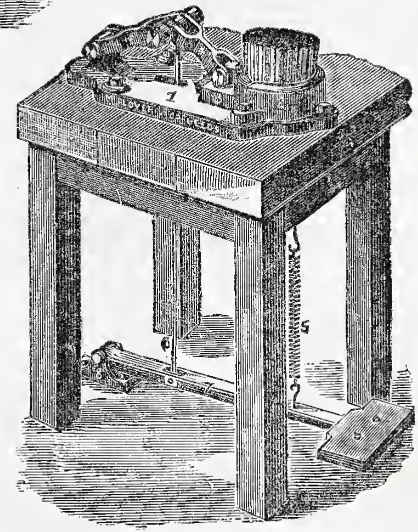

Fig. 3.—"Excelsior" Patent Firewood Bundler.

It seems at first sight somewhat marvellous that machinery of such size, power, intricacy of construction, and value, should be necessary for carrying out such simple operations as splitting and bundling firewood. Its very existence, however, proves the demand that there is in the present day for labour-saving apparatus, even for work of the most ordinary character. The Editor.

A Corner for Those who Want to Talk It.

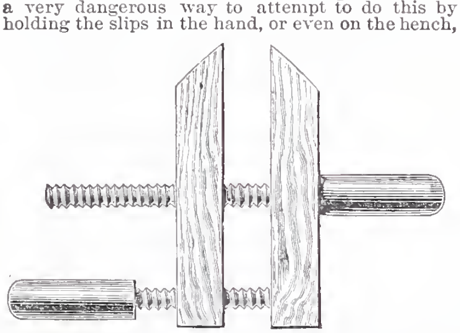
*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Circular-Saw Rigs for the Lathe.—A Foreman Pattern Maker writes:—"As the writer of the article on 'Circular-Saw Rigs for the Lathe,' I have tried to understand the meaning of your correspondent's criticism (G. E., *Camberwell*, p. 78), but in vain. He speaks of 'Fig. 1' as representing 'a superfluous amount of work for small results to an amateur in the screwing or tapping a chuck to obtain a counterpart.' From this I gather that G. E. takes exception to the trouble of cutting the thread in the saw spindle. But the same objection would apply with equal force to the fitting of lathe chucks of any kind. Fig. 3, without the thread, and made square ended for a square hole chuck, and lathe centres, is 'much better adapted,' but 'the square should taper 15°.' Well, I do not attempt to give dimensions, or taper to suit any particular chuck at all, and those who possess square hole chucks can make spindles to suit them. I simply give the general design. Again, 'the saw driven between centres of 60° is the most lasting, and less liable to run out of truth.' I don't see why a chuck like Fig. 1, tapped for the mandrel nose, should run out of truth any more than an ordinary lathe chuck. I know a wood turner who has been using spindles and saws, rigged like Fig. 2, for several years, without their running out of truth. And in the article, I advised steadying one end of the spindle with the poppet centre in cases where the fit of the thread may be imperfect. Besides, your correspondent should remember that a mandrel nose terminates in a collar, which helps to steady the chucks, and minimises the evil due to badly-fitting threads. I do not quite understand why G. E. thinks the table let into the rest socket the best. It certainly has the merit of simplicity, but I prefer Figs. 4 or 7, because they can be fitted with fence."—[The diagrams to which reference is made here will be found in No. 1 of Work, pages 8 and 9.—Ed.]

Metal Ball Making.—A Reader of "Work" writes:—"I should very much like to see an article on sheet metal press work in your valuable Work. It is a subject that does not seem to be very well understood by writers in technical papers generally. I once saw some hollow balls made from one piece of sheet brass, with only a small hole where the metal had been brought round to. I asked in one of our leading mechanical papers what tools and appliances had been used, but could get no answer. And then there are such things as military ornaments, some of which are quite works of art. I hope you will be able to see your way to insert an article on the above subject."—[Probably the balls you mention consisted of two hemispheres moulded by pressure, or produced by a process known as "metal spinning," and then joined edge to edge and neatly brazed or soldered together. Perhaps some reader may be able to give you the information which you failed to get from the quarter indicated, in the form of a letter, etc.; if necessary, a paper describing the means used.—Ed.]

Sharpening Carving Tools.—J. W. B. writes:—"In No. 7 of Work I notice a reply to Tom on the mode of using slips to sharpen carving tools. It is a very dangerous way to attempt to do this by holding the slips in the hand, or even on the bench,

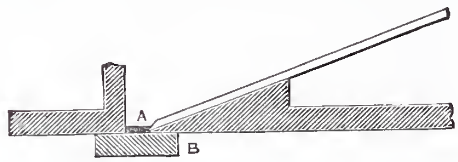


as the tool may slip as well. A much better way is to secure the tool in a hand screw (shown in illustration), and then fix the latter in the bench vice.

A Good Word for Work.—Dulcimer writes:—"I have taken in Work since the commencement of its issue, and have circulated the copies amongst friends, who have almost, without exception, determined to become subscribers. I think no one can do less for a work which will probably have more effect in rendering home healthier and happier than any legislative measure can do. The various ways in which this can be effected need no comment."

"Disgusted Abandonment."—E.C. (*N. Brixton*) writes:—"Buying No. 6 by chance, seeing its hook-binding diagrams, I ordered No. 7, in reasonable expectation of its being concluded or continued *seriatim*, but it is neither so, nor any intimation present or future; so, though it may be imagined a bond of continuance, it may equally end in disgusted abandonment, if one can never reckon on things being *regularly* carried through. Perhaps washing would not be thought work, else there is a new system with solid paraffin used which would be of general interest."—[I hope you are now buying Work regularly, as you ought, and have come on the continuation and conclusion of "Binding made Easy," which duly appeared in No. 9. For my part I think the expectation of continuation of any subject from week to week the reverse of reasonable, for many reasons, the chief of which is that if such a course were rigidly followed, variety would be unattainable. Be assured that nothing once commenced will ever be discontinued, save under circumstances that are not influenced by human control, such as the death of a writer before he has completed his subject, and even in this case another would be sought to gather up the broken threads, and carry out the work. The ladies say—especially those who take it in hand—that washing *is* work, and hard work too. So if you will kindly enlighten those who buy Work—and I believe there are many who do—with an account of the new system, they will be sincerely obliged to you. The fact of your writing shows that there will be no "disgusted abandonment" of Work on your part, but that you are on the look-out for a rejoinder to your remarks. Well, here it is.—Ed.]

Pattern of Plane for Casting.—E. P. W. writes:—"I have read the article on home-made planes, and I think it is my duty to mention that when a pattern is made for a casting, it should not be cut quite through, and there should be a thin piece glued or tacked on to the pattern where the mouth is to be, because it is difficult to have a clean casting when the mouth is cut through, and the part that forms the bed for the iron, being very thin, cools very



quickly, and is sometimes so hard that a file will not touch it. This will prevent it, and there will be no trouble in chipping or grinding the projection off, and then when the casting has been planed or filed up, as the case may be, the mouth will be through, and there will be no trouble. I hope the writer of the article will not be offended, as I do not write this to offend him, but for the benefit of any one that may be following his instructions, and be fixed, as I have been. I speak from experience."

Work's Utility.—F. E. writes:—"As one who has benefited by your Work, I feel constrained to inform you that I too made use of No. 1 (though not the cabinet), but I made one of Mr. Adamson's tables, putting the shaped top on to the shaped stand, which, after being enamelled a pink colour (probably terra-cotta would have been better), I found was a pretty table, acceptable to my employer. I hope you will, in due course, treat of the *Upholstery and Polishing Trades*, in which I am more immediately interested. The articles by Mr. Denning and those on the cutting, etc., of tools, I regard as especially good."—[We are all glad to know that No. 1 of Work has proved genuinely useful to you. I am sure that hundreds of workmen will find it useful in the same way—namely, as a mine from which to quarry ideas. Try the overmantel in No. 2. Upholstery and polishing will be treated in due course.—Ed.]

Tube Saws for Ivory.—F. A. M. writes:—"Many of your readers will envy me when I tell them I have just paid a visit to the workroom of a famous ornamental turner, Rev. C. C. Ellison. Amongst the many interesting things were some tube saws for cutting blocks of ivory into cylinders with the smallest possible amount of waste—a most important object with ivory at its present high price. Those who have read Mr. Evans's book on 'Ornamental Turning' will remember that it contains a description of some bent cutters for use in the spherical slide rest, contrived by Mr. Ellison for cutting a number of hollow half spheres out of a solid one; these tube saws are the complementary tools for similar use where cylinders are concerned. I was first shown a series of ivory cylinders about $\frac{3}{16}$ in. thick, one within the other, and at least 4 in. long, whilst there was only about $\frac{1}{16}$ in. between the internal diameter of one cylinder and the external diameter of the one within it. Evidently a parting tool could not produce such work. A little further on I came upon a set of cylindrical or tube saws, and the secret was revealed. Mr. Ellison procured a set of solid drawn steel tubes from the Credenda Steel Tube Works, Birmingham. The length of the smaller, from 1 in. to 2 in. in diameter, is 6 in.; the larger sizes, from 2 in. to 4 in. diameter, are 9 in. long. These tubes, being too stout, were reduced by turning to about half their original strength, when they became from $\frac{1}{16}$ in. to $\frac{1}{32}$ in. in thickness. The pitch of the teeth, as well as the thickness of the saws, gradually increases with the size, from $\frac{1}{16}$ in. to $\frac{3}{16}$ in. from point to point, and the teeth are set rather upright. The saws are advanced into cut by the back centre, whilst the block of ivory revolves in the lathe. A shouldered cylinder of hard wood is fitted into the hinder end of the saw, which piece of wood has in it a conical hole to receive the point of the back centre. A groove is cut with a parting tool in the face of the work to form an entry for the saw, which must be wet when the material operated upon is ivory, and the saw has to be frequently withdrawn to clear it of cuttings. Mr. Ellison considered the saws could not be so well made by bending round and brazing a saw blade. Perhaps some practical workman who sees this will give an opinion upon it; and possibly some firm of tool makers will be found to undertake the manufacture of such sets of saws, and will tell us what they think they can be supplied for."

Fretwork Cabinet.—Engine Driver writes:—"I feel quite jealous of the honour you have bestowed on T. F. of being the first to use No. 1 presentation plate. I had finished a fretwork cabinet on the 20th, and would have wrote telling you of it, only I had used a cigar box for my fretwork (don't let Mr. White know this). However, I have got a real nice cabinet, and you will please give Mr. White my humble thanks for his beautiful design. I must also thank Mr. White for his 'tip' for ebony staining, and Mr. Denning for his valuable hint for mixing glue. I could never make glue stick until I read his article, and now I think I could make glue that would make an M.P. stick to his promises. I wish you every success, and have to tell you, by the way, that six of my shopmates who have seen my cabinet intend to get Work regularly."

Cabinet in Fretwork.—T. F. (*Willington-on-Tyne*) writes:—"I thought I would just like to write and let you know that I did not allow the little difficulty I met with in commencing to make the first cabinet dishearten me; far from it, for I never allow any sort of fretwork or plain inlaying to be my master, and when first I got sight of the cabinet pattern in No. 1 of Work, I took a great liking to it, for it is the very best I have met with, and as the designer said it was certainly worth doing well. So I thought I should like to let you know the trouble I am going to to make it, as near as possible, a success and a good finish. In the first place I have used up four of the cabinet patterns during my experiments. First I cut out one door $\frac{1}{16}$ in. thick, and filled in with a composition of different colours, using the proper system of indicating colour: red for the flower, yellow for the stem, and green for the leaf, but this did not please me. So then I tried another door, in plane tree, which is white. I cut the pattern all out first, and then I stained the glue quite black, and glued the pieces, and put them all back again, and when it was cleaned up the black glue showed the line of the pattern up something nice, although this was not quite to my taste. So now I am inlaying the three right-hand doors with plane tree laid into a walnut ground, and the three left-hand doors are being inlayed with walnut into a mahogany ground, so I think it is as near to perfection as one could get it. I forgot to say that I tried very thin wood, but it does not bring the pattern out so well as my last experiment, but of course a lot of patience is required, and unless beginners in fretwork or inlayers are not prepared with a lot of patience and time, or if they do not take a delight in the art, they had better not commence it. I have been now twenty-two years at fretwork, and my patience has never once yet run short, although I have many times been weary in it but not of it. Here is a proof of the trouble and time I have been to. I once, while I was in China, made a basket called the stag hunt; it took me many months to finish it, for there were over 1,500 cuts in it, and some of the pieces as small as a pin's head. How many beginners in fretwork are there who would go to the trouble of first cutting that pattern out with his penknife—for I have that pattern still by me—and then paste it on to wood, and then cut it out with his fret saw, making altogether 3,000 cuts, and still have his patience as fresh as ever? I should like some day, sir, if I can find time and you space, to let you know, or rather your readers, how I treat my fret patterns, for I never destroy them; some I have had by me this twenty years, just the originals as I bought them. I have two books full, and they are very nice scrap books to look at. I have never fell across any one in England who treats these patterns as I do, but of course there may be some who do."—[Your patience and perseverance are remarkable, and eminently praiseworthy. By all means let us know how you treat your fret patterns. The knowledge will be useful to many readers.—Ed.]

Something Cheering from Kerry.—Iernus writes:—"Being a subscriber to the *English Mechanic* for some short time back, I happened to see in an issue of that paper of about the 1st March last an advertisement of Work, and seeing that it seemed to be the kind of paper I wanted, I sent to Dublin for a number of it, and it turned out to be indeed all I could desire. So you see the first number of your paper found its way even to 'the wilds of Kerry.' I need not tell you I have continued to get it since, and that I will recommend it to all whom I can. I am sure some articles on speculum grinding, and silvering and telescope making, would be very acceptable to many besides myself. Perhaps Mr. Bonney would be kind enough to give us some articles on telephone making. I must mention with regard to all articles which have appeared in Work up to this that they are all as clearly written and as useful as any one could desire. I may say, in conclusion, that I wish a long and prosperous career for Work."—[Thank you for your good wishes and commendations of Work. I am glad to say that Irishmen are numbered among the contributors to the Magazine as well as among its readers. On my staff are writers of ability and experience on the subject you name, and these will be taken up as soon as opportunity offers. Meanwhile, ask any question in reference to either, or both, of them, and your inquiries shall meet with the best replies that can be given.—ED.]

Touching "Shop."—G. P. B. (*Darlaston*) writes:—"Having taken in WORK from the commencement, and being immensely pleased with it too, I desire to add my little meed of praise to that you have received from so many correspondents. I have been particularly struck with your 'Shop' column, and the courteous manner in which all letters of inquiry on a vast variety of technical questions have been answered week after week. Although I, too, have many questions to ask I refrain for the present, seeing that this week you have more questions to reply to than ever, but before long I shall have to trouble you. In the meantime may WORK go forward and prosper as it deserves to do; the very fact that so many apply to it for advice proves conclusively how much the venture is appreciated, and that a long and useful career is assured."—[I do not know that I deserve your commendation for courtesy in replying to letters of inquiry. I should be sorry to be otherwise than courteous to any man living. It is my belief that it is by kindness in speech and manner that one chiefly obtains influence over others. Believe me when I say that in all I say in WORK or do with respect to it, I am chiefly actuated by a wish to be useful in and to my generation, God permitting. Ask what you will, when you please, and, if possible, an answer shall be forthcoming from one of my staff or myself. Failing this—for we do not pretend to know everything, either individually or collectively—your queries shall be submitted to WORK'S readers at large, in the hope that one or other of them will be wiser than we on the point. It is impossible to put more than a quart into a quart measure, and equally beyond possibility to put more into WORK'S sixteen weekly pages than what they contain at present, having regard to legibility, etc. I suppose WORK will have to grow in superficial area one of these days.—ED.]

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Type: How Made.—ELECTROTYPE.—Types are cast in moulds from type metal, which is a composition of lead, antimony, and tin, in various proportions according to the size of type.

Work on Electricity.—ELECTROTYPE.—Possibly the best work for your purpose will be "Electricity in the Service of Man," edited by Dr. Wormell, now publishing in monthly parts at 6d., and of which three parts are published to the present time.

How to Obtain a Patent.—A. D. (*Bury*).—In the reply to a correspondent to which you refer, £1 10s. was inadvertently or accidentally written for £1. At the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C., a "Circular" may be obtained giving all information on the course to be taken to obtain Patents for Inventions in the United Kingdom. Possibly you will wish at first to obtain provisional protection. This lasts for nine months, and during this time you can be developing your patent with the view of obtaining complete protection at the end of this time. Or you can obtain complete protection at once. If you merely require provisional protection the fee is £1; with another fee of £3 for complete protection at the end of nine months. For complete protection at first the fee is £4. You can obtain the form of application through any money order office at a few days' notice, and by prepayment of value of stamp. At Bury, where you reside, you may obtain the necessary form at once from the head office on application, and payment of fees, for I note that Bury is named in the list of places in the United Kingdom where forms of application are kept on sale. The "Circular" to which I have alluded above, and which is obtainable at the Patent Office, will afford you all other information in detail.

Kit of Carpenters' Tools: its Cost.—COST OF TOOLS.—Anything relating to practical work is worthy of attention in this column; but I am afraid very little in the way of direct answer to your questions can be given. First, it is impossible to say what constitutes a complete outfit. If you make a "hobby" of your tools you may run to any cost you like; and, on the other hand, you may get a very fair assortment for general work for a very few pounds. At the most, the outlay at any one time is not heavy, if you go the right way about it, just adding a tool as you find it advisable, or as opportunity occurs for getting what seems likely to be useful. The quantity and style of tools also depend a good deal on the class of work to which you devote yourself, and whether you have one or two good-natured shopmates who are willing now and again to lend a youngster some out-of-the-way tool he may not possess. In many shops no tools at all would be required at "just starting," for the simple reason that the work is almost confined to attending to, and waiting on, the men; but you may, I think, take it for granted that for the first twelve months a sovereign would well cover your outlay for tools. Much, however, would depend on what your employer or foreman might consider necessary, and this you can always ascertain before being engaged. If you go "on trial" for, say, a month, you would not probably be expected to possess any tools during the probationary period. You will thus see the difficulty of giving you definite answers, but what I have said will, no doubt, be of assistance to you.—D. A.

Practical Method for obtaining the Bevels of a Bevelled Hopper or Box.—X. Y. Z. (*Orkney*).—The reason that this question presents some difficulty to the average mechanic or amateur is because the sides are not at right angles or upright with the top or bottom, as the case may be, but bevelled. If the angles of the box or hopper were square, it would be simple enough, and all that would be necessary would be to set a bevel or square to the bevels or joints required. Fig. 1 given herewith represents the section of one side

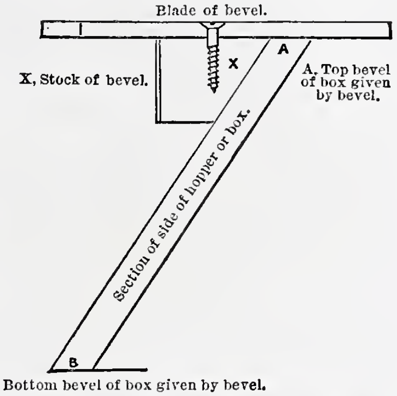


Fig. 1.—Section of Side of Bevelled Hopper or Box.

of a bevelled hopper or box, and all that is necessary is to make a simple wooden bevel, with one side of the stock bevelled, as shown at X, to the splay required, and set the blade of bevel to the necessary angle, as if the sides of box were upright with the bevelled side of stock against the work (always setting angle of blade of bevel from the square or upright side, which is marked darker in the diagram). Fig. 2 represents the plan of bevel,

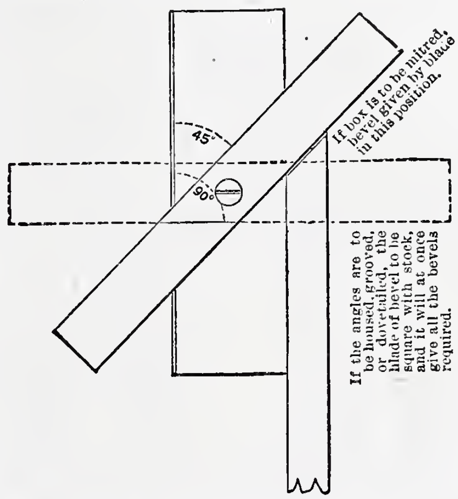

Fig. 2.—Rough Sketch of Bevel, for giving at once all the Bevels required for making Bevelled Hopper, Box, or Splayed Window Linings, etc.

with the blade set to an angle of 45°, or, practically speaking, a mitre, and shows the method of applying same to mark the mitre of angle—that is, if the hopper or box is to be mitred. If the angles are to be dovetailed, housed, or grooved, the blade must be set to an angle of 90°, or square, just the same in all respects as if the hopper were square, with the one exception that one side of the stock of bevel is splayed to suit the splay of hopper required. Fig. 3 shows the method of cutting out

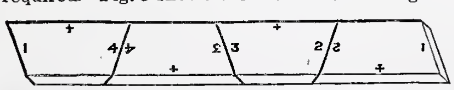

Fig. 3.—Showing Method of Cutting out Sides of Box to save Material.

the sides to save waste of material, and it will then be seen that after cutting and turning two alternate pieces upside down the angles will coincide. Of course, if the angles are not to be mitred, allowance must be made at each cut for overlapping. If X. Y. Z., after getting his stuff to the proper width, first bevels the top and bottom of his sides (the position of bevel, in Fig. 1, determines these bevels), and then marks the splays required, as Fig. 3, he will, on applying the bevel, at once see the simplicity of this method. The same rule also gives the bevels for the angles of splayed window linings, and that much-discussed problem—the bevels of a washing tub.—E. D.

Preparing and Polishing Wood.—G. W. (*Bermondsey*).—A series of articles on this subject will appear in due course; but, pending their publication, I shall be happy to help you in this column if you will let me have particulars of what you want to know. It would be of the very greatest assistance if you and other inquirers would state the kind of wood and the style of finish desired, as at present to answer the question fully would require a complete treatise. For example, I do not know whether your things are pine to be stained to imitate some superior wood; then whether they are to be polished or varnished, or whether they are of wood—say mahogany—to be finished bright or dull, darkened, or natural colours, etc. If you will write again I shall be pleased to tell you, as you are quite right in supposing that I am prepared to help workers; but, of course, before I can do so, it is necessary I should know as many particulars as possible. With these in hand, you may depend on getting reliable directions.—D. A.

What to Do, and How to Do it.—W. H. M.—You say, "I am in the Post Office, and have a lot of spare time on my hands, and feel that that time is absolutely wasted, having next to nothing to do; so what I have long desired is to learn something about joinery and carpentering, and I wish I could get to know some carpenter or master from whom I could obtain some knowledge in return for any services I could render." From this I gather that you are a letter carrier, and have spare time between the deliveries that you wish to utilise. If I am wrong, forgive the incorrectness of the inference; but reading between the lines of your letter, I am led to this conclusion. Well, you seem to be possessed of a little ready money as well as spare time, and if this be so, spend a guinea or two with some friendly carpenter that you may learn how to hold, use, and sharpen your tools, and go through all the preliminary exercise in carpentry, in which, however, you can only attain perfection by practice. You will subsequently find it has been a guinea or two well spent. As to tools, buy good ones. You will often pick up excellent tools at the unredeemed pledges' shops—the pawnbrokers—and even the marine store dealers'—otherwise known as "rag and bone shops." Never mind if they look a little the worse for wear; an hour or two spent in furbishing them up, cleaning, polishing, and refitting, will work wonders, like old Time, and lend quite a new aspect to things that looked dingy, battered, and next to useless. A little money goes a long way in second-hand tools, and by care in selecting and buying, you will soon gather together a very decent kit. Buy anything that is cheap and worth having, whether you want it immediately or not. Everything, don't you know, is useful once in seven years, and I am sure this applies particularly and especially to tools, for I never yet bought a tool that did not come in handy at one time or another. Once I bought a capital hardwood bevel for 2d. that I use to this day. Having got a few tools—a hand saw, tenon saw, rule, square hammer, jack plane, smoothing plane, half a dozen chisels, and some bradawls and gimlets of different sizes, are indispensable—and having learnt how to handle them, look out for a few jobs in repairing, and make for sale some of the pretty things that are described and illustrated in WORK—such as the Summer Fitment for the Fireplace, in No. 9. If you are a letter carrier, as I suppose you to be, have some cards printed when you are skilful enough to work in a workmanlike manner, and leave them at houses where you are in the habit of calling; you will soon get a connection. And if you are a householder, and have a handy window, put a few things in it on sale—such as a gipsy or fancy table, two or three brackets, and other pieces of work that are likely to take the fancy of those who have money to spare and spend. Very simple instructions on lathe making will soon appear, from the pen of a "born lathe maker."

Wood Engraving.—T. O'C. (*Plumstead*).—You say:—"I have a fair knowledge of drawing, and in order to make that knowledge marketable, I want to work it up so as to draw for the various illustrated weeklies—to become an artist on the staff, not an occasional contributor." To become "an artist on the staff" you must be possessed of a decided talent for drawing; and if you can really draw well, you might submit some sketches to some of the powers that be on the illustrated papers. At the same time, I must warn you that there are many others on the same trail as yourself—prospecting for happy hunting grounds in this direction. To be an artist, you need not be practically acquainted with wood cutting and engraving, but it is decidedly of advantage to an engraver to be able to draw. I am not acquainted with any good book on wood engraving, but I think I may venture to say there is one on the road, which, I trust, will find publicity in WORK. I am sorry I cannot give you better advice than to first catch your editor of an illustrated paper with inducements and enticements in the form of well-executed and taking sketches. This is the hardest part of the business, as you will find, but having landed your editor, the rest is comparatively easy.

Upholstery.—A. S. (*Edinburgh*).—Complete and thorough instruction will be given on this subject in WORK, as well as on all things that are more or less directly connected with it.

Glue-Paste.—J. G. (*Stanningley*).—Paste mixed with glue—*i.e.*, glue dissolved in the hot water when adding it to the flour—will be found sufficient, as glue for so large a surface is difficult to manage.

Bronze Powder.—I. G. W. H. (*Uxbridge Road*).—Hughes & Kimber, West Harding Street, Fetter Lane, supply the bronze powders in every shade and quality.—J. G. G.-W.

Bunsen Battery.—ENGINEER writes to point out a clerical error in the second article on the Bunsen battery. On p. 22, second column, near the bottom, instead of "·08 volt," read ·08 ohm. Thank you for your kindly criticism. It was merely a slip of the pen, as you will observe by comparing it with the calculations just below the line in which it occurs.—G. E. B.

Model Making.—BABY MODEL MAKER.—I must answer one question by another. What kind of model do you require? Of what do you wish to have a model? Model making covers a tolerably wide field, and although I have nothing whatever to urge against model making, I cannot help thinking that what is now appearing will prove of equal assistance to yourself—a youth of fifteen, in the first six months of your apprenticeship—and your fellow-apprentices. You say you think WORK "ought to centre more on wood and metal working and trades. Such topics as (Bunsen) electric batteries, painting photographs, and electro-plating, are rather out of the proper sphere and mission of WORK, and are only interesting to a very small portion of the readers, while to the large majority of wood and metal workers it is of no use." It is not probable that everything that appears in the pages of WORK will be equally welcome to every reader; but I may say, that on the principle that everybody is somebody's darling, or ought to be, so every pursuit is somebody's hobby. Take up one of the subjects that you look on as being of no use to you and make it your hobby. It will widen your experience, and, perhaps, some day, when you may least expect it, it will prove of positive use to you in the money-earning point of view.

Index to Numbers of Work.—INDEX.—I am obliged to you for your suggestion, which is noted for adoption, if it be found necessary at any future time. As each number of WORK consists of separate papers of some length, and not of a number of short paragraphs, "a condensed index of the contents of the number" seems scarcely requisite. Mostly each article is headed with a brief synopsis of its contents, which is indirectly an index to its subdivisions.

Composition for Raised Ornament.—H. S. F. (*Worcester*).—If the ornament is only to be slightly raised on the card, etc., for the display of gilding or bronzing, a raising composition is sold for the purpose by artists' colourmen, or one may be made by mixing whiting, flake white, and gold size. If the card or paper be quite smooth, roughen it a little with the edge of a knife, and the composition will stick. Paint it on with a camel-hair brush, which should be kept well filled at the point to flow properly; the composition should be as thick as treacle. Successive coats, with intervening dryings, can be laid on till high enough. It makes a good ground for gilding upon. If the relief is to be considerable, and on wood, etc., it may be well to satisfy the grain of the wood with linseed oil, to prime it with linseed oil and whiting, and to model the ornament on in a putty composition (whiting and linseed oil). Flake white added to this will make it set harder, but it is poisonous. A better composition for modelling ornaments for fancy articles is said to be plaster of Paris, with 2 per cent. of powdered althea root. This can be worked upon for an hour, after which it sets as hard as ivory; but more difficulty might be found in making this stick to the board.—M. M.

Advertisements in Work.—R. G.—Your suggestions shall receive attention, and shall be adopted if possible.

Organ Building.—R. B. (*Salford*).—The subject of American organ building will be taken up first, and that of making pianos. I do not think it likely that instructions will be given for making a barrel organ.

Artificial Legs.—BERNHARD.—I must draw the line somewhere, and I think I must draw it in one direction at artificial limbs, legs, arms, and eyes as well. The only man I know whom I could ask to write on the subject is Mr. James Gillingham, of Chard, a specialist of the highest order on this branch of manual and mechanical work, and he is far too busy at all times to put pen to paper. It may be that this may meet the eye of some one who is suffering, or who has friends suffering, from loss of limb, spinal complaint, distortion of any kind, etc. All such as these I strongly recommend to send for Mr. Gillingham's book, which will show in how many remarkable cases he has been most helpful and most successful.

Model Steamship Construction.—M. M. (*Glasgow*).—I will not pledge myself to a series of articles on this subject, but I may say that papers are in preparation on a steam launch, which will afford instructions on the method to be followed in building such a vessel from beginning to finish.

Sounding Board of Dulcimer.—DULCIMER writes:—"I should feel obliged if you would inform me of the proper dimensions for the sounding board of a dulcimer of twenty-one notes, eighty-four strings. Of course the frame would be on the same angle. I think a description of such an instrument would be welcomed by many subscribers, as it is easy to make and to play when made."—[If any writer likes to send in a paper on the construction of the dulcimer on approval I shall be glad to receive it.—ED.]

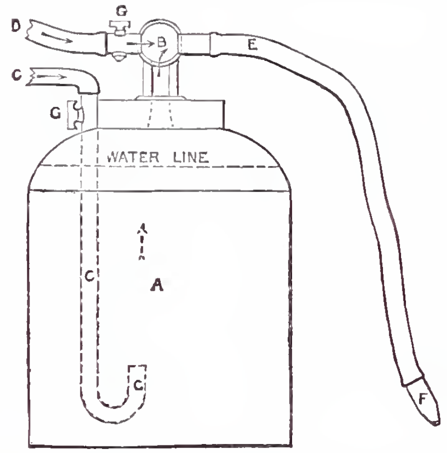
III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Polishing Oak Floors.—H. N. (*Bexley Heath*) asks, "How to polish oak floors that have been polished before. He has tried beeswax and turpentine, but that does not answer very well."

Fretwork Patterns.—W. E. M. sends two sheets from a fretwork pattern book, and is desirous to know who may be the publishers of the book, as he is anxious to get the book itself, regardless of expense. He is told that it is an American publication. If any reader can give the desired information will he kindly do so? The patterns sent to me are on sheets 14 in. × 11 in.; they are printed in black on white. Plate 2 (thus numbered) is a photo frame, with imitation door covering photo opening on hinges on one side. The door is fret sawn, and so is the gable-shaped finial with which the frame is surmounted. On each side of the top is a spray, the outline of which is shown on the frame in white dots. Fittings for supports of frame are also given. Plate 15 gives nine small patterns, embodying the adventures of a man and his donkey and donkey cart. The man comes to grief at first; but at last, by the advice of a passer-by, he puts the donkey into the cart—a proceeding which, apparently, causes trouble to both the bipeds. Perhaps this description of the particular plates may lead to the identification of the book itself.—ED.

Refrigerator.—URGENT writes:—"Being a reader of your excellent paper, and seeing you are willing to give advice to amateurs, I would take it as a favour if you would answer the following: *How to construct a refrigerator*, or ice chest, to keep meat, fish, etc., during hot weather. I have been asked to make one by a friend; the space I have is 7 ft. long, 3 ft. broad, and 3 ft. high, and also to use the top as a counter. There is also a descent for drainage, if wanted."—[This subject is thrown open to all constructors of refrigerators, and doubtless a paper on the subject from a practical man will soon be forthcoming.—ED.]

Oxyhydrogen Blowpipe.—T. W. B. (*Barnsley*) writes:—"I enclose a sketch of an oxyhydrogen blowpipe which I have devised, although I have never seen one. I enclose it for your inspection. Kindly answer me through 'Shop,' and say if you think it will be a 'workable' and 'safe' instrument. In the sketch, A is a tin chamber containing



water through which the hydrogen gas bubbles up from the pipe, C, into the chamber, B, where it mixes with the oxygen from the pipe, D, and passes immediately to the burner, F. G, G, are stop taps."—[I have given a half-size reproduction of your sketch, which was full-size, and I leave it to readers who are skilled in this matter to determine if your blowpipe be in every respect that which you hope it is.—ED.]

Wood Colouring.—"OX GALL" writes:—"I have made an overmantel in deal, and I want to know how to stain it a very dark colour in imitation of old black oak; also how could the dull polish seen on such wood be simulated with as little labour as might be consistant with a good effect."

French Polishing.—T. A. (*Belfast*) asks for "some information on the different methods of polishing wood, French polishing, wax polishing, etc. I French polish my fretwork as well as I can, having oiled the wood with linseed oil first, but invariably after a time the oil comes through the polish and spoils the work. I would like to know what preparation I should use to prevent its doing so."

Glaze for Finishing French Polishing.—W. H. B. (*Redditch*) writes:—"Could you tell me, through your valuable paper, WORK, a good receipt for making glaze for finishing off French polishing?"

Photo Colouring.—EXPECTANT (*Hull*) writes:—"I am an amateur artist (or, rather, try to be), and your articles on Crystoleum Painting and Sign Writing have interested me considerably. I should esteem it a favour if some one would kindly inform me whether photographs can be successfully coloured with water colours; and, if so, what is the best method, as I have often tried to colour them same as ordinary paper, but always failed."

Trade Notes and Memoranda.

SUGAR has been recently recommended by an Italian engineer as an anti-incrustation agent for steam boilers. In a boiler containing 126 tubes, the use of 2 kilos. (about 4·4 lbs.) of sugar per week had the effect of so far reducing incrustation, that at the end of four months only a very thin scale was formed, which was easily removed.

SOME of the remarks made by Mr. Sanders in his recent lecture on "Wood Carving" at the theatre of the Albert Hall are well worth perusal. He told his audience that carving should never detract from the use of the object, or weaken its construction. To construct decoration, instead of to decorate construction, is one of the greatest crimes an architect can commit. The use of glass paper is most mischievous, for it obliterates the mark of the tools, taking away all life and vigour, and leaving nothing but an inert mass of dulness behind. He said he looked forward to the day when the State would provide an institute for the carver, furnished with the best examples of ancient and modern woodwork, a reference library, and a staff of duly qualified masters, for construction, design, and carving, assisted by the advice of the great artists of the day.

AN enormous block of coal has been cut at the Abercarne Colliery as a specimen of the Welsh mining industry for the Paris Exhibition. It measures 7 ft. 6 in. high by 5 ft. 6 in. wide by 3 ft. 6 in. deep, and weighs 5 tons 10 cwt. It was hauled about a mile through the workings to the pit shaft. Five other blocks, each weighing 2 tons, will accompany it.

A PAPER read at a recent meeting of the International Society of Electricians in Paris contains the following items:—The total cost of the Exhibition to the French Government and town of Paris is estimated at about £2,000,000. There are, in round numbers, 50,000 exhibitors, each of whom will spend on an average £120, representing an additional outlay of £6,000,000. The number of hours during which the public will have access to the Exhibition is 2,520, making the cost of the Exhibition per hour about £3,000. The total electric lighting of the Exhibition is estimated to be equal to that of about $1\frac{1}{2}$ million candles.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

THE TENANT'S GREENHOUSE.

UNATTACHED TO THE SOIL AND REMOVABLE AT PLEASURE.

BY GEORGE LEBRUN.

PREPARATION OF GROUND—FRAME OR SILL—FRAMING OF HOUSE—BELT RAILS—FILLETS—SASHES IN ALTERNATIVE FORMS—VENTILATOR—END OF HOUSE—APPEARANCE WHEN COMPLETE.

THE possessor of a piece of garden ground, who is fond of cultivating choice flowers, often finds himself wishing for the addition of a greenhouse, in which he may rear those delicate plants that to leave in the open air, exposed to the many changes of our variable climate, would soon kill. Doubtless, many do erect a small conservatory, and find much delight in its possession, while, if the house and garden are their own property, it adds considerably to their value. But there are plenty of less fortunate individuals who simply rent their houses from year to year, or even from month to month; and although the erection in their garden of a small greenhouse might not be very costly, still the knowledge that, upon their removing to other premises, the landlord would step in and claim it as his property, often acts as a deterrent, and so the luxury is foregone, and they have to content themselves with what flowers they can manage to rear in the open air.

Now, without entering into the merits, or the justice, of this right of the landlord to claim all erections put up by the tenant that are fixed *in* the ground, I propose to show how a greenhouse may be built *on* the ground, and so, in a legal sense, may be removed in the same way that a barrel or box could be taken away if only left lying in the garden; that is, I mean to say that it will simply lie on the ground in the same manner as the barrel or box, and be in no way fixed to it. Further, as the several pieces and sections of the building will be held together by means of screws, it may, I think, with every right be considered a "tenant's fixture," and be taken down, removed, and re-erected in the new garden.

The particular greenhouse for which the design, details, and sizes are given, will be 12 ft. by 8 ft.; this is a very suitable size for a small garden, and does not cost much for material, while those whose requirements or aspirations demand a larger size can easily increase the dimensions, the manner of construction remaining the same.

Firstly, then, the ground on which the house is to be put up must be laid off and nicely levelled; then four 7-in. by 5-in. battens, two of which are 12 ft. 3 in. and two 8 ft. 3 in. in length, are taken and joined at the four corners by halving them into each other, as in Fig. 1. Two holes, 1 in. in diameter, are bored down through the halved parts at each corner, and oak pins, fitting tightly, driven through them.

You have now a frame 12 ft. 3 in. by 8 ft. 3 in. There is no need to plane up any of this framing, but, after cutting off the ends of the oak pins that project from the corner holes, it should receive a good coating of coal tar. This frame forms the sill or foundation of the house, the upper part of which rests upon and is fixed to it. The frame I have described can now be put in its final position *on* the ground previously levelled up, care being taken to get it perfectly square by measuring diagonally across from corner to corner, after the manner of squaring a sash. There is an alternative method of joining the ends of the sill that may be adopted; it is shown at Fig. 2; the corners are dovetailed, and a single pin driven through to prevent slipping. This mode of joining is the best, but entails some extra care and labour.

For the framing of the house four posts are required 7 ft. long by 4 in. square; also four rails for the sides 11 ft. 8 in. by 4 in. by 2 in., four rails for the ends 7 ft. 8 in., and five upright pieces 6 ft. 9 in., all of the same width and thickness as the side rails. The dimensions given are the *exact* sizes when squared up and finished, so that allowance must be made for cutting when procuring the wood. The top and bottom rails are dovetailed into the posts in the manner shown in Fig. 3, and secured with two long screws in each end. One upright piece is put in the centre of each side, one in the centre of the closed end, and two in the front end, 2 ft. apart, to serve as door frames. The upright pieces are cheeked ½ in. into the top and bottom rails, and are also secured by screws put in on the angle. Fig. 4 is an elevation of the framing of one side, showing the manner of attaching it to the sill by means of 5-in. wood screw bolts, the heads of which must be sunk flush with the surface of the wood. Pieces of the same scantling as the rails are now put in at a height of three feet from the upper side of the sill; they are halved and screwed in the same manner as the uprights, and, for the sake of clearness, I will term these pieces the "belt rails" when I have occasion to speak of them in the course of my description.

Fillets 1 in. wide and ⅝ in. thick are now put round all the openings on the inner side. These fillets should have a bead run on the edge, and be mitred at the corners, so as to form a better finish to the inside of the house than if they were left plain; these fillets may be put on with ordinary nails. ⅝ in. matchboarding is now cut into lengths to fit between the bottom and belt rails, and put in its place *without nailing*, and a moulding, mitred to fit the opening, put round the outside, and fastened in with screws; this keeps the matchboarding firmly in its place and allows of easy removal. Narrow matchboarding (about 3 in.) should be used, and, if thought necessary, two bars can be nailed along the inside at top and bottom so that the whole of the pieces come out like panels. The boarding can either be put in upright or diagonally, the latter having the nicest appearance. Fig. 5 shows the various details in section.

The upper openings are filled in with sashes, made to fit, and secured as shown in Fig. 5. The stiles and lintels are of 2½-in. by 2-in. stuff, the soles 3½ in. by 2 in., and the sash bars 1 in. by 2 in. These sashes can either be made square as in Fig. 6, or, if a little extra labour is of no moment, may be made of an ornamental character by putting in a deep lintel and cutting out either circular or Gothic tops, in which case the moulding and glass cheek will require to be worked by hand; this and the sawing out is best done after the sash is glued and cramped together. (Fig. 7.) The piece of dead wood between the panes can be lightened by cutting a trefoil or other ornament out of ⅜-in. wood, and putting it on the top rail between the openings. The closed end of the house is filled in in exactly the same manner as the sides, and the upper part for the support of the roof is framed up by two pieces of 4-in. by 2-in. wood, dovetailed together at the apex, and let into the tops of the corner posts at their lower ends. A square opening is formed with 4-in. by 2-in. stuff, in which an opening sash is hung on pivots, and the triangular openings at the top and sides are filled in with sashes made to fit them. The construction of the end is shown in detail at Fig. 8, which is an elevation of the end framing.

In Fig. 9 a perspective view of the greenhouse, when completed, is shown with alternative methods of making the sashes. I shall allude to this illustration in a future paper, in which I shall speak of it more fully. I give it here, however, as most of those who wish to erect such a structure will wish to see what it will look like, even before commencing operations.

I have described a house technically known as a "span roof" house, partly because a correspondent has asked for instructions for erecting such a structure, and partly because it is better fitted for the requirements of a tenant than a "lean-to" greenhouse, which in ninety-nine cases out of a hundred is reared against the wall of another building, and has not in reality a back of its own. Should any one, however, wish to put up such a greenhouse on his own premises he has simply to nail a wall-plate to the wall to take the upper ends of the rafters and sash bars, and provide for ventilation by a lifting light in the roof. If he wishes to put up a removable "lean-to" on another's premises he must put a back to it.

(To be continued.)

ON CUTTING REBATES.

BY DAVID DENNING.

If the question, what kind of plane should be used to form rebates or rabbets with? were asked of two men, both workers in wood, but one of them a carpenter and the other a cabinet maker, the answers would probably differ. The carpenter would probably say a fillister, the cabinet maker a rabbet plane; perhaps going a step further, each would say the other was making a mistake. The inference which might naturally occur to the mind of the non-technical from such different opinions would be that either tool might be used, or that neither of the men knew what he was talking about. Parodoxical as it may seem, both these inferences are correct, for either the rabbet plane or the fillister may be used in making any ordinary rebate, and the man stating that one or other tool should be used exclusively, could certainly know very little of the work to be done by the other.

How then does it happen, it may be fairly and properly asked, that two men, both presumably skilful in their own departments of joinery, one the cabinet making and the other the building, use different tools to effect the same result? The answer is simply because each finds the tool he advocates is the best for his own purposes. Ask a cabinet maker why he prefers a rabbet plane, and he will at once say that it is better for the comparatively small work he is generally employed in making. It is to the fillister what the smoothing is to the jack plane. Even the joiner will at once acknowledge that if a finely-finished rebate is wanted, the rabbet plane may be used with advantage, but only after the fillister has done its share of the work. The cabinet maker, on the other hand, will object to using the fillister at all, unless, indeed, on exceptional pieces of work or from personal idiosyncrasy. He will state that any advantages which may exist in the fillister are rendered useless from the amount of labour required to force the cutter in front of the iron through hard wood—a piece of Spanish mahogany, for example. He is not far wrong, for though it would be incorrect to say that a rabbet could not be cut with a fillister—the side fillister in ordinary cases preferably—in hard wood no sensible man would voluntarily choose the tool which induces the greatest amount of fatigue when another would answer his purpose as well or better. In soft wood, such as the builder mostly uses, the fillister cuts well enough.

But, says this individual, only just look at the convenience of being able to "set" the fillister to any gauge, and the fence to serve as a guide; the rabbet plane is destitute of these, and with it the work cannot be so well done. What is there to keep the plane straight?

Well, skill assuredly counts for a good deal. If a man has been in the habit of working without a fence, he does not feel the need of it so much as another who has been trained to depend on it. Of course, a line to work must be marked in some way, with an ordinary gauge, for instance, or, where extreme accuracy is not required, by drawing with a pencil. Careful manipulation does the rest. As for the actual details, such as the mode of holding the plane and the use of accessory tools, they vary. One man will use the plough to form a groove to the required depth, another will be content with cutting gauge and chisel to remove a little of the waste wood before taking up the rabbet plane, while a third will simply rely on his fingers. Each, if he be intolerant of other ideas than his own, will claim his own method as the best, and doubtless it will be for him; but if he be a man of liberal mind he will at once say that there is no absolute best, and that it altogether depends on the custom of the worker.

It is rarely indeed that a good practical artisan, who has arrived at the years of discretion, has not found out which is the most convenient way for himself personally to use the ordinary tools of his craft. He may go to the length of telling youngsters who ask him which way he finds best, or even in friendly chat will discuss with others equally as competent as himself the pros and cons of various methods, but as for saying that every other but his own must be wrong—well, to do so would not reflect credit on his intelligence, but it might, and very likely would, be very strong presumptive evidence that his work would be that of a "duffer." Not that even such workers are not useful sometimes, so if any of them read these lines, and feel inclined to take umbrage, perhaps they will kindly remember that the word is used in a Pickwickian sense, and that they are frequently to be thoroughly relied on for doing whatever they have been accustomed to do—turning the grindstone, for instance, to the entire satisfaction of all concerned.

But, it may be inquired, do no workers fall into bad habits in their methods? do they invariably choose the best for their particular purpose? To answer this fully it would be necessary to consider many points in detail; but without by any means suggesting that absolute perfection exists in any workshop, professional or amateur, it may safely be conceded that most mechanics have a very fair idea of what suits them best. The cabinet maker and the carpenter can therefore very well agree to differ on cutting rabbets and the proper tools to use, remembering that to find fault with each other simply shows imperfect knowledge of the requirements of both trades, however competent one may be to express an opinion about his own. "Eh, mon, it's a graat peety that we canna a' think alike; but ah'll no change ma ain opeenion for that o' ony ither body." "Ma ain opeenion" is that it is at any rate rash to condemn other methods or tools if we do not know the reasons for them being used; and that occasionally, very occasionally, the least little bit of toleration of other people's mode of working might be better than none at all, or wholesale condemnation.

BURGLAR ALARUMS:

How to Make, Work, and Maintain.

BY GEORGE EDWINSON BONNEY.

INTRODUCTION — ELECTRIC ALARUMS — HOW TO CHOOSE AN ELECTRIC BELL—HOW TO MAKE THE ELECTRIC BELL—THE WOOD BASE—THE METAL FRAME—THE MAGNETS—THE CORES OF THE MAGNET.

How truly delightful it would be if all honest people could dwell together secure from alarm from burglars, in an Arcadia where bolts and bars and locks were not needed, because "thieves do not break in and steal!" Such a state of security cannot be attained in "happy England" by persons holding portable property, for thieves are ever on the alert to enter an unlocked and unlatched door or climb through an open window to relieve the honest householder of his worldly goods. Because of this failure on the part of dishonest neighbours to recognise the law of *meum et tuum*, the honest man is compelled to live in an atmosphere of suspicion, and secure his property under the safeguard of locks and bolts in safes and strong rooms. Those of my readers who have read the "Real Detective Stories," by William Henderson, in CASSELL'S SATURDAY JOURNAL, must know how the thieving fraternity make light work of locks and window fastenings when they have decided to "crack a crib," *i.e.*, break into a house. Locks that cannot be easily picked fail to securely fasten doors when these are under the persuasive influence of the burglar's boxwood and steel wedges, and window fastenings spring back readily as they feel the thin blade of the thief's knife. Not a winter passes over our heads without leaving a long newspaper record of the doings of Bill Sikes and his "pals" in town and country wherever their fancy may lead them. A hand-to-hand encounter with an alert burglar, wide-awake and armed with a steel jemmy, whilst you are just newly aroused and can only defend yourself with the pillow, is not at all a pleasant surprise in the middle of the night. A loaded revolver under the pillow has been suggested as a remedy, but the remedy seems to me to be only one remove from the disease, for burglars now arm themselves with revolvers, and it is the man who gets the first shot who is likely to win at the game of bedroom duels. Revolvers are also dangerous tools to have about a house, or, indeed, anywhere else, for they have an unpleasant knack of going off just when you least expect them to do so, and at such times some friend is sure to get in the way of the bullet.

We want to be apprised of the thief's intentions before he walks, unannounced, into our bedrooms, and we want to receive warning of his operations before he has cleared out all the valuables in the lower rooms. Dogs have been tried, but a dog, however faithful, may not be proof against the bribe of a poisoned bait. Many amusing tales have been told of amateur burglar alarums and their failures; of tea-trays and fire-irons clashing together whilst puss, in her zeal, pounced on the thievish mouse; of torrents of shot making an unearthly din in a milk-pail in the dead watches of the night, because the plug of the pouch had been set too loose: and sundry other futile attempts to set automatic sentinels.

All such failures should now be relegated to the dark ages before the invention of electric bells: there is not any excuse in the present day, on the part of well-to-do householders, for leaving their premises unguarded. For a few shillings, not exceeding one per cent. of the value of the property to be protected, a thorough system of electric alarums may be set up in any house, and these generally scare the thieves away ere they can effect an entrance, whilst they arouse the soundest sleepers to take part in the defence. Electric alarums, properly fixed, are also so certain in their action that they do not give false alarms, nor do they fail to give an alarm should a thief *attempt* to open a door or window guarded by them. They also serve a useful purpose in detecting an open door or unfastened window when all should be closed at night, and it goes without saying that they also prevent the lambs of the house straying from the fold when all the inmates should be wrapped in sleep.

Such a system I hope to fully describe and illustrate in this first paper of the series and succeeding articles.

Electric Alarums.—Electric alarum systems have one feature in common. An electric bell of the continuous ringing type is placed in communication with springs, so inserted in the doors or windows to be guarded as to be kept from ringing the bell when all is secure, but to spring into instant action when an attempt is made to open a door or window. The first necessary article is, therefore, a bell of the right type, and this may be bought at prices varying from 4s. up to 25s., according to quality and size, or it may be made by any man accustomed to the use of tools in metal working. Electric bells vary very much in quality and type. A badly-made bell is dear at any price, for any purpose, but is specially objectionable when set as a sentinel. If badly-wound magnets are employed, and leaky connections are made, it will ruin the best of batteries, and failure will be put down to an exhausted battery. If hard or badly-annealed iron is used in the magnets, the armature will stick close to them on the first contact, and fail to ring the bell. If badly-fitted screws are employed, or badly-constructed contacts are used, or the metal parts improperly fixed to the wooden base, the bell may cease to act just when most required, and effectiveness is sacrificed to false economy. Even as the ship was lost for lack of the proverbial "ha'porth" of tar, and for want of a nail the horse was lost, so a house may be lost for want of a proper bell.

How to Choose an Electric Bell.—As so much importance attaches to the bell, I will here show the good and bad points of electric bells as a guide to their choice. If a bell mounted on a metal frame with a wood base is chosen (and some of the best bells are so made), see that it is made of teak or mahogany, or some such wood not easily warped by changes in the moisture and temperature of the air. If the base is of iron or brass, or the bell is of the Jensen pattern, see that the contact pillar is well insulated from the metal work with collars of ebonite above and below, and that the connecting screws are similarly insulated. See that the set screw has good threads, is well fitted, and is provided with a good lock-nut. If this part is defective, the armature spring will work out of contact under the jarring action to which it is subjected. Have the bell set a-ringing, and then try to stop it by placing the forefinger lightly on the armature; if this sticks to the magnet in any way, and does not readily recover itself, reject the bell, for the iron of the magnet is, doubtless, unannealed. A good electric bell magnet should attract iron filings when the current is passing through its coils, but should drop them the instant the current is interrupted. The set screw should be tipped with platinum, and this tip should be in contact with a speck of platinum soldered or riveted to the armature spring. Get the vendor to guarantee these parts to be of platinum, as German silver or aluminium is sometimes fraudulently substituted. A drop of nitric acid from the tip of a glass rod will turn German silver green, and a drop of hydrochloric acid, applied in the same way, will dissolve aluminium, whilst these acids, separately, have no effect on platinum.

Specially made bells for alarums, fitted with automatic relays, are now sold by respectable dealers in most large towns. If these cannot be obtained, the next best will be a good 3-in. bell of the vibrating or trembling type. Single stroke bells are useless for this purpose. A fairly good 3-in. bell costs 10s. 6d., and the same with automatic relay from 17s. to 18s.

How to Make the Electric Bell.—I have received so many grateful testimonials from working men who have made electric bells from my instructions, that I begin to think almost any man can make such a bell if he has the means at his command to get the tools and materials. It should be understood, however, that there are grades of makers as well as grades of bells. The man who buys materials and sets men to work for him in making bells claims to be a maker of electric bells, although he may not know how to put the parts together. Another man buys the various parts, and, putting them together, says he has made an electric bell. Who will dispute his claim? The various parts were not an entire bell until he put them together. It is to such a would-be maker of electric bells I now write. To each and to all I would say, make as many parts of the bell out of the raw material as you can; only a stickler for originality will go to the extent of exacting such a strict adherence to the letter as to require a maker to cut his own wood, cast his own metal, draw the wire, and cover it with silk spun by himself. Very few, if any, makers of electric bells draw the wire and cover it, or cast the gongs, as this is better and more cheaply done by persons who make it their business.

The Wood Base.—The first requisite for an electric burglar alarm bell is a piece of wood for the base. If the base is for a plain 3-in. bell, select a piece of sound well-seasoned teak or mahogany 8 in. by $4\frac{1}{4}$ in. by $\frac{7}{8}$ in. If the base has to carry a relay in addition to the bell, the wood should be two inches longer. Plane both sides smooth, then cut the planed wood to the form shown in Fig. 1, and bevel the edges on the face of the base. Fill in the grain of the face and edges, and French polish them in the usual manner.

The Metal Frame.—The next requisite is a metal frame to hold the magnet, armature, contact post, and bell pillar. This may be of sheet iron, sheet brass, sheet copper, or even stout sheet tin cut to the form shown in Fig. 2. Or it may be cast in this form in brass, gun metal, or iron. The dimensions are, from A to B $5\frac{1}{4}$ in., from C to D 3 in. As the main use of this frame is to hold all the parts together, and not allow them to be shifted in their relative positions to each other by changes of temperature and jarring motion in the bell itself, the frame may have other forms and be equally useful. Some of these are shown at Figs. 2, 3, 4, and 5. The reference letters in each figure correspond with each other. B shows the hole for the foot and tang of the bell pillar; P, the hole for the foot and tang of set and contact screw pillar; S, the lug or turned-up angle to which the armature spring is fastened; and M, the position of the magnets. The position of the magnet bobbins is shown in Figs. 4 and 5 by dotted lines. The yokes of the magnet cores are, in these forms, made separate from the base plate, and fixed to it afterwards by studs or set screws.

The Magnets.—The next articles to engage our attention are the magnets. These are made up in three parts:—1, the cores; 2, the bobbins or reels; 3, the wire. The following table, from Mr. S. R. Bottone's book on Electric Bells, will show at a glance the relative sizes of these parts for several different sizes of bells:—

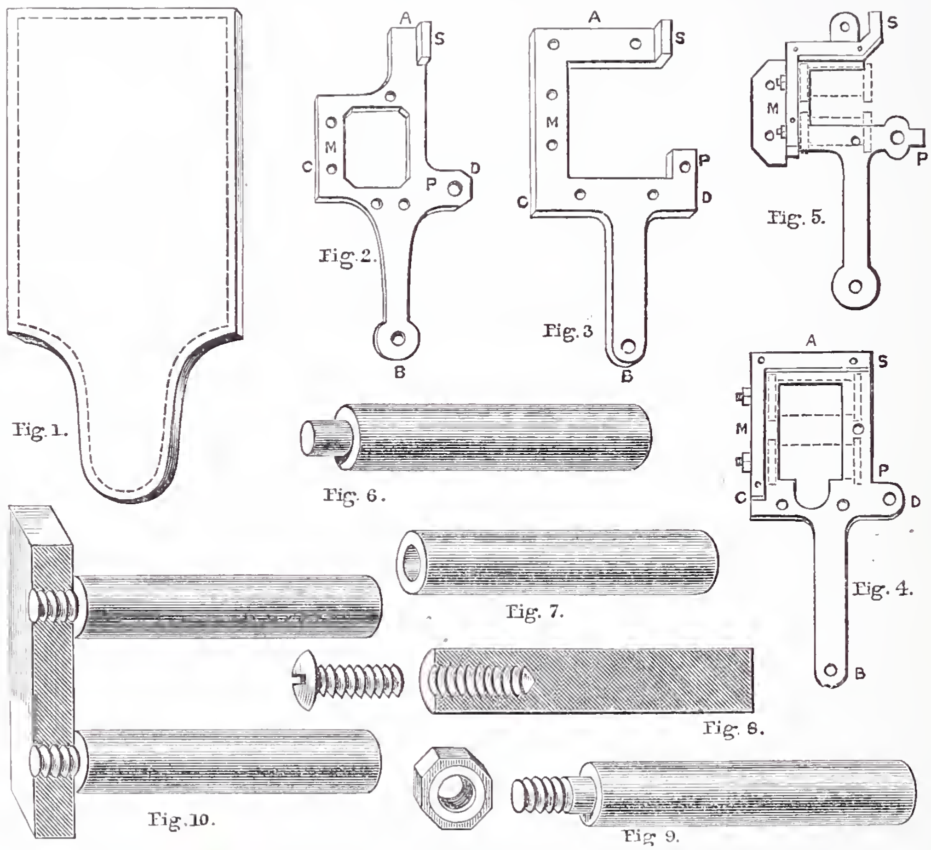

Fig. 1.—Form of Wood Base for Electric Bell. Figs. 2, 3, 4, 5.—Some Forms of Metal Bases for Electric Bells. Fig. 6.—Core of Magnet with End turned for rivetting to Yoke. Fig. 7.—Core of Magnet with End bored and tapped. Fig. 8.—Section of same, showing Screw Stud. Fig. 9.—Core of Magnet with End turned and screwed to receive a Nut. Fig. 10.—Magnet Cores turned and screwed into Yoke.

PROPORTIONATE PARTS OF MAGNETS.

Diameter of Bell.	Length of Magnet Cores.	Diameter of Magnet Cores.	Length of Bobbin.	Diameter of Bobbin Head.	B. W. G. of Wire on Bobbin.
Inches.	Inches.	Inches.	Inches.	Inches.	
$2\frac{1}{2}$	2	$\frac{5}{16}$	$1\frac{3}{4}$	$\frac{3}{4}$	24
3	$2\frac{1}{4}$	$\frac{3}{8}$	2	$\frac{7}{8}$	24
$3\frac{1}{2}$	$2\frac{1}{2}$	$\frac{7}{16}$	$2\frac{1}{4}$	1	22
4	$2\frac{3}{4}$	$\frac{1}{2}$	$2\frac{1}{2}$	$1\frac{1}{8}$	22
5	$3\frac{1}{4}$	$\frac{5}{8}$	3	$1\frac{3}{8}$	18
6	$3\frac{3}{4}$	$\frac{3}{4}$	$3\frac{1}{2}$	$1\frac{5}{8}$	16
7	$4\frac{1}{4}$	$\frac{7}{8}$	4	$1\frac{7}{8}$	16
8	$4\frac{3}{4}$	1	$4\frac{1}{2}$	$2\frac{1}{8}$	14
9	$5\frac{1}{4}$	$1\frac{1}{8}$	5	$2\frac{3}{8}$	14

The Cores of the Magnet.—The cores must be made of good tough iron rod (Swedish iron is recommended). The length given in the above table allows for the ends being turned down and screwed to receive the nuts which hold them in the yoke. Some makers dispense with nuts, and secure the cores to the yoke with screwed studs entering the cores. If this plan is adopted the ends of the cores must be drilled and tapped to receive the studs, and it will not be necessary to cut the pieces of iron so long as when they are to be fastened by nuts. However tough and good the iron may be, it must be annealed to make it quite soft after the cores have been cut off. If the cores are made of hard iron, or are imperfectly annealed, they will retain some magnetic influence over the armature after contact is broken. Iron cores are annealed by heating them to a blood-red tint in a good fire, covering fire and cores with hot ashes and allowing all to cool down gradually for some ten or twelve hours before disturbing the iron.

After they are annealed, the back end of each must be turned down to form a tang with shoulder to fit in the yoke, and the front ends filed level and smooth to form faces for the armature. If the iron rod is quite round and smooth the cores need not be turned, but the roundness and smoothness should be seen to, so that the cores may fit the bobbins of the coils, for it is most important that the wood of the bobbins should lie close to the cores.

If the cores are to be riveted to the yoke, this must next be done. If they are to be attached by nuts, the tangs must be screwed and the nuts tapped to fit them. If they are to be fastened by screws or studs, the holes must be drilled and tapped to receive the studs. At any rate, all this must be done before the bobbins are made, and wound with wire. In Figs. 6, 7, 8, 9, 10, I show several ways of attaching the cores to the yoke, but I consider the neatest and best to be either Fig. 7 or Fig. 10.

Before bringing this paper to a close, I may remind the readers of WORK that prevention is better than cure, and that it is better to frustrate Mr. William Sikes's amiable intentions towards your belongings and yourself, if need be, by fitting a house with alarums that cannot fail to herald his approach and declare his presence, than to have to calm down scares, or, perhaps, plug bullet holes in body or limbs. Moreover, prevention is the cure itself, for if burglars could be treated wherever they went to an experience of this, the veritable "burglar's horror," they would be compelled in self-defence to betake themselves to honest ways.

(*To be continued.*)

SOME LESSONS FROM AN OLD BUREAU.

BY DAVID ADAMSON.

(*Continued from page* 116.)

II.—Insides of Drawers—Cutting Out—Gluing and Dowelling—After Jointing Up—Hints on Dovetailing—Fitting Drawers—Inner Top and Rails—Antique Furniture—Facing Slips.

At the end of the preceding paper I made mention of the "insides" of the lower drawers. If I were writing for professional workmen only, I need not say anything as to what is implied by this term. I must not forget, however, that I am writing for amateur workmen as well, and as some of them may not understand what is meant by "insides" of drawers, I may explain that the sides (or ends), back, and bottom of a drawer are often thus designated. Thus, in speaking of a chest of drawers—which is very much akin to the bureau—it is perfectly well understood when it is said to have "pine insides" or "mahogany insides," that the drawers themselves are made of the wood specified. Where pine is not considered good enough, ash insides are commonly used with oak, and mahogany with walnut or mahogany work. There is no hard-and-fast rule on the matter; but by accepting and adopting trade customs—where they are not prejudicial to durability—the amateur artisan may to a great extent avoid the "amateurish" character which so frequently betrays itself to the experienced eye. His work may be equally serviceable, but, as a general matter, it is not well for him to depart from the methods which are found the best by practical workers, unless he has some good reason to do so. This is far from saying that improvements are not to be made, nor recognised when made, either in tools or methods; but as a rule, if there is anything good in them, they are the outcome of study and thought, prompted by such experience as the amateur can hardly expect to have. These remarks may seem hard on amateurs and beginners, but I trust those who may be inclined to resent them will consider they are given in a friendly spirit by way of enabling those who wish to do so to turn out work in the best possible style.

But with regard to the "insides:" if pine is to be discarded for these parts, it is only necessary to read Nos. 32 to 36, both inclusive, as being of the wood preferred to it. By the way, referring to mahogany for these parts—and I may say that, personally, I like this wood even with oak—it is not to be supposed that choice wood is necessary. Cheap baywood is quite good enough; but the reminder that mahogany insides are often made of *cedar* may be of service. The cedar used for such purposes is the kind of which cigar boxes are made, and must not be confounded with what is commonly called pencil cedar. It is easily worked, and is a most suitable material for "mahogany" insides. Perhaps the mention of pencil cedar may suggest to the would-be maker of the bureau that the small drawer insides might be made of it. It is a nice delicate wood for the purpose; but the fact must not be overlooked that the oil contained in it, and on which its fragrance depends, is sometimes apt to discolour note-paper, etc., left long in drawers made from it. Moth, however, object to cedar (pencil), so that there are advantages attaching to its use, and any materials subject to the attacks of these little destroyers placed in cedar may be regarded as secure from their ravages. When the wood is finally decided on for the various parts, the bureau may be proceeded with.

The first thing is to cut them out to the sizes ascertained from the working drawing and list. It is hardly likely that the stuff will be wide enough in the plank to allow of such parts as the ends and large drawer bottoms being got in single pieces, and they must be jointed up. Do this, to get the necessary width, before smoothing the stuff—that is to say, while it is still rough. Thin parts, such as drawer bottoms, will merely require gluing together, but the ends should be dowelled as well. It can hardly be necessary to explain the operation of dowelling, as it is presumed that, before attempting to make a piece of furniture such as this bureau, the rudiments of joinery will have been mastered; but as it is just possible some may be stuck by not knowing what dowelling means, the hindrance may be removed by referring them to an ordinary extending dining-table. If they will open this out and look, they will find that on the inner end of one of the halves there are a few round pegs, which, when the table is closed up, fit into corresponding holes in the other half. These pegs are dowels to all intents and purposes, but they are only glued at one end. Put similar pegs, glued all over, between two boards, also with their edges glued, and we have what is known as the "dowel joint," a full description of which has already been given. Gluing the boards together might do, but dowelling, when properly done, makes the joint stronger. Another part that may require jointing up, in order to get the necessary width, is No. 3—the table-top. If the part under the pigeon-holes is pine (which is suggested merely to save cost of material), a join will certainly be necessary, and it will be well to see that it is so made that it will be out of sight—viz., a little back under the superstructure. In connection with the top, another small economy may be practised without detriment to the work, though it is almost a "bull" to say this, as, if the work were to suffer through any niggardliness in the use of material, it could hardly be called economy. Wood costs money in proportion to its thickness, and a ¾-in. or even ½-in. piece of oak will do very well for the part under consideration. If, however, it is of this thickness, the front edge must be lined up to improve its appearance, and also to allow of the lid being made a proper thickness—½ in. would not be enough for this, and, as will be seen later on, the lid, and, at any rate, the front of the part to which it is hinged, should be of the same thickness.

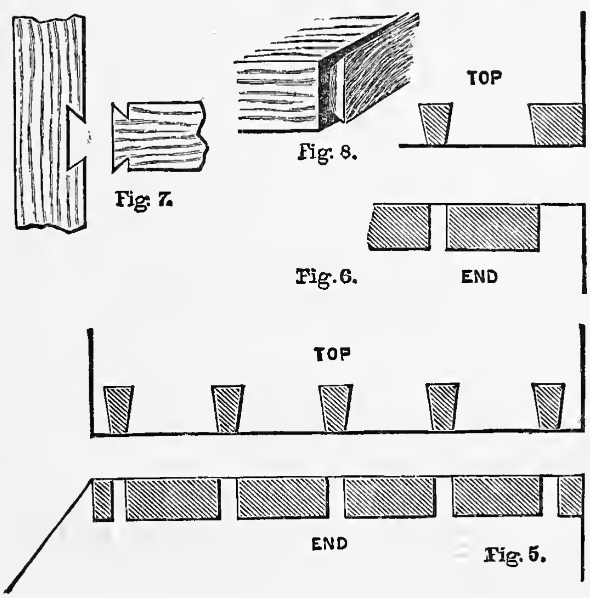

Fig. 5.—Dovetailed End of Top. Fig. 6.—Ends and Back: Top Corner. Fig. 7.—Joint for Drawer Bearer. Fig. 8.—End for Drawer Bearer.

In Fig. 3, the piece thickening up the front edge is indicated, though it will be understood it is not necessary if the top is made of 1-in. stuff; in fact, it would only be a hindrance unless the lid were made thicker too. After jointing up any pieces it will be well to let them stand by for a day or so in a dry warm place for the joint to set firm, before using them roughly. The next proceeding may be to plane up and smooth the ends and top (No. 2), after which they and the bottom may be put together. The method of fastening them is by dovetailing. In the bureau we are working from the plain dovetail is used, but as this shows the end grain of the top on the ends, and of the ends on top (see Fig. 5), in which the shaded portions represent end grain, it may be objected to by some who like the neater-looking appearance of the mitred dovetail joint. This, however, is rather difficult of construction, and as an explanation of the method of making it would almost require an article by itself, more need be said about it. One thing, however, may be said in favour of the plain dovetail: that is, it is stronger than the other, and if it is neatly made, there is no real reason why it should be regarded as unsightly. It is primitive rather than objectionable in appearance. Do not fall into the common mistake of making the pins or dovetails—*i.e.*, the pieces of the ends which fit into the spaces cut into the top—too thin, under the idea that they look better when they taper away almost to nothing. In such a case as the present they will look paltry if they are less than ½ in., and may be larger still with advantage. The number of dovetails shown is five, but there is no necessity for adhering to this.

It occurs to me that a bureau would not suffer in appearance by having the pins and sockets equal, but this is merely a matter of opinion which the maker must decide for himself. To some, the last pin, the one nearest the back, may appear a little objectionable, and that it would be all the better for being a little further from the edge, or even omitted altogether, and the end carried up as shown in Fig. 6. At any rate, if this plan is adopted there will not be the same risk of splitting the top that there might be in the other if the pin happened to be fitted into its socket with too much force or unevenly. A very little reflection will show why. Not that such an untoward event would happen in the hands of a skilful worker, but as it might with others it will be as well to avoid the risk, especially as the second method is at least equally good joinery. The bottom should be manipulated in the same way, and should be left projecting a trifle in front—say ¼ in.; if a little more it will not matter, as any surplus can easily be planed away afterwards. These pieces, the ends, top and bottom, should only be fixed together dry as yet, *i.e.*, without any glue. If the dovetailing has been properly done they will hold solidly enough when they are wanted to be together. It will be noticed that the ends cannot be forced outwards from the top and bottom, but that any pressure laterally binds the parts more firmly together, owing to the wedge-like spread of the dovetails. It is of the utmost importance that the greatest care should be taken to fit the top, bottom, and end pieces perfectly square and true, otherwise it will be impossible to fit the drawers correctly, so that they may run smoothly and easily. All corners must be right angles, and the width at the back and front be exactly the same. If there is any doubt about getting them so, let the ends slope a trifle, and it should be but the merest trifle, outwards towards the back. I almost hesitate to say this in case any one should mistake the intention and purposely try to make the back wider than the front. This should not be done. The aim ought to be to get the ends perfectly parallel, so that the space at back and front may be equal, but as this would be perfect adjustment, which it would be almost unreasonable to expect except at the hands of the most expert, the caution is given that any excess in size should be towards the back. Indeed, as a rule, the best workers make drawer carcases in this manner.

Perhaps a few words of explanation may be of service, for what applies to this applies equally in all similar cases, and it is just as well to know the "reason why." It will be remembered that drawers are intended to be fitted into this space. Now, just consider how these would run, or rather how they would stick, if, being properly made—that is to say, of an equal width in front and behind—they were forced into places too narrow for them. Of course, wood not being a sufficiently compressible substance, to squeeze the drawers into a space less in size than themselves they would have to be made to fit. This might be managed by making them out of the square, which certainly is not satisfactory, or the fronts would have to be made no larger than the backs, which is hardly an improvement. Mind, I do not say that the drawers would be altogether unserviceable, for if this were so, many a comparative novice might be discouraged from attempting the work. No; they would probably be serviceable drawers, but they would not run easily and smoothly; in other words, they would fit badly, besides being unsightly. Now, if the ends of the carcase spread ever so little outwards to the back, the drawer fronts may be fitted tightly to the front, and the drawers being fairly made, they will run firmly and smoothly without either jambing or wobbling. This is the result to be aimed at, but there are various degrees of excellence between the drawer that fits almost air-tight and yet moves easily, to the drawer that requires a most carefully equalised pull or push to move it. We all know the latter—don't we?—the drawer that starts so easily, but so soon sticks fast, and won't move further till it has been pushed and pulled, first at one end and then at the other. Such are not nice, but they are not worthless; so if all the drawers in the new bureau won't work as they should, do not be unduly despondent. A drawer is not the easiest thing in joinery to make, and if you only get them to run moderately well, be satisfied; but try to do better next time.

In making the bureau, the next thing may be to fit the inner top and rails, or bearers between the drawers, as in addition to the drawing, we have now the ends set up to guide us. It will be noticed that the drawers are graduated in depth, the two short drawers, immediately under the top, being the shallowest, and the bottom one the deepest. The spaces must be accurately set out on the ends, lines representing the thickness of the rails being drawn across their inner sides. The rails are fixed into the ends by dovetail joints, but if this is considered too much labour, a very serviceable plan is simply to dowel them, or even to use the mortise and tenon joint. The best way is, however, undoubtedly to dovetail them. There are several ways of going about this, or rather modifications, but I don't know that any are better than that in the old bureau. The dovetail is cut at each end of the rails right across, and fits into a correspondingly shaped groove in the end pieces (Fig 7). It is obvious that these rails must be pushed in either from the back or from the front till they are in position, and equally obvious that it will be simpler to do so from the front. Now, if they were pushed back till their edges and those of the ends lie flush, it, the dovetail, would show, and it is to hide this that the facing slips mentioned in the remarks column against No. 1 in the wood list are required. Some may prefer that the dovetails should show, and there is no reason why they should not be visible, if they are made as they should be, neatly.

There are, indeed, I may say, critics of woodwork who go the length of saying that it is bad form to hide or conceal any detail of construction. They prefer that methods of construction should proclaim themselves. Of course, those who think so have no need of the facing slips, but I think these will be an improvement. But perhaps it may be said by some who admire the style of joinery that would show all the construction, "because it is so honest, you know," that any concealment is a modern innovation to hide bad work. Truly, if they are correct, there is very little indeed now made that is good. Is it, however, the fact, that to cover up joints, and, by so doing, improve the appearance of a piece of furniture, is an indication of "scamped" work? I say, and so will any one who is acquainted with fair modern woodwork, most emphatically, No! Our ideas of good finish have enabled us to improve on old forms, good enough in their way, but, after all, somewhat rough and crude. It may, however, freely be conceded that it is not the primary object of a piece of furniture to proclaim every detail of its construction to those who are only superficially acquainted with joinery. Perhaps this is where the difficulty is felt by more than one of those who affect to despise modern work, and would have us return to antiquated construction. They can understand the latter, but the former requires more knowledge than they possess. Yes, my theoretical friends, that's the reason for most of your ecstasy over pinned-through joints and other barbarities. I yield to none of you in my admiration of good sound work, but there is no reason why elegance of finish should not be added to it. If it is thought that the slips are not an improvement, do not use them, but it may be said they are on the bureau which is described. As it, to all appearances, dates from the end of last century, and it is certainly not less than eighty years old, in copying it, even the most enthusiastic admirer of our great-grandfathers' work won't be doing violence to his principles. As eighty to one hundred years ago may not seem sufficiently remote to entitle the bureau to be called "old," I may say that the age of articles of furniture is often very much exaggerated in popular ideas by those who have not studied the subject. For example—and it is only one of several similar which have come under my notice—a sofa was once shown me which its owner stated was made during the reign of Henry VIII. Unfortunately for the accuracy of this date, the sofa was made of *mahogany*, and the style of the work showed it to have been made some years after the time "when George the Third was King." Yes, an ordinary piece of furniture which was made a hundred years ago may fairly be called "old"—not antique, perhaps, but still old. Very little furniture, indeed, is as much as 300 years old. The cabinet-making industry was not an extensive one in those days; such as it was, it ran principally into chests. One or two of them may be useful and interesting, but they are apt to become monotonous if one wants to furnish a room with genuine Elizabethan stuff, even though one might be fortunate enough to pick up a settle, a cabinet, and a chair or two to correspond. Sideboards, easy chairs, and the hundreds of convenient forms of furniture now so common, had then no existence.

But, through this digression, the bureau is being temporarily overlooked. We were at the rails, about which it only remains to be said, that if facing slips are to be fixed to the ends, due allowance must be made for them. Perhaps it will save trouble to decide on the exact thickness of these slips at the present stage. They are nominally ¼ in. thick, and must be the exact thickness of the ends in width. Well, whatever the thickness of the slips, cut away just so much from the dovetails on the front edges of the rails so that, when all is fitted up, these and the front of the facing slips will be quite flush. Fig. 8 shows the end of dovetail cut away. The lowest bearer, the one immediately above the bottom board, need not be fastened in so elaborate a manner, but may be simply cut to fit within the ends and lie on the board, to which it can be fastened by a few screws. The effect of this rail is to thicken the bottom board at the front; and the reason why the board was not to be trimmed off flush with the ends may now be perceived, though it will be still more obvious, a little later on, when we come to consider the plinth.

(To be continued.)

PAPIER-MÂCHÉ.

How to Mould It, and how To Ornament it.

BY SYLVANUS WARD.

III.—Decoration—Materials and Appliances—Japanning—Pearl Inlaying—Gilding—Dead Gilding—Designs for Dead Gilding—Raising Composition for Dead Gold—Working Fret Patterns in Gold.

Materials and Appliances.—Of these the most important required for the decoration of papier-mâché are:—

Black japan varnish, which is dark and thick like treacle. It is inexpensive, and is bought by the gallon (price 3s. 3d. to 3d. 6d.) at such shops as Thornley's, 6, Snow Hill, Birmingham. Copal varnish costs from 10s. to 16s. per gallon. Japanners' gold size costs 9s. per gallon. Ordinary tube oil colours, brunswick black, turpentine. Gold leaf, deep and pale; silver leaf, bronze powder of different colours. Also gold powder, if the worker thinks that he can afford so costly an appliance; but as it costs some £5 per ounce, and bronze 10d. only, most persons will content themselves with the humbler substitute, notwithstanding the greater and more permanent brilliancy of the gold.

Pearl, for inlaying. Of this there are three standard kinds:—1. White pearl. 2. Scotch or snail pearl. 3. Aurora pearl. The white is obtained from the shell of the large pearl muscle, the same from which pearl buttons are made. It was the first kind used, and was originally very costly. This is to be procured in the largest pieces, and is, therefore, employed in inlaying on a large scale, as in the squares of chess boards, etc. It has less iridescence than the other varieties, and is lower in price. Snail pearl has a pleasing blush, and colours nicely varied. It is to be had in fairly large pieces. Aurora pearl is obtained from a univalve, auriform shell. It is of finely varied colour, but the pieces are comparatively small. There is also a fourth variety, which has a beautiful iridescence, green being the prevailing hue, but it is less apt than the other three to be sound and reliable. The pearl shells are reduced to flakes by grinding by persons who make it their business to prepare them for inlayers. Pearl may also be procured from these persons stamped out into certain stock forms, such as discs, diamonds, stars, roses, vine leaves, shamrock leaves, bells, etc. These will be in snail or aurora, white not being showy enough for such small matters. By judicious combination, pleasing designs may be formed from these stock shapes. Pearl is purchased by the ounce.

Brushes—a thin sable, an inch long, for fine and moderately thin lines, known to japanners as an "etcher;" also a somewhat thicker sable, half an inch long, known as a "sprigger." In selecting a brush it should be held up to the light, and the thumb nail pressed against the bottom of the hair; this, if the brush is a good one, will cause the top to spread out evenly, and the ends of the hairs will alike be fine. If many thick, blunt hairs appear, reject the brush; if there are only two or three thick hairs they may be removed with the points of a sharp pair of scissors. Wet the brush (the colourman usually has a cup of water at hand for that purpose), and see if it then comes to a good point. Sometimes a brush, otherwise satisfactory, may appear to have too fine a point, owing to one or two hairs projecting beyond the others. This defect may be corrected by laying it on any flat piece of wood, and carefully removing so much of the hair as causes the weakness with a keen penknife.—[N.B. The above remarks may be useful not only to papier-mâché decorators, but to others who use fine brushes.] A camel-hair pencil of the same size as the "sprigger" will also be needed for "pencil varnishing." For laying the transparent varnish over larger surfaces one of the broad, flat, camel-hair brushes sold as "varnishing brushes" should be had; one at about 9d. will suffice. A large round brush will also be wanted for japanning, that is, for laying on the black varnish.

Pumice-stone, rotten-stone, hard and soft, whiting, and a little olive oil, will also be wanted for polishing. Most, if not all, of these requisites may be obtained at the shop above mentioned.

Japanning. — The article being taken from the linseed oil bath is set on a tray to dry, and when oil no longer appears on its surface, a coating of black japan varnish may be brushed over it. Such an article as a vase or a spill cup may be japanned all over at once, but a flat thing, like a tray, after japanning on one side needs to be dried before the varnish is put on the other side. The stove, or oven, in which it is placed should be slightly warmer for this than for drying paste. When dry the coating has to be, to some extent, removed by scraping with a plane iron drawn backwards. So much of the varnish has to be taken off as will remove all gloss, and so much left as will form a ground for after processes.

Should a hollow show itself at this stage it must be filled up with paper dust and black varnish (a mixture technically known as "bomption"), drying it, and scraping it level. In japanning, the worker is tolerably sure to blacken his fingers freely, but the varnish may be readily cleaned off with tar spirit.

If pearl inlaying is intended the papier-mâché is now ready for the first stages of that process, but as the art of japanning can be most clearly described by going straight on with it to the end, we will consider the article under treatment to be intended for gold and colour decoration only, and deal with pearl inlaying later on.

Such, then, being the case, the use of the black varnish has to be continued, drying after each coat, and rubbing down all knots and air bubbles with pumice-stone before the succeeding coat is laid on. Three coats are usually sufficient. To prepare the last coat for decoration it should, after the usual pumicing down, receive an extra rubbing with picked (the finer) pieces of pumice-stone. It has then to receive a still further smoothing by being thoroughly rubbed over with a large bob made of rag, and what is technically known as "sand," that is, pumice-stone pounded very fine in a mortar, and applied wet. After this comes a rubbing with wet, crushed rotten-stone, applied with a smaller rag bob, which application must be continued till all cuts and scratches left by the pumice-stone are rubbed out. If *dead* gilding is to be employed the surface is now ready for it.

If, however, as we will assume, *bright* gilding is to be used, the surface which has now been thoroughly *smoothed* has also to be *polished*. This must be done by rubbing with the palm of the hand and finely powdered *dry* rotten-stone, and afterwards in the same way with whiting, and just a spot of olive oil after this. Care must be taken that there is no grit in the whiting, or it will make scratches. A soft, flat palm gives the best polish, and if properly done a most brilliant jet-black surface will be the result. We now have the proper surface for *bright* gilding.

The different stages of the work at which it is proper to apply pearl, dead gold, and bright gold, have now been shown, and I may next proceed to describe those processes.

Pearl Inlaying.—When this art was first introduced the practice was to cover the required surface of the pearl flake with some acid-resisting paint, such as asphaltum, and then to bite out the form with acid, a process patented by Jennens & Bettridge, of Birmingham, but it was afterwards found that the pearl might be cut. Rectangular forms are best cut with a sharp knife, such as that used by shoemakers for leather, which has been converted into a fine saw by drawing it against a file. Simple curved forms may be cut with scissors; soaking the pearl in water makes it cut more easily, and lessens the danger of breakage. For cutting intricate forms, a very delicate and minute fret saw must be used. Formerly, it was usual as a means of preventing breakage whilst sawing to glue the pearl to a sheet of thin metal, but the later practice has been to glue several flakes together, sometimes as many as six, and to saw through them all at once. The flakes are afterwards separated by soaking in hot water. If the cutting is not quite accurate, any little inequality can be concealed at a later stage of the work with black paint.

Pearl may be used in several different ways—for covering the entire surface, for diapers and set patterns, for forming buildings, for giving brilliancy and richness to fruit and flower subjects, to the wings and breasts of birds, to insects, etc. In all these it is employed in combination with more or less painting or gilding, or both.

To cover the entire surface with pearl is a simple mechanical matter, demanding only neatness and accuracy. It is easy to lay out the ground in lozenges or other rectilinear spaces, as in Fig. 22, and to cut the flakes of pearl to fit them, variety being attained by placing white and snail alternately, or, if the figure should not exceed a square half-inch or so, aurora also may be employed, the pieces of this pearl being too small for larger patterns. On a flat surface this is simple work, but if it has to be carried over any slight curvature it becomes difficult, and will be best accomplished by cutting the pearl into strips; even then it may not be found easy to make good joints. Before laying the pearl in place, japanners' gold size has to be spread over the surface to fix it. The black-lead lines drawn to indicate the pattern will show through the size.

Fig. 22 gives a design for this "solid" pearl inlaying, in which the size of the component spaces is so considered as to allow the employment of all the different kinds of pearl. The letters, W., S., A., and G., indicate those for white, snail, aurora, and green, respectively. The dotted lines show where the larger spaces may be subdivided if desired without injury to the effect of the design; and it is well to remember that pearl lies flatter and better in small pieces than in large ones.

Diapers and set patterns, made with stock or other forms in pearl, require to be first laid out with black-lead lines. A design of this character is shown in Fig. 23. In this the strips of pearl forming the border would be cut with the roughened knife mentioned above. The other pieces of pearl are common stock forms. The dotted lines represent lines drawn in black lead, on which to arrange the diaper.

In inlaying for flowers, fruit, etc., a solid piece of pearl is laid where the flower or other object will come, and the exact form left to be made out afterwards in the painting, which will be with transparent colours.

In blocking out buildings in pearl, more care is desirable. It is well so to arrange the joinings of the pieces as to make them fall in places where they will be least seen—as, say, along the perpendicular lines at the corners of the structure, the horizontal ones at cornices, string courses, etc. In Fig. 24 the black lines show where the joinings ought to fall, and if further joinings should be found necessary, the dotted lines indicate where others might be carried with little injury to the effect of the work. The narrow ragged strip at bottom of the tower shows how scrap strips from the sawing-knife operation may be made of use.

After the pearl has been put upon the sized surface, the article should be placed in the stove for the night; the gold size will take rather longer in drying under the pearl than where exposed. As the flakes are often not absolutely flat, it is probable that in the morning one may occasionally be found to have "sprung." If so, work a little paste into the hollow beneath it with the finger, and put a weight upon it. But in doing this, be careful not to let any superfluous paste remain round the edge of the pearl, or it will cause the varnish, which will afterwards be laid on, to crack. After half an hour in a coolish stove, the "spring" will be found to be set and firm.

When the pearl is fixed, another coat of the black varnish has to be applied to the entire surface, covering pearl and all, and, after stoving and drying, this has to be pumiced down till the pearl is cleared. Then the worker has to varnish again, and so to repeat the operations till japan and pearl present a perfectly level surface. Three coats will generally do this, but something will depend on the thickness of the pearl; white pearl, which is thick, will require more than the thinner aurora. Where two kinds of pearl are used together, the thicker may be filed down, or, in the later processes, be pumiced down, to bring it flush with the thinner; but this, by-the-bye, will be at the risk of some of its brilliancy.

A level surface having been reached, it has to be smoothed and polished as above described, just as if there were no pearl. If *dead* gold has to be used with the pearl, it can, as already mentioned, be applied after smoothing and before polishing, though it can be also applied upon the polished ground. If *bright* gold, this *must* be laid on after polishing. We will suppose both smoothing and polishing to be done, so that we shall now see the pearl shining out from a brilliant jet-black ground, to all appearance a perfect example of inlaying, though, as we have seen, the process by which this effect has been reached cannot accurately be called inlaying at all.

When pearl and gold come in close contact, the gilding must be done before the pearl is finished. For convenience of description, however, it will be desirable that finishing the pearl should first be

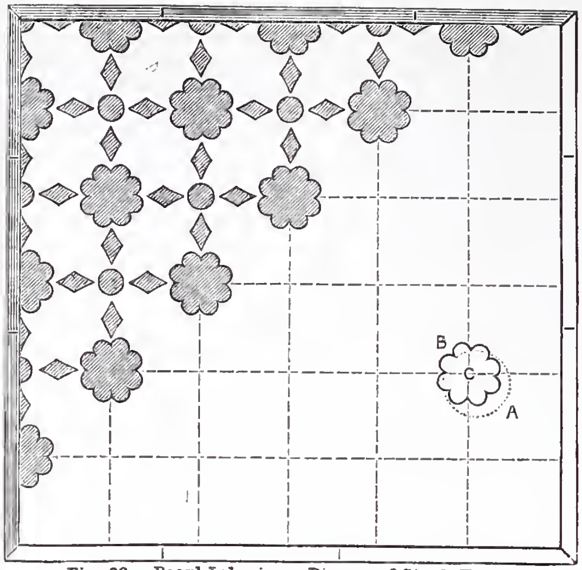

Fig. 23.—Pearl Inlaying: Diaper of Stock Forms.

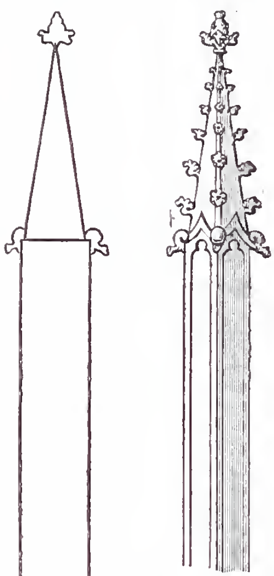

Fig. 25.—Use of Pearl Colour.

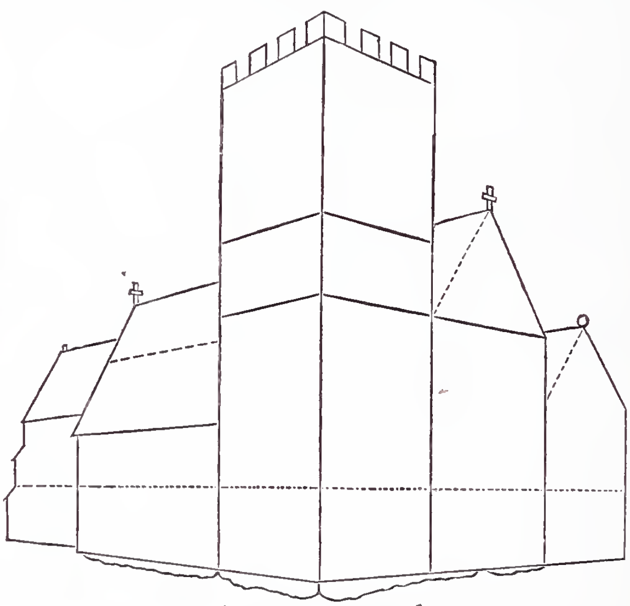

Fig. 24.—Arranging a Building in Pearl.

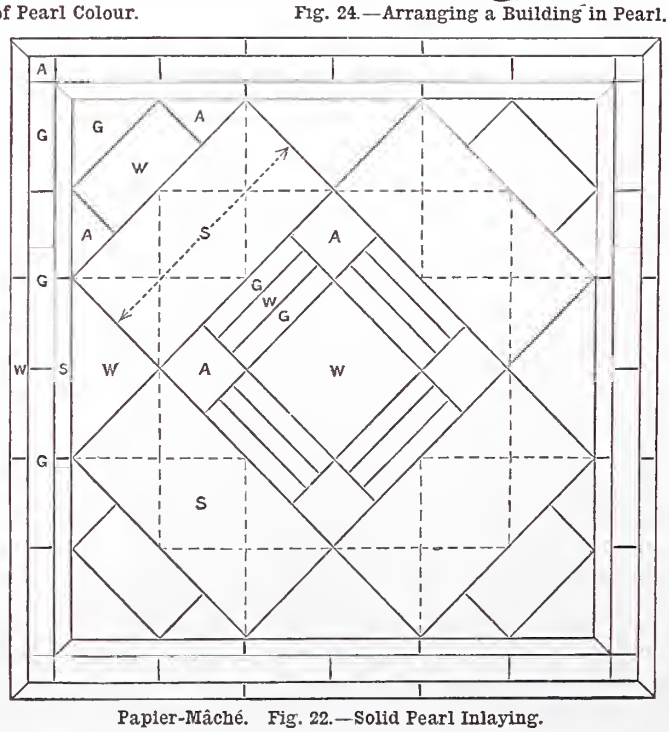


Papier-Mâché. Fig. 22.—Solid Pearl Inlaying.

spoken of. If any little flaw appear in the pearl, or if it should have been worn through in any part in the pumicing, the fault will have to be repaired by touching with what is known as "mending" or pearl colour; this is a mixture of flake white, crimson lake, a little black, and a little blue. It is important to remember this mixture, as in all cases of pearl inlaying it will probably be wanted.

This "pearl" or "mending" colour will also be necessary in painting buildings, since, in them, the joinings of the pearl have to be hidden, and there are often little projections, such as those made by crockets and finials in Gothic buildings, which it is not possible to cut out in pearl, and which, therefore, have to be painted in this colour. At Fig 25 we have a pinnacle: A, shows the plain outline laid in with pearl; B, shows how its crockets and finial have afterwards been added in mending colour. If, however, such details should be of any appreciable size, little pieces of "scrap pearl," *i.e.*, the odd pieces which break off in cutting, may be laid in to form them, and afterwards be brought to the required shape with colour. And it may be mentioned that there are other ways in which "scrap pearl" may be found useful in decoration, of which I may have occasion to speak later on.

It will sometimes be found that, during some of the stovings to which the work is subjected, a pearl form may have slipped somewhat from its place. This will probably be owing to too great a flush of gold size beneath it, which has been temporarily softened in the stove. Such an accident is indicated by the dotted circle at C, Fig 23. There is no way of actually restoring the pearl to its place. What has to be done is to block out with black, as at A, that part of the pearl which has passed its proper limits, and to add with pearl colour so much of the form as is wanting at B. If this is neatly done the defect will escape any ordinary scrutiny. All little slips of this nature are to be corrected in the same manner.

When the entire surface is covered with pearl, a mere line, generally of white paint, drawn neatly over the joinings, is all the finishing required. Some diapers and set patterns will perhaps need nothing more to render them sufficiently decorative than the mere correcting of irregularities of outline with black paint (vegetable black). Others will need more work. In such patterns, for instance, it is often desirable to connect small forms by thin lines of

Papier-Mâché. Fig. 26.—Simple Design in Dead Gold.

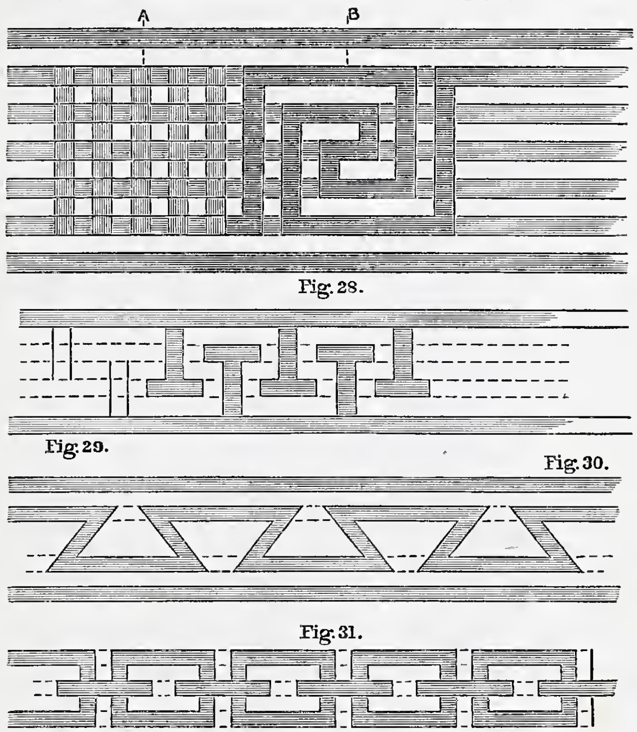
earl. Now thin nes cannot well e cut; it is neces- ry to make the rips of pearl mewhat broader han is desirable r effect, but they an now be light- ned and made to ok thin by draw- g a black line long the middle f each.

Some description f the methods of ainting and finish- ng buildings, flow- rs, figures, etc., on earl, will need to e given, but this vill, for sufficient reasons, best be deferred ill the more elementary processes of gilding ave been dealt with.

Gilding.—The gold leaf used on papier- nâché is the same as that employed by gilders generally. It is of two colours, deep and pale, the latter owing its lighter hue to an alloy of silver. Gold leaf is purchased n books of 24 leaves, 3 inches square, and costs from 1s. 2d. to 1s. 6d. per book. There is beside these a green gold which might be used as a variety; it is, however, more in favour in France than with us, being rarely seen in this country. A cheap substitute for gold leaf is Dutch metal, which is sometimes used in inferior japanning work, and which may be bought at 2d. or 3d. a book.

Dead Gilding.—It has been mentioned above that the proper surface for *dead* gilding is that before the polishing with hard rotten-stone and whiting. It is indeed possible to do dead gilding upon the polished surface, but chrome yellow or some similar colour has then to be mixed with the gold size to enable the worker to see what he is doing; and as this tends to weaken the size it is undesirable, unless the nature of the work requires it, as is the case when bright and dead gold are intermixed.

The design should first be drawn on paper and transferred to the papier-mâché by pouncing—that is, by pricking holes along the lines and dusting whiting through; no more whiting should, however, be used than is necessary, or it will make the outline ragged. The design is then to be pencilled with a sable brush in japanners' gold size. The gold leaf is to be laid on when the size has so far dried as to be merely "tacky," which will be in from one to three hours, as the size may be quicker or slower. To hasten drying the sized article may be held to the fire and then let cool again; to retard drying it may be put in a cool place, also a drop of poppy oil mixed with the size causes it to dry less quickly. A gilder's "tip" can be used if the worker is accustomed to one, and can apply gold more readily in that way than any other; if not, as the surfaces to be dealt with are all comparatively flat, most persons prefer to cut the book of leaf into convenient pieces, and to lay on the gold with the paper of the book. The leaf has to be pressed down in the usual way with a little ball of cotton wool, and superfluous gold dusted off with the same. Should any gold adhere in wrong places, as for instance to the ground, owing to a little greasiness from a finger touch, it may be removed with the wetted corner of a silk handkerchief.



Papier-Mâché. Fig. 28.—Method of Gilding Greek Key. Figs. 29, 30. —Method of Gilding Frets. Fig. 31.—Method of Gilding Chain Fret.

If, as in the design for dead gilding in Fig. 26, both deep and pale gold are used, the processes of pencilling, laying on the gold, and drying have to be gone through *separately* for each colour. The deep gold being of the most importance is generally applied first.

A day or two is sufficient to dry gilding, or less time in a stove of low temperature, and it has then to be protected by varnish. If the gilding covers but a small part of the surface, it has to be pencilled over with transparent varnish—usually copal—care being taken to put as little as possible on the black japan beyond the gold. The japan will not polish so well where the varnish goes. Nevertheless, if the gilding covers a great part of the surface, it is usual to go over the whole with the broad varnishing brush. If a loose hair from the brush should get entangled in the varnish, it should at once be removed and the place smoothed over.

If, however (as is the case in the designs for dead gilding, Figs. 26 and 27), the effect depends less or more upon "cutting-up" with black lines, this work must be done before varnishing; so also must any correction of outline which may be required. It should be borne in mind, however, that in this latter particular as little as possible should be left to need correction, for the black paint now applied will never equal the depth of the black japan. The paint to be used may be ordinary tube colour (vegetable black) mixed with varnish. The older plan was to grind the colour in turpentine and then add varnish; this cost more trouble, but it dried more quickly.

When the varnish over the gilding is thoroughly dry, the whole surface has to be polished. It has first to undergo a slight rubbing with the bob and soft, wet, rotten-stone, and afterwards one with the hard, dry, rotten-stone, whiting, and a spot of oil, as already

Papier-Mâché. Fig. 27.—Border in Dead Gold.

directed. This is, indeed, the method of finishing all decoration on papier-mâché, as will be noted more particularly farther on.

Fig. 26 is a simple pattern in deep and pale dead gold from old japan work. In this it will be seen that the gilded forms are very little "cut up" by lines of paint—the cutting up being confined to the fibres of the leaves and a single line up each petal of the flowers. The thin stem work, the leaves, and the centres of the flowers are in deep gold; the petals of the flowers, the balls, and the thick portion of the stem are in pale gold. The little shading seen is in wash black.

Fig. 27, also from old japan work, is a running pattern in dead gold, for the edge of a tray or any similar use. In this, the cutting up is much more elaborate. The border lines, as well as the stems, leaves, and centres of flowers, are in this design in deep gold; whilst the petals of flowers are in pale gold. The shading, as before, is in wash black.

Raising Composition for Dead Gilding.—In old japan work it will be observed that some parts are occasionally considerably raised above the general ground, as in such objects as the bodies of butterflies, the front petals of flowers, etc. To effect this, a mixture must be made of whiting, flake white, and gold size, of somewhat greater density than treacle. With this the form to be raised has to be painted in with a camel-hair brush, care being taken to keep the brush well charged at the point, so that the composition may the more readily flow upon the surface of the papier-mâché. This raised work has to be dried, and if necessary pumiced a little to correct roughness. It may then be sized and gilded in the ordinary way. This work must be done on a dead, not on a polished, surface, since on the former alone will it properly take hold, and it is always used in connection with *dead* gold.

Working Fret Patterns in Gold.—Both in old oriental and in English work, we not uncommonly meet with varieties of the "fret" ornament in gold, used as borders, and when so used always looking well. In the East, where time and labour are of little value, designs of this class are pencilled in line by line, but English japanners have adopted a shorter method. For instance, the "Greek Key," Fig. 28, is produced by the worker first drawing a series of lines (in this case seven, inclusive of the two border lines) with his pencil and gold size. He then crosses the five central ones with other lines at right angles, as shown at A. The whole has then to be gilded at a single operation, and the parts of the lines not needed for the pattern, as shown by the dotted lines at B, are afterwards blacked out. By this same process of lining and blacking out the different frets shown in Figs. 29, 30, and 31, with many others, may also be produced.

The way in which to draw these long horizontal lines accurately is by holding the hair pencil in the usual manner, but at the same time placing the third finger against the straight edge of the article under decoration. This steadies the hand, and by this means the required number of parallel lines may be drawn slowly and firmly. To do such work satisfactorily demands some skill in the use of the pencil; with practice, however, it may be done with precision and rapidity. These directions are, of course, supposed to apply to working frets in dead gold. In bright gold (of which I shall next have to speak), frets may, however, be worked in the same manner, except that, instead of blacking out, the superfluous gold will then have to be removed with a wetted box point.

NOTES AT THE ARCHITECTURAL AND BUILDING TRADES' EXHIBITION, 1889.

(*Continued from page* 155.)

MANY an individual, nowadays, when looking at the mantel with which his dining- or drawing-room is embellished, rests fully content in the conviction that the said mantel is marble, and that of an exceptional quality too. Such a display as that set up by Messrs. Corfield & Morgan, Tredegarville, Cardiff, would, however, be to those confiding individuals what is vulgarly called an "eye opener," for there were to be seen various productions in enamelled slate, which it would need an expert connoisseur to distinguish from marble itself. If people are determined to have the beauty of marble, and yet cannot afford the price for the real material, Messrs. Corfield & Morgan's enamelled slate offers itself as a remarkable substitute; and for those whose means will go to the genuine article, that firm are in a position to fulfil any commission entrusted to them.

The display of marble chimneypieces, enamelled slate chimneypieces, tiled stoves and hearths, iron mantelpieces, overmantels, and other goods of that description which bore the name of Messrs. Betts, 33, York Street, London Road, S.E., was most comprehensive in its way, and several of the designs shown by that firm gave pleasing evidence of the great strides made in that section of the hardware trade of late years.

An interesting novelty, and one which is likely to make its way in the market, was shown by the Ambrose Patent Bedstead Company, 16, Newgate Street, E.C. As the style and title of the company indicates, the invention is named the "Ambrose" patent bedstead, and it possesses many advantages of really genuine value. One of the chief objections urged against the old wooden bedsteads was the difficulty of keeping them clean, but many people have refused to adopt iron ones, in consequence of their more hard and ungraceful appearance. It is just this aspect of the matter which has been adopted by the inventor of the "Ambrose" bed, and we must say that the result of his cogitations may be looked upon as a most "happy medium." This new invention is introduced with the object of supplying a bedstead which, while perfectly free from the objectious met with in the old wooden ones, at the same time combines the comfort and elegance found in them with the cleanliness, durability, and cheapness of those made of brass or iron. The head and foot are composed of various woods, turned, carved, or otherwise decorated, while the frame and laths are entirely of metal, thereby ensuring the utmost freedom from anything objectionable. Owing to the extensive adoptiou of metal bedsteads of late years, the woodworker has been debarred from exercising his talents on that indispensable article of furniture. But, by this new invention, the cabinet maker would once again have an opportunity to make the bedstead "a thing of beauty and a joy for ever;" and even if it were only for that reason, the "Ambrose" bed should receive the heartiest welcome from all who have to use such an article.

The decoration of glass is a field which has enticed many inventors, and numerous are the methods by which plain glass may now be so manipulated as to rival stained glass more or less successfully. It is to Messrs. T. Baillie & Co., 187, Wardour Street, W., that we owe the latest invention in that direction, and the examples which they had on show at the Agricultural Hall proved conclusively that the "Valère" translucid enamelled glass, as their production is styled, will constitute a formidable rival to other materials of a like description. The novelty of this patent rests in the fact that the enamel is translucid, rendering both sides of the glass decorative, so that windows, screens, etc., display a rich effect on whichever side the light plays. At night, when illuminated by artificial light, the effect is specially charming, as the enamels appear translucid from the outside, while from the interior they have exactly the appearance of opaque enamels. The beauty of the tints and the variety of treatments which these enamels permit of place them very high, and they would be particularly valuable for such purposes as heraldic decorations on windows and in other similar associations.

Other exhibits were, of course, to be seen in large numbers, but those chosen for notice herein have been fairly representative, and with them we must conclude this necessarily brief report.

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

STRAIGHTENING AND BENDING PLATES AND BARS.

PLATES which are required to be finished with curved edges may be ordered from the rolling mill of the most convenient shape from which to cut it out, but its edges will have to be straight lines, though its corners need not necessarily be square. Although plates ordered to special forms will cost a little more than ordinary rectangular plates, yet where the waste in the bridge yard would otherwise be large and extra labour required, it is the most economical course to pursue.

The curve to which the edge of the plate is to be formed having been accurately marked upon it, as much of the superfluous material as is convenient is taken off in a shearing machine, and the edge finished with a chipping chisel.

There is a point in connection with the setting out of bridge plates to which the attention of the operative must be directed, otherwise he may get wrong. Girders in single spans are usually made with a slight rise or camber (about 1 inch for each 40 feet of span), the object of which is that when loaded they shall not "sag," or deflect below horizontal lines drawn from end to end of each girder. Commonly the girder is drawn as straight and parallel, and a note made of the camber to be given. This, then, must be arranged for in setting out the work for the yard. The girder, instead of being straight, will be a segment of a ring of very large radius, and the top flange being of larger radius than the bottom, it will be longer in the same proportion. The web plates will therefore be wider at the top than at the bottom; but the deviation from a straight line of the theoretical edges of the web plates will not be sufficient to necessitate their being made curved in practice. The rise due to camber being given for the whole length of girder, the exact radius of the bottom flange is found from the following rule :—Divide three times the square of the length in feet by twice the rise at centre in inches, and add one-twenty-fourth of the rise. This last addition is, however, so very small compared with the rest that it may be neglected in practice. The rule will then stand thus :—To find the radius in feet of the bottom flange, divide three times the square of the length in feet by twice the rise at centre in inches. Should any fraction occur, take the next whole number above it. For example :—Let a girder be required 108 ft. long and 9 ft. deep, cambered to give a rise of $2\frac{1}{2}$ in. in the centre. One hundred and eight multiplied by itself, 108, gives its square, 11,664, which multiplied by three is equal to 34,992; this divided by twice $2\frac{1}{2}$—5, gives 6,998$\frac{2}{5}$, so 6,999 ft. will be taken as the radius of the bottom flange; the radius of the top flange will be 9 ft. more, or 7,008 ft., and in the same ratio will be the bottom and top edges of the web plates. Let the web plates be 4 ft. wide at the bottom; then by proportion, as 6,999 is to 7,008. so 4 ft. is to 4 ft. $\frac{1}{16}$ in.

(To be continued.)

OUR GUIDE TO GOOD THINGS.

44.—The "Line and Design" Series of Art Drawing Copies.

Prompted by a desire to show that a foundation in design can be laid as soon as a student can use the pencil freely, Mr. Donald W. Robertson, Head Master of the School of Art, Walsall, has produced the "Line and Design" Series of Art Drawing Copies, a well-conceived and carefully-executed collection of copies which deserve attention in all schools where drawing is taught, and from all persons whose vocation it is to teach drawing, as being eminently suggestive of the means by which drawing lessons may be made even more interesting and attractive than they are under the ordinary *régime* of instruction in this most important art. It is a desirable thing, no doubt, to reproduce, with pen or pencil on paper, any form, whether regular or irregular, that may be set before the student, but it is still more desirable for him to find the disposition of certain straight lines and points, which are at first drawn as guide marks, gradually grow, as I may say, by the addition of a few more lines, straight and curved, into a design or pattern, which is at once symmetrical and satisfactory alike to eye and mind. Mr. Robertson has been successful in producing a series of copies that will well pave the way for original design for any student who is conscientious in his work and desirous of rising above the dead level of the mere copyist. Additional interest has been lent to them by the introduction of colour in flat washes, which serve to bring out the patterns and impart to them a distinctness and individuality that no drawing in simple outline in black or white, or *vice versâ*, could ever possess. The examples in the series are intended for pupils preparing to pass the Second Grade Examination in Freehand Drawing of the Science and Art Department. Directions for drawing and colouring are appended to each example. Good designs for monograms are included in the series, whose London publishers are Messrs. Simpkin, Marshall, and Co., Stationers' Hall Court.

45.—The "Monarch" Play Chair.

Many a boy, and girl too, for the matter of that, will welcome the addition of the "Monarch" Play Chair to the furniture of the nursery. There are many combination tools in existence in which, by various adjuncts and contrivances, one thing is made to serve the purpose of many, but although I have been permitted to learn that even the hard and unyielding carpenter's bench may be converted into a comfortable if not luxurious bed, I have never yet met with a chair that was so chameleon-like in its constitution, and variable in its capacity, as the chair which is distinguished above its fellows by the proud title of "Monarch." For this capital play chair it is

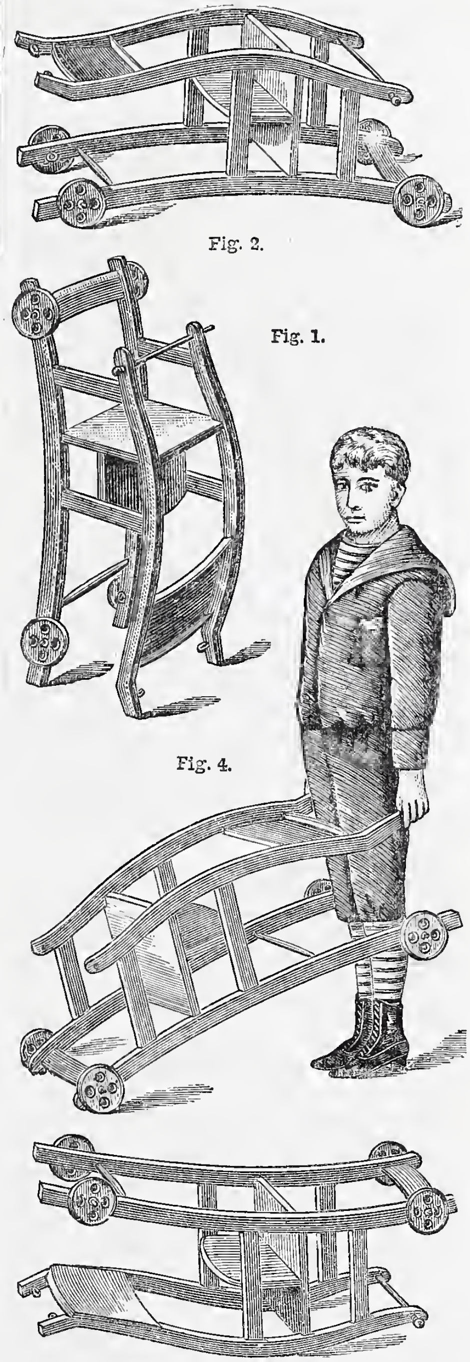

Fig. 2. Fig. 1. Fig. 4. Fig. 3.

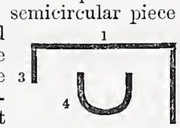
The "Monarch" Play Chair. Shown in Fig. 1 as a Table Chair; in Fig. 2 as a Cart with Play Table; in Fig. 3 as a Rocker or Sleigh; and in Fig. 4 as a Wheelbarrow.

claimed by its inventor and patentee, Mr. Thomas R. Weston, 61, Hampton Park, Bristol, that it is "convertible into a cart, stool, rocker, table chair, play table, wheelbarrow, sleigh, enclosure, go cart, and, when carried by two persons, into a sedan chair, and when attached to ropes into a boat-swing." Some of its phases are shown in the accompanying illustrations, in which it appears erect in Fig. 1 as a table chair, or rather as a chair in which a child may sit at table securely pinned in by the rail or bar in front. Put it on its back, and, by the aid of the four small wheels attached thereto, this Proteus of a chair becomes a cart with a play table, as in Fig. 2, the seat of the cart being furnished by a board attached at right angles to the underside of that which serves as its seat when used as a table chair, and the play table, that part of the front which served as a rest for the child's feet when sitting in it at table. Put it on the ground once again on its front part, and it becomes a rocker or sleigh, in which a child can sit and rock itself or be rocked according to circumstances. This last transformation is shown in Fig. 3, and in Fig. 4 it appears how, by taking hold of the ends of the top to the left, as it is shown in Fig. 2, and tilting it on the wheels to the right, it may be converted into a wheelbarrow, though, I fear, the boy who is using it as such in the illustration would find difficulty in occupying it as a table chair. Among the good points of this piece of toy furniture, are its attractive appearance, its strength, its excellent finish in the best style of workmanship, the absence of any movable parts, the front rail excepted, to get out of order, to get lost. or to injure the child, and that any child can alter the arrangements at pleasure by simply turning the chair about into the various positions. The price is 15s. It may be obtained at all cabinet makers and toy warehouses. The wholesale manufacturers are Messrs. James Cox and Son, High Wycombe, Bucks.

46.—The "Era" Printer.

To use the words of its inventor and manufacturer, Mr. Fred. J. Bowditch, 5, Waldo Road, College Park, Kensal Green, London, W., the "Era" Printer "prints anything;" and so it really does, although that "anything" must be taken *cum grano*, as meaning not everything, but any letter or figure that it may be desired to print by its aid. It is an invention which supersedes stencil plates for marking and numbering bags or boxes, and printing window tickets and brief notices, being useful, in short, for any purpose where bold lettering is essential. Thus it will be found desirable for all offices, warehouses, shops, timber and builders' yards, and all places in which lettering is sometimes required, being inexpensive to buy, always ready at hand, and practically indestructible. The means for printing are contained in a small box, and consist of a stamp, a bottle of ink, and a brush for spreading the ink on the ink pad attached to the front of the box, which falls forward on lifting the cover. It is the stamp only which requires any comment and explanation. On taking it up, it presents the appearance of a short stick of composition with a flat piece of india-rubber at one end, and a semicircular piece at the other. The end and sides of the flat piece are shaped as shown in the margin at 1, 2, and 3, imprinting three straight strokes of different lengths.



The semicircular piece is of the shape shown at 4. By these forms, either used singly or in combination, any letter of the alphabet or numeral can be printed. Thus No. 1 will print I, M, N, V, W, X, each letter being formed by one, two, three, or four impressions of No. 1. Again, A, E, F, H, L, T, are formed by combinations of Nos. 1 and 3; K, Y, Z, of Nos. 1 and 2; P, B, of Nos. 1 and 4; R, of Nos. 1, 2, and 4; J, U, of Nos. 2 and 4; C, O, Q, G, of Nos. 3 and 4; S, D, of Nos. 1, 3, and 4. Of the numerals, 1 and 2 are formed by combinations of Nos. 1, 2, and 4; 3, of Nos. 3 and 4; 4, by No. 1 alone; 5, of Nos. 2 and 4; 6, by No. 4 only; 7, by Nos. 1 and 2; 8 and 9, by No. 4 only; and O, by Nos. 3 and 4. I think sufficient has been said to show the ingenuity and utility of the invention, and that it is applicable for all lettering for which stencil plates are now used, although the results may not be so neat and regular as the impressions by means of plate and brush. The stamps are made in different sizes to suit different purposes, and range from about $\frac{1}{2}$ in. to 2 in., as regards size of letters. The set for stamping 1-in. letters is supplied by the inventor, post free, for 1s. 3d.

The Editor.

A Corner for Those who Want to Talk It.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

What a Glasgow Man Thinks of Work.—W. C. T. (*Glasgow*) writes:—"I am very glad that (as the *Glasgow Herald* says) you have made a bit with Work. It deserves to be a success. It was just needed by fellows who job at home like myself. I think that if you have loose covers on the weekly numbers they would help to keep them clean, for the Work weeklies get dirty on the outside with our dirty hands, being black squadders, and that does not look well in a bound volume. The covers could be made to pay by advertisements."—[I am obliged to you for your letter, and the notice of the patent darning weaver. Your suggestion with regard to wrappers for the weekly numbers is a good one; but it would not prevent the pages from being soiled by turning them over while reading. To keep the outside fairly clean, make a loose cover of pasteboard as recommended in "Binding Made Easy," Nos. 6 and 9, and put four or five strings along the back, inside from top to bottom, to take as many weekly numbers.—Ed.]

Cabinet in Fretwork.—Buhl writes:—"I have been waiting to see if there were any among your readers of Work that had undertaken the making of the inlaid cabinet; and, if so, to read what their experience was, because it is an almost impossible pattern for 'amateurs;' a professional would not think of executing it, being too much labour for little effect. A 'marqueterie cutter's' mode of operation would be to trace the pattern given upon strong tracing paper, then perforating it with a fine needle, from which he pounces several patterns. He then takes his ground woods—say four (it is generally four they cut)—and gums a pattern on one of them, and then four coloured veneers, of whatever colour the ornament is to be, and gums his ornaments on to one of them; a piece of greasy paper will be put between the first and second veneers of each packet, and then pinned up separate. He will now make a saw, then start cutting his ornaments, laying them out in a tray as he does so; having cut the ornament, he proceeds to cut the grounds. Having done that, and having no shading to do among the ornaments, he will put them together, when they will fit as near as possible to air-tight. Now fancy an 'amateur' following the instructions of the 'designer' in a pattern like that, by using a shop saw, and cutting 'buhl,' or one into the other, fashion; he would either break all his groundworks, or lose his ornaments in space; in the one you would have no saw kerf, in the other you get hardly anything else. I could not resist writing on the above subject, as it is a line in which I have been engaged for some considerable time, in all its branches—the 'cutting,' 'engraving,' and 'designing,' in the principal 'London' West-end firms. Accept my best wishes for Work."—[I am pleased to have your letter, as it gives evidence of the interest taken by men of every trade in Work, and of their readiness to assist by instruction, reproof, caution, etc.—all of which we ask for and desire. You will learn from other letters on this subject that amateurs have managed the work, and got through the cutting of the design, although it is certainly elaborate, as you say. Will you send me some of your own designs to look at? for, in the case of Work, it is always a selection, and, therefore, a survival, of the fittest; and if your designs surpass those of the "designer" of the "Cabinet in Fret Cutting," both he and I would be glad to find you numbered among the contributors to Work.—Ed.]

A Good Word for Work.—J. L. (*Elgin*) writes:—"I have taken Work since its commencement, and am much pleased with it; and having the 'Technical Educator' complete, I should be fairly well instructed by it. You will, no doubt, receive so many advices and hints how to conduct the 'paper,' as, if followed, would only leave you as a machine to be moved at will, and I have no intention of adding an infliction in this way. Everything can't appear at once, as we impatient patrons would like; and, while adding my congratulations on such a good start, would merely suggest that thoroughly reliable papers on such subjects as forging, brazing, and soldering, would interest not a few. How few can practically treat the various grades of steel when such a thing as welding is necessary? and being practical myself, know the value of such information."—[Thank you for your good wishes. I do indeed receive much advice, and many hints. Well, I read all, and I am truly thankful for the kindly endeavours that are made to lead me in the path in which each individual writer thinks I ought to go, but I pursue the even tenor of my way, imagining, vainly enough, perhaps, that I know my own business best. There was a man once who called his wife an *obstinata mulier*, putting something else before *obstinata*, which I omit for propriety's sake. He only meant, poor fellow! to say that she was an obstinate woman, which, possibly, she was, and he relieved his feelings in Latin, trusting that his little outburst would thus escape notice. The woman kicked, however, and said she wasn't going to be called an obstinate mule by any man living, and certainly not by her husband. It may save much trouble if I allow at once that I am a very obstinate mule myself, but that I do not in the least mind being called so, with any word by way of prefix that may be preferred.—Ed.]

Hints to Amateurs.—M. A. writes:—"Being interested in amateur work, especially what I deem the most useful branch—viz., carpentry, joinery, etc.—I hail with satisfaction the appearance of your journal. The hints to amateurs in a recent number were very good, but in my opinion just left off where they should have continued. The great difficulty with all amateurs is not how to mix glue, to saw a straight line, etc., but to make a good joint; and this, I think, is a point that should be thoroughly set out in your journal, together with the explanation and diagrams illustrative of the various kinds of joints, and the explanation of the technical terms used, etc. etc. Such matters are easily enough learned in the workshop, but it is only the very few who can obtain such help; and, moreover, as they are unwilling or unable to invest in expensive books, they look to obtain the information in your valuable journal."—[In reply to your remarks on this subject, first let me say that I am in complete accord with you in considering carpentry and joinery as one of the most useful branches of manual labour to which an amateur workman can turn his hand. Gluing-up and ability to make a straight saw cut are matters which require practice, I can assure you, and it is as necessary to give instructions on such points as these as on other things mentioned in your letter. If you can make and use glue in a proper way yourself, and can rip down a board from end to end, holding the saw so truly that the saw cut is straight throughout, and the edges thereof at right angles to the surface of the board, you are well advanced on the road to excellence as a carpenter. Let me ask you, when you are sawing through a plank lengthways, and wish to do the work as truly as possible, how you test your progress and ascertain that you are not bearing on the saw so as to drive it out of a truly vertical plane (supposing the board to be truly horizontal) either one way or the other. It is a very simple matter, and, doubtless, you know all about it, but—if you do not, you will agree with me that it is even desirable to show, as you put it, "how to saw a straight line." Well, as to "jointing boards," papers on this very important branch of carpentry are already in the printer's hands, and are being translated—if I may use the expression—into type. With regard to the explanation of technical terms, whenever any term that may not be perfectly intelligible—as, for example, "bolection" moulding—is used, the meaning will be given; but it is possible that there may be many omissions in this respect, for the simple reason that writers who are thoroughly conversant with the subject often forget that those for whom they are writing are not so well informed on minor points and technical terms as themselves. But when any term is used that is not readily understood, a few lines pointing out the difficulty will always meet a ready response in "Shop," which will tend at once to dissipate any cloud of mystery that may appear to hang about it.—Ed.]

A Vote of Thanks.—S. D. writes:—"If Mr. Adamson would derive any pleasure from the knowledge of the fact that he has been the means of encouraging some youthful amateur to push his endeavours to a successful end, I consider, out of common gratitude and justice, he deserves to have that satisfaction. From his design I have made an overmantel; but instead of using waste timber, such as packing cases and the like, or even tea chests, I have gone to considerable expense in buying the best white pine and mahogany. It is, in my estimation, false economy to utilise that timber for such purposes. The damage done to planes and utensils and the increased amount of labour necessary quite neutralise any advantage that might be gained in the first cost. But of course that is a matter for individual consideration. Mr. Adamson was very successful in introducing his design to the readers of Work in an attractive form, and I beg most heartily and sincerely to thank him for being the cause of my possessing a really handsome piece of home-made furniture."—[You will notice that your letter has been translated into long hand. Shorthand has its advantages, I know; but my education was sadly neglected in that particular branch, and your letter, as it was, was thrown away upon me. However, I can generally manage to get on the other side of anything, whether shorthand or trade secrets, or anything else that may happen to be somewhat cloudy. But I trust that no one else will follow your example, because if it is done to any extent, I shall have to provide myself with a special shorthand clerk, which will be to me an expensive luxury.—Ed.]

About Work.—D. T. D. (*Cardiff*) writes:—"I desire to supplement what so many of your readers have already said as to the value and worth of your able production, Work. I need not say how useful I find it in my recreative moments. Being engaged all day with a great deal of arduous brain work, you can understand my appreciation of amateur's work, therefore my high appreciation of the articles in your able edited publication. I wish your every effort every possible success. There is one thing I should like to suggest if you will allow me, and that is, that a wrapper be put around Work, in order that the advertisements may not be bound up with the readable matter. Doubtless that has already engaged your attention, and I have no doubt that your enterprising firm will, when the publication is better known, accede to the wishes of your readers in this direction."

Asking for More.—T. J. H. (*Trowbridge*) writes:—"For many years past I have taken in all of your publications that have come within reach of the average workman's pocket, but the most tantalising is your latest, Work. Why, it's like feeding a lot of donkeys with one oat at a time, and making each donkey wait for his turn to get the oat. Could you not double or treble the thickness (I would not increase the size of the pages) of Work, and charge us 2d. or 3d. for it, and so enable yourselves to give us a few articles on other subjects? I am sure the readers of Work would not object to double the information (for a start) at 2d., at the same time putting an end to the 'crowding out.' Alas! if you had to buy instead of sell Work you would not object to its being issued in a spare or advertisement cover. If you lived (as I do) in a country town, and saw your favourite Work, with other papers, thrown out of a train (like a lot of fish guts at Billingsgate) into the dirt on the railway platform, well, perhaps you would not swear, but you might think some very strong words that will not appear in your 'Encyclopædic Dictionary.' I should like to see the opinions of fellow readers of our Work on these points."

Tea-Chest Wood.—G. W. M. (*Westbourne Park*) writes:—"Both Barrington and yourself are right with regard to old tea chests. Being in the grocery trade I am always on the look out for anything useful in the way of old boxes. The tea chests sent over by the Chinese are almost useless for anything but firewood, but those sent over with Assam, Ceylon, and Indian teas, can often be put to good purpose. Assam, and sometimes Indian, tea chests are made of teak, the boards being from ½ in. to ⅜ in. thick, and from 6 in. to 9 in. wide. The Ceylon chests are made of a rather soft reddish wood, not unlike Spanish mahogany when the grain is good, but much lighter, the boards sometimes being as much as 12 in. and 14 in. wide. Another useful box is the American bacon box. These boxes are made to hold five sides of bacon, being made of inch pine about 3½ ft. long by 2 ft. 6 in. deep, and 1 ft. 6 in. wide. The boards used vary in width; from two to four are used for the sides, but the tops and bottoms are usually in one piece. They can be obtained at most wholesale cheesemongers at from 1s. to 1s. 6d. each."—[I have used the American bacon boxes with good effect for fencing and ornamental work in the form of plant boxes, for what I term "wall gardening." The boxes in which honey, lobsters, Swiss milk, etc., are sent to this country, I have often utilised as plant protectors, converting them into small frames by cutting sides and front to the proper slope, and then making a light to cover the top. It is surprising to find how much can be done with boxes that are generally considered as being fit only for firewood.—Ed.]

About Work.—J. P. A. writes:—"After reading a prospectus setting forth the great amount of information and practical instruction to be got out of Work, I immediately ordered it. But I was greatly disappointed, for I find it almost useless to practical men, although it may be otherwise with clerks and such like, who want to put off their time by a little wood spoiling or something else. But I am a practical cabinet maker and joiner with my bread to earn, which is as much as I can do, without wasting my time making such useless trifles as you give such full instructions about. But to be more particular. You take up a great deal of valuable space (I say valuable not because it is valuable, but because I think it might be made so) in giving instructions about making such things as iron trying planes; but where is the man who having need hasn't got one? or if he hasn't he can buy one a great deal cheaper than he could make one, or he could make one without any need for instructions. Another large space wasted is that on hinges, and how to fix them. How can you take up space with such trifles when you say you have so much waiting? In your 'Guide to Good Things' you only describe the stock of two firms, and then only unimportant things, or if important, things which working men know just as well as yourselves. Very few would want such a thing as a Lukin lathe. The last number is now in my hand, and in it one of the designs for a lattice-work blind is very bad—in fact it could hardly be made as shown. In your 'Guide to Good Things' you describe a circular saw which you say will cut 4-in. stuff. Well, I have seen a good many treadle saws, but I have only seen one that has been worked at all after the first week or two; the rest have invariably been thrown on one side. This is one made by the master (my father), which we have had *in constant use* for about two years, and it is more used now than ever it was. Don't think I am prejudiced because you may think I had a hand in making it. I would describe it, as it is made on an entirely new principle; it has never got out of order, although it has only been made of odds and ends, only the saws being bought, all the other parts have been made out of whatever was handiest; but the inventor is seriously thinking of patenting it. Some day you may perhaps find room for an illustration in your 'Guide to Good Things,' as it has nothing in common with any I have yet seen. Of course it is easier to find faults than to mend them, but by way of suggestion I think it would be better if you followed rather more in the steps, or rather in advance, of the 'Technical Educator,' with a few such papers as Dr. Dresser's 'Principles of Design,' or Prof. Church on 'Colour,' or 'Building Construction,' or such papers as 'Electricity' in Dr. Lardner's

'Cyclopædia,' or other papers in the same series, and gave a few good drawings for *carving* or illustrations of *good old or new furniture* or good inventions, with a few papers on such a thing as handrailing. You talk of a practical man taking pupils for a short time; a short time will do the pupils little good, and certainly will do the rest of your readers much less. I have Jeay's book on handrailing before me. I think this makes it simple enough, but the majority of joiners will not consult a book, whereas they will often follow the instruction of a journal. The 'Cabinet Maker and Art Furnisher,' though cheaper, has much more information than WORK. I hope you will accept this criticism in the spirit it is written, and if you cannot altogether make such sweeping changes, at least do what you can, or else before long you won't be able to number a practical man in your subscribers. P.S.—I can supply your correspondent with as many Elizabethan twists as he likes, finished, direct from the lathe."—[Your strictures are sufficiently answered by other letters in this number without any rejoinder on my part.—ED.]

About Work.—H. C. F. (*Great Bedwyn*) writes:—"I must take this opportunity of telling you how pleased I am with WORK; it is a paper which has been much wanted, and to such as me (a country joiner) will prove a great boon, as the classes in towns are beyond my reach. I have already the pleasure of supplying three monthly parts, and each of these customers speak very highly and hopefully of this practical and useful publication."

Plans and Specifications of Buildings.—AJAX (*Huddersfield*) writes:—"In reference to the introduction of *plans, specifications*, etc., into your much valued WORK, I think myself, *coupled* with the opinions of fellow subscribers, that it would be of decided interest, and the means of a large circulation, and would not fail to please all generally."

How Work is appreciated.—H. G. writes:—"I am very pleased to tell you that I shall have each volume of WORK bound, because I know it will be the means of assisting my children in gaining a technical education. Success to yourself and WORK."

Lacquering.—FAL writes:—"Some of the readers of WORK who go in for repoussé work may be glad to know that the silico enamel sold by all dealers in cycling requisites is a first-rate thing for superseding lacquer. It flows as ready as water over the brass plate, and as no heat is required all the difficulty which the use of lacquer involves is avoided."

Muzzle for Ferrets.—FAL writes:—"The plan described by OPIFEX is good, but it has the disadvantage of requiring a separate muzzle for each ferret, as their heads differ a good deal in size. The ferret, also, will be apt to hurt his jaws if he works too energetically, as the projecting pin will catch against the sides of the top when he and the rabbit are at close quarters; this, of course, has a tendency to make him slack. The best plan I ever met with for 'coping' ferrets was taught me by a warrener in Warwickshire, many long years ago. I used it for twenty years on a large manor, where we killed from 1,000 to 1,500 couple annually, and found the ferrets would work quite as well 'coped' as they did when free. All that is required is a piece of tape and a little soft twine. The tape should be tied round the ferret's neck, so as to form a collar, and should be kept on permanently. When required for work make a single knot in the centre of a piece of twine, but do not have it taut. Open the ferret's mouth by pressing the sides of the jaws, and then slip the loop of the knot over the canine teeth in the lower jaw, and draw the knot close; bring the two ends over the nose, and make a double knot, slip one end of the twine through the collar, and knot both ends together. It requires a little practice to get the right tension in the knots; if they are too taut the twine will hurt the ferret, if too slack he will get his claws in the twine, and pull it off. I can cope a ferret by this method in less than half the time it has taken me to describe how to do it."

Bookshelves.—SCOTO-IRISH writes:—"I have just been turning over the pages of your interesting paper, which I hailed with delight when the first number was published. The subjects treated, so far, don't give me a chance to exercise my spare moments upon, as they are rather intricate for me, or require tools that I don't possess; but I live in hope that ere long my patience will be rewarded by seeing some article that will specially interest me. What I should particularly desire to see described in your journal is an article on how to construct a plain, substantial bookcase, free from turning or fretwork, but which might be made with the aid of a saw, plane, and chisel. I am sure I don't stand alone in my desires. I had a request from a friend in Scotland if I could furnish him with a design for same. I purpose making a start shortly to try and make a case to hold my books, but if I get any encouragement from you I will hold it over until such times as an article may appear, that may go beyond the appearance of a *packing case or box* in its construction."—[A paper entitled "Some Rational Bookshelves" will shortly appear, which, I think, will please you and meet your requirements in every way. Certainly no pains will be spared to render both the text and the diagrams so explanatory that any one able to handle a tool need not long be without a useful bookshelf.—ED.]

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Photographic Apparatus.—W. W. (*Devonport*).—Articles will appear in WORK describing the construction and use of cameras and all kinds of photographic apparatus, with such details as you ask for.—T. C. H.

Half-Plate Camera.—J. R. (*Hebden Bridge*).—See answer to W. W. (*Devonport*) above.

Adjustable Callipers.—E. B. (*Manchester*).—As you say you "have tried most tool shops in Manchester and failed to get" these useful appliances, you had better send to Messrs. R. Melhuish & Sons, 85 and 87, Fetter Lane, London, E.C., who have them on sale.

Wood Carving and Carving Tools.—P. P.—You give your name only, and no address, so I am unable to write to you on the subject of your letter, as I should have done. If you will send me a set of your tools and accompaniments, with specimens of carved work and instructions supplied to your customers, I shall be better able to judge of their utility. If they are up to the mark, I will notice them in "Our Guide to Good Things." When next you write to me on this subject do not omit your address. Every one who writes, under his or her own name, should give address, not for publication, but to enable me to communicate with them direct, if there be any necessity for it, as in your case.

Hatchet.—J. P. (*Gt. Keyne*).—To make a hatchet, procure a piece of flat iron of the best Staffordshire quality—say, Lord Ward's—and file it down to the shape in Fig. 1. If the head has to be steel-faced,

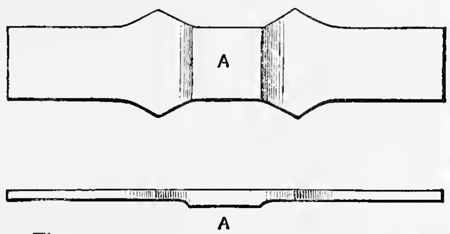

Fig. 1.

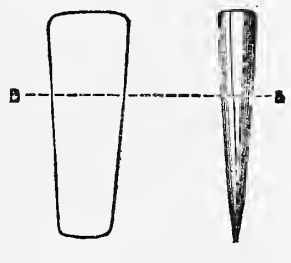

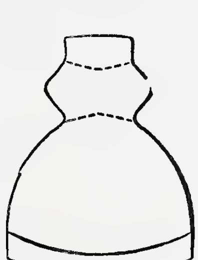

Fig. 3.

Fig. 2.

SECTION B–B

weld a piece of steel on at A. Make a wrought iron mandrel, like Fig. 2, bend the strip around this to form the eye of the hatchet, and weld to complete the eye, but leaving the tails apart. Insert a strip of steel between the inner faces of the tail portions so bent over below the eye. Then weld the whole together, and draw out under the hammer, and flatten both lengthways and sideways to form the blade, Fig. 3. When finishing the eye, the taper mandrel is entered from both sides, so that the eye is smaller in the centre than at the outsides. This is necessary in order to prevent it from slipping off the handle after wedging. Shear steel, or double shear steel, should be used for the edge. To temper, heat the hatchet to a low red, and partly quench in water. Then take out and allow the heat to go back to a light purple, or plum colour; then quench until entirely cold. Leave the forged edge a fair thickness for grinding away.

Cost of Patent.—P. T. S. (*Sheffield*).—The statement referred to was a clerical error. The Government stamp of £1 on depositing the provisional specification secures protection for nine months. If you intend to proceed with the application you must within that period deposit a final specification, the stamp in this case being £3, and the papers obtainable, the same as for the provisional specification, on application. Two months are then allowed to elapse to afford opportunity to any desiring to oppose the sealing of the patent. After that period you can obtain the sealed patent on application. Until the patent is actually sealed you should observe secrecy in regard to your invention.—F. C.

Weight of Fly Wheel.—F. W. M. (*North Brixton*).—There is a great deal involved in such a question as this. There are several rules based upon cases in practice; but since conditions vary, the rules are not applicable to all cases. Perhaps the best is one of Molesworth's:—

$$W = \frac{\cdot 6366 \, P \, S \, C}{D}\left(\frac{N}{60}\right)$$

where P=pressure on piston, in tons; S=stroke of engine, in feet; D=mean diameter of rim, in feet; N=number of revolutions per minute; C=constant, varying from 3 to 4 in ordinary engines, and rising to 6 when great uniformity is required; and W=weight of fly-wheel rim, in tons.

Another rule, which does not take account of piston speed, is

$$W = \frac{P \, S}{45 \, D}$$

where W=weight of rim, in cwts.; D=mean diameter of rim, in feet; P=total average pressure on piston, in lbs.; and S=stroke, in feet.

The principle, however, is as follows:—An engine would, in the absence of the fly-wheel, run at varying velocities at each single stroke, due to the ever varying nature of the forces operating on the crank pin. The governor regulates the admission of steam to the cylinder, and so determines the *mean* speed at which the engine is to run. But the fly wheel regulates its degree of *steadiness* under the continual fluctuations of velocity to which it is subjected. In marine engines with cranks at right angles, the motion of the paddle wheels, or of the screw and its shaft, tends to equalise the motion of the engines. In locomotives the weight of the engine has the same effect. In hand engines the fly wheel is necessary to absorb energy when that is in excess, while it gives out some of this store of accumulated energy again when the power of the engine diminishes, and thus maintains equable motion. The fly wheel is in effect a falling body—that is, its accumulated energy is correctly calculated as though it were a body falling perpendicularly and gathering energy as the square of its velocity. The weight of the rim alone is taken account of. Knowing piston area, speed, and steam pressure, it is easy to calculate the amount of power given out by the engine at every stroke. It is necessary, however, to assume some arbitrary relationship between the stored-up energy in the fly wheel and the power of a single stroke. It must be more than that given out in a single stroke, but the precise relationship will have to be settled by existing conditions. A slow running engine will require a greater reserve of energy than a fast running one. Engines badly balanced require a heavier wheel than those whose balancing is perfect. Some machinery is thrown into and out of action more frequently than other kinds, thus subjecting the engine to extremes of stress. A variation of speed permissible in some machinery would be injurious to the motion of others. Usually the reserve of energy of the fly wheel is estimated as being equal to that given out in six single strokes of the engine—that is, equal to area of piston × pressure per square inch × 4 to 6 single strokes, the result being in foot-pounds. A mean diameter is assumed for the fly wheel as most convenient—say, length of stroke × 3 or 4. From the number of revolutions of the engine per minute the velocity of the fly-wheel rim of a given diameter can be calculated in feet per second. Having found this velocity, the height from which a body must fall by gravity to acquire such velocity is estimated. The energy in foot-pounds of the number of single strokes first taken or assumed is then divided by this height, and the quotient is the weight in pounds which the rim of the fly wheel must have in order to possess a quantity of energy equal to 6 single strokes of the piston. By this method, a cylinder 6 in. in diameter, 10 in. stroke, with 40lbs. of steam, would, assuming 6 strokes, work out thus:—

$$6 \text{ in.}^2 \times \cdot 7854 \times 40 \times 6 = 6768 \text{ foot-pounds.}$$

Assuming 200 revolutions per minute, and fly wheel 3 ft. 4 in. mean diameter, then—

$$3 \text{ ft. } 4 \text{ in.} \times 3\cdot 1416 \times 200 = 2094 \text{ feet per minute, or } 34\cdot 9 \text{ feet per second.}$$

To find the height from which a body must fall to acquire this velocity, square the velocity in feet per second and divide by 64·4=18·9 feet. The energy given out by 6 single strokes divided by this is the weight of the fly-wheel rim in pounds, thus:—

$$\frac{6768}{18\cdot 9} = 358 \text{ lbs.}$$

This weight may be disposed in any sectional form about the mean radius of the rim.—F. C.

Violin Tools.—J. W. (*Battersea*).—I am not acquainted with a tool bearing the name you give ("fillitere"), nor do I see the use of it. Veneers may be reduced to any desired thickness with a five-toothed veneer plane. If you are desirous to make purfling—which may be bought very cheaply—you might do as follows:—Cut two strips of dyed veneer and one strip of white two inches wide,; glue the white piece and one black piece together; when set, plane the white side to the thickness you want, and then glue on the other black piece. These being dry, the sheet should be planed, so that both blacks are the same thickness; and the whole sheet is $\frac{1}{16}$ in. thick. Plane one edge true, on the shooting board, and with a sharp knife and steel straightedge divide into strips of $\frac{1}{32}$ of an inch. Please specify the particular tools you require.—B.

Wooden Copying Press.—You ask me to "minutely describe how to make the wooden screw and threaded block through which the screw revolves" for the wooden copying press described in WORK No. 2 (p. 27). The screw is first turned in a lathe, and then cut with a box and tap; and to describe the process as you ask would be practically useless to you. Mr. Denning tells you that in making his press he used "a discarded bench screw." I recommend you to do the same; but if you do not happen to have one, and cannot get one elsewhere, go to any dealer in tools, and buy a wooden bench screw. It will cost you about 1s. 6d. or 2s.

Papier-Mâché Pulp.—W. H. (*Dover*).—Without fuller information it is not easy to say why W. H. should have failed to make his pulp set properly. Possibly he may not have used enough pressure to expel superfluous moisture, or his paper may have contained saccharine matter, or his paste may have been too thin, or the flour used may have been what is called "self-raising." The glue paste is made by boiling flour and glue with water, and this has, after boiling, to be most thoroughly and intimately mixed with the pulp. A subsequent boiling might make the incorporation more complete, but would otherwise be immaterial. The mixture must be a thick mass before any attempt is made to mould it. In modelling in pulp (*i.e.*, building up forms in it with the spatula), only a little should be added in a day, and then dried. For trade purposes, considerable heat (stoving) is used in drying. A mixture of pulp with the above-described paste, when properly freed from moisture, can scarcely help setting into a solid mass. Glue alone would serve, as in the composition for stopping holes in wood; but when used on a large scale would be liable to crack, which the paste is not.—S. W.

Casting from Life.—J. E. S. (*Stoke Newington*).—Casting a hand or foot is simple when one side only has to be moulded. Take the hand; the back only to be shown. Rub a very little olive oil over the skin, place it palm downwards on a cloth so arranged as to fill up the hollows beneath as far as possible, and pour on the plaster. When this is set (say, in five minutes), the cloth may be pulled away, and the mould eased with a knife where necessary to let the fingers be drawn out. Well rinse the mould with clean water, and it is ready for making the cast, either in plaster or wax. If both back and palm are to be moulded, bury half of the hand in sand, mould it, turn it, and clean sand from edges of mould, which brush over with clay and water to prevent the two pieces of the mould adhering. Make second half of mould, remove the hand, and tie the two pieces tightly together before filling. To the second query of J. E. S. we would reply that articles, with illustrations, fully explaining the whole art and mystery of plaster-casting, are in preparation, and will soon appear in WORK.—M. M.

Lathe for Wood Turning.—F. S. (*Crewe*).—In reply to your queries:—(1) A conical mandrel fitting is best for wood turning, because the friction is less than parallel fittings. (2) No advantage whatever, unless you have corresponding block to raise the headstock. (3) This is a grave question on a common lathe; it is essential first to have front of headstock planed square with bed or bearer; then to have a casting (brass will do) to form base-ring for adjustment of oval. The cost of a trustworthy chuck to produce ovals of from 1 in. to 12 in. would be more than the value of an ordinary wood-turner's lathe. F. S. should try his hand at plain turning. First reach the first rung of the ladder before mounting the top.—G. E.

Overhead Motions.—J. E. J. (*Portsmouth*) writes:—"Referring to the valuable articles now appearing in WORK concerning lathes and turning appliances, and more particularly the portion dealing with 'Overhead Motions,' will you kindly point out the objections to the accompanying arrangement which I propose adopting, and which appears much simpler and easier to make than any shown in your last number? I ask your advice on this subject as your contributor recommends amateurs to be cautious in adopting ideas of their own in preference to those generally approved by our best makers."—From a practical point of view there is scarcely any objection to the form of overhead which you have sketched. As a cheap rig-up it is a very good substitute for the more expensive, and only slightly more efficient, pieces of apparatus shown in p. 92 of WORK, and with a few very slight modifications in design it will answer your purposes as well as those. First, for the wooden supports which you show at the left-hand end of the lathe-bed I think I should substitute iron—either parallel rectangular bars, between which the horizontal bar for the guide pulleys would be pivoted; or a single stout bar forked at the upper end to embrace the horizontal one, similarly pivoted. Then, instead of fastening these bars to the top of the lathe-bed, I would bring them down past the end and attach them to the standard. It is not clear how you intend to adjust the pulleys to suit the position of slide rest, as the centres of the pulleys in your sketch correspond with the longitudinal axis of the horizontal bar. I would suggest making a light casting to slide along the bar, to be pinched in any position with a set screw. From an eye in the bottom end of this casting I would suspend the guide pulleys by means of cord, so that they should be free to revolve on their spindles, and to turn into any required position to suit the drill spindle in the slide rest. This would be better than having the pulley spindles rigidly fixed in the horizontal bar. With these slight modifications your overhead will prove a good and efficient one.—J. H.

Bronze Powder and Frames.—G. A. (*Sheffield*).—Fig. 17 is described in second column of p. 74. The bronze powder at 6d. an ounce is hardly likely to last. Hughes and Kimber, of Fetter Lane, E.C., keep many qualities at various prices. I confess I do not quite understand your query. You say "Fig. 1 is mentioned as making a beautiful panel, but no mention is made of any frame; the same of Fig. 17." The latter I have referred to above, and the former is described on p. 72.—J. G.-W.

Printing Machine.—H. C. F. (*Great Bedwyn*).—The wooden copying press described in WORK No. 2 (p. 27) would not do for a hand printing press, in which the impression should be given by the action of a lever. Your letter shows that you are very much in the dark with regard to everything relating to printing, especially when you say that among your difficulties are, "how to fix the type, and how to use it when fixed." To attempt to give you the necessary instructions through "Shop" would be useless. You shall be shown how to make a small press, and do a little elementary work in printing, in some papers devoted to a consideration of the subject by a practical printer who is also a good woodworker.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Etching Names on Cutlery.—J. W. C. (*Walkley*) writes:—"Can you, or any correspondent, please tell me how to do it; or can you give me the name of a book that will give full instructions? I am told I shall want a small copperplate printing press, and I have to print the name I want to etch on a small slip of paper with a special kind of ink, and then use some transferring process. I should be very thankful to get full particulars of etching, as it is very much used in Sheffield trades."

Composition for Covering Pipes.—R. A. P. (*London*) says, "I should feel much obliged if a reader could give me a recipe for a composition for covering pipes to keep them from frost."

Machine for Current of Air.—BELLOWS (*Gloucester*) asks, "How a machine, to answer the purpose of an ordinary household bellows, should be constructed in order that it may be worked by a rotary motion, and give a constant current of air instead of an intermittent one."

Cleaning Oil Paintings.—L. S. (*Lower Broughton*) writes:—"I have an oil painting which has got very dirty, and should be glad if some one will inform me, through 'Shop,' how I could effectively clean it without injuring the figure."

Organ-Builders' Tools.—W. P. (*Grantham*) says:—"I want you to tell me where I can get the best list of piano and organ builders' tools, as I want several. I have got Mr. Melhuish's list, and I find tools for every trade marked, but none mentioned for the above, being an organ builder."

Chuck for Frame Turning.—R. C. H. asks:—"Would any reader of your valuable paper enlighten me on the subject of an eccentric chuck for turning oval frames and handles, and favour with drawing of same; or state where such can be obtained, and also what is the price?"

Joints in Indiarubber.—W. P. (*Grangetown*) writes:—"Will any kind reader tell me how the joints in bicycle tyres are made, also how to vulcanise indiarubber?"

A Pronged Ring.—BATTLEMORE writes:—"I want a malleable cast-iron ring with three prongs 1 in. diameter and $\frac{3}{32}$ in. thick. I might require them made in quantities of thousands. Can any reader give me the name of a good firm who could make them at a reasonable price?"

Moulded Indiarubber.—OSLEK writes:—"I want a piece of circular-moulded indiarubber 1 in. diameter and $\frac{3}{8}$ in. thick. Could any correspondent tell me where I could get them manufactured at a reasonable rate?"

Facsimile by Electro Process.—ELECTROTYPE asks, "How may I obtain a facsimile of a letter in relief for letterpress printing by the electro process?"

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Etching on Steel.—P. J. E. (*Hackney*) writes in reply to EXCELSIOR (see page 125):—"Seeing that you want to know how to etch on steel, I beg to submit the following receipt:—First clean your steel, and then dip it into hot white wax; then let it stand till it is hard, then dig again, and let it stand till hard as before; then take a needle, or anything with a sharp point, and draw your subject on the wax. After this use the following solution:—Pyroligneous acid, 5 parts; alcohol, 1 part; nitric acid, 1 part. Mix the first two, then add the nitric acid, pouring the preparation over the plates where the traces of the picture are. Let it stand till it has eaten sufficient depth, then wash the plate in cold water, dry it, and place it near a fire till all the wax is melted off."

Model Beam Engine.—ELECTRO writes in reply to W. J. P. (see page 125):—"I am at present making a model beam engine $1\frac{1}{2}$-in. bore, 2-in. stroke, and got a very good sectional drawing of the engine, full size, from Mr. R. Thompson, engineer, Church, near Accrington, and also the whole of the metal, and brass castings of same, at a very reasonable price."

Trade Notes and Memoranda.

A FOUNTAIN, fourteen yards in diameter and eleven yards high, ornaments the base of the Eiffel Tower. At the top are eleven figures. Six of them form a central group; and five lower down represent Europe, Asia, Africa, America, and Australia.

THE plant employed on the works of the Manchester Ship Canal is now worth more than three-fifths of a million sterling. By about the end of June there will be 20,000 men employed. Nearly one-third of the total excavation (reckoned at 47,000,000 cubic yards) has been finished.

TELEGRAPH poles are preserved in Norway by boring a hole about 2 ft. deep into the ground, and plugging coarse crystals of sulphate of copper around the wood. The wood absorbs the chemical, becoming of a greenish hue. This is said to be a perfect preservative, but requires occasional renewal.

AT last it is probable that a monument will be erected to the memory of William Symington, whose remains have laid in the churchyard of St. Botolph, Aldgate, since 1831, with no memorial to mark the spot. His steamer, the *Charlotte Dundas*, was held in the Forth and Clyde Canal in March, 1803, and to him undoubtedly belongs the honour of being the pioneer of steamship propulsion. A committee has been formed to commemorate the centenary of his early experiments in 1788 and 1789, from which period the history of steam navigation undoubtedly dates.

IT is difficult to harden thin steel plates without causing them to become warped in the process. A correspondent of the *American Machinist* gives the following method as one which "he has used for many years with universal success":—Provide two pieces of iron, about 6 in. by 6 in. by 1 in., with one surface on each block planed, and spread a liberal supply of good sperm oil on each planed surface. Immerse the plates to be hardened in molten lead as far as they are required to be hardened. When a red heat is obtained, drop the piece quickly upon the cold surface of one of the iron blocks, and simultaneously lay the other block upon the work. When cool it will be found true. The blocks should be kept cool and also level to ensure an even thickness of oil.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable every where throughout the United Kingdom on Friday at the latest.

HUMPHRIES' CAMERAS, 1889.

THE DRAYTON.—Most compact. Every movement best workmanship. Highly finished; low price. Illustrated Lists free.—W. H. HUMPHRIES, Photographic Apparatus Manufacturer, 116, Highbury Hill, London, N. Factory, 70, Elfort Road, Drayton Park, N.

ESTABLISHED 1851.

BIRKBECK BANK,

Southampton Buildings, Chancery Lane, London.

THREE per CENT. INTEREST allowed on DEPOSITS, repayable on demand.

TWO per CENT. INTEREST on CURRENT ACCOUNTS calculated on the minimum monthly balances, when not drawn below £100.

STOCKS, SHARES, and ANNUITIES Purchased and Sold.

HOW TO PURCHASE A HOUSE FOR TWO GUINEAS PER MONTH or A PLOT OF LAND FOR FIVE SHILLINGS PER MONTH, with immediate possession. Apply at the Office of the BIRKBECK FREEHOLD LAND SOCIETY, as above.

The BIRKBECK ALMANACK, with full particulars, post free on application. FRANCIS RAVENSCROFT, Manager.

HOME ART WORK.

NEW MONTHLY SERIES OF "THE ART DESIGNER." **Price SIXPENCE.**

HOME ART WORK is the only publication printed in England giving full-sized reproductions in facsimile from the Artists' Original Designs, for Painting, Wood Carving, Needlework, Brass Repoussé, and every other variety of Art Work. PART II., published April 1st, contains a Magnificent Design of Fighting Dragons, by WALTER CRANE. Crackle Design, by G. C. HAITE, F.L.S., for Needlework, Repoussé Work, or Flat Carving. Grecian Figure for Panel Screen, Designs for Cup and Saucer. Repoussé Bowl, Church Embroidery, Glass Painting, &c. Notices of Amateur Prize Exhibitions, Art Notes, Reviews, &c.

"I feel I *must* express my great delight at your charming publication. I have only quite recently made its acquaintance, since which I have procured all the back numbers. I look forward to my 'Designer' more than to any other magazine."

"A capital paper, well printed and well edited, which is devoted to the practical encouragement of the Arts and Crafts."—*Tablet.* [5304

HARGER BROS., SETTLE.

WHELPTON'S VEGETABLE PURIFYING PILLS

Are one of those pure Medicines which for their extraordinary properties have gained an almost **UNIVERSAL REPUTATION.** Recommended for Disorders of the **Head, Chest, Bowels, Liver** and **Kidneys**; also in **Rheumatism, Ulcers, Sores,** and all **Skin Diseases**—these Pills being **a direct purifier of the Blood.**

WHELPTON'S PILLS AND OINTMENT.

ESTABLISHED **1835.**

WHELPTON'S HEALING OINTMENT

Stands unrivalled for the Cure of **Cuts, Burns, Bruises, Ulcers, Sores,** and all kinds of **Skin Diseases.** A Specific for **Eczema.** *Burns, Scalds, Cuts, etc., happen when least expected—Be Prepared!*

Both Pills and Ointment are sold in Boxes, price **7½d., 1s. 1½d.,** and **2s. 9d.,** by G. WHELPTON & SON, 3, Crane Court, Fleet Street, London, and all Medicine Vendors at home and abroad. Sent free by Post in the United Kingdom for 8, 14, or 33 stamps. [8094]

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the **Inventor** *and Manufacturer,*

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

ASPINALL'S ENAMEL.

COLOURS—EXQUISITE. *SURFACE—LIKE PORCELAIN.*

Testimonials from the Queen of Sweden, the Marchioness of Salisbury, &c.

FOR ALL SURFACES OF WICKER, WOOD, METAL, GLASS, EARTHENWARE, CHINA, &c.

"Simply Perfection."—*The Queen.*

Made in over 100 Colours. Sold in Tins, 4½d., 1s. 3d., and 2s. 6d. For Baths (to resist Hot Water), 1s. 6d. and 3s. Post free, 7d., 1s. 6d., 3s.; 1s. 9d. and 3s. 6d.

READY FOR USE. A CHILD CAN APPLY IT.

SOLD EVERYWHERE.

A CHEAP ENLARGING CAMERA.

BY G. LE BRUN.

INTRODUCTION—MATERIALS—CAPACITY OF CAMERA—BASEBOARD—BACK AND FRONT—BOX—GROUND GLASS AND DARK SLIDE—SILESIA CLOTH—INTERIOR—HINTS FOR WORKING—USE OF MAGNESIUM LIGHT—RULING GROUND GLASS—ADJUSTMENT OF PARTS OF CAMERA.

ALMOST every amateur photographer, whose kit consists of a quarter or half-plate set, after a time feels a yearning for larger pictures than he can produce with his apparatus; for, however artistic and beautiful his pictures may appear when mounted on cards, or in the album, they are too small for wall decoration, and could scarcely repay the expense of framing, being completely dwarfed when hung beside larger works. Now the great majority of amateurs are workers of small sizes, and of this majority the greater number are tied to size, more on account of expense than from choice; while the difficulty of getting a suitable room that can be darkened for the purpose of daylight enlarging, and the high cost of enlarging apparatus for artificial light, render the practice of this part of their chosen art out of the question.

Now, I have "been there;" I could only utilise a room for enlarging that had two very large windows, and a fanlight over the door; I tried the blocking out of daylight by making frames to fit the windows and covering them with brown paper. But, oh! the valuable time I lost in the attempt, and the stuffing of dusters, etc., into crevices to shut out straggling rays that would force their way in, till I found the game not worth the candle. Then, as my purse was unequal to the purchasing of an enlarging camera, I set my wits to work and devised the simple apparatus that I will endeavour to describe in this paper. When made, I found the process of enlarging easy and pleasant, and a most engrossing pastime.

The materials required are not expensive, the entire cost of the whole being under five shillings. The construction is easy, and quite within the powers of the merest tyro in carpentry who can handle a few simple tools, while the results are equal to any that can be got from apparatus costing many pounds; and the amateur who devotes a little time and perseverance to its construction will find himself the happy possessor of a useful appliance, and be able to decorate his walls with capital enlargements from his small negatives.

The particular apparatus I describe is made to enlarge up to $12\frac{1}{2}$ in. by $10\frac{1}{2}$ in., and of course to take any smaller size, but the size can be increased to suit individual requirements, the principle of construction remaining the same.

Referring to the accompanying drawings, Fig. 1 represents the baseboard, which is 3 ft. in length, 11 in. wide, and 1 in. thick; a piece of 1-in. wood, 4 in. wide, is screwed on the under side at each end to serve as supports, and also to prevent any tendency to warp; two slits, $\frac{3}{8}$ in. wide, are cut 1 in. from and parallel to each edge of the board; these slits extend from within 3 in. of one end to 9 in. of the other end, and are for the screw bolts securing the back and front of the apparatus to slide in.

The back and front of the camera, as I suppose we should call it, are made of pine 4 in. wide and $\frac{5}{8}$ in. thick, their outside size being 15 in. by $13\frac{1}{2}$ in. The back is shown in section in Fig. 2, with the fillets for holding the dark slide, one of which is put on the edge, the other on the inside. Of course it will be noticed that one end of the back must be kept $\frac{7}{8}$ in. narrower than the sides and other end to allow of the insertion of the slide; this is indicated by the dotted line, A, in Fig. 2. Fig. 3 shows the back of the camera complete.

Now for the front, which is shown in section at Fig. 4, and in elevation at Fig. 5. It is somewhat more complicated than the back, as an opening has to be arranged for to allow the box carrying the lens to be attached, and the front side has to be closed in. By referring to the figure it will be seen that two pieces of wood run right across between the ends, and they again have two pieces between them, thus forming an opening the size of which is 9 in. by $7\frac{1}{2}$ in., which must be exactly in the centre of the front; the slips of wood used for this purpose are 2 in. wide and $\frac{1}{2}$ in. thick; the spaces between them and the sides of the front are covered in with pieces of $\frac{1}{2}$-in. wood, leaving the opening clear.

A box must now be made to fit the opening tightly, the length of which is 9 in.; it is made of $\frac{1}{2}$-in. wood, and, when finished and fitted to its place, should have a small fillet put round the outside to prevent any light entering through the joint (A, Fig. 11). This box has no ends, and another box must be made to slide easily within it; this inner box is only 5 in. long, and is closed in one end, in which a hole is cut, and small fillets are put on the outside to allow of the insertion of the sliding front of your small camera and its lens, and, when fitted, which should be done as correctly as possible, a piece of black velvet is glued round the open end of the box so as to make it tight when in position. Fig. 6 shows these boxes in section with the negative carrier on the end of the larger one. This negative carrier is a piece of wood fitted to one end of the larger box, and having a hole cut in the centre of it large enough to carry the negative: of course, if you are going to enlarge from both quarter and half-plate negatives, you will have to make two carriers, one for each size. The hole must be cut with a small rebate of about $\frac{1}{8}$ in. to hold the negative, which is held in its place by two small turn buttons as shown in Fig. 7; the carrier itself is held in position by a hook and eye on each side.

Two pairs of $2\frac{1}{2}$-in. screw bolts with thumb nuts must be got; a pair of these are put in the bottoms of the back and front of the camera to coincide with the slits in the baseboard; small washers should be put on each screw bolt so as to prevent the nut destroying the wood on the underside of the baseboard when screwed up.

A ground glass back and a dark slide are now to be made; they are shown in section in Figs. 8 and 9 in full size. The back of the dark slide is made of wood $\frac{5}{16}$ in. thick, while the sliding front is simply a piece of thick millboard. I use millboard in preference to wood, as it is not so liable to warp; a piece of wood is glued across the top of the slide so that when it is closed no light can enter through the joint. (Fig. 10.) The ground glass being put in the frame and neatly puttied in, the camera is complete, so far as the woodwork is concerned, and can be put together, when it presents the appearance shown in section in Fig. 11.

Four yards of black silesia cloth are now bought (costing about sixpence per yard); this is doubled and sewed along the edges, then the ends are sewn together, and you have a bag with open ends; slip this bag over the front and back of the apparatus to serve in lieu of bellows, securing it by tying with tapes round the camera, put in your lens, and you are ready for enlarging.

The paper is secured in the dark slide with a drawing pin at each corner, and, as there is plenty of room between the back and the front of the slide, glass plates or opals can be manipulated, securing them in the same way as the paper.

The inside of all the woodwork must be stained a dead black; this is best accomplished by coating it with a mixture of lamp black and turpentine, adding a few drops of terebene to ensure drying. The whole of the outside wood I stained and varnished to represent mahogany. Instead of using silesia cloth, workers with plenty of spare time can of course make a bellows, but the labour entailed is great and the job messy; while the cloth bag is easily made and serves every purpose.

In focussing, slide the back of the camera only, keeping the front rigidly fixed in position; when the picture is sharp on the ground glass secure the back by means of the thumbscrews. To facilitate focussing I have drawn lines $\frac{1}{4}$ in. apart at right angles across the baseboard; these lines serve to guide the worker, as when once he has focussed a particular size of picture by marking the line at which the back was, he will have no trouble next time in finding the focus for that particular size.

When working with this camera I generally put it on a table close up to the window, and raise the front of it by placing a few books underneath, so that it may point towards the sky, and obviate the risk of getting a few stray chimney pots or tree tops in the picture that are not in the negative; when thus used the whole apparatus looks like Fig. 12.

As all the parts separate, it is easy to pack the camera away on a shelf or in any odd corner, and, as the trouble of putting it together is small, it is always ready when wanted. It has also the additional advantage that its use is not confined to daylight. I have got some very fine enlargements on Ilford rapid paper at night by placing a piece of white tissue paper in front of the negative and burning 18 in. of magnesium wire at 6 in. distance, waving it slowly in front of the negative so as to diffuse the light equally over the picture.

I would suggest that the ground glass be ruled with lines corresponding to the various sizes of paper, and the inside of the dark slide with exactly similar lines, so that when a picture is focussed on the glass the paper can be put in the slide in exactly the right position, and thus obviate the danger of getting only about two-thirds of the picture on the paper, as I did several times before adopting the lines. Care must also be taken that the back and front of the camera stand perfectly perpendicular on the baseboard, and also parallel to each other, as if they do not distortion and fuzziness will be the result. I say nothing about the *modus operandi* of enlarging, as that can be found in any elementary book on photography.

I have no doubt if any photographic enthusiast makes and uses a camera of this simple description he will be thoroughly satisfied with the work he can do with it, and the ease with which it can be used, while its inexpensiveness will commend it to all who have large aspirations and small purses, as is most unfortunately the case with the writer.

CYANOTYPES OR BLUE PHOTOGRAPHS.

BY L. IVOR POOLE.

THE Cyanotype—or, more familiarly, the blue process—although not for a moment comparable with the ordinary silver or other A1 methods of producing photographic prints, so far as highly finished pictures are concerned, has, nevertheless, so many good qualities, that many who waste a good deal of time with more complicated processes might well bestow a small amount of attention on it with satisfactory results.

The preparation of the paper is extremely easy, and the cost small. No toning is required, and the fixation is effected by simply washing the print in water. The process is most useful for copying fretwork and other designs, these being used as negatives from which to print; and it is perhaps better adapted for such work than for the production of photographic pictures as these are ordinarily understood. Still, for many photographs, the effect of the blue colour is decidedly pleasing. The technical defects may be briefly stated to consist in the difficulty of obtaining half tones, and in the loss of detail, though this latter depends a good deal on the kind of paper and the manner in which it is coated or rendered sensitive. It is, however, not my purpose so much to give complications of the simple process, although finer results might be obtained, as to give such directions as will be of service to the vast majority of those who want a cheap and easy means of sun printing.

The chemicals required are only two in number, viz., ammonio-citrate of iron, and ferri-cyanide of potassium ($K_6F_{e2}C_{12}N_{12}$), or, as it is sometimes called — the *red* prussiate of potash, to emphasise the difference between it and ferro-cyanide of potassium ($K_4F_eC_6N_63H_2O$), the yellow prussiate, which is of no use for the purpose. Both the iron and potash preparations are to be obtained through any druggist; but the red prussiate, not being used medicinally, may not be so familiar as the yellow prussiate to the ordinary chemist. It is to this cause the want of success sometimes complained of with the blue printing process may possibly be attributed—one prussiate having been used instead of the other.

An ounce of each will be ample to sensitise a large quantity of paper, and as they are both very cheap it will scarcely be worth while to purchase in smaller quantities. Great care, however, must be used with the prussiate, as it is a most deadly poison, and should never be carelessly left lying about, or where it might be mistaken for something harmless.

Whatever the quantity, the proportions are as follows:—Four parts of water to one part of each chemical, thus—1 oz. ammonia citrate, 4 oz. water; 1 oz. prussiate, 4 oz. water. The chemicals are readily soluble in water, so there will be no difficulty about this part of the preparation. The solutions should be made and kept separately, as there is then little or no risk of their becoming useless as they will do if mixed, unless they are carefully excluded from light. Some directions state that they should be mixed, and kept so ready for use; but I can see no advantage from doing so, unless that sometimes it may be more convenient to have one bottle than two. Even when unmixed, it will be just as well to keep the solutions in a dark place, though I have never found that a moderate amount of light does them any harm. Immediately before using—that is, applying them to the paper—equal quantities of each solution should be mixed, and not exposed to any strong daylight. It is not necessary to work in the ordinary photographic dark-room—that is, one illuminated only by ruby or orange light. It will be quite safe to use a moderate amount of gas or candle-light; or, in the daytime, to partially darken the room by drawing the curtains to or the blind down.

The mixture should not be effected till the paper is ready waiting to be coated.

A good deal has been said, and may be said, about the kind of paper best suited for the cyanotype process. For ordinary reproductions there is, however, no occasion whatever to be very fastidious about its make or quality, as any that is non-absorbent will answer. Naturally more care will be given if a print of a picture is wanted than if it is merely a design for fret cutting. I have frequently used ordinary writing paper and found it do very well. The better the paper, or perhaps it will be more correct to say, the harder and finer its texture, the better the print will be. The kind known, I think, as bank post, which is hard without much sizing, is perhaps the best. Of course, when pictorial effect is aimed at, paper free from water marks should be used.

A very small quantity of the liquid is required to sensitise the paper, on which it should be painted rather than rubbed in. Some advocate that the paper should be damped first, but this is not necessary. It prevents the paper curling up when the sensitising solutions are applied, but otherwise it only complicates the process.

The paper may be sensitised by either floating on the solution or by painting it on. A sponge may be used, but I prefer a large-sized camel-hair brush—one such as is used for damping the pages of press-copying books—to any other kind. The brush should be washed out directly afterwards, and may then be used for its ordinary purpose without suffering any injury.

Some small amount of care will be required to get the solution evenly spread over the paper, which, when coated, should be laid by in the dark to dry. It will, if protected from light, keep for a considerable time, though it does not improve, and on that account more should not be prepared than is likely to be used within a limited period. The fresher it is, the more quickly it prints, and the purer will be the high lights or white parts of the picture.

The exposure is made in an ordinary printing frame, and will be much longer than for silver prints, say from five or ten minutes in a bright sun with quick-printing negative, to several hours. The brighter the light, the more brilliant will be the picture, of course, provided that the exposure has not been unduly prolonged; as, if so, the high lights, instead of being pure white, will be tinted with blue. A bold, "plucky" negative gives the best results, while from a thin one it is hardly worth while taking a blue print.

The exposure must be prolonged till the darkest parts assume a greyish metallic appearance, the middle tones being decidedly a dark, but by no means a brilliant, blue; while the high lights remain much as they were originally, viz.: greenish hue, much lighter than any of the other portions of the print. Perhaps the best way for a novice to note the different colours, will be to lay a piece of the paper uncovered in the sun, and note the changes which take place. There will then be no difficulty in recognising the final depth to which the print should go. It will be understood that the image becomes visible, though detail is to a great extent lost.

To complete the print it is only necessary to wash it thoroughly in water till this runs off clear without any yellow tinge. So long as there is any yellow in the water which drips from the print, washing must be continued. The most convenient way to wash the prints is to hold them under the tap and let the water flow over them. This part of the process does not take more than a few minutes, during which the unfixed chemicals are washed away, leaving the high lights perfectly white and the remainder of the picture in shades, down to deep intense blue in the darkest shadows.

In conclusion, I may say that I have found that by holding the print under a tap of hot water the clearing and fixing are much expedited, the print being developed with an almost startling rapidity, which, in the case of an ordinary negative, would more than suggest over-exposure.

A "CHEVAL SCREEN" ESCRITOIRE.*

BY J. W. GLEESON-WHITE.

THERE are divers attributes required of furniture. One man I know always cries out for "stable" fittings. He does not mean, I find, that he wishes racks and mangers in his drawing-room, but that his upholstery should be of a rigid and monumental character. At once I must confess that the piece of furniture herein to be described would hardly meet his requirements; yet the original cabinet which supplied the motive of this combined screen and escritoire, was, at least, a hundred years old, possibly more. If our construction lasts out the century—not this century, but the hundred years from date—it will, probably, outlive our reputation, most likely our very memory. The individual who writes, and the one who is now kindly reading it, will most probably be entirely gone from human knowledge by 1989. If only space allowed, this theme would be a much more tempting subject to display one's newly acquired odds and ends of information, furbish up one's old stock of trite aphorisms, and moralise vaguely and generally, like the leading article of a sensational daily on New Year's Eve.

This piece of joinery is of somewhat ambitious order; it should not follow a rabbit-hutch, the ordinary first work of the youthful carpenter, unless the rabbit-hutch was a *very* good one. And if the tool chest is limited to a sort of hammer, a saw that makes excursions upon erratic anatomical deeds of daring in the back kitchen, and a bradawl that frequently (eager to do a little more than is required of it) attempts to fulfil the purpose of the nail, by staying firmly in its hole and parting company with its handle—the work had better not be attempted. This great triad of amateur tools must not be too lightly spoken of; they do a lot of mischief, and little good (like most of us), in the course of a year. Even as Mrs. Partington's mop, that was excellent for a puddle, but of doubtful good to drive back the encroaching waves of the Atlantic, these tools may be left to those whom they satisfy. But for the skilled amateur, whose work, by reason of special tools, ample time, and general good taste, is often quite equal to the very best professional work, there is no hidden mystery in this cabinet, which demands only good work of ordinary joinery: no angles fitted on Euclidian, unlikely, radiating lines; no curved work or elaborately-wrought turnery; only ordinary mortise and tenon, dovetail and mitre; yet since its purpose is for "my lady's chamber," it must be finished just as neatly as the craftsman is able to do it.

One point, I own, is doubtful: whether it would be trustworthy when in use, or whether, by a simple arrangement suggested in Fig. 3, it would not be needful to provide more support for the weight of the arms of the writer on its desk. Of course, it might be screwed to the floor; since it is a bric-à-brac what-not as well its movability is unimportant, and a single screw at each foot would not seriously affect the carpet, nor make it an awkward fixture in "spring cleaning." Of course, the legs might project more; perhaps that is the simplest way to overcome the difficulty; but in the original, so far as a hurried inspection serves, the general dimensions were about those given here, certainly not more spread out at the base.

The whole character of the design being somewhat Japanese, I would suggest either a red lacquer-like finish, or if that be too *outré*, and its alternative, black and gold, is impracticable or disliked, then, walnut holly, with satin or other light wood for the panels, might be adopted. The panels of the door and escritoire top, as suggested, are for inlaid work; better still, of real lacquer. Shops for the sale of Oriental goods have often damaged tea-trays that are procurable cheaply and cut up well for this purpose, or panels finished on purpose for ultimate framing. Painted decoration would also be in keeping, or the panels might be left plain. The design given is less a working drawing (although it is intended to fulfil that purpose) than a suggestion for a motive, to be varied according to the needs or will of the maker.

The whole piece of furniture should be neatly backed, either in panelled wood or with painted design; or finished by some fluted silk or other textile fabric; the idea of the structure being that it stands out, away from a wall, and showing all its sides.

Space is a valuable commodity; next to time perhaps the most in demand. Time and space are mighty words to deal with,

* When the same idea occurs to two different writers, and both make use of it according to their respective idiosyncrasies, the second in the field is set down by the charitable as a plagiarist. In Mr. Gleeson-White's "Cheval Screen Escritoire" readers will note a marvellous resemblance to Mr. Adamson's "Screen Secretary." Yet in neither case was one of them the outcome of the other. The "Screen Secretary" is followed by the "Cheval Screen Escritoire" to show how in all cases bent of mind influences treatment.—ED.

and a suggestion to save either sounds more like a motive for a sermon than for WORK; yet, if we can save either, or both, we will risk the allusion.

I see no reason why a duplicate, as it were, of the front, minus the secretaire itself, or a neat set of shelves for books, should not be added; this would, of course, make the thickness double, but (if a bookcase) at once remove any doubt as to its stability, and give additional use to the whole thing.

I should like to explain the making of this escritoire in words, but I have done so in diagram so exhaustively (at least, so it seems to me, if exhausting and exhaustive are synonymous), that I feel like an orator talking against time, and trying to lengthen out ten minutes more when he has already said all he had to say.

The whole framework should be, as far as possible, made to fit in one construction, that is, the main shelves and uprights should all fix together, so that they may hold in their place without a nail. I mean the sort of letter-H arrangements should fit like the divisions of a drawer for birds' eggs—I forget if there is a technical term for this process—the shelf that projects on either side being one piece, bracing the two main supports, and, if possible, being fitted to the two inner supports in like fashion. But it is hopeless to put this into words; if you cannot see what I mean by the diagrams, I can only regret having not been more clear in the drawing, and will readily supply the required information in "Shop."

The lining at the back of the shelves is intended to be covered with Japanese gold leather paper or a dark plush, to set off the china and other bric-à-brac.

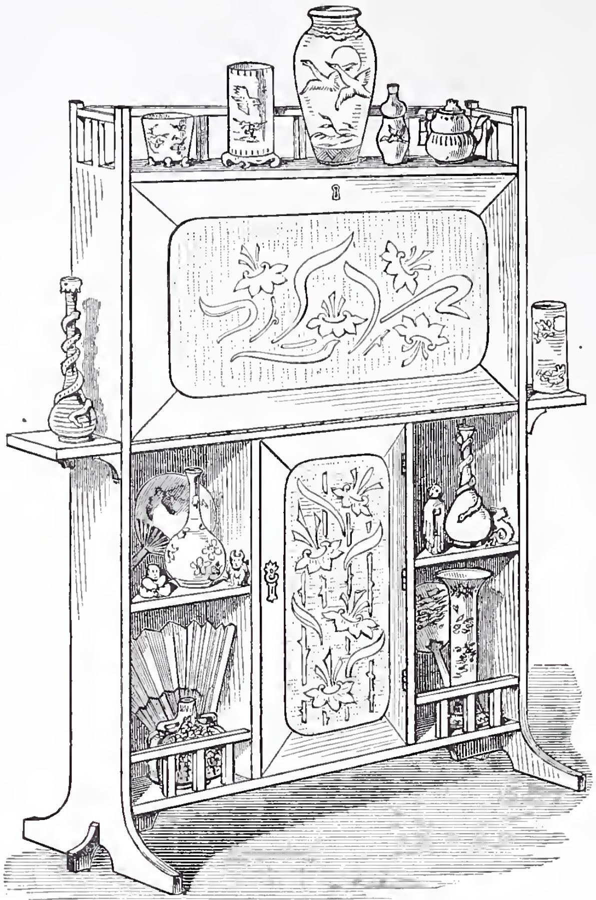

Fig. 2.—The Cheval Screen Escritoire with Cupboard and Shelves below.

If the edges of the shelves can be reeded, so much the better; if they can be inlaid, better still. If in place of the simple rail, which would look well in lacquer finish, but not in any other, a turned balustrade is preferred, all the Japanese ornaments should go, and a more formal pattern be chosen for the panels—such as Adams or Sheraton used so often.

The original escritoire charmed me—it was of inlaid wood, and had an arched top and cupboards enclosing all its space; whether, in attempting improvements, I have spoilt the idea, I cannot say.

I need say nothing about Fig. 1, which, as I have said, explains itself. In Fig. 2 the central space below is converted into a cupboard. The panel of the door and of the flap above may be hand painted or fitted with lincrusta walton.

Figure 3 shows a variation from the same main lines, but with fretwork introduced for the cupboard doors, and (although not shown in the sketch) has panels in the fall-down top, which forms the writing-desk.

To conclude, I would reiterate the advice to depart entirely from the model, if wished; but, if so, do it consistently. A mixture of styles is unbearable; *no* style is bearable; any style, if adhered to, is good of its sort, but a mixed style is generally as contemptible as the word mongrel, which fitly describes it.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

(*Continued from page* 164.)

Analysis of Formation of Letters of the Alphabet.

Let us now, in our intervals of rest from practice, consider together the letters of the alphabet as they stand in relation to the sign writer and his work, for which purpose I distribute them into five divisions, for the sake of clearness and the proper understanding of the subject.

The easiest letters to form are those, of course, which consist wholly of straight lines, or, more properly speaking, of parallel lines at right angles to each other. These letters are shown in Fig. 28. This drawing brings us to another class of letter, viz., the sans-seriff order, which are given here in outline only. In forming letters, no given rule can be followed as to their general construction and symmetry, and for this reason — letters may be of an average width and length, or they may be "elongated" or "extended," and consequently the width between all parallel lines vary accordingly. Referring to Fig. 28 and the letters E and F, I would point out that the middle *members* (this is a technical expression used in the trade, and indicates each individual portion of which the letter is constructed, or "built up" with) should never be quite so long as the outside ones. They may be nearly so, but should never be less than one-half as long as the other members. The letter H has one horizontal member exactly in the middle of the two uprights. This should be of the same width or thickness as the rest of the letter. Mr. Ellis A. Davidson, in his book on "House Painting," and in the chapter devoted to sign writing, argues that the middle member of the H should be thinner than the horizontals in other letters; but this, although having learnt much from his book, I entirely disagree with—in fact, his own drawing disproves the theory, which, I may say, is not followed by practical men. It is one weak point in an otherwise excellent book. The other three letters are some of the easiest to form, and require no further remarks other than that the top member of the T should always be equally distributed on each side of the upright.

Fig. 29 shows the only three letters which are composed of slanting or oblique lines. The first, V, is not a difficult letter to form, care being taken not to give it an appearance of falling or leaning on either side, and to allow each arm or member to slant at the same angle. W, the next letter, resembles two V's joined together; it must not, however, be so wide as two V's would be if they were actually joined, or it will give a very unsightly appearance to the whole word of which it is a part. The average width of the W should be about half as wide again as the letter F or N. That is, of course, for letters of normal dimensions, as elongated and extended letters are not at present under consideration. The X is generally formed in a rectangle, and the upper triangle of the two, formed by the members crossing each other, should be a little smaller than the lower one, but very slightly so. The lower portion, however, must never be the smaller of the two, or the letter will look ugly and top-heavy.

The letters which are formed of vertical, horizontal, and oblique lines combined with each other are given in Fig. 30. The A is simply a V inverted with the addition of a cross member. This should be nearer the bottom than the top, as shown in the drawings. The K is a somewhat difficult letter to draw to give it a pretty appearance. There are various ways of drawing it, which depend greatly on individual taste; the one given here, however, is that which is generally accepted as the true style, at least for all plain lettering. The M is, of course, a wider letter than the N, but the middle member should not be shortened, as we sometimes see it, but allowed to come right down to the base line. Some writers have compared this letter to the letter V, supported on each side by two perpendiculars, the outer lines of the V starting from about the middle of the top of each of the vertical members. This is a very good description of the letter. The way to draw the N is to make the perpendicular lines equal in width, and then to draw the oblique one from the innermost angles. The letter Y is fashioned after a V, but supported on a single leg or stem, and Z is formed within a rectangle. We next come to letters made up of both straight and curved lines (Fig. 31). The B and the R are very similar in construction, the only difference being that in one case the lower member curves inwards and in the other it curves outwards. In B the lower curve should always be slightly fuller than the upper one; it is thus prevented from having a top-heavy appearance, and looks altogether more solid. The D consists of a perpendicular and one full curve, the P of a perpendicular and a half-full curve, the J a perpendicular with a curved base, and the U a curved base continued into two perpendiculars. I have purposely left the five most difficult letters to the last, and these consist entirely of curved lines (Fig. 32). It

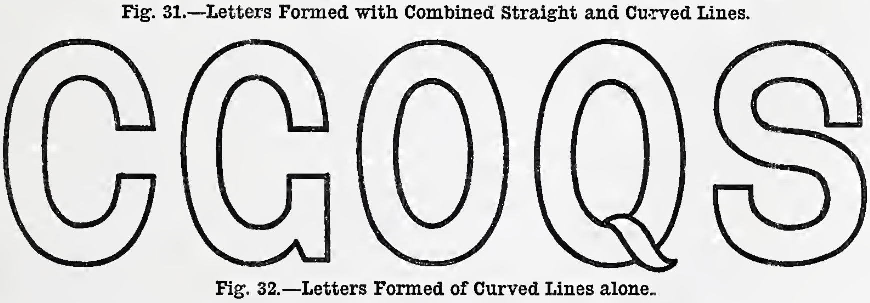

Fig. 32.—Letters Formed of Curved Lines alone.

should here be pointed ont that the O is the foundation or base upon which is constructed the C, G, and Q, and that the O should be a perfect ellipse. The S is the most difficult letter for a novice to draw, bnt if he has been assidnonsly practising the freehand lessons, he should soon be able to give it a graceful rendering without any extraneons aid. Having so far eschewed any reference to the mechanical ways of drawing letters, it would be out of place to give any directions here for treating the S in this manner; suffice it to say, therefore, that the letter should be contained within a parallelogram, and that it should have a proportionate appearance throughout. Of conrse, if the learner so wishes, he can at once adopt certain guide lines for the correct drawing of this letter, but it is uot recommended, for—to quote a well-known authority—"if the eye be not trained to a correct perception and an accurate discrimination, and if the hand has not, as the result of experience, the power of exact definition and precise demonstration, the ultimate result will be indefinite and unsatisfactory."

SMITHS' WORK.

BY J. H.

(*Continued from page* 147.)

POSITION OF THE SMITH IN ANCIENT NATIONS—FORGING OF ARMOUR—ARTISTIC METAL WORK OF MEDIÆVAL TIMES—CASTINGS IN METAL AND BRONZE—HAMMERED METAL WORK—CANDELABRUM IN MILAN CATHEDRAL—FITTINGS OF DOORS AND GATES—CAUSES OF MANY-SIDEDNESS OF OLD ARTISTS—INFLUENCE OF RELIGION.

THE smith was far and away the most important craftsman of ancient and mediæval times. It is only since the modern perfecting of the processes of casting, and because of the introduction of machines for the simplification of many of the operations of smiths' work, and also because of the very small demand for high artistic work in malleable iron, that the smith has fallen into a position among craftsmen inferior to that which he formerly occupied. From the periods of sacred and ancient history, down through the mediæval ages, in the wildest aud most turbulent times of crusade and chivalry, and in the ages of faith, the smith was the artificer whose services were in constant request by king and court, knight and pope, bishop and priest.

In ancient times one of the greatest evils by which a conquered people could be afflicted was the deprivation of their smiths.

When the Philistines conquered Judea they captured the smiths, "lest the Hebrews make them swords and spears." And the Israelites then "went down to the Philistines to sharpen every man his share, and his coulter, and his axe, and his mattock."—1 Sam. xiii. 19, 20.

When Jerusalem was taken by the Babylonians, they adopted the policy of carrying away the smiths captive to Babylou (2 Kings xxiv. 16).

Cyrus, after the conquest of the Lydians, ordered that no weapons of war should be kept in their possession.

In the peace which Porsena granted to the Romans he stipulated that no iron was to be forged, save for purposes of agriculture.

In the old chronicles and romances the smith figures as a conspicuous and important individual. As a maker of swords and armour, or forger of chain and plate mail, he was of the highest value in turbulent times.

The Romans worked and smelted the iron ores of this country extensively. Their cinder heaps have been found in North Derbyshire, North Yorkshire, Northamptonshire, in the Forest of Dean, in South Wales, Sussex, and other districts, and the smith was a mighty man both in the armies and in private dwellings.

In Anglo-Saxon times the smith was treated as an officer of the highest rank, and took precedence of the maker of mead and of the physician. In the ancient Welsh Court he sat near the king and queen, next the domestic chaplain.

Weland the Saxon Vulcan was a smith who is reputed to have forged the sword "Galatin" of Sir Gawain, and "Joyeuse" of Charlemagne. Among the Northern nations traditions of magic swords, the work of the smiths, long lingered.

William of Normandy brought over smiths and farriers with him to Britain, and the coat of arms of the earldom of Ferrers long consisted of horseshoes. It may be uoted that William I. introduced the practice of shoeing into this country. The ancieuts did not shoe their horses. The horseshoe came to be regarded with a certain kind of reverence, and horseshoes were hung on church doors to propitiate St. Martin, the patron saint of those who travel on horseback.

Edward III., it is said, sent to the Forest of Dean for smiths to act as engineers for the royal army at the siege of Berwick.

Iu Edward III.'s reigu the pots, spits, and frying pans of the royal kitchen were classed among his majesty's jewels.

Readers of "Waverley" will call to mind Andrea de Ferrara, a great smith in Highland story. He is said to have worked iu a dark cellar, the better to observe the colour necessary for the tempering of his blades. He could temper a sword so that by bending, the point might touch the hilt and spring back uninjured. Patten describes these swords as "all notably broad and thin, universally made to slice, and of such exceeding good temper that, as I never saw any so good, I think it hard to devise better."

The forging of armour was a most important section of the smith's work, and in course of time became a separate craft. So late as the year 1690 the workmen armourers of London presented a petition to Parliament, complaining that their trade was well-nigh ruined. As a matter of fact, the use of armour nearly died out with the Commonwealth.

Armour was used by the Anglo-Saxons, but the Normans employed it more extensively than did the conquered people, elaborating it until they became clothed *cap-à-pie,* and their steeds were largely encased also in armour.

Some of the aucient armour in the Tower is well worthy of close study. Helmets aud visors, breastplates, gauntlets, greaves, and so forth, are marvellous specimens of handwork—everything so thin and light, yet so strong withal. The chain mail is the older, having been superseded by the plate armour in the fourteenth century. The art appears to have reached its height about the time of Henry VIII.; witness that monarch's suit in the Tower which was presented him by the Emperor Maximilian. The armour of this period was sometimes fluted, ribbed, engraved, damascened, russeted, and otherwise ornamented. As indicative of the importance of the art of the smith in the mediæval period, during which its ascendancy was supreme, we note that in 1282 there were seventy-two forges leased from the Crown by iron smelters in the Forest of Dean alone. No marvel that the name of Smith or Smythe is so common. And the Scotch have their Gowans or Cowans, the Germans their Schmidts, the Italians their Fabri, the French their Le Febres or Le Fevres. There are also the Nasmyths, the Arrowsmiths, Goldsmiths, blacksmiths, whitesmiths, etc.

But the demands of the men-at-arms by no means occupied the whole time, or exhausted the skill of the smiths of the Middle Ages. There were arts of peace as well as of war, and there were the vast demands of the wealthy and ubiqnitous Chnrch. Craftsmen and artists—and the terms were often synonymous—vied with one another in rendering her service. The labours of workers not only iu iron, but also in brass, copper, and the precious metals, were pressed into her service.

Byzantium early became a great centre for the production of artistic metal work. From thence the art spread, in the ninth and tenth centuries, to the Rhenish provinces of Germany, to Italy, and Western Enrope. Bronze doors, altars, candelabra, and other ecclesiastical adornments commanded the highest skill of the Middle Ages; and untold wealth was expended on these works in bronze, copper, iron, gold, and silver. Of these, some were cast, some were hammered.

Cast iron is not suited for fine work, neither taking very minute impression of lines, nor capable of being worked into such delicate tracery as wrought iron, copper, and brass. Cast iron also requires to be so proportioned that the relative masses of adjacent portions shall not be very dissimilar, else shriukage stresses will be set up that are apt to cause fracture. Cast iron cannot be made of such extreme tenuity as wrought metal and brass. For these reasons, thongh it answers many of the purposes of the engineer most admirably, it was not used to any exteut worth naming, scarcely at all, in fact, by the mediæval workman. The common use of cast iron as a structural material only dates from the sixteenth century, when the process of smelting by pit coal instead of by charcoal was introduced.

The greatest refinement in the art of casting in bronze appears to have been attained by the great Italian artists. The method, as described by the Florentine artist Cellini, is as follows:—The figure was first roughly modelled in clay to a size very slightly smaller than the casting. Over this was laid a skin or thickness of wax, representing the thickness of the intended casting. A moulder will recognise in this the counterpart of the "thickness" on a loam pattern. The perfect figure of the cast was imparted to this wax with modelling tools, all the fine lines, expressions, etc., so perfect, as to leave little for after touching-up. Then a mixture composed of clay, pounded brick, and fine ashes, made with water to the consisteuce of cream, was applied with a brush, completely filling every interstice, and afterwards this was enclosed in a substantial body of clay, and the whole banded with iron hoops. Then the mass was baked in an oven, and the wax melted and escaped through holes left for the purpose. Rods of bronze passing from the outer mass to the inner core maintained the thickness of the interspace left by the melted wax constant, and into this space the metal was poured. After the removal of the baked clay the casting only required touching up.

But much of the old metal work was hammered as we now do repoussé work. The sheet metal was laid upon a bed of cement, composed of pitch and pounded brick, and the design was beaten into relief with hammers and punches, the pitch yielding, and so preventing fracture of the metal, however great its tenuity. This method was practised by the Assyrians and Greeks, as well as by the mediæval artists. The gates of Shalmaneser II. date from 859—824 B.C., and the Siris bronzes by Greek artists, both of which are in the British Museum, and are fine examples of repoussé work. In the latter the heads of the figures, though standing out life-like, and little thicker than paper, have been nowhere broken by the punch.

The great candelabrum in Milan Cathedral is a wonderful work of art, and dates from the twelfth century. It is fourteen feet high, has seven branehes, and is supported on four winged dragons. Even the minutest details of this work are finished with all the care that can be bestowed on the most delicate bit of jewellery. There is a plaster cast of this at South Kensington.

In the thirteenth and fourteenth centuries wrought iron came into general use for screens for chapels and tombs, and grilles for windows. It is impossible in this paper to so much as mention the greatest works of this character. Florence is rich in these precious antiquities, true works of art in which the skill of the smith is made to embody the creation of the artist, in which the boldest design and the most delicate imitations of nature harmonise, works which have been the wonder and despair of succeeding generations. The Italian smiths were famous for their skill, so too were the English, and specimens of their handiwork are to be seen at South Kensington.

Even the hinges of the doors which remain from mediæval times are true works of art and craftsmanship. The earliest English hinges date from about the tenth century, soon after the Conquest. They are stiff and cramped. Specimens occur on the west door of Woking Church, and at Compton, Berks. But in the Early English style they become very much elaborated and ornamented. The hinges on the refectory door of Merton College, Oxford, date from the fourteenth century.

Other specimens of door hinges occur at Radford Abbey, at Nottingham, Butleigh Church, in Somerset, Rouen Cathedral, St. George's Chapel, in Windsor, the doors of the Chapter House, York Minster, the south door of Durham Cathedral, and other localities.

In all the mediæval works, whether hinges, screens, gates, or cathedrals, there is the same grandeur of conception and beauty and perfection of execution, which inspire us with astonishment, reverence, and delight.

We marvel much at the many-sidedness of the old artists and the mediæval craftsmen. We wonder that men could master so much and so thoroughly like Leonardo da Vinci, mechanician, engineer, sculptor, artist, and man of science; Michael Angelo, painter, sculptor, architect; Quentin Matsys, blacksmith and artist, and others whose names will occur to the mind; and we attribute it to the small extent of ground which was covered by any single art or science in those periods as compared with the present. But this is not by any means the whole of the truth. If we have gathered a greater array of facts and details, the men of those times had grasped the broad ideal, underlying and encircling the practice of their craft, and they were not slaves to a little section of the same. Trades were not divided into sections, each man making the fractional part of a pin, of a garment, or of a machine, as is the case with us. The present division of labour, so profitable as a money-making system, so ruinous and depressing to the individual, did not then exist.

Those who have given attention to the history of the craft guilds of the Middle Ages are not at a loss to understand why the artisans of that period reached so high a degree of excellence in workmanship. As voluntary associations of brotherhood for mutual interest and protection, these guilds date under various aspects from early Anglo-Saxon times, probably even earlier. (The Blacksmiths' Company was incorporated in 1325.) They were strengthened by the most powerful sanctions of morality and religion, and solemn rite and ceremony. In the periods of their supremacy, every craftsman was compelled to belong to his proper guild, which exercised the most despotic power, usually for good, over him. No person was admitted a member who had not served a regular apprenticeship, the admission of whom was generally done in a solemn manner either at the Town Hall or at the guild meeting. The apprentice formed a portion of the family of his master, who was compelled to teach him his craft, and was held responsible for his morals. The regulations of the guilds were such that neither inferior materials nor bad work was permitted. As yet there was no division into capitalists and workmen, for most craftsmen shortly became masters and took apprentices. The guild statutes before the fourteenth century do not even mention the workmen, and it is not till about the middle of that century that regulations concerning them, as distinguished from their masters, were necessary.

Nor must we forget the influence of religion on the mediæval craftsmen. The Church was the principal patron of the arts and handicrafts. The great cathedrals and churches, with their altars and tombs, absorbed the best work of their time. Wealth there was in abundance to pay for the labour of years, whether that labour was engaged with the body of the building itself or on its adornments. The Church was the supreme power in society, overshadowing and overawing the kings and ministers, the warriors and the burgesses. The guilds, too, had their patron saints; they set up painted windows, erected altars, distributed alms, and went in solemn procession to church. Though such relations are ousted from nineteenth century industrial life, they, nevertheless, were a most vital factor in the mediæval period.

(*To be continued.*)

PANELS FOR WOOD CARVING.

BY FRED MILLER.

(*Continued from page* 145.)

The Plum, the Blackberry, and the Wild Rose.

All craftsmen should desire to design their own work, for it is not only more interesting to carry out the ideas that have emanated from one's own brain, but there is every likelihood that the work itself will be more spirited if the hand of the cunning worker is used to express his own ideas. I cannot do better, therefore, than offer a few suggestions on "designing for wood carving."

The three designs that accompany this paper are based on familiar forms, the larger panel (Fig. 1) showing the plum, and the smaller panels (Figs. 2 and 3) the common bramble or blackberry and the wild rose. I have purposely chosen familiar plants, because I want my readers to go to nature for themselves, and get the inspiration that is always to be derived from a study of nature direct from the fountain head. Every craftsman should make a point of drawing plant form whenever he has an opportunity, for all design is based on an intelligent study of plants. Draw any plant rather than none, but exercise your faculty of selection, and study particularly those plants which are what designers term "ornamentally suggestive," for a form like the bramble is full of suggestion, almost all its features giving the craftsman "opportunities." The leaf itself, made up of five small leaves growing from a common stalk, is most adaptable, and can be rendered effectively in wood. Then the way the leaves articulate from the stem in what is termed a "whorl," or around the stem on the principle of a spiral, is a point to be noticed. The stem, again, with the spines is an ornamental feature, and one that can be, and should be, made much of. In the panel it will be noticed that I have introduced a flower and buds as well as fruit, in order to enforce practically the axiom that every suggestion should be made the most of by the craftsman, and as the flower is seen at the same time as the fruit, such a trait should be utilised and insisted upon. The fruit, again, with its numerous little beads or "drupes," is most effective in carving, as the surface being broken up, catches the light, and casts numerous shadows, which give brilliancy and relief to work, and prevent any tendency to tameness.

The skill in wood carving is seen in the way the surface is broken up or "thrown about," as carvers say. In other words, it depends for its effect on some forms being prominent and receiving light and others being kept back and producing shadows. The throwing about can less easily be studied in a sketch than in modelling in clay, for one is more occupied in disposing the various forms, filling out the space, and arranging "lines" than in studying it as a piece of carving. I have endeavoured to suggest by light and shade which parts should be prominent and which should be kept back, but in actually carrying out the design many modifications would doubtless present themselves. Many wood carvers model the design roughly in clay, and work from this rather than from the design on paper, and undoubtedly a more accurate estimate of the finished work can be thus obtained than by the most elaborate of pencilled drawings. But this is a branch of the subject which must be treated on another occasion.

To return to the designing. To make the best use of plant form, it is necessary to draw the plant many times, until one is thoroughly imbued with its spirit and knows all its salient features by heart. For in designing you do not want to think of any one particular specimen you have on some occasion seen, but your object is to put into your design the characteristics of the plant, and not the adventitious and individual peculiarities of some *one* specimen. And to get freedom as a designer one must be able to depend largely upon recollection (the stores of a well-stocked memory accumulated by patient and thoughtful observation), rather than upon reference to fragments. The planning and disposition of the main lines of the design should, at all events, be studied apart from any individual specimens; for if one has recourse to such data, the design is apt to be local and petty instead of general and dignified. In other words, the letter instead of the spirit will be found in your work when the recollection is not largely depended upon.

A designer has to first of all dispose his forms so that they occupy the space without crowding it, and the skeleton of the design should have balance, proportion, and grace—qualities which largely reside in the designer's inner consciousness: for you may have made a most excellent drawing of a bramble, and yet utterly fail to adapt a portion of it to occupying a particular space agreeably, or in such a way as shall give the beholder the feeling that the bramble filling out the panel was designed for that space, and that alone, and could not have been employed elsewhere.

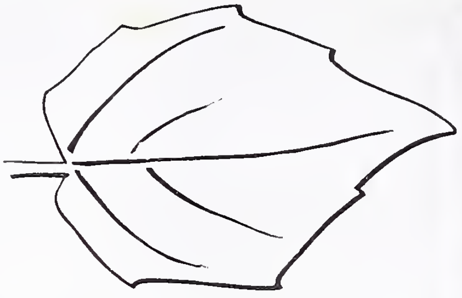

Fig. 4.—Angularity in Leaf Form to be followed in Wood Carving.

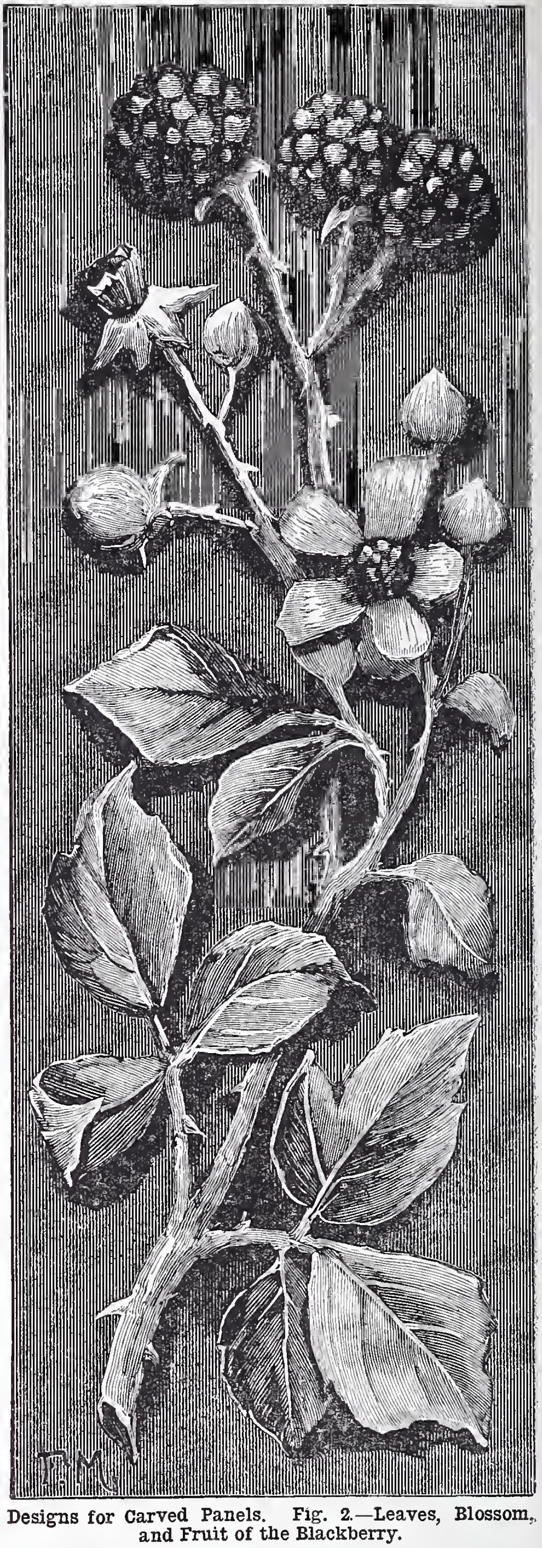
Designs for Carved Panels. Fig. 3.—Foliage and Fruit (Hips) of the Wild Rose.

Then the capabilities of your material and the possibilities of your craft have to be considered. Remember always that you are not, as a wax modeller does, imitating a piece of bramble in wood, but are carving a *design* suggested by the bramble. A great deal must perforce be generalised, for if we think a moment it is evident we cannot cut all the stamens in the centre of the flowers, or make the spines on the stem as sharp as they are in reality, or put every vein in the leaves. But we can *hint* that the stem is set with excrescences we call thorns, and can suggest that the leaves are veined in one way and not another, and that the stamens are many. We shall be truer by our generalising than we should be if we attempted to reproduce all we know to be there if we look for it, for then we should fail, owing to the impossibility of carrying out such a task, whereas we can entirely succeed if we only attempt to suggest the marked peculiarities or individuality of the bramble. We must draw what appears—what strikes the eye when we look intelligently at an object—and not what we know from previous study to be there; and this rule applies with even greater force to the work of the chisel.



Designs for Carved Panels. Fig. 2.—Leaves, Blossom, and Fruit of the Blackberry.

Start with the main stems, and get these placed so that they form either agreeable curves or "nervous" angles with each other. At the same time put down your leading features, as the plums in centre panel, for the objects being

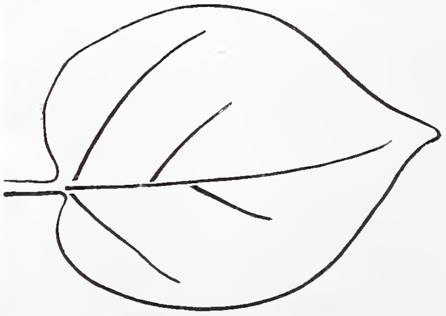


Fig. 5.—Rounded Outline in Leaf Form to be avoided in Wood Carving.

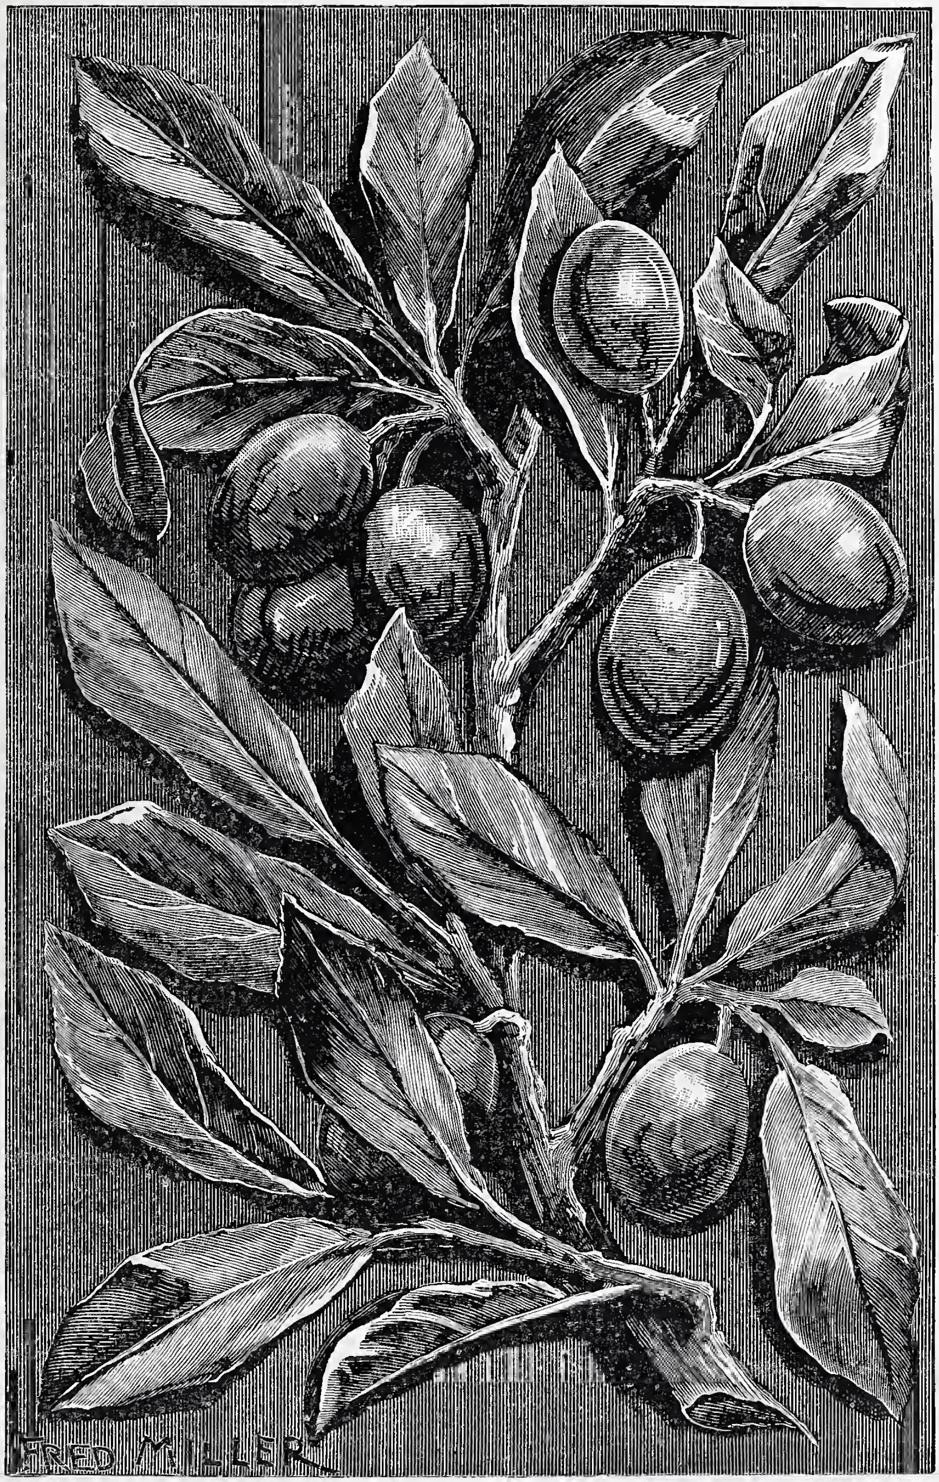
prominent must be thoughtfully arranged so that they do not (*a*) all come in one place and leave the rest of the space vacant, and (*b*) fall one under the other in perpendicular lines, but are spread about, so that if we drew lines from one point to another we should make a series of triangles instead of squares. Having roughly fixed upon the position of stems and fruit, we can now think of the leaves. These want most carefully arranging, and many considerations step in. We must not have too many leaves — not nearly as many, in fact, as we might find on a piece of plum, for we want to keep our design simple. Then some leaves can fall over the fruit and stems, for the stems should here and there be broken up by leaves or fruit, to take away the look of *stalkiness*. As we proceed with our design we shall modify some of the features already indicated, for second thoughts are often the better. It stands to reason that as all forms have a relation to each other, the introduction of a leaf or fruit may cause us to slightly modify the disposition of some particular piece of stem, though adhering generally to our first suggestion. Thus you see a design is gradually built up or put to pieces like a puzzle, and not set down as a whole, complete in all its details from the outset.

In carrying out the three designs, an enlarged drawing should be made the size you intend to carve them — say three times larger than their dimensions in Work, or fully the natural size. The enlargement should then be transferred to the wood, or pasted down upon it if you do not require the design again. The depth of the "grounding out" (taking out the background) depends upon the thickness of your wood; but I would advise those workers who are still novices not to attempt too much relief. Keep the design as a low relief, for the carving or "throwing about" is *the* difficult part of the work, and the more relief you attempt so are your difficulties increased. I should be disposed to tiy the designs not more than half an inch in depth; even three-eighths would be sufficient. The "grounding out" is much more difficult the deeper it is taken into the wood, and at the outset the general difficulties are quite enough to overcome, without courting others. It is much better, I hold, to succeed in a humble way than egregiously fail by over ambition; and I always make a point whenever I have taught to put a very moderate programme before my pupil, and direct my assistance to enabling him to overcome such difficulties as arise, so that succeeding with a moderately simple piece of work, he is emboldened and encouraged to go from more to more.



Designs for Carved Panels. Fig. 1.—Plum.

My remarks, as well as the designs themselves, are intended for those who have had some practice in wood carving; but in another number of Work I will take the reader back to preliminaries, and begin *de novo*.

One word more. I spoke just now of the stems making *nervous* angles with each other. A design is said to be "nervous" when there is vigour, crispness, angularity in it — qualities, in short, the reverse of tameness. Now, getting the work *angular* is what gives work its nervous quality. Instead of the edges of leaves being round or continuous, they should be in a series of angles (as in Fig. 4), and not rounded (as in Fig. 5). Examine leaves for yourself, and you will notice that nature is full of angles. The leaves break vigorously from the stems, and the stems again form most beautiful angles with each other. "Round" lines are always a sign of want of skill, and are sure to produce a feeling of insipidity and feebleness. Do not be afraid of letting your chisel show itself in your work. Good wood carving looks as though the craftsman had executed his work by a series of well-directed bold cuts rather than a number of nerveless timid ones.

I see that I have mentioned the need of an enlarged drawing if you wish to reproduce the designs on a larger scale than that in which they are given in the engravings, but I have said nothing about the method to be followed in enlarging, which some readers possibly may not know. Suppose you wish to produce a copy of Fig. 3 *twice* its size (that is to say in linear dimensions, for the area covered will be *four* times the area of the original), divide the drawing into squares $\frac{1}{2}$ inch each way by drawing lines across it and from top to bottom at intervals of $\frac{1}{2}$ inch. Then rule a piece of paper in the same way with lines one inch apart, and having done this copy the outline, square for square, on the paper thus prepared. You will thus get a true and exact enlargement.

ARMATURES AND ASSAYING.

BY GEORGE EDWINSON BONNEY.

AQUA REGIA—ARMATURE—ARSENIC—ARSENIOUS ACID—ASSAY: ASSAYING—ASSAYING FOR GOLD BY THE DRY WAY.

Aqua Regia.—A mixture of nitric and hydrochloric acid has long been known by this name. This also is a compound of two Latin words meaning "royal water." The name was probably derived from its well-known property of being able to dissolve gold, the royal metal. The usual mixture of the two acids employed to dissolve gold is composed of hydrochloric acid three parts by measure, to nitric acid one part by measure. The both acids should be pure, and only mixed just before they are required, as the mixture will not keep good for any length of time. Even when enclosed in a glass-stoppered bottle it is liable to be decomposed and cause a separation of chlorine from the other constituents. A druggist related to me a short time ago a little experience of his illustrative of this property. A careless assistant mixed some aqua regia, put it in a glass-stoppered bottle, tied the stopper down to prevent any escape of chlorine, and placed the bottle, with other drugs, near the shop window. Shortly afterwards the sun shone strongly on that window, and then there was an explosion, which not only shattered the aqua regia bottle, but also several other bottles around it, and filled the shop with suffocating fumes. Aqua regia will dissolve platinum, but more slowly than it dissolves gold. On some other metals it acts more strongly than any single acid, but on silver it has scarcely any action, owing to formation of the insoluble chloride of silver which forms a crust on the metal, and protects it from further action.

Armature.—A name given to the iron keeper of a permanent magnet. It is also applied to that part of a dynamo-electric machine which is rotated within the influence of the field magnets. In the greater number of those machines, the armature is made to revolve within the field, or magnetic influence of the magnets, but there are some exceptions in which the magnets are caused to revolve and the armature is stationary. Revolving armatures and fixed field magnets have the merit of adding stability to the machine and steadiness to its running and the output of the current. Each inventor of a new dynamo-electric machine appears to have adopted a special form of armature, hence we have as many forms of armature as there are inventors of machines. The armatures of dynamo-electric machines are generally furnished with iron cores, around which the insulated copper wires are wound. Machines have been constructed without iron cores by Messrs. Siemens, Ferranti, & Thompson. In those machines a looped or zigzag band of copper is attached to a brass spider, mounted on a spindle, and forms the armature Armatures are divided by Sir W. Thompson into four types:—

"(1) *Ring armatures*, in which the coils are grouped upon a ring whose principal axis of symmetry is its axis of rotation also.

"(2) *Drum armatures*, in which the coils are wound longitudinally over the surface of a drum or cylinder.

"(3) *Pole armatures*, having coils wound on separate poles projecting radially all round the periphery of a disc or central hub.

"(4) *Disc armatures*, in which the coils are flattened against a disc."

Of these it is as well to say that examples of the first type are furnished by the machines of Gramme, Schuckert, Gülcher, and Brush. Examples of the second type are found in the Siemens (Alteneck), Edison, Weston, and Elphinstone-Vincent machines. Examples of the third type may be seen in the dynamos of Allan, Elmore, and Lontin. There are few useful examples of the fourth type, but several combine the first with this, as where flat rings, or discs, are used side by side. When solid iron is employed for an armature core, it abstracts a portion of the electric current from the machine, and this is employed in heating the iron. The current thus abstracted, forms what is called eddy currents in the iron, and causes the machine to become hot. Iron armatures should, therefore, be built up of thin sheet iron discs, or plates, or hoop iron, each piece of iron being insulated from its neighbour by varnished paper or calico. The armature coils should be of pure copper wire, well insulated with cotton steeped in paraffin, and the wires should be as short and thick as is consistent with the requisite E.M.F. without driving the machine at an excessive rate of speed. For further information, see notes on *Dynamos, Electric Machines*, etc.

Arsenic.—Chemical Symbol, As. A crystalline and very brittle metal of a steel-grey colour and high metallic lustre which readily tarnishes in the air. It is found combined with sulphur in the ores of several metals, and as an arsenide with iron, nickel, and cobalt. When these ores are roasted, the arsenic in them combines with oxygen, and forms crude arsenious acid. This is purified by sublimation, and roasted with charcoal in a retort where the arsenic is reduced to its metallic state. The combining or atomic weight of arsenic is 75. It readily combines with oxygen on being heated, and is converted into arsenious acid. Heated in a retort, it volatilises without fusion. Arsenic may be made to combine with metals, and the alloy thus formed bears a close resemblance to that of an alloy of the same metal with phosphorus. The general effect of its presence in a metal is to increase its hardness and lessen its conductivity. Impure copper is sometimes contaminated with arsenic.

Arsenious acid, named also *white arsenic*, and *white oxide of arsenic*.—Chemical symbol, As_2O_3. Molecular weight 197·8. This is the only compound of arsenic used by the electro-plater. Professor Fownes says of it:—"It is a heavy, white, glassy-looking substance. When freshly prepared it is often transparent, but by keeping becomes opaque, at the same time slightly diminishing in density, and acquiring a greater degree of solubility in water." Boiling water will dissolve arsenious acid in the proportion of 11·5 parts acid to 100 parts of water, but 8·5 parts of the acid is thrown down when the solution cools. Agitated in cold water, even less acid is dissolved. These solutions will redden litmus paper. Alkaline solutions dissolve it freely, forming arsenides with the alkali. It is easily soluble in hot hydrochloric acid. The vapour of the acid is colourless and inodorous. "The acid has a feeble, sweetish, and astringent flavour, and *is a most fearful poison.*"

A solution of arsenious acid in water may be easily detected by the following methods:—

1. Add a solution of silver nitrate. At first there will be no precipitate, or merely a slight cloudiness in the solution. On adding a little alkaline solution or a drop of liquor ammonia, a yellow precipitate of arsenide of silver will be formed. This precipitate is soluble in an excess of ammonia, and also in nitric acid.

2. Add a solution of sulphate of copper. This gives no precipitate until a little alkali is added, when a yellow-green precipitate (Scheele's green) is formed. This is also soluble in excess of ammonia.

3. A slip of copper foil boiled in the liquid suspected to contain arsenic, will become whitened if the liquid has been previously acidulated with hydrochloric acid.

There is no simple antidote for arsenical poisoning, but calcined magnesia mixed with water will give relief. Death may be averted by the timely use of the stomach pump, and remedial agents prescribed by a competent medical man. See also notes on *Poisons, and Poisoning.*

Assay: Assaying.—An analysis of metals, notably those denominated precious metals, with a view to determine their purity. The apparatus necessary to conduct assaying operations is too costly to be within the reach of electro-platers working in a small way of business. But all large firms engaged in the manufacture of goods in which large quantities of gold and silver are used, should have means at hand for assaying the goods. Only a mere outline of the process can be given here. Full information can be obtained in Mitchell's "Manual of Assaying." Assaying for gold and silver is performed in the dry way by the use of suitable furnaces and crucibles, or in the wet way by the use of acids and certain chemical re-agents.

Assaying for Gold by the dry way.—First of all weigh out a sample of the metal to be assayed in a delicate balance capable of indicating to 100th of a grain. The sample should be some easily divisible part of the pound troy or the pound avoirdupois, just as the answer may be required, or it may be some aliquot part of 100 grains. If it is suspected to contain more than one-fourth of its weight of gold, it must be fused with enough silver or copper to bring the proportions to exactly 1 part gold to 3 parts alloy. The bead of metal thus obtained must now be flattened out to a thin disc, or rolled to a thin riband and annealed. It is then placed in a thin glass flask, or beaker, or in a porcelain capsule, together with 2 parts pure nitric acid to 1 part of distilled water, and heated over a sand bath until all ebullition has ceased and the hot liquid ceases to give off bubbles of orange-coloured nitrous oxide. The acid solution of copper and silver must then be poured off into another beaker, and the finely divided gold dust or sponge of gold well washed with distilled water ejected from a wash bottle. Finally, the gold must be washed into a small porcelain crucible or into a cornet pot, dried, and fused to cause coherence of its particles. It may then be accurately weighed, and the proportion of gold calculated.

It is not possible for me to complete my Notes on Assaying in this number, and I must therefore postpone to the next paper the further consideration of gold and silver assays in the dry way, as well as the assays or analysis of metals that are known to contain silver. The subject is one of considerable importance as well as interest, and therefore deserves and demands attention. I shall not detain the reader long with this subject, and I shall then pass on rapidly to other topics which have been kept waiting through sheer inability to give greater instalments at a time.

OUR GUIDE TO GOOD THINGS.

47.—Steel Calliper Gauge.

In Fig. 1 in this page is shown, full size, a very handy little instrument for machinists and tool makers, manufactured by Mr. Chesterman, of Sheffield, and sold by all dealers in tools and hardware merchants throughout the United Kingdom. Beautifully made, accurately divided, and exquisitely finished, it demands the attention, and should be in the possession, of every workman of the trades for which it is chiefly intended. The Steel Calliper Gauge is made in four varieties, distinguished by the divisions marked on them, each variety being made 3 in., 4 in., and 6 in. in length. The four sorts are known by numbers stamped on the instruments to facilitate distinction, the numbers being 1400, 1401, 1402, and 1403. They are sold, the 3 in. at 5s., the 4 in. at 5s. 6d., and the 6 in. at 6s., in all varieties except No. 1401, the prices of whose three sizes are 6s., 6s. 6d., and 7s. respectively. It will be useful to say that No. 1400, as shown in the illustration, is divided, the inches into 32nds, and centimetres into millimetres and halves. In 1401 the metric divisions are the same, but inches are subdivided into 32nds, 48ths, and 50ths. In 1403, divided for inches only, the subdivisions are into 32nds and 50ths. No. 1402 differs from the rest, in having inches and circumference measure shown upon it, of which the former is divided into 32nds and the latter into 16ths. The particular use of this gauge is that if the diameter be known and the movable arm adjusted thereto, the upper end of the arm will also indicate the circumference in inches, and *vice versâ;* if the circumference be known the diameter may be read off the scale by adjustment of the movable arm. The construction of the instruments may be seen from the illustration. A flat steel bar, which is carefully graduated, is set on the fixed arm of the Calliper Gauge at right angles to it. On the bar slides the movable leg, kept in position by a projecting arm at the bottom and a spring at the top. At the top there is always a binding screw by which the movable arm may be held in place and rendered as rigid as the other.

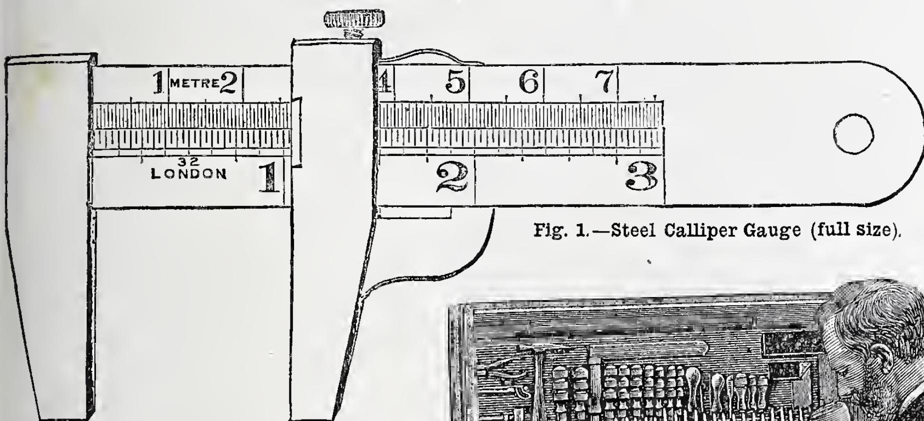


Fig. 1.—Steel Calliper Gauge (full size).

48.—Barrett's Improved Combination Roller Gauge.

This capital tool is an importation from the United States, in which it was patented barely a year ago. It is manufactured by Mr. C. E. Jennings, 79 and 81, Reade Street, New York, the maker of the well-known Jennings' Twist Bits. Its nature may be seen from the illustration of it given in Fig. 2, which is just half size. It consists of three parts, and is composed entirely of metal, the head being of superior grey iron, and the beams of Bessemer steel finely polished and nickel-plated throughout. The head is octagonal at top, as shown in Fig. 3, and circular below. It is pierced with two holes in which the beams work, the latter being secured, when adjusted, by binding screws, which appear clearly enough in Fig. 2. The larger beam is 8 in. long, and is graduated throughout its length in inches and 32nds of an inch. The smaller beam is 4 in. long. In place of a spur or point, rolls of the finest steel are used, bevelled to a fine edge, hardened and revolving on the shank of hardened steel screws, enabling them to run over cross-grain, knots, and rough surfaces with perfect ease and accuracy, making a nicely-finished, easy, and perfect working tool. It may be used both as a mortise gauge and as a marking gauge, but when it is used in the latter capacity the head or roller of the shorter beam must be dropped into the recess made for its reception in the plate, and shown to the right in Fig. 4. It is a nice tool to handle, and much superior to the ordinary wood gauges. It is only recently on the market in this country yet, and its price is 9s. 6d. post free.

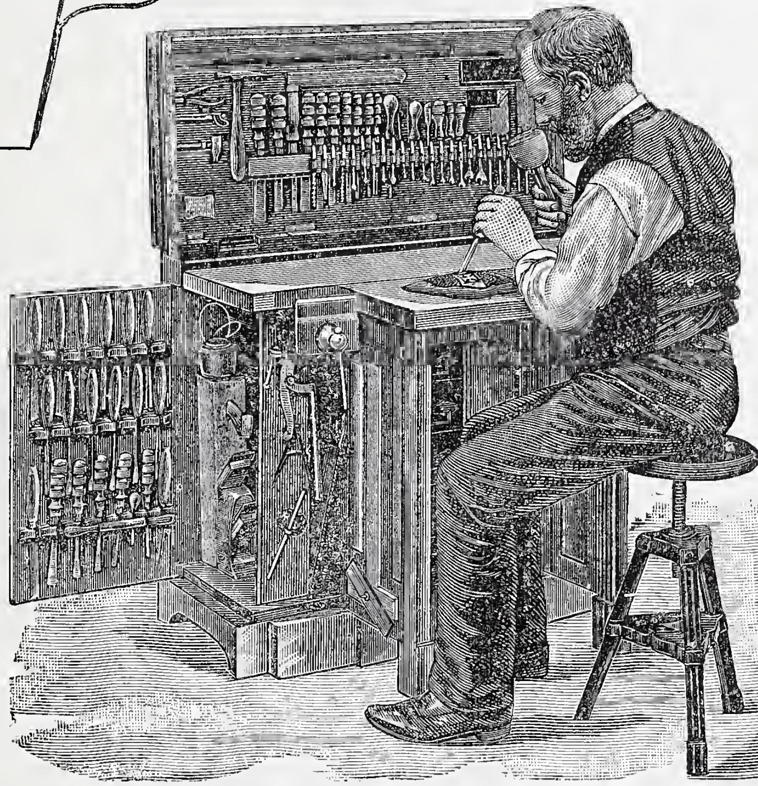

Fig. 4.—Melhuish's Tool Cabinet and Wood Carver's Bench Combined.

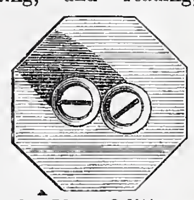

Fig. 3.—Plan of ditto seen from above (half size).

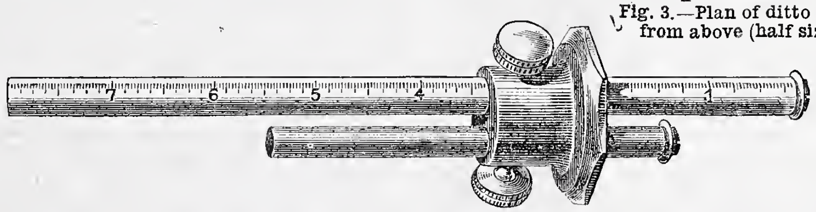

Fig. 2.—Barrett's Improved Combination Roller Gauge (half size).

49.—Patent Combination Tool: Joinery and Carving Work-Bench Cabinet.

In No. 6 I drew attention to this Cabinet in its primary form, and alluded to certain modifications which were about to be made in it by the inventors and patentees, Messrs. R. Melhuish and Sons, 85 and 87, Fetter Lane, E.C. The Cabinet may now be had in its alternative form, as represented in the illustration given in Fig. 4, fitted with tools complete, for £25 8s. The alterations and improvements effected are these. The lower drawers, which came to the front in the first form, have been reduced in width and recessed, giving more space for the workman when standing in front of the bench at work. The front of each side of the Cabinet opens outwards on hinges as shown, travelling on surface rollers under bearers, thus by direct bearing forming a solid and perfectly rigid support for an addition to the work bench in the form of a stout, well-made board, which is attached to the longer part of the bench by dowels. To this the supports are bolted by flush bolts of peculiar arrangement, which, being fixed by springs, remain unmovable, and are free entirely from the vibration which would be caused in ordinary bolts by percussion occasioned by the use of hammer or mallet on the bench above. This carving board, as it is called, when not in use, is stored away in a recess shown in the engraving, just under the joiner's vice, which it fills to a nicety, its width and length corresponding to the depth and height of the Cabinet. It can be utilised for carving, as shown by the operator at work, who is represented seated on a convenient revolving stool resembling a music stool, but of stronger make, whose height may be regulated at pleasure. In the carving board are two holes, bushed and surrounded with plates flush with the bench. In these, nicely made holdfasts may be inserted to hold work in process of carving. These holes are further utilised for the reception of a brass stand for a drawing board, which may be inserted in either hole and moved in any direction, thus giving facilities for drawing, painting, and reading, by using the board as a reading stand. The transition of the drawing board from a horizontal to a vertical position, or any angle between, is effected by a rack and pinion attached to the T plate screwed to the under surface of the drawing board, and actuated by a large milled head attached to the rack. It is difficult to imagine a more convenient piece of furniture for an all-round man who likes to use tools of all kinds, pen and brush alike, but is somewhat limited for space for the using. The drawing board is stored when not in use in a recess contrived for its reception at the back of the Cabinet, entered from the right-hand side.

I.—Letters from Correspondents.

Circular Saws Running out of Truth.—A. R. (*Scorrier*) writes:—(1) "In perusing the pages of Work from time to time, I hope to derive some benefit from queries answered and letters written by practical workmen, who are kindly invited by the Editor to give such information relating to their trade as may be in their power to give. And as we live by each other, I think it is the duty of all readers of Work to do what they can to instruct their fellow readers, and at the same time be the means of helping to make Work a most interesting and valuable paper. Therefore, the few remarks I may make on circular saws I hope will be of benefit to those interested in the same, and any question asked through 'Shop' on saws for general work I shall be pleased to answer to the best of my ability. There are many reasons why circular saws deviate from a true path; I will endeavour to give some of the principal reasons. First there should be plenty of power to drive the saw or saws a regular speed; if power is limited, the saw will be merely dragged through the timber, and not driven through as it should be, consequently the saw soon gets dull and requires sharpening often; if worked dull saw plate will be strained or buckled, and it will commence to run out of truth. (2) In driving saws from 24 in. diameter and upward, the distance between centres should not be less than 16 ft., nor more than 24 ft. or 25 ft.; if the belt is short the tension has to be great, consequently the bearings become hot, the heat is conveyed to the centre of the saw, and it will bulge and run out of truth; if the belt is too long it will sag, and the bearings soon begin to cut, and the same results follow. (3) Belts should not be less in width than one-seventh the diameter of saw, and pulleys on saw spindle not less in diameter than one-third the diameter of saw. (4) A bearing should be near the pulleys on spindle to take the pulley belt, so as to prevent vibration of saw spindle; should it vibrate it will be conveyed to the saw, and undue friction will be set up; after a short time the saw gets buckled, and runs out of truth. (5) Bearings of saw spindle should fit very nice, and end play should be avoided. (6) The collar washers should be slightly concaved, or the saw will bulge or dish, and run out of truth. (7) The saw should be properly packed; the proper packing of a circular saw is of great importance, and various are the opinions of men on this point; but my experience is that if a saw is evenly hammered it should be packed a little warm at the centre, and the warmth decreased toward the rim, where, when running, it should be quite cool; this will allow for the extra friction which will be going on at and near the rim of saw, the speed being much greater than at the centre. (8) All timber, before presented to the saw, should be properly bedded, or made perfectly steady by some means. How often do we see a man with a piece of round, rough timber, as much as he can lift, trying to push it against a circular saw, and quite unable to keep it steady: the man with fear, as he knows there is danger attached to it. He pushes the piece a few inches, and the saw brings up the belt and slips over the pulley. The saw being freed the work is again commenced, and after a while the cut is got through, and the saw will tell it has not been rightly treated, as it knocks about in a fearful manner, and if you should put the back of your fingers against the saw plate you will find it scalding hot; this heat is caused by undue friction set up by the timber not being steady, and as the friction increases the saw runs out of truth, and at last becomes crippled. The rack bench as well is often used for cutting round timber, with nothing to keep it steady but its own weight, and sometimes a little of the ends sawn off, which, in many cases, spoils the timber of certain work; all such timber should be so clamped as to keep it perfectly steady, and it would, to a great extent, prevent saws from getting crippled, and from running out of truth. (9) The speed of the saw is an important point; should the tool be driven too fast it becomes pliant and runs untrue. The following will be found to be a good speed, if saws are of proper gauge, from 8,000 to 9,000 ft. per minute, at the point of saw teeth; and for hard wood generally, such as elm, ash, etc., a speed of about 6,000 ft. at point of saw teeth. Circular saws kept in good order and properly worked will do good work at the above speeds. (10) The saw should not fit light on spindle nor on steady pin; should heat be conveyed to the centre of saw, it will bind on saw spindle, and the saw will run out of truth. (11) How often do we see a circular saw enter a log of timber, and the sawyer go to the other end of the log, and with pinching bar move the log transversely, the other end of the log acting as a lever on the front of the saw; consequently the saw draws thick or thin, as the term is. The cause of the saw drawing is often put to the bad sharpening and irregular setting of the saw. This moving of the timber, after the saw has entered it, should, by all means, be avoided. If the timber is not in position, it should be brought back and freed from the saw before being moved in any direction. (12) Timber deeper than the saw will reach should not be sawn when the saw is buried. It is impossible to see whether the saw is running true or not, and the plank being sawn off cannot be spread as it should be, so as to prevent friction on the saw plate, which is sure to be great near the rim of saw; consequently the saw gets winding, and gives an amount of trouble to the sawyer by running out of truth, also to the man that has to sharpen the saws. (13) The most essential point is the sharpening of the saws. Unless a circular saw is properly sharpened it will soon become crippled and run out of truth; men vary greatly in opinion on the sharpening of saws. I am of opinion that no man is perfect in the work of saw sharpening, especially of circular saws, and I calculate within the past eighteen years I have sharpened more circular saws than any two men in the county in which I live, and feel I am far from perfect, and that a deal of practice is required. There should be a certain angle for each class of work, and only by practice can we know the best angle to give saw teeth to suit the work it has to do. A frame saw may be put into the sharpening machine, and the emery wheel set to a certain angle, so as to give the teeth their proper rake, and if the saw is used only in one class of wood, we will say soft wood generally. The wheel, when once set, will do at the same angle as long as the saw is being worked; but this is not the case with the circular saw, though many so-called saw sharpeners think it will do. When I go into a works, and see a man put, we will say, a saw 50 in. in diameter in the sharpening machine, and set the wheel to a certain angle, afterwards take another saw much less in diameter, and commence with wheel at the same angle, I am at once convinced he is not the right man for the place—that he does not know his work. If the saw teeth are to be sharpened to an angle of 65° to 70°, it is impossible to give the same angle to a saw of 30 in. diameter as one of 50 in. diameter. Keeping the wheel at the same angle in the smaller saw, the teeth would be much more acute, and not at all adapted for the work. The best rake, as far as my experience teaches me, for teeth of circular saws for soft wood, generally, is to an angle of from 70° to 75°, and bevel of front and top of teeth about 65°; and for hard wood, generally, rake 80° to 85° bevel of front, and top of teeth 75° to 80° in cutting very soft wood. The angles may be more acute than the above, but for general work good work can be done at the above angles. Again, the setting of circular saws is of great importance. If the set is too much more power is required; if not enough the saw will not free itself, and will get overheated. A saw 24 in. in diameter for general work, from two to three gauges set, or about the 36th part of an inch, the set to be increased as the diameter of saw is greater; practice alone will teach the amount required. Again, some are in favour of setting circular saws with hammer, and to a sharp angle, such setting gives a rough surface to the work, and more power will be required to drive the saw. For fine surface work I prefer a hand set, and for thick saws one with two handles, setting the teeth a little curved, and gauging every tooth with a gauge made of a thin piece of steel, saws set as above. If saw plate is true, the saw will cut very clean, providing it is perfectly round. Much more might be said on sharpening and working of circular saws, but some of your readers who are not interested in the above may think I am intruding on valuable space. However, I hope many of your readers may be benefited by remarks I have made, and, if adhered to, saws will not require hammering until so reduced in diameter as to require regrinding, after which they will be as good as new if done by a good maker."

Die Chuck.—H. J. N. (*Malvern Wells*) writes:—"I have had your first issue of Work, and I think it a very useful book for amateurs, etc.; they can see the issue of tools, machines, etc., and it also gives good instruction. Your dog chuck which you have illustrated is very useful and simple. I have much pleasure in submitting a method of making a die chuck, and I should be pleased for you to put it into Work, if you think it worth doing so. The method I propose is to get a disc of hard wood, oak, elm, mahogany, or beech, and turn it down in the lathe to about 8 in. diameter. To make it screw firm on the nose of mandrel, it is best to get a piece of iron of suitable size square in shape, and drill it in each corner, and countersink for screws, then let the plate in flush at the back of wood disc, and screw it tight home with four short wood screws, having first tapped it to size of nose; this ought to hold it firmly, if the plate let in be of sufficient thickness to allow three or four good threads being cut. Now, to proceed with the chuck, go to a blacksmith's and get a disc of iron ¼ in. thick and just over 8 in. in diameter cut; the reason for having it a little over the size of wood disc is to allow for it being turned down to same size. Get it drilled, as marked in Fig 1, and countersunk for head of wood, screws to lie flush with surface. Now get two pieces of V-shaped iron about 6 in. long, or if not obtainable get flat, and file carefully up to shape shown in Fig. 2, which is an end view of chuck, showing V irons fastened on. If you have a large-size old square file, put it in the fire and get it to a full red, and put it on the ground to cool. When cool, cut off two pieces the same length and size, and file up clean and smooth; these are to be the dies. If you have fastened V irons on the face plate as they should be, that is, an equal distance apart from the centre of face plate, and parallel to each other, you can file your pieces of old square file to fit. They should fit tight, but also slide between V bars without binding. The shape they should be filed to I have shown at A, Fig. 2. The V-shaped irons should be drilled for screws to fasten them down by; about four screw holes each for wood screws is sufficient. They should be countersunk. You will also have to drill holes in the iron disc for the screws to pass through into the wood. This you can easily do, first getting the irons true on disc as mentioned before, and then mark for drilling. The next thing to do is to get two pieces of iron about 1 in. wide by ½ in. thick, and file them up to shape shown in Fig. 3. The hole in the centre having been tapped for pins, the two screws in the feet must have corresponding holes in the iron disc, so as to bring the hole with thread exactly in the centre between V irons at each end. These plates, fastened down with screws through feet and through hole in metal disc into the wood, ought to stand a good deal of strain; they should be opposite one another at each end of bars. Now to make the pins to screw through hole in each plate to slide the steel dies, you will want two pieces of iron of suitable length and size the same size; then cut thread on them same size as the thread in plates, and drill

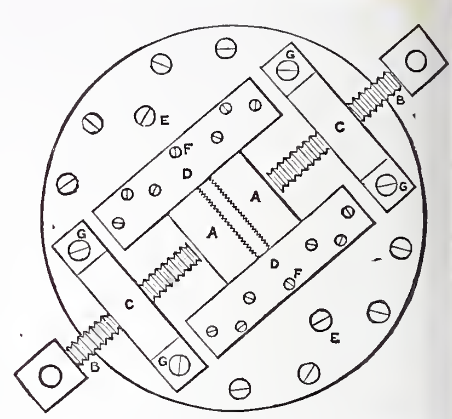

Fig. 1.—Die Chuck, One-fourth Size, Complete.

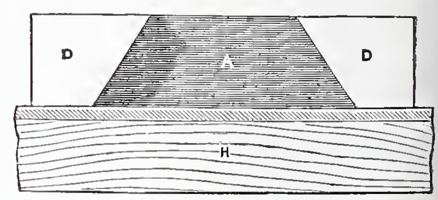

Fig. 2.—View of Chuck Edgeways.

This diagram shows shape of Parallel V Bars (D, D,) for Dies (A) to slide in; also showing Iron (I) and Wood (H) Discs in Section. Not to Scale.

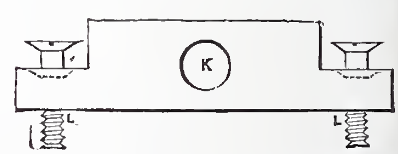

Fig. 3.—Shape of Iron Plates (C, C, in Fig. 1) for Capstan Screws to work through.

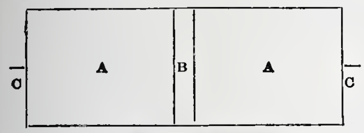
K, Threaded Hole for Male Screw. L, L, Wood Screws through ends of Plate and Iron Disc into Wood: Head countersunk.

hole through the end to insert rod, to screw them in and out. Before putting dies in you will want to harden them. The way to do so is to heat them to a full red, and drop them in cold water. If you find them too brittle you can easily let them down by heating a bar of iron red, and placing them on till they take a straw or violet colour, and then drop them into a tin of linseed oil, and let them cool out. The dies should be cut with a three square file along the faces that come next to the work before hardening, or those faces may be left rough when filing up and fitting. As this is optional the maker may please himself. Now put the dies in and screw the plates on at each end, and put a bar between dies and screw up with pins, and you will find that you have a chuck that will hold if proper care and time have been executed, and I hope those who make it will take that trouble, as it will repay them. I have made a few rough drawings of the parts, and, as I have said, if you think it worth putting in Work I shall be pleased for you to do so."

Building Construction.—W. P. (*St. John's Wood*) writes:—"In reply to your request regarding plans and specification, as a consistent reader of Work, if you can see your way clear to assist your readers in this too much neglected study, you will confer a lasting blessing upon a large number, and greatly help others to understand what they need when building."

Building Construction.—A. E. D. (*Westcombe Park*) writes:—"Being a subscriber, and feeling greatly interested in the several articles that have appeared in WORK since its commencement, I am sure the proposition of opening out a course of instruction in building construction, as regards modern dwelling houses, would be highly satisfactory for the merits of WORK, and also meet with a great deal of approval by its numerous readers. The foundation you set forth for the treatment of drawings, etc., as a course of assistance to all interested is a remarkably good one—as you say, beginning with the cottager's dwelling, town and country, and so gradually advancing till you get to the more superior villa residences or mansions, which would be valuable information for the educated as well as the uneducated in such matters. I think, as an inducement to secure the co-operation of the readers generally, and so receive a fuller outcome of what we want, it would be well to introduce prize competitions, say, once a month; it would, I am sure, create a closer tie between the practical as well as the theoretical, and be an inducement to maintain WORK as a useful paper in the building trade, where it is, no doubt, having an increased circulation. I conclude with best wishes for your highly valuable paper."

Portfolio for Weekly Numbers of Work.—SCOTO-IRISH writes:—"Will you allow me to give a suggestion for the preservation of the weekly numbers of WORK, or any other weekly publication? I do not like to see my literature soiled, particularly if I wish to bind it in volumes. So I got a straw board—strong paste or millboard will do better—I cut board in two, slightly larger than a page of WORK, then glued a strip of cloth on boards, forming a back about 2 in. wide, as per annexed diagram,



Portfolio for Weekly Numbers of Work.

A, A, Sides of Millboard. B, Back of Cloth. C, C, Ribbon.

and fastened a bit of ribbon to the outside of each board, with which you can tie boards together after placing weekly part within. If desired, I will send instructions how to make a blotting folio or pad."—[You can send these if you like.—ED.]

Utility of Work.—JOINER writes:—"I beg to add my testimony to the immense value of your paper. I have showed it to many of my fellow workmen—some of whom are subscribers—and they all agree with me that WORK is the best and most useful paper of its kind that has as yet been published. It is a paper which claims the attention of every right-thinking and right-acting man, whether he be a professional mechanic of whatever trade, or a man of independent means, who takes up any craft merely as a hobby."

Patents for Inventions.—P. J. (*Royston*) writes:—"I think working men will appreciate your kindly offer which you made to W. J. P. in No. 8. There is a great number of working men who have inventive genius, which is lost through not having the wherewith to patent their inventions. I would suggest that a subscription be got up in WORK for the purpose of helping those who cannot help themselves. I am sure, sir, if any working man got help through that means and prospered thereby, he would not forget those who helped him."

Gold Leaf.—PAINTER writes:—"I notice in 'Tips for Tyros,' by OPIFEX, in No. 8 of WORK, that a book of gold leaf, which is quite good enough for such purposes, can be bought for 6d. Having had some little experience as a painter and decorator, I feel bound to say that if you want work to stand, it must have something better than so-called gold, at 6d. per book. The best material is much the cheapest. For this work buy a book of 'transfer gold' at any good oil and colour shop. It will cost about 1s. 3d. The gold is already transferred on loose leaves which interleave the book, and only needs to be lifted or drawn out, and then cut up as needed. In winter, use quick-drying gold size; in summer, use slow-drying gold size. The gloss is almost sufficient to hold it."

Utility of Work.—AJAX writes:—"Being a constant reader of the SATURDAY JOURNAL, it was with pleasure that I saw the announcement of your new publication, WORK—not so much for the hints it is likely to give me regarding my own trade (cabinet making), as the information I may get from it respecting other trades. I shall put each number carefully away, so that my son, who is now ten years old, may have the benefit of them when he is older."

Elizabethan Twist in Lathe.—C. C. E. writes:—"Permit me to make a slight correction. I did not say that an Elizabethan twist cannot be cut in a lathe (I believe a lathe might readily be constructed to cut one, at any rate, in hard woods and ivory), but that I do not believe there is any lathe in existence by which they can be produced. You ask why, if a spiral groove can be cut, cannot the sharp edge of the groove be removed, and the twist finished without rasp or file? No doubt it can, and by apparatus too complicated to describe, very fairly be done; but if you will go to your lathe and try to make a convex curve die into a concave without a break, you will soon realise the difficulty, and, justly proud if you succeed, will yet have to confess that it is not in the range of practical mechanics. During a hunt of some thirty years I have met many such men as you describe, and with precisely the same result. The lathe which produced the twist is always somewhere else, and you can never 'run it to ground.' Lathe-users, not generally lathe-makers, are the men to assist us in difficulties. It is one thing to make a piano, but quite another to play upon it. And pig-headed though I may appear, I am of the same opinion still, 'that there is not any lathe in existence by which a true Elizabethan twist can be produced,' and I shall be very glad indeed to be proved wrong."

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Papier-Mâché for Outdoor Work.—"PAPIER-MÂCHÉ" (*Burnley*).—Outdoor ornamental work, such as for palisades, can be made from paper pulp, and the moulds used would be of cast iron. Thoroughly japanned, such work would resist weather alone for a considerable length of time. But exposed as it must be, it could scarcely escape accidental injuries, which, letting in the damp, would ruin it. On the whole, cast iron would be both cheaper and better. Pulp on a large scale would be more cheaply bought than made. Messrs. Rubery & Evans, of Birmingham, used formerly to supply it, and probably do still.—S. W.

Tools for Repoussé Work.—W. E. S. (*Oldham*).—These may be obtained of Gawthorp, 16, Long Acre, London, who also supplies all materials necessary, and makes the special cement referred to in the article. The simplest method of transferring design to metal is to place a sheet of carbon paper between the design and the metal (the *black* side being in touch with the metal), then trace over the whole of the design with a blunt steel point, and the design will be found in black upon the metal. Scratch this in with a sharp steel point to avoid rubbing out. To smear the metal with turpentine, and allow it to dry before tracing with carbon paper, or drawing with lead pencil, is a good tip.

Electrotyping with Bunsen Battery.—ELECTRIC.—The Bunsen battery is not suited to this work, because its E.M.F.—that is, the intensity or pressure of the current—is too high to produce *tough* copper. I should say that you get a good tough deposit from your 3-gallon Smee. If you wish to increase the rate of the deposit, add more cells as the deposit spreads, and connect each cell to the work by a separate wire; 60 square inches of copper plate $\frac{1}{8}$ in. in thickness will weigh about 29 lbs. Copper is deposited at the rate of 17 grs. per hour for each ampère of current passed through the solution. It will take 50 ampères of current per hour to deposit 60 square inches of copper $\frac{1}{8}$ in. thick in 10 days, and this cannot be obtained from a single-cell 3-gallon Smee. Are you sure as to the dimensions of your electrotype? An eighth of an inch is thick for an electro.—G. E. B.

Tea-Chest Wood.—BARRINGTON.—Thank you for the specimen of tea-chest wood sent to me. It is a very decent kind of wood for working up into articles for home use, as you said, and I am glad to have had it brought under my notice. It is possible the chests came from India, for all tea-chests I have seen from China are made of thin hard wood that will split at the slightest provocation. There will be no chance of discussing the subjects to which you allude in the pages of WORK. They are strictly tabooed; so your mind may rest relieved of any apprehension of squabbles over well-gnawed bones of contention, that no really reasonable man would care to discuss.

Tea-Chest Wood.—J. S. W. (*Norwood*).—I am obliged to you for the sample of Indian tea-chest wood sent, which, as you say, "is not at all a bad-looking wood—in fact, very much like black walnut." I append the rest of your letter, which conveys much useful information, and runs as follows:—"I have seen numbers of chests of the same kind at Cooper Cooper's, King William Street (London Bridge), and they could be procured at any large tea merchants. I remember seeing an article not long ago, but I quite forget where, by a gentleman in India, in which he said that Indian, and particularly Ceylon, tea-chests were often made of quite valuable woods. He had come across one himself made of a beautiful spice wood, which he had had made up into some article by a native workman, and which was well worth it. The sample I send is part of a chest from North India. I am delighted with WORK. I have recommended several friends to take it, with success."

Hand-Loom Weaving.—G. O. (*Sheffield*).—I trust a beginning will soon be made in this direction with a spinning wheel and a simple loom. It is desirable, in dealing with such a subject as this, to begin at the beginning, and these preliminary papers will be most useful in the colonies—Manitoba, for example, where they have plenty of wool and no machinery for working it up into yarn and cloth.

Binding Screws and Clamps for Battery.—A. A. (*Grantown-on-Spey*).—These may be bought of any dealer in electric wares. The price of the binding screws for the zincs should not exceed 8d. each; the clamps may cost from 1s. to 1s. 6d. each, according to width of jaw, ranging from $1\frac{1}{4}$ in. to $1\frac{1}{2}$ in. If you cannot get them at Inverness or Perth, you may have them sent by post from Messrs. H. Dale & Co., 26, Ludgate Hill, London, E.C.—G. E. B.

Carbons for Bunsen Battery.—M. I. (*Horsham*).—Your perseverance in trying to make carbons for the Bunsen battery is very creditable, and if this alone could command success it would certainly be assured. Every man to his trade, and this must be gained by experience. Carbon moulding and baking is a trade by itself, and there are several little wrinkles in this, as in all other trades, not revealed to outsiders such as myself. I believe, however, that the coke must be ground to fine dust, and this mixed with fine dust of *caking* coal. The mixture is then pressed into a strong iron mould of the shape required for the carbon, and heated strongly in a furnace. The baked mass is found to be porous (as your carbons were) when the mould is opened. The porous mass is soaked in gas-tar or in sugar syrup, and again heated in the mould. This process is repeated until the carbon block has acquired the necessary solidity. If you still intend to persevere in trying to make the carbon blocks, I hope this will help you. But why try to make carbons for this, or for the single-fluid bichromate battery, when you can get carbon plates $\frac{1}{4}$ in. thick for about 1d. per square inch?—G. E. B.

Electric Lighting by Accumulators on a Small Scale.—YORKSHIRE.—(1) To estimate the capabilities of an accumulator for electric lighting, calculate each square foot of positive surface plates to yield six amperes of current per hour. Find out the resistance of the lamps, and calculate one pair of elements, or 1 cell=2 volts, to each 2 ohms of resistance, including that of the connecting wires. As 10 c. p. lamps vary in their resistance, I cannot say what would be the resistance of five of these. If we put it at 20 ohms each, and the five are arranged in series, we shall get a total resistance, including the leads, of, perhaps, 102 ohms; this will require an E.M.F. of 102 volts, obtainable from 51 cells arranged in series. If the plates in the cells are each 1 square foot, the battery will probably furnish light to this number of lamps for five hours. By using a battery with plates having an area of 5 square feet, and coupling the lamps in parallel, eleven cells will furnish the same light for five hours. (2) The second part of your query contains an almost impracticable demand. Of course it is possible to connect a motor to a sewing machine, and to cause the motor to generate a current capable of charging an accumulator by reversing its action and treading the other way. But who would undertake to devote himself to such drudgery? You would have to exert 20 per cent. more power during five hours to charge the accumulators than would be required to work the machine itself by the foot! When an accumulator is charged, the bubbles of gas shift over to the opposite plate, and the cell discharges itself, if not disconnected from the machine. (3) A secondary battery, *i.e.*, an accumulator, will work a sewing-machine motor very well. The chromic acid battery is said to be the next best for the purpose, and is generally used when primary batteries are employed for this purpose.—G. E. B.

Sale and Exchange Column.—F. J. B. (*Kensal Green*).—I note your reply to F. T. (*Bristol*), relative to a Sale and Exchange column in WORK. I think it would be very popular, and shall be glad to give it my support.

Address.—JACK PLANE.—We cannot give you the address you ask for, as we have not got it on record.

Bicycle Making.—W. E. (*Kirkcaldy*).—This is a subject for winter work. It would be impossible to give instructions which would enable bicyclists to make their own machines for use this summer, which is already upon us.

Harp Making.—G. L. (*Sheffield*).—Your request shall not be forgotten, but it is impossible to enter upon the subject at present.

Enamelled Paper Letters.—J. W. (*Bradford*).—Enamelled adhesive waterproof advertising paper letters and figures, ornamentations, etc. etc., may be had from the sole and original manufacturers, S. H. Beit & Co., 4, Hyde Street, New Oxford Street, W., who will forward price list and sample sheet on enclosing stamp for postage.—N.B. The nearest on their sheets to samples sent is No. 20 $\frac{3}{4}$ in., which is a very near match.—H. L. B.

Photographic Camera.—G. L. (*Sheffield*).—Instructions for making a camera will be given shortly.

How to Make a Wardian Case.—W. P. (*Southport*).—An article on this subject will appear shortly.

French Polishing.—T. W. (*Leek*).—Articles on this subject will be commenced very shortly.

Electric Motors, etc.—J. S. (*Orkney*).—Articles upon all these are in preparation, and will appear in due time.

Treadle Fret Saw, etc.—E. G. (*Malvern Link*).—A member of my staff, who is an accomplished fret sawyer, has this subject in hand.

A Patent: Its Cost and How to Get It.—A. M. (*Birmingham*).—If you have not read reply on this subject to P. T. S. (*Sheffield*) in No. 12, p. 189, please do so, as you will find in it a sufficient answer to your query. You can get the £1 form for application for provisional protection at the chief post office in Birmingham.

Mixing Colours.—C. S. B. (*Glasgow*).—Papers on house painting and decoration will appear shortly, and in these the subject of mixing colours will be carefully considered.

Sign Writing and Lettering.—H. C. (*Camden Town*).—We have some more of these papers, and their publication has been resumed, as you will have seen before this meets your eye.

Magic Lantern Slide Painting.—T. A. G. (*Stratford*).—This subject will be treated in due time, but the present season is scarcely the right opportunity for me to commence it.

Greenhouse.—Signalman.—You will have seen in No. 12 of Work instructions for building such a greenhouse as you want. Do not hesitate to ask me anything about gardening and garden appliances, for gardening is one of my hobbies, though I have very little time to indulge in it, as you may suppose. You say you have made three handlights. It will interest you, then, to know that I hope soon to be able to tell you about an entirely new thing in this kind of appliance which I have been testing for some time, and find to be a most useful article.

Fret Machine.—Joiner (*Glasgow*).—The subject has my attention. I quite agree with you as to its utility; but you, as a canny Scot, will know that everything can't be first. Thanks, all the same, for the suggestion. Meanwhile, you do not say whether you have a lathe or not to which you fit an arrangement for fret cutting.—D. A.

Finishing Fretwork.—M. C. (*Nottingham*).—French polish decidedly, rather than varnish. Polish the wood in the usual manner before cutting, or, if the fret is already made, polish without using any filling.—D. A.

Plane for Cutting Rebate.—A. D. (*Canonbury*).—You say there is a "mistake in thinking, or, rather, saying, that a rabbet plane is used for the purpose of making a rabbet or rebate," and that "the plane used is either a sash fillister or side fillister, according to the work that is being done. A rabbet plane is only used for reducing a rabbet or anything similar, if required in fitting the work together. It is a mistake that most writers on woodwork fall into unless they are in the trade." I cannot agree with your remarks about this. In making up such work as that described, few cabinet makers would use any but the rabbet plane. It would be simply a waste of time to set the fillister if only a single article were being made, and be quite contrary to custom to do so. In the joinery or building trades the tools you name are no doubt preferable, as you say, "according to the work being done." Even in cabinet work the side fillister is sometimes useful, though not generally; and it may astonish you to hear that many cabinet makers with a good stock of tools do not possess one. The other, as far as I am aware, is never, or but rarely, used by cabinet makers. You have, I fear, yet to learn that in different trades, or branches of the same trade, different tools are used. Because one man prefers to use one in preference to another, it does not follow that it is a "mistake." Writers on the construction of furniture, if they know what they are writing about, certainly will very often fall into what you are pleased to call a mistake, especially when they are "in the trade" (cabinet making), as the writer of the article you refer to is, and has been for many years.—D. A.

Paper Replicas of Relievo Subjects.—G. M. (*Calvine*).—The reliefs referred to in "'Tips' for Tyros," April 6th, are issued in series of twelve each by MM. Monrocq Fres., 3, Rue Suger, Paris. Series D are classical heads. I am sorry I cannot give a definite address where they are retailed in this country, but try Messrs. Gawthorp, 16, Long Acre, London. I shall be happy to send querist a specimen, should he desire it.—Opifex.

French Polishing.—E. B. (*Lymington*).—Unless you are acquainted with the process of French polishing generally, it is impossible in a short space to give such an explanation as is likely to be of service to you. If you want to know how to polish any particular wood, let me know, and I will direct you; but your present question is far too general to be answered in this column. Briefly, the process consists in coating the wood with a film of lac, which, dissolved in spirits, is the principal ingredient of French polish. This is rubbed in till the spirit has evaporated and a bright surface is obtained. In some woods it is necessary to fill the grain with filling, and the colour is generally improved by oiling. Both filling and oiling are generally done, and light wood is often stained.—D. A.

Joints and Cabinet.—R. M. W. (*Burnley*).—Don't apologise for troubling me. Letters such as yours are not regarded in that light. The desire is to make Work useful, so that practicable suggestions and encouragement are always welcome and cheering. I am glad you, among others, have found the friendly hints to amateur woodworkers helpful. Mr. Denning, to whom your thanks have been conveyed, has papers on both the joints you name in preparation, as well as other topics of a similar character, all of which, no doubt, you will find of assistance, and your "sincere hope" is cordially re-echoed. The cabinet—by which, if I am right in thinking you mean the piece of furniture commonly known among cabinet makers as a nest of drawers—will have attention at an early date. In case you do not understand what a nest of drawers is, I may say it is a kind of square-cornered pedestal fitted with drawers only. These run from side to side, and are usually secured by one lock fitted on a hinged style to the right of them. If this is not the kind of thing, let me know, and I will see what can be done to meet your wants. In any case, I think I may safely promise that sooner or later a description of whatever the piece of furniture you wish to make will appear in Work. Why not send me a rough sketch or diagram of the article? No matter how roughly drawn, a sketch often shows more plainly than any description what is really required; and when the subject seems likely to be of general utility, you may be sure that arrangements will be made for a paper on it. I am pleased to hear you are making one of the tables described in No. 1, and I trust it will come up to your expectations. Thanks for your good wishes.—D. B.

Tin-Plate Working.—W. H. F.—A thoroughly competent man has this subject in hand, and his papers, I trust, will soon be commenced. By all means give the readers of Work the benefit of your experience by "talking 'Shop'" whenever you feel inclined to do so, and by writing papers on any particular subjects connected with your trade which seem to you to require elucidation. You are right in saying, "I think if greater help were given by those well up in their respective trades, we should have a healthier body of workers, and the country at large would be greatly benefited by it." Yes, there is nothing like mutual assistance; like mercy—

"It is twice blessed;
It blesseth him that gives and him that takes."

By helping one another through the medium of Work, workmen will be able to do much to improve the quality of work done throughout the kingdom and the empire at large, and to foster that enthusiasm in one's work without which no work, be it what it may, is thoroughly and effectively done. Enthusiasm is the very soul of work, the begetter of success, and no man can hope to produce, create, or make or do anything approaching to excellence unless he enters heart and soul into his labour, and has pride in, and respect for, the work of hand or brain.

Papier-Mâché Boat.—S. T. (*Shepherd's Bush*) does not state whether this is intended as a mere model, or toy, or as a boat for actual use. A toy boat in papier-mâché will stand water, and last a long time, with only ordinary japanning. If, however, it is to be left swimming on the water much, it will be well to give it a couple of coats (nail-heads, if any, and all) of boiled linseed oil before japanning. If the boat projected is for actual use, S. T. is warned that papier-mâché is a material highly sensitive to changes of temperature; that all copal varnish, which would, when thus used, be liable to crack, should be avoided, and that wooden ribs would be necessary. For this purpose two or three coatings of the boiled oil, before japanning, would be desirable. Any injury should at once be stopped with the paper-dust and japan varnish compositions, and the whole re-japanned. It is doubtful whether the grey paper expressly made for the papier-mâché trade is still in the market; but any paper warehouse could supply a porous paper of medium weight proper for the purpose.—S. W.

Book on Plumbing.—A. H. (*Gosport*).—Buchan's "Text Book of Plumbing," 3s. 6d., Lockwood and Co., is the only one I know. Hellyer's "Plumber and Sanitary Houses," 4th edition, 10s. 6d., Batsford, is a good book, but I cannot say whether it gives what you require.

Wood for Violin Making.—Fiddler (*Highbury*).—I do not know of any one (beyond the wholesale dealers) who makes a business of selling violin wood; but if Fiddler experiences any difficulty in getting what he requires he can be supplied from my own stock.—B.

Government Patent Office.—W. R. (*Hulme*).—The Government Patent Office, to which specifications of patents must be sent, is the Great Seal Patent Office, Southampton Buildings, Chancery Lane, London, E.C. You can obtain stamped forms for patent purposes at provincial post-offices.—F. C.

III.—Questions Submitted to Correspondents.

Resilvering Looking-glasses.—R. C. (*Bingley*) says:—"Being a subscriber to your valuable paper since its commencement, I venture to ask you, or any of your numerous subscribers, if you could inform me how to resilver looking-glasses, trusting you will excuse my encroachment on your time and space."

Making a Xylophone, or Dulcimer.—Correspondent writes:—"Could you, or some musical correspondent, give me a few hints on the construction of the xylophone or wooden dulcimer? What is the best sort of wood for the purpose, and where can I get it? Do you know of any information, article, or papers on the subject?"

Resilvering Glass.—J. S. (*Taunton*) wishes to know what the solution or mordant may be that is poured on the glass in this process after it has been washed with pure whiting and putty-powder and distilled water. He also asks where he may be able to obtain it. Further, he wishes to know the right shape and proper material for the leather squeegle, which is used to wipe over the glass, and remove the surplus solution, after another solution of nitrate of silver has been poured over the glass, and the silver precipitated by the action of the mordant on the second solution.

Trade Notes and Memoranda.

Sir John Lubbock recently laid the foundation stone of the Battersea Free Library.

During the course of the present exhibition at Paris, no less than sixty-nine International Congresses will meet under Government patronage, besides others of a non-official character.

Another, though less brilliant, illustration of the happy union of scientific with commercial pursuits is afforded by the career of the late Mr. R. S. Newall, of Gateshead. He was the pioneer of wire rope manufacture, and the earlier submarine telegraph cables were turned out from his works at Gateshead. The 1850 cable between Dover and Calais; the Holyhead, 1852; the Dover and Ostend, 1853; the Black Sea, 1855; the Red Sea, 1859, were made by his firm. He was devoted to astronomical pursuits, and had a 25-in. repeating telescope made by Cooke, of York, which, shortly before his death, he presented to the University of Cambridge. He was an F.R.S. and an F.R.A.S., was twice mayor of Gateshead, and had been requested to fill the same office during the present year, on the occasion of the visit of the British Association to Newcastle.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable every where throughout the United Kingdom on Friday at the latest.

SCIENTIFIC & ELECTRICAL MATERIALS.
IMMENSE STOCK of Appliances and Materials for Construction of **Electric, Optical,** and **Scientific Apparatus.**
ELECTRIC BELLS, INDICATORS, WIRES, TERMINALS, CARBONS, BATTERIES, LENSES, AND FITTINGS.
Electric Catalogue, 100 pages, 4 stamps.

H. DALE & CO., LTD., 26, LUDGATE HILL, LONDON, E.C.
(HENRY J. DALE, Manager.)

Specialty for Photographic Cameras, Lenses, Stands, Sensitised Paper and Dry Plates. New Patent Aneroid Barometers and Thermometers. Electric Light. Every New Invention or Appliance. **Buy of the Actual Manufacturers,** and get full Scientific Knowledge, and **Save** all Intermediate Profits. Send for ILLUSTRATED CATALOGUES of any branch of SCIENCE—A GUIDE TO BUYERS.—DALE, 26, LUDGATE HILL, E.C.

WHELPTON'S VEGETABLE PURIFYING PILLS
Are one of those pure Medicines which for their extraordinary properties have gained an almost **UNIVERSAL REPUTATION.** Recommended for Disorders of the **Head, Chest, Bowels, Liver** and **Kidneys;** also in **Rheumatism, Ulcers, Sores,** and all **Skin Diseases**—these Pills being **a direct purifier of the Blood.**

ESTABLISHED
1835.

WHELPTON'S PILLS AND OINTMENT.

WHELPTON'S HEALING OINTMENT
Stands unrivalled for the Cure of **Cuts, Burns, Bruises, Ulcers, Sores,** and all kinds of **Skin Diseases.** A Specific for **Eczema.** *Burns, Scalds, Cuts, etc., happen when least expected—Be Prepared!*

Both Pills and Ointment are sold in Boxes, price 7½d., 1s. 1½d., and 2s. 9d., by G. WHELPTON & SON, 3, Crane Court, Fleet Street, London, and all Medicine Vendors at home and abroad. Sent free by Post in the United Kingdom for 8, 14, or 33 stamps.

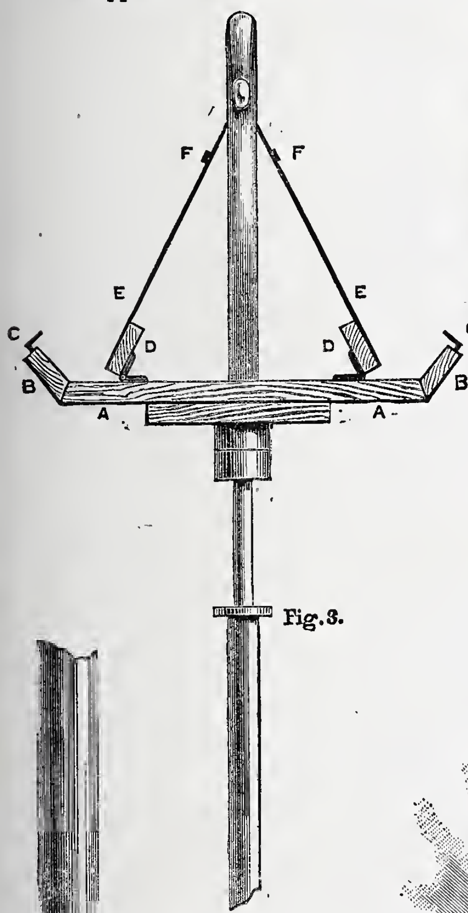
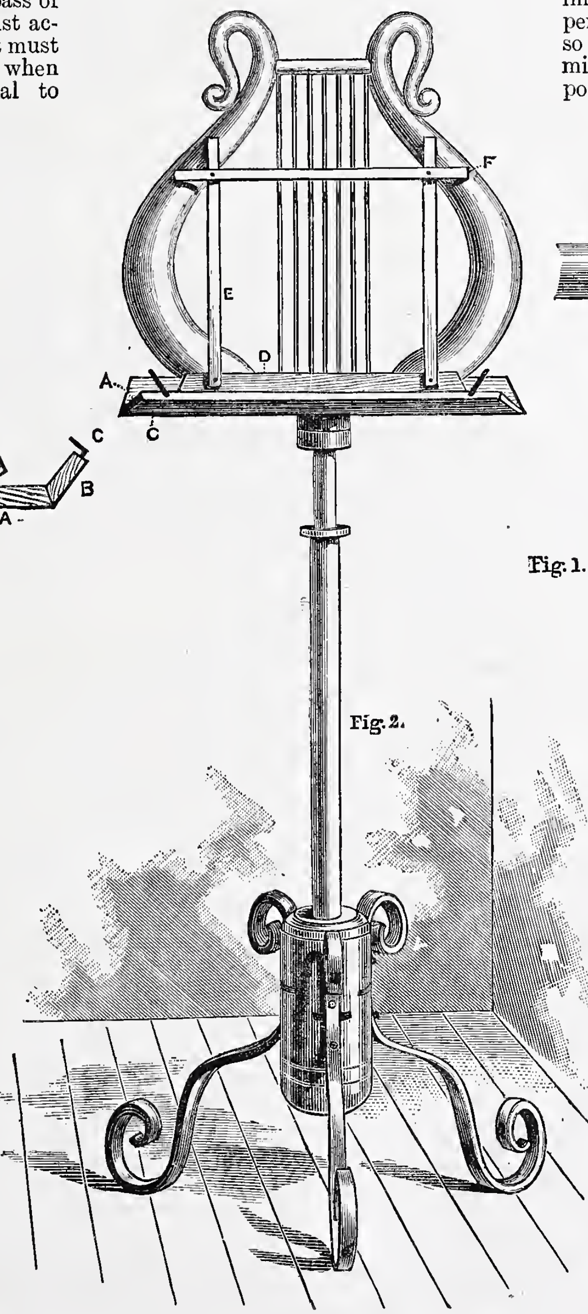
VOL. I.—No. 14.] SATURDAY, JUNE 22, 1889. [PRICE ONE PENNY.

MY DOUBLE MUSIC STAND; HOW I MADE IT.

BY O. B.

I WANTED a music stand, but beyond the conditions I required it to fulfil I knew very little indeed. The conditions were these: First, it must be well within the compass of an amateur to make; secondly, it must accommodate two performers; thirdly, it must be adjustable in height; and, lastly, when made its appearance must be equal to parlour society. I cast about in my mind for a type to work by, but I could remember having seen nothing that just met my needs. The only stands that I was familiar with were the portable folding umbrella-like arrangements and the heavy reading-desk form; but these did not suit me. I required one handsomer than the first, and less cumbersome than the last. So there was nothing for it but thinking the subject out for myself; consequently, donning my studying cap and finding refuge in my studying chair, I began to work, when slowly and phantom-like there arose the image of the stand I wanted. Snatching my pencil I hurriedly sketched its features, and so the more firmly impressed it on my mind; then at my leisure, by the wonderful powers which even the humblest workman





Music Stand. Fig. 1.—Side of Music Rest (half size). Fig. 2.—Stand Complete. Fig. 3.—Side View of Rest. Fig. 4.—End of Sliding Rod in Tube. Lettering in Figs. 2 and 3 is merely intended to show correspondence of parts in each diagram.

possesses, I, by slow degrees, materialised the idea and produced the thought in concrete form. The illustration (Fig. 2) will give a general idea of the stand. It so fully meets all my requirements that I have thought that perhaps others who are both mechanical and musical in their tastes would be glad to get a hint.

I found in working, however, that had I obtained a hint here and there I might have done better and have saved some trouble, and with that view before me I write this article.

As it will be seen, the music rest is somewhat in the form of the conventional lyre. One side (Fig. 1) should be struck out on a piece of cartridge paper the exact size, and then be cut out as a template. If one has practised freehand drawing no difficulty will be experienced; but for those not so experienced I have drawn the side to scale one half size, so by simply doubling the squares any one can draw it full size.

Plane up a piece of mahogany $1\frac{1}{4}$ in. thick, and lay the template on it, and carefully mark it out on the wood. Now, when I got as far as that I was puzzled to know how I should cut wood so thick to the shape. My tools were not very numerous, and I seemed to have nothing more likely to do it with than a fret saw. Consulting a practical man, he said he should just use such tools as he had, and that nothing would answer better than cutting a line of holes with a brace and bit. I was surprised to find how simple my difficulty now became; in a few minutes the two sides were cut roughly to form. With a chisel, spokeshave, and file, the wood should be brought down to the line; let them be worked together that the curves may be alike. Carefully mark where the bar at the top is to be placed, and with a half-inch centrebit bore a hole in each; be sure that the centre of the holes coincides. Draw a line $\frac{1}{4}$ in. each side the hole; up to this line the edges must be rounded off, whilst the one inch containing the hole must be left square; the reason of this will be seen further on. Before the limbs are rounded off, the tenon at the foot must be cut; great care must be observed here, as if they are not alike the lyre will not be true. The base must be 16 in. × 10 in. × $\frac{3}{4}$ in. Draw a central line and mark the place of mortises. When the sides are put in position they must be both perpendicular and in line with each other.

For the top bar, turn down a piece of wood with a pin at each end to fit the holes in the top of the standard. See that the shoulders of the pins are quite square. The sides of this bar must be planed off so that in section it is oval. Glue and pin the bar in its place. The portion of wood at the hole which was left square is now to be cut away to match the top bar; by this means we shall have a neat joint. I overlooked this, and consequently the finish at this part is not so neat as I should like it to be. Our mistakes are not altogether failures, if by them others are taught wisdom.

The distance between the standards, both top and bottom, is exactly 3 inches. Seven holes must be bored or drilled $\frac{1}{2}$ in. apart in the bar and base, sufficiently large to take small brass rods. I made mine of the stoutest brass wire I could get, say about $\frac{1}{8}$ in. Care here too must be observed that the rods stand equidistant and perpendicular. The holes must not be drilled through the bar, but must be put through the base, so that the rods may be pushed up. After we have fitted the parts together, but before the standards are glued in their places, the base must be finished. Cut two pieces of wood the exact length and thickness of the base and $1\frac{1}{2}$ in. wide. The edges of these must be planed off at a small angle, as shown in Fig. 3.

To make a good joint the shooting plane must be sharp and finely set. Perhaps it would pay many an amateur to get the shooting done by a joiner. Take four pieces of the brass rod 3 in. long; flatten down one end for about an inch so as to make it wider and thinner than the other part; file out the hammer marks and polish; on the other end cut a screw thread; now bend them at right angles, and screw them into the edge of the base. They are for the purpose of clipping the music on the stand as on a piano. The edges and corners of the base can now be rounded off, the standards glued in, and all worked off with fine glass paper.

Turn two pieces of wood, one to receive the top of the support or leg with a pin turned on it to enter a block; the other as shown to receive the other part of the leg and the feet. Boring the holes so that the whole thing shall stand perpendicular will, perhaps, be the most difficult part of the whole business.

Feeling this, I took mine, after having turned them, to a joiner. It looked all right whilst he was doing it, but when the thing was put together it was like the tower of Pisa. I turned it now one way and then another, and got it to look true when one was facing the stand, and tried to persuade myself it did not matter for falling over a little in the other direction; in fact, I almost think I went so far as to persuade myself it looked very well. But try as I could *I knew* it was not upright, and that it *ought* to be, so I had no peace of mind until I took it to pieces and rectified it. It is well, I think, to let *ought* rule, not only in the moral, but in the mechanical world. To rectify the matter I did what should have been done before—bored from the opposite end, then, with the humble appliance of a red-hot kitchen poker, I managed to make the hole true.

The leg I made as follows:—

I procured 2 feet of 1-in. brass tube, or, rather, iron covered with brass, and 2 ft. of $\frac{3}{4}$-in. ditto. To make a neat finish to the lower portion, I took a short length, say $1\frac{1}{2}$ inch of brass tube that would fit into it, and turned down one end true. I then soldered this to a disc of brass just a little larger in diameter than the leg; this I put in the lathe and finished off with a central hole to receive the smaller length of the leg. Out of $\frac{1}{8}$ sheet brass I cut a strip 8 in. × $\frac{1}{2}$ in., and bent it in two in the centre and bellied so as to act against the inside of the larger tube. This is fixed to the tube by a pin (Fig. 4). I find in practice that it is quite sufficient to support any weight likely to be placed upon it in the way of music, and is for many reasons, I think, better than having a screw to press against the sliding rod. From a smith I procured three iron scrolls for legs as shown; these are fastened by two screws. If two lugs or ears are welded to the scroll between the screw holes, curved to fit the wooden boss, it will render the legs much more firm. I have shown such ears in the illustrations.

We shall now need a rack for the music to rest against.

Two pieces of wood 11 in. × $1\frac{1}{4}$ in. must be fastened to the base by small hinges; two pieces of wood 9 in. × $\frac{3}{4}$ in. × $\frac{1}{8}$ in. must be riveted to each, with a similar bar riveted to the top. Care must be taken that the distance between the rivet holes in the top bar and in the hinged flap must be exactly the same. The stand is now complete with the exception of painting the feet and polishing the woodwork. When this is done it will be found to be a most useful and even elegant adjunct to a musical home.

"LINING UP."

WITH A FEW CONSIDERATIONS ON ART AND ITS TEACHERS.

MEANING OF "LINED-UP" TOP — LEGITIMACY OF CONSTRUCTION—PRACTICE AND THEORY—WHY PRACTICAL WORKMEN LOOK COLDLY ON THEORISTS—ART OVERDONE—WEAKNESS OF SOME ART DESIGNS—THE WORKMAN AS A JUDGE OF ART PRINCIPLES.

THE meaning of a "lined-up" top is too well known among cabinet makers to require any explanation to any craftsman; but to the amateur, or even the professional critic of woodwork, who, in too many cases, is merely a theoretical individual, neither the technical expression nor the work involved may be understood. Perhaps it should also be added that the amateur critic, even though he be one who poses as a teacher of art principles in books (mostly published at his own expense), will probably denounce lined-up tops as a sham, and therefore to be eschewed by all honest workers. His argument in the main would run somewhat thus:—The effect of lining up being apparently to give thickness to the wooden slab, to make the top of a sideboard, a chest of drawers, or other piece of furniture look thicker than it really is, the operation must be deprecated.

Now, were lining up resorted to with the intention of even tacitly implying that a top so finished is throughout of equal thickness, no justification of the practice could be urged. It would evidently be a dishonest construction contrived for the express purpose of deception. I would, however, ask if those who have the slightest practical knowledge of the subject could possibly be deceived by any lining up, however cunningly it might be done. It can be understood that a person who, in ignorance, jumped to the conclusion that a top is the same thickness as on the moulded edge, and afterwards found out his mistake, might be disposed to imagine that the intention of the worker had been deceptive. Should he, however, on that account blame the artisan or the manufacturer? No; I would rather put it, that owing to his limited knowledge he is merely a living exemplification of the motto, "*Honi soit qui mal y pense.*" He imagined a wrong thing, and therefore concluded that the worker—I refer not only to the artisan who actually manipulated the wood, but to the designer or draughtsman, as the case may be—was actuated with a reprehensible desire to produce something which should convey a false impression. To those who are acquainted with joinery or woodwork in its minor and finer branches, such as furniture making, as distinguished from building and architectural construction, the idea that lining up could be regarded in any other than a decorative detail is so preposterous that it verges on absurdity.

But it may be urged that the foregoing remarks have nothing to do with the practical work of lining up, and that in making them theory has received undue attention. I should be sorry for this, as I conceive that theory is a necessary part of any good worker's technical education. Practical men are met on all sides by theoretical objections to their methods of working, by teachers who, without in any way disparaging or impugning their good intentions, are too often singularly deficient in practical training. I do not now so much refer to manipulative skill as to those numerous considerations by which every man who earns his living by his work, *i.e.*, professionals as distinguished from amateurs, must be influenced. I would ask all artisans engaged in any artistic craft, if it is not because of the neglect or ignorance of the circumstances under which things are made, that many writers on art applied to manufactures fail to produce a good effect; nay, I will even go further and say, that they hinder the spread of technical education and the study of applied art. They excite a feeling of antagonism in the minds of those they would teach by assumption of superior knowledge. They may be acquainted with art principles in the abstract, and so far they are deserving of respect, but when they, at the same time, make statements which every craftsman knows to be incorrect about mere mechanical details, the inference too naturally follows, that the man who holds forth on art and craft knows no more about the one than the other. His influence is gone, and instead of benefit being derived from his acquaintance with and exposition of art principles, harm is done, if not by an outspoken protest, at least by a dogged sullenness which will not listen to anything bearing on art. Now this should not be. It is a lamentable state of affairs, but is it not true? Why is it that the craftsman does not respond so freely as those who wish to, and doubtless can teach him much, would like? Why are the efforts, often, I must confess, put forth in all sincerity, not responded to with more cordiality? Is it because the artisan—please note I do not use the word "working man" or "mechanic," but artisan, the artist worker—is so sunken that he will not learn? or is it that he imagines he has nothing to learn beyond the "bread and cheese" portion of his trade? Truly, one not acquainted with the workers, the artisans, the designers, the employers of artistic skill, might excusably think so, if only the utterances of the professional æsthete be regarded. I unhesitatingly say, that were our would-be teachers a little more familiar with the every-day requirements of practical work, with its demands, with its commercial considerations, and if they would regard these when endeavouring to raise the standard of our artistic productions, they would have no reason to complain of having the cold shoulder turned to them. Is that not so, my brother working men, fellow craftsmen, even though we may work in different departments? Would any one of us object to learn from any source whatever anything that could improve our manufactures? I venture to say no; but we are not inclined to learn from any one who dogmatises on art, and at the same time shows his ignorance of practical work, or what I have called the mechanical details of work. Can we do anything but laugh at the art professor who wants to lecture to craftsmen, not boys at school, but grown-up men who must *work*, not play, and because they won't attend his *afternoon* classes thinks them apathetic? The professor in question might have got men to listen to him had he suggested *evening* lectures, but even then surely it would be more charitable to suppose that though the spirit is willing the flesh is weak, and that men do get too tired to listen to theory after working all day, instead of charging them with indifference to refining influences. If they did an honest day's work, doing that which their hands found to do with all their might, surely that was better than listening to "art" talk, most of it, without doubt, very incomprehensible. We, who have any practical experience of the exigencies of work, know too well that the real cause why artistic productions are not more common is not because the worker will not or cannot take the necessary pains, but because the public, *i.e.*, the purchasers, will not encourage them. No, they will sneer at the modern worker, advise him, but they will not pay a fair price for good honest work, and none are greater sinners in this respect than the so-called patrons of art. This may seem a serious charge, but I would ask any artistic tradesman if it is not unfortunately too true. Let him put his best work into any preliminary design, and how often is he not mortified by the huckstering spirit that shows itself in the patron. This, however, is by the way.

No one recognises more readily than I do that both the worker and the theoretical exponent of art occupy legitimate places in the sphere of labour, and it is much to be regretted that they do not sink, if possible, their differences with the view to acting more in harmony. The workers have to some extent been benefited by the teachings of the professors and writings of those who have opportunity of becoming students of art, though not of applied art, but their efforts have been dwarfed by their having failed to grasp the conditions under which things are made. Art is just now the fashion, and is being done to death; attention to art is very well in its way, but in urging its claims many who are enthusiasts, either from love of it or for monetary considerations, are tending to produce a revulsion against it among our actual workers, upon whom after all its application principally depends. Let them take a friendly word of warning, and not cause these to loathe the very name of art by their insistence on it as being the end and aim of every manufactured article.

Surely, a thing, whatever it may be, of any artistic merit should not proclaim the art or artifice by which it is vulgarly recognised as an artistic production. If we look at the stilted affected designs which one sees occasionally bearing the names of leaders of public opinion on art, the bewildered student, who with an intuitive perception that truth and honesty of purpose are the true principles on which art is founded, may well be disposed to think the contrary.

Now all this may seem dreadfully "Philistine" and to proclaim the outer barbarian, but artisans in whatever craft I ask you is it not time that we should have our say in the world of art? The literary art student, or, if he prefers it, art worker, has, from circumstances which need not be enlarged on, hitherto almost alone had the ear of the public, but now that we have WORK, a real technical journal not devoted to any one branch of labour, and in which professional and amateur meet on common ground, it will be our own fault if, however feeble our pens, we do not give forth our opinions. We, whatever our trade or craft, have opportunities of being familiar with its practical side, and to give the British worker his due, he is not so deficient in intelligence as to be necessarily one whit behind the theorist in true perception of art principles and their application to his own special avocations.

On these grounds I have, therefore, ventured to digress to some extent from the practical consideration of "lining up," and I can only hope that none of the foregoing remarks will be in any way misconstrued to mean that due attention should not be given to art in relation to manufactures, only it must be done in a manner consistent with common sense.

(*To be continued.*)

THE TENANT'S GREENHOUSE.

UNATTACHED TO THE SOIL AND REMOVABLE AT PLEASURE.

BY GEORGE LE BRUN.

FRONT END OF HOUSE—DOOR—RIDGE BOARD—ROOF SASHES—FINIAL—IRON STAYS—FLOOR—SHELVES OR STANDS FOR PLANTS—DISPOSAL OF RAIN-WATER—PIT FOR SURPLUS WATER.

THE front end of the house is put together in a similar manner to the back (as described in the previous paper), but two upright pieces are required, and they are placed at a sufficient distance apart to admit of a door 2 ft. wide being hung between them. This door is lined with matchboards in the lower panel to correspond with the rest of the house; the upper part is filled in with glass, a sash bar dividing it into two panes. The door stiles are cut away above the belt rail to a width of $2\frac{1}{2}$ in. in the usual glass-door manner. The wood for the door should be $1\frac{1}{2}$ in. thick, and a suitable width would be 4 in. for the stiles and top rail, and 7 in. for the belt and bottom rails. The door is best hung to open outwards, as it is then out of the way when attending to the plants. Fig. 10 shows the framing of the front end, in the square opening of which, above the door, a fanlight is hung on pivots.

A ridge board is now put on of 7-in. by $2\frac{1}{2}$-in. wood; it must be bevelled on the top edge to the rake of the roof, and, when in position, project the thickness of the roof sashes above the framing of the house ends. It is secured by means of iron plates, two at each end, screwed on as shown in Fig. 11. A fillet 1 in. square is put along the entire length of the ridge board on each side for the sash ends to rest on. (A, in Fig. 11.)

The roof sashes come next. They are made in four sections, two for each side, and project two inches over each end of the house, and the same distance over the sides; the four end stiles must therefore be 6 in. wide. The inner stiles may be $3\frac{1}{2}$ in. wide; they are grooved on the upper side to allow of the water running off, and so preventing leakage to the inside; a bead covers the joint, and projects midway over these grooves. This mode of jointing is shown at Fig. 12.

The finishing of the ridge is given at Fig. 13, and a design for cutting an ornamental ridge board of a simple and easy design at Fig. 14, Fig. 15 being an alternative design for the same purpose, which, however, is far better fitted to be cut in zinc than in wood. A finial is placed at each end of the ridge to form a finish; it may be of any design to suit the builder, from a simple piece of turned work to an elaborate octagonal, a design for which is given at Fig. 16.

Two iron rods are put across the house in the inside, about 4 ft. from each end, one end of the rod having a snap head and washer, the other a nut and washer to allow of tightening up. These rods are best put through the top rails of the framing; they prevent any tendency of the sides to spread from the outward thrust of the roof, and they can be utilised to hang pots or baskets from.

The house being put together, the inside demands our attention, and the first call upon it is the floor. Now we will eschew wood, it holds water and rots easily, and utilise whatever may be most handy in the way of concrete slabs, slate, or cement; in any case we will require joists, or sleepers rather, of 5-in. by 2-in. wood, cut to fit between the sides of the sill, and levelled down so as to come even with the top side of it. If concrete slabs are used for the floor, the sleepers must be put at sufficient distances apart in order that the edges of the slabs may rest evenly upon them; while, slight fall towards the closed end of the house, from which end of the gutter a pipe, $1\frac{1}{4}$ in. diameter, is taken inside (by boring the end sash stile), and led into a tank or cistern underneath the table. This tank will have a tap from which to draw a supply of water when required, and an overflow pipe to carry off surplus water, and so prevent any chance of flooding the house in the event of a very heavy rainfall. This overflow pipe should be 2 in. in diameter, and may be led into the nearest drain, or, if that is inconvenient, a large hole may be dug in the garden and filled with broken bricks to within a little of the surface; over the bricks lay a few boards, and level up with earth. The overflow pipe should be dug in the earth about 4 ft. deep and 30 in. in diameter. The pit should be filled up to about half its depth with brickbats thrown loosely in one on the other. On this some brushwood should be thrown to prevent the entrance of the earth, with which the pit is filled up, and a 2-in. drain pipe should be set in the earth extending from the surface of the ground to the brickwork. The free end of the overflow pipe should be introduced into the drain pipe, and the mouth of the latter closed round the pipe with cement or some other suitable material.

Pits made and filled in this manner are most effectual for carrying off surplus water,

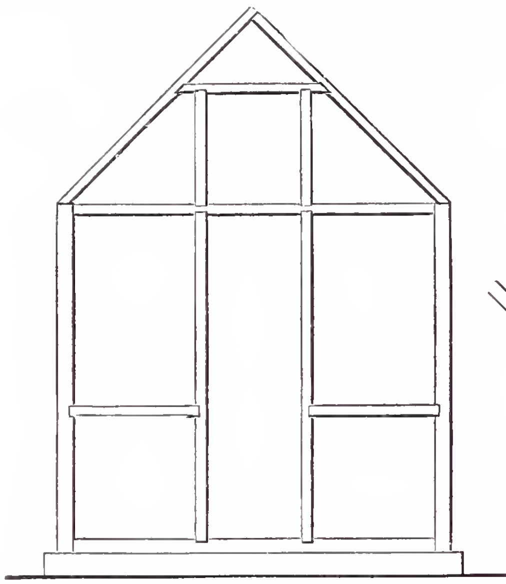


Fig. 10.

Fig. 14.

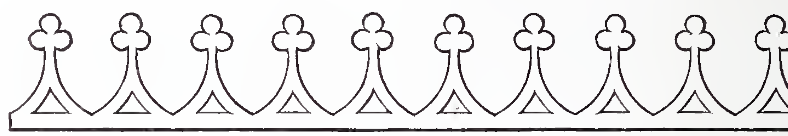

Fig. 15.

Fig. 16.

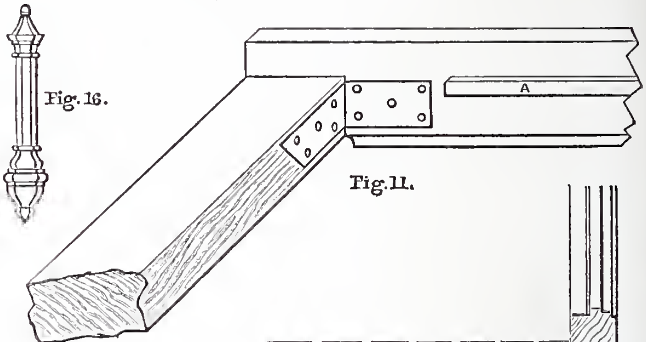

Fig. 11.

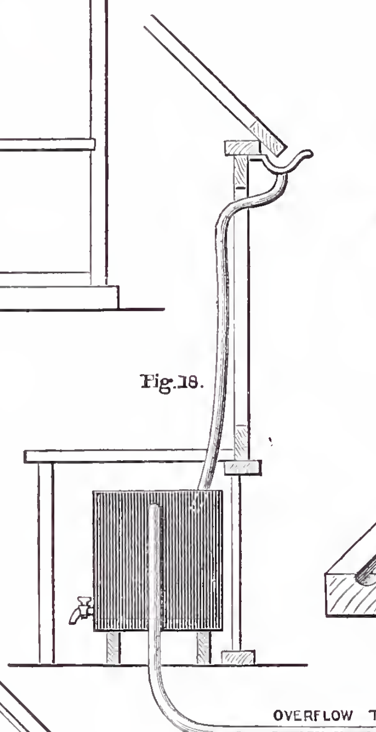

Fig. 18.

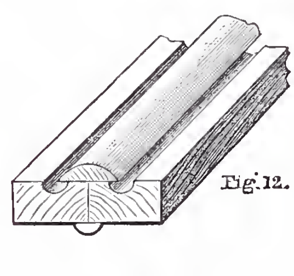

Fig. 12.

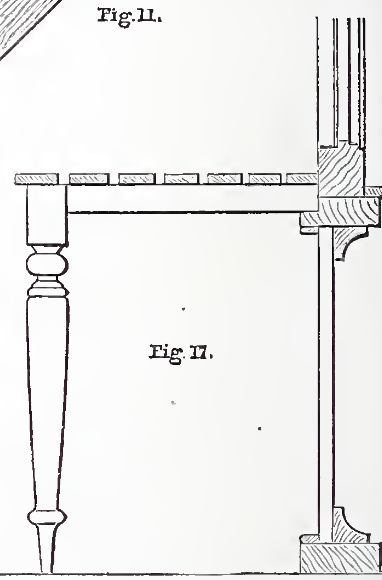

Fig. 17.

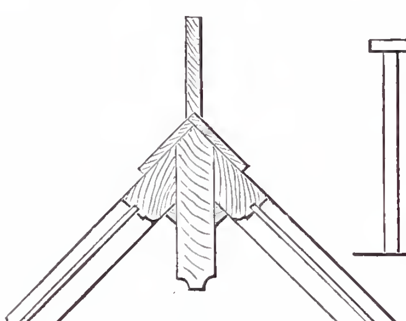

Fig. 13.

Fig. 10.—Elevation of Framing of Front End. Fig. 11.—Mode of Putting on Ridge Board. Fig. 12.—Details of Joint of Roof Sashes. Fig. 13.—Details of Ridge in Section. Fig. 14.—Cut-out Ridge Board. Fig. 15.—Alternative ditto. Fig. 16.—Octagonal Finial for End of Ridge. Fig. 17.—Details of Inside Shelves. Fig. 18.—Section showing Cistern for Rain-water with Mode of Collecting and Disposing of Overflow.

if a cement floor be decided upon, rough slates or boards can be utilised to form a bearing for it, and the sleepers put in accordingly.

The width of the greenhouse (8 ft.) allows of shelves for plants nearly 3 ft. wide along either side, and the mode of supporting these tables is given at Fig. 17. One leg only is used, the inner end of the support, or table rail, resting on the belt rail of the house, into which it is checked and screwed. The shelves are spanned with 3-in. by 1-in. stuff about 1 in. apart.

Instead of allowing the rain-water from the roof to run off on to the ground and go to waste, it can be utilised for watering the plants with, and so we will run a neat zinc gutter along each side of the roof, having a may then be led into this hole, which will absorb all the surplus water that is likely to reach it. A sketch of this cistern arrangement is given in Fig. 18, in which only the pipe from one gutter is shown; the pipe from the other gutter is taken inside the house in the same way, brought down under the table, and led under the belt rail of the framing across the end of the house to the tank. A large tub or barrel can be used instead of a square tank if it is found to be handier. The overflow pipe must be led under the house before the floor is laid down, or it may be taken out through the end if that method suits best; in fact, many minor alterations can be made to suit individual tastes.

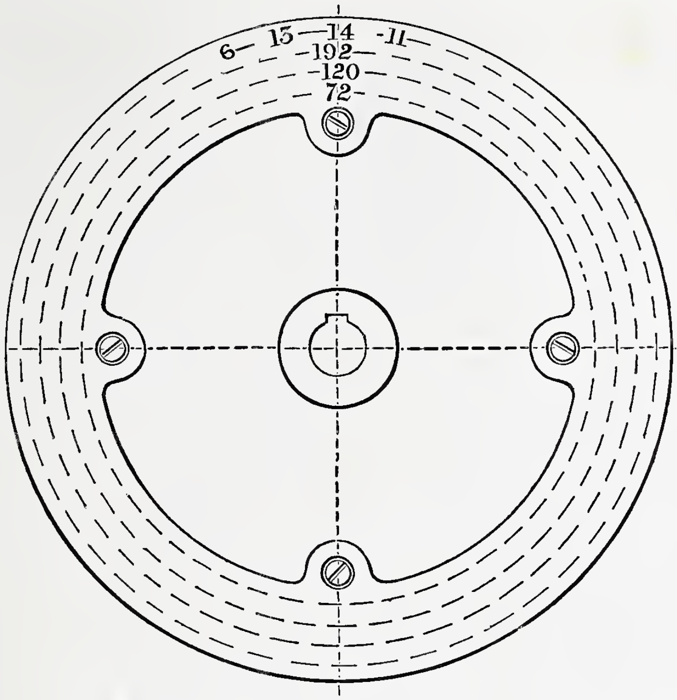
To get rid of the surplus water, a pit and by the interior arrangement described water for the plants is always at hand except in very dry seasons, when showers are few and far between, and any dirt or annoyance from drip round the house is utterly prevented.

LATHES AND TURNING APPLIANCES.

BY F. A. M.

VI.—The Worm Wheel and Tangent Screw.

When wheel cutting is to be done by means of the division plate, it will often be found that the required number of teeth cannot be produced by means of any of the circles at command. Clockmakers' dividing engines, which have large horizontal division plates, on which are drilled a large number of circles, may contain every number that is at all likely to be required in clockwork, but the 5-in. lathe pulley cannot well contain more than six or seven circles; and if the table given with the paper on the division plate be examined, it will be seen that none of the eleven circles of holes given there can be divided by the prime numbers 11, 13, 17, 19; yet this table is only carried up to 20. Had it been continued still further, many other numbers would have been found which would not go exactly into any of the eleven circles of holes; and therefore it would have been difficult, with these numbers only at command, to cut wheels having 11, 13, 17, 19, etc., teeth. The worm and wheel about to be described may be considered a universal dividing engine, inasmuch as that, with a little contrivance, it will cut any number of teeth whatever.



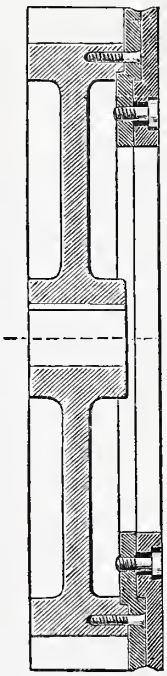


Fig. 26.—Worm Wheel and Gear Wheel: Front View. Fig. 27.—Ditto: Section.

In ornamental turning it will not be necessary to go beyond the powers of the division plate to find an unusual number. Yet the worm and wheel, otherwise called the tangent screw movement, with segment stops, is of as much importance as in metal work, because it provides for a very slow movement of the mandrel, and also enables the workman to confine this movement between two circular stops, called segment stops, so that he can drill or cut out only part of a circle. Fig. 24 will give an idea of the way in which the tangent screw and worm wheel is generally arranged upon the ornamental turning lathe, where there is no back gear. There is a circular fitting upon the small end of the pulley, accurately turned, and the worm wheel has a shallow recess which fits upon this, and then the two are fixed by screws put in from the left. The tangent screw is underneath, and it is turned by the upper one of the two square heads seen. The lower square commands an eccentric, by means of which the frame carrying the screw can be raised, so that the screw will gear with the wheel, or can be lowered out of the way when the band is in use.

The writer's lathe is fitted with back gear, which made it inconvenient to attach the worm wheel as in Fig. 24; also the bolt upon the face of the large gear wheel (by means of which this wheel and the pulley are caused to revolve together) does not clamp them immovably, and might even come to allow a little shake between the pulley and wheel. It was therefore necessary to attach the worm wheel to the large gear wheel in front of the pulley (see Fig. 25). The worm wheel cannot well be less than ⅝ in. thick, and there may be some difficulty in getting it in; but it will certainly

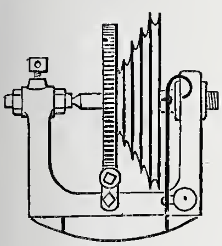

Fig. 24.

be impossible to get the tangent screw in beneath it. However, its frame can be easily fitted into the ball of the index peg, which will suit very well, since they will not both be used at once. Besides, it will be very easily removed and put away for safety when not wanted.

It would be difficult to fit such a worm wheel into one's own lathe without a second lathe to work with. It would be still more difficult to cut the teeth of the worm wheel perfectly. The amateur is not advised to attempt that part of the work; he may have a worm wheel fitted and cut for about 50s. He can then correct it himself, make the tangent screw and frame, and then, by means of the worm wheel, he can drill the front as a division plate. This is the work now about to be described, not, however, with quite so much detail as the former paper contained, since no one should attempt such a piece of work who is not already something of a workman.

Figs. 26 and 27 are a front view and section of the front gear wheel of a 5-in. back-geared lathe, showing how the worm wheel was attached. The worm wheel is 7 in. in diameter, and the ring is rather less than 1 in. wide. (It would have given room for plainer figures if it had been $1\frac{1}{4}$ in. wide.) There are four rows of holes. The *first* is $6\frac{5}{8}$ in. diameter, and it has holes which divide it into 6, 11, 13, and 14 equal parts. Six is contained in the other circles, but it is often required, and is easier to pick out quickly in this circle. Every hole of the 6, except the zero or starting hole, is marked with a (6), so that it is easy to pass from one to another. Every hole of the 11 divisions is marked (11), and every hole of the 13 but the first (13); every hole of the 14 divisions (14). The first or zero hole is not marked, as it is easy to pick that out, and from it to divide the circle into 2, 3, 6, by the 6 divisions; 7 or 14 by the 14; and 11 and 13 besides. Thus you only have to keep to the holes marked 11 for 11 divisions, or to those marked 13 for 13, etc.

All the holes are about $\frac{1}{12}$ in. in diameter, so that it would not have been possible to divide still further the same circle into 17 and 19 without the holes clashing, *i.e.*, cutting one into another in certain places. The *second* row of holes contains 192, which contains multiples of 8 and 12; also it is twice 96, and it is much used in "double counting." The figures 192 are stamped over the zero mark of this row, and numbers are placed at every 12 holes, dots above (or outside) the holes at every third, and inside opposite every fourth hole. The circle is $6\frac{1}{4}$ in. diameter. The *third* row has 120 holes, chiefly useful because it enables one to divide the circle into 5, 10, 20, etc., divisions. It is therefore figured at every twelfth, and has a dot opposite every sixth and third hole. This circle is $5\frac{5}{8}$ in. diameter. The *fourth* and last circle contains 72 large holes, about $\frac{1}{5}$ in. in diameter and $\frac{3}{8}$ in. deep. These are intended to hold the segment stops—little steel pegs which fit the holes, and project from the plate about $\frac{3}{8}$ in., so as to meet and be arrested by the head of adjustable fixed screws, and so confine the revolution of the mandrel within certain limits. There is, however, a short shoulder upon the index peg (described before, see Fig. 6, page 92), which fits into these large holes, and allows of their being used in connection with the index, which is useful, because 72 contains 9 and 18, which the others do not. It is marked at every eighth and fourth hole.

Looking at Fig. 4, it will be seen that the worm wheel is made as two flat rings, which are screwed together by four cheese-headed screws passing through four lugs or ears inside the rings. The first ring is strongly riveted by six rivets to the gear wheel, after having been carefully fitted to the circular fitting. It has itself a circular fitting, into which the second half of the plate must fit very exactly. The four screws are, however, purposely fitted with a slight amount of play in the plain holes, so that they shall not control the set of the second plate upon the first half. It is, however, confined by the circular fitting, which ensures the two halves remaining rigidly concentric. The gear wheel, with the worm wheel attached, should now be chucked perfectly true in a wheel-cutting engine, and the edge cut with 240 teeth, inclined to an angle of 2°, which will leave them very nearly 11 to the inch, the pitch of a $\frac{5}{8}$ Whitworth bolt. At this point the amateur may take the work in hand himself.

First take out the four screws, turn the front plate half round, and replace them, taking care to examine the fit or correspondence of the teeth all the way round; when this correspondence is as near as possible, fix the screws, and then you will see how near to truth your worm wheel is. Dividing engines are not perfect; of course, too, it is very easy to chuck the worm wheel a little out of truth, which would cause the teeth to be closer together on one side than on the other; and you will very likely find a tooth edge projecting $\frac{1}{50}$ in. in one direction one side, and $\frac{1}{50}$ in. in the opposite direction on the other side of the wheel. Observe carefully whether you have "split the difference;" if not, release the four screws, and do so.

Here it may be pointed out that as one object of the four screws is to enable one to fix the outer plate in four different positions upon the inner so as to equalise any error in the spacing of the teeth, it is necessary that the number of teeth chosen should be a multiple of (*i.e.*, divisible by) four: for instance—had we to deal with seventy teeth we might have turned the plate half round and found the teeth correspond, but if we had turned it one quarter round, their edges would have been "at sixes and sevens."

The tangent screw or worm, with its frame, will now be described as seen in detail in Figs. 28 and 29, its application to the headstock appearing at Fig. 25. A is the frame, a casting of brass, cast with a projection, B, shown dotted at the lower end of Fig. 28, intended to aid in the chucking, and cut off as soon as the turning is finished. File up the back or straight flat side of the casting, then measure the distance, *D*, on your lathe from side of ball to centre of worm wheel, subtracting $\frac{1}{8}$ in. from that distance, scribe the height of the centre of tangent screw on both ends of the casting as it lies on the flat back, and also on the lug, C, Fig. 28; now file up one side of the casting, and, laying it on that side, scribe across these lines to get the centres for the screw and for turning and boring the piece. Punch and bore centres at both ends, put the work in the lathe with B against the running centre, and turn up the neck, D, Fig. 29; round the shoulder, substitute the boring collar for the back centre, and bore and screw the hole for the coned bearing, F; now drill the hole at C for $\frac{1}{4}$-in. Whitworth screw, putting the drill in through the collar on to the punched mark made where the scriber marks cross. This is to ensure the hole at C being in line with the spindle when fitted into F. Take the piece out of the lathe, cut off the projection, B, and tap the hole at C from that end. Now turn the coned bearing, F, of brass, not forgetting the short conical shoulder, which is quite essential. Turn up the spindle, G, fit F upon it, at first tightly, so that you can turn up the outside of F, and thread it; or it may be driven on another mandrel; or, better still, the neck, D, might be cast so much longer that the piece, F, might be turned there, bored out, screwed, and cut off, and then the part, A, screwed to fit it. Make two long ferrules, H, to fit into G; both should be threaded alike with eleven threads to the inch and both of cast steel, one of these to have oblique grooves filed out to form it into a kind of hub; it is then hardened and used to equalise the teeth of the worm wheel and bring them to fit the plain screw. Make the small centre screw and nut at C and harden its point; turn the piece, J, of steel, fit the point into the index ball, and fit it into the frame with a $\frac{3}{8}$-in. screw. The piece, K, screws into the base of the headstock just like the ball, and through it goes a $\frac{1}{4}$-in. screw with a milled head and pointed end, which takes into J and ensures that the frame shall be held firmly and without shake; the piece, K, should be far enough away to allow J to pass it when the frame is taken out of the ball, otherwise K would have to be removed every time. Now make the ball, M, so that the screwed end of N shall come opposite the casting of the headstock, where the $\frac{1}{4}$-in. tapped hole, P, Fig 30, is bored to receive it; see also Fig. 25. It is by means of the milled head on the screw, N, that the frame with the tangent screw it carries is brought into close contact with the worm wheel, or released so that it can be turned down or taken out altogether. At Fig. 30 are seen the segment stops, S, S, in the innermost row, consisting of large holes. At Q is seen a forging firmly screwed upon the top of the headstock; it leans backward so as nearly to touch the face of the division plate, and it carries two capstan-headed screws, R, R, easily adjusted, against which the segment stops abut: the piece, Q, is not in the way, and remains where it is even when not in use.

We now come to the most interesting part of the apparatus. The top of the frame and spindle, G, rise clear of the worm wheel, and enable us to fit a large collar, T, of which there are several, on to the circular fitting D, which keeps it concentric with the spindle; these collars have small binding screws to fix them in any position. On the upper end of the spindle, G, goes a spring handle, V, secured by a binding screw; the arm of V is made of a bit of the blade of a hand saw, and the square hole at the large end is riveted firmly into the boss; there is a little steel rounded pin riveted into the middle of the blade just over the edge of the cup-shaped collar, which pin acts, in fact, like a short index peg, for it can drop into shallow holes in the edge so that the handle can receive one or more turns exactly, or half a turn, one-third, one-fifth, etc., or one and one half, two and one third, etc. etc. By slightly lifting the little knob-handle as it is turned, the spring bends enough to allow the little peg to pass without touching. Make any number of these collars you think you may require, say five; fit each on to D, turn it up, and divide the edge by drilling 5, 7, 11, 12, 13 shallow holes, one row in each collar; provide each collar with a fixing screw, and lay them aside.

To equalise the teeth of the worm wheel, drive the hardened ferrule, H, upon the spindle, and fix a small pulley upon the upper end of the spindle, so that you can drive it from the overhead motion, then bring up to cut by turning the screw, N, and take care that the mandrel is quite free to revolve, as it must do, while the cutting is done. Continue cutting till the mandrel has made several revolutions and till the teeth of the worm wheel are touched almost all over; then take out the four screws, turn outer plate half round, and repeat the cutting; then return to the first position and cut again, then to second position, till the teeth coincide in both. After this turn plate one quarter round and continue the process till the teeth correspond in all four positions; be patient here, and persevere, for a week if necessary, and when you have got it right you will have made a most valuable addition to your lathe.

Now the holes of the division plate may be drilled upon the front of the worm wheel. A drilling spindle and overhead motion will be required, also a slide rest. Make a very short drill, which should be turned up *in its own drilling spindle* to an angle of about 18°; it need not project more than $\frac{1}{4}$ in., so as to be as stiff as possible. The drill is shown enlarged at Fig. 31; it is flat, point of the usual form, but sides bevelled off with the file, then hardened and sharpened on an oil-stone; try it on a spare bit of brass, and when it cuts perfectly be very careful not to break it till the whole of the work is done. You will require a second and larger drill made to a sharper angle for the larger holes. The small holes may be $\frac{1}{8}$ in. deep and $\frac{1}{12}$th diameter at the mouth. There must be a stop on the slide rest to regulate the depth, so that each hole will be of the same size and depth.

The principle on which the divisions are obtained must now be explained. If between every hole the tangent screw were given one turn, then, since the worm wheel has 240 teeth, and at every turn of the handle the screw passes one tooth, therefore we should divide the circle into 240 divisions, and the last turn would cause the drill point to drop again into the first hole. Evidently, if between each hole we gave the screw 2, 3, 4, 5 turns, we should get $\frac{240}{2}$, $\frac{240}{3}$, $\frac{240}{4}$, $\frac{240}{5}$ numbers of holes=120, 80, 60, 48 holes; on the other hand, if we give $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, $\frac{1}{5}$ turns, we get

$$\frac{240}{\frac{1}{2}},\ \frac{240}{\frac{1}{3}},\ \frac{240}{\frac{1}{4}},\ \frac{240}{\frac{1}{5}},\ = 480,\ 720,\ 960,\ 1{,}200$$

holes. Therefore, whatever number of holes or divisions you wish for, divide 240 by that number, and you get the turns or part of a turn of the handle of the tangent screw which you must make between each cut.

Applying this rule to the numbers chosen for our division plate (see p. 153), we have

$$\frac{240}{72}=3\tfrac{1}{3};\ \frac{240}{120}=2;\ \frac{240}{192}=1\tfrac{1}{4};\ \frac{240}{14}=17\tfrac{1}{7};$$

$$\frac{240}{13}=18\tfrac{6}{13};\ \frac{240}{11}=21\tfrac{9}{11};\ \frac{240}{6}=40;$$

so that to divide the inner circle into 72 we must between each hole give the tangent screw $3\frac{1}{3}$ turns, and the use of the divided collars becomes apparent.

In the same manner the tabular statement just given shows the number of turns that must be given to the tangent screw between each hole in order to divide the inner circle into 120, 192, 14, 13, 11, and 6. I have endeavoured to make the explanation as clear and complete as possible, and I do not see how it could well be made plainer; still, if any reader fails to understand anything that has been advanced, I will endeavour to give him fuller information through "Shop."

The following table shows how many turns are required for any number up to 50:—

Divisions.	Turns.	Divisions.	Turns.	Divisions.	Turns.	Divisions.	Turns.
2	120	15	16	28	$8\frac{4}{7}$	41	$5\frac{35}{41}$
3	80	16	15	29	$8\frac{8}{29}$	42	$5\frac{5}{7}$
4	60	17	$14\frac{2}{17}$	30	8	43	$5\frac{25}{43}$
5	48	18	$13\frac{1}{3}$	31	$7\frac{23}{31}$	44	$5\frac{5}{11}$
6	40	19	$12\frac{12}{19}$	32	$7\frac{1}{2}$	45	$5\frac{1}{3}$
7	$34\frac{2}{7}$	20	12	33	$7\frac{3}{11}$	46	$5\frac{5}{23}$
8	30	21	$11\frac{3}{7}$	34	$7\frac{1}{17}$	47	$5\frac{5}{47}$
9	$26\frac{2}{3}$	22	$10\frac{10}{11}$	35	$6\frac{6}{7}$	48	5
10	24	23	$10\frac{10}{23}$	36	$6\frac{2}{3}$	49	$4\frac{44}{49}$
11	$21\frac{9}{11}$	24	10	37	$6\frac{18}{37}$	50	$4\frac{4}{5}$
12	20	25	$9\frac{3}{5}$	38	$6\frac{6}{19}$		
13	$18\frac{6}{13}$	26	$9\frac{3}{13}$	39	$6\frac{2}{13}$		
14	$17\frac{1}{7}$	27	$8\frac{24}{27}$	40	6		

Remembering that our collars are divided into 5, 7, 11, 12, 13 divisions, and looking through the fractions in the list, we find we could divide into any of these numbers except 17, 19, 23, 27, 29, 31, 34, 37, 38, 41, 43, 46, 47, 49. Now, although these numbers, and those others which would be discovered to be beyond our range if the list were continued, might, very likely, never be required; yet these, and, in fact, any number whatever, can be obtained by a little trouble. Take, for instance, 239 divisions, one short of 240; here it would be necessary to give between each cut $\frac{240}{239}$ turns, that is, one whole turn and $\frac{1}{239}$th of a turn. This is an extreme case, but it could be managed by making or buying a paper scale having on it 239 divisions of about $\frac{1}{32}$ in. in length, so that the length of the strip would be some 8 or 9 in., the circumference of about 3 in. Take the dividers set to about $\frac{1}{32}$ in., and step them along the edge of a piece of paper, cut off the strip when you have made 239 marks, and your strip should be about 8 in. long. Now prepare a collar of hard wood, fit it upon D, and then carefully reduce its external diameter, till the strip will just meet round the edge; fix it there with fine pins or tacks (gum might alter its length). Now between every cut make one whole revolution and one division. By carrying the divisions on to the upper surface, and making a mark on each one as it is used, mistakes may be avoided. The general rule would be, divide 240 by the number of divisions required, reduce the fraction if possible, let the collar be divided into a number of divisions equal to the denominator, and count between every cut as many of these divisions as you have units in the numerator.

The apparatus just described will divide into as many divisions as are likely to be required with great convenience, and, with a little trouble and contrivance, it will divide into any number whatever. It will serve also to give a very slow motion by hand to the mandrel, which is often of great use. It is often quicker to use than the division plate, since one turn of the handle, two turns, or three, or one and a half, for 240, 120, 80, 160 divisions, can be given more quickly than the index peg can be moved, and with less chance of error. The tangent screw must, of course, be held close up, so that there can be no possibility of shake between it and the wheel, and then the work will proceed with certainty and despatch.

I have now put my readers who are given to lathe work in possession of much information on Lathes and Turning Appliances that, I trust, will be useful to them; and here I shall stop, for the present at all events, leaving other appliances for consideration, if required, at some future period.

JAPANESE MOTIVES FOR FRET CUTTING, STENCILS, AND SIMILAR PURPOSES.

Illustrated from Native Books.

BY J. W. GLEESON-WHITE.

II.—Of Flower and Insect Forms.

In the former chapter of this paper enough was said of the general laws of Japanese art, but little of the possibility of using it upon English articles; and yet this is a very pertinent aspect, for while there are objects that may be embellished with direct copies of Japanese ornament, others are so emphatically European in their shape and purpose that the Eastern decoration fails to combine with them, but tells distinctly as applied ornament, that might be removed with no great loss to the article so treated. For example: a modern coal box, spatter Japanese birds all over it as you will, looks always what it is; yet in such an extreme case I think a little modification of the accepted shape might bring the discordant qualities into harmony.

In woodwork—more particularly the subject to-day—we notice that the Japanese almost entirely eschew our conventional mouldings, prefer square posts to turned ones, are content to let a square rod end with a simply cut-off finish, not always longing for a little knob to decorate it. They know eminently where to leave off, and in all art the best artists have recognised the value of this critical quality.

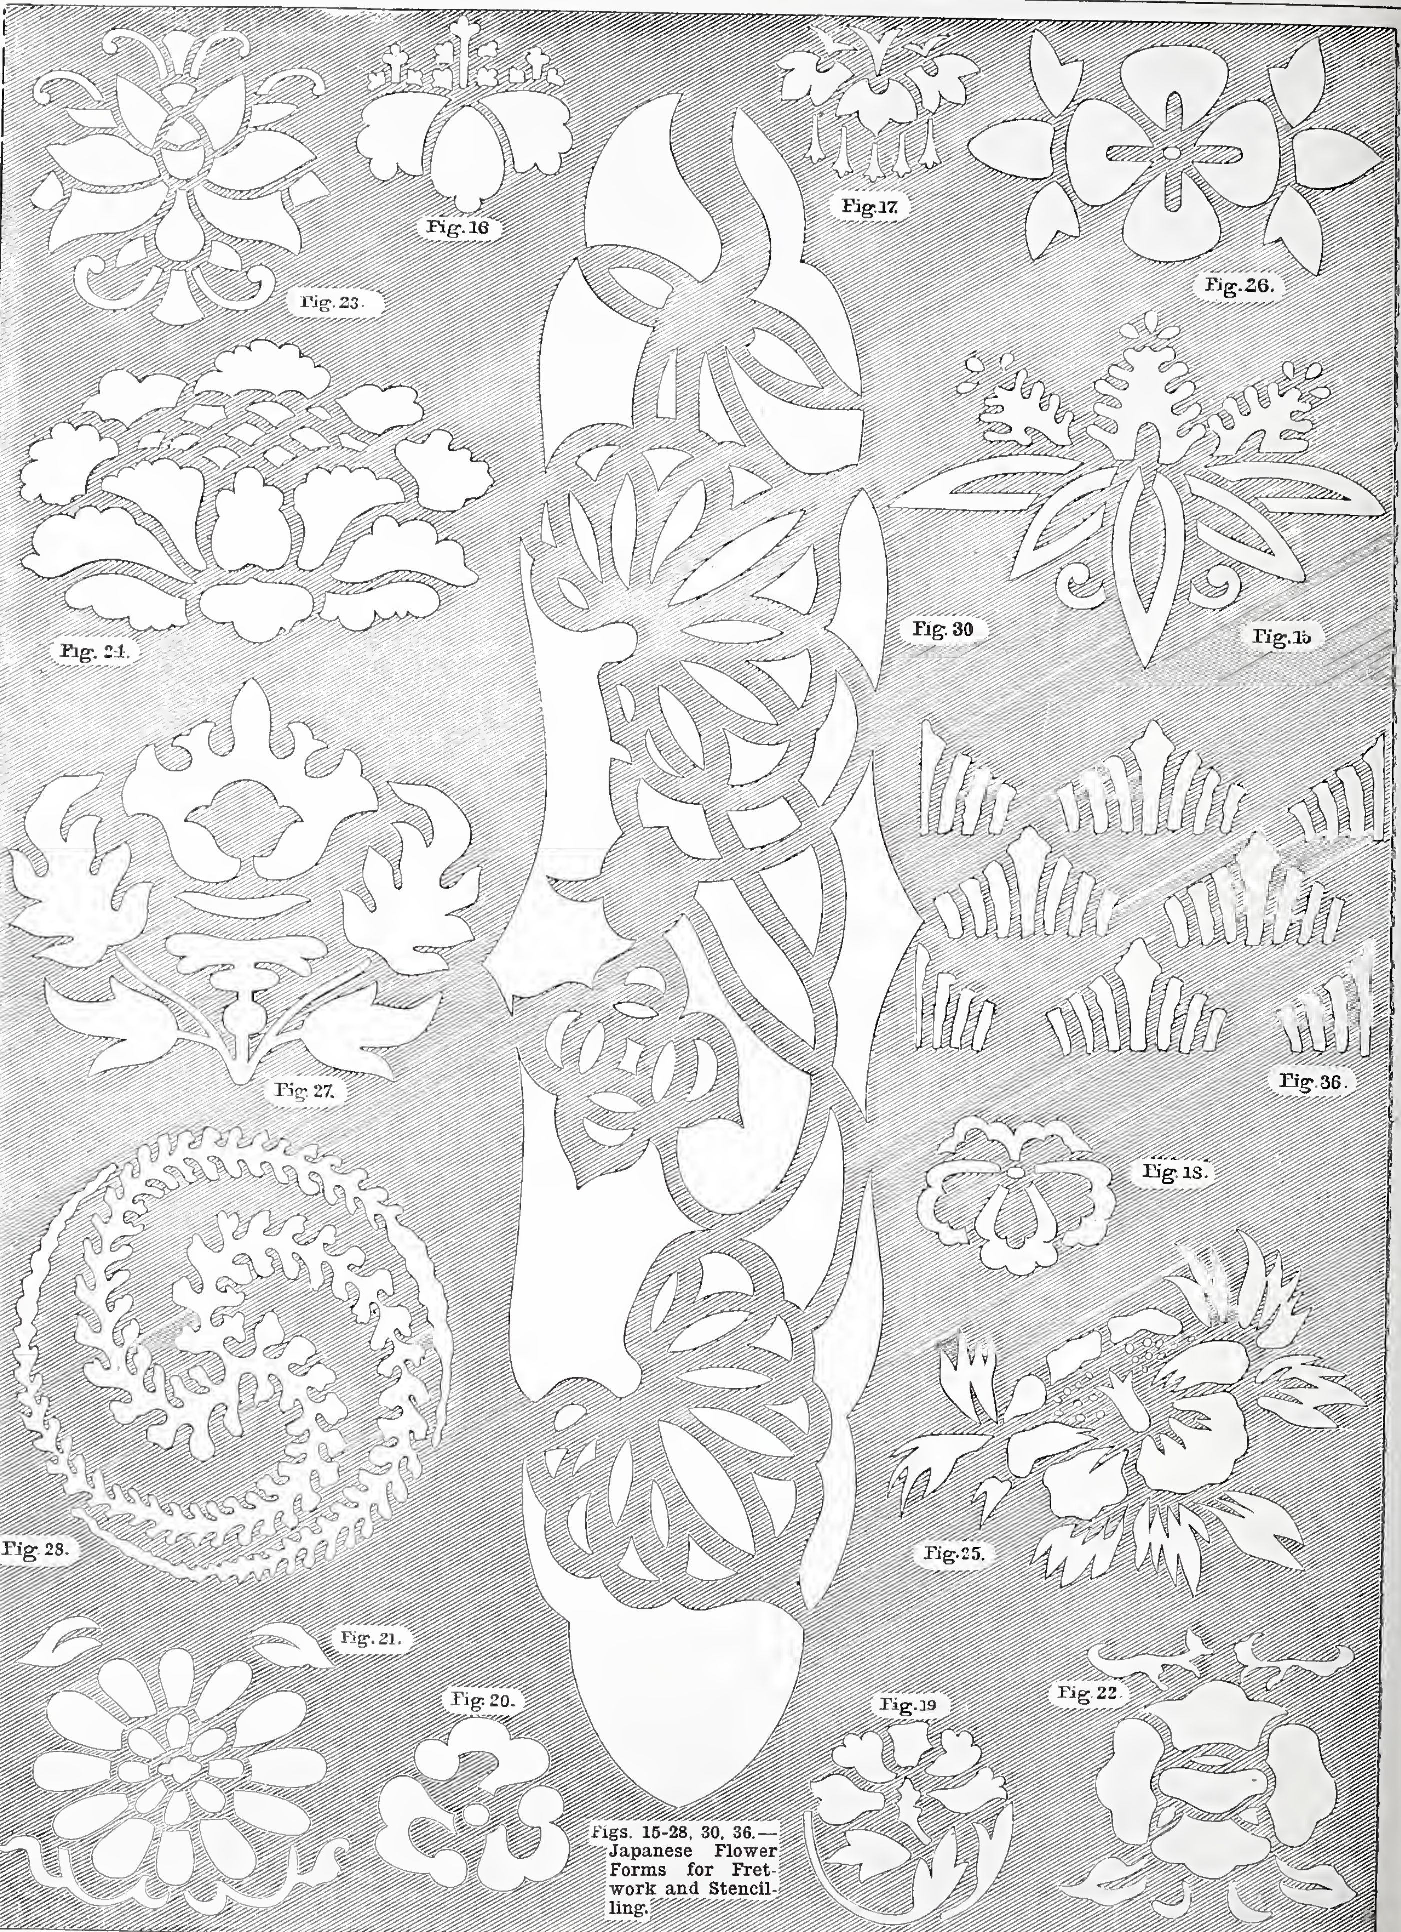
Suppression and reticence serve to display the beauty of the rest. If you lavish ornament on every part, like much modern Indian carving, the whole thing becomes a mere excrescence, and kills itself.

The value of an undecorated portion to give repose and breadth to the whole work, be it a palace or penwiper, is a quality worth trying for, and more truly artistic than any other, be it what it may.

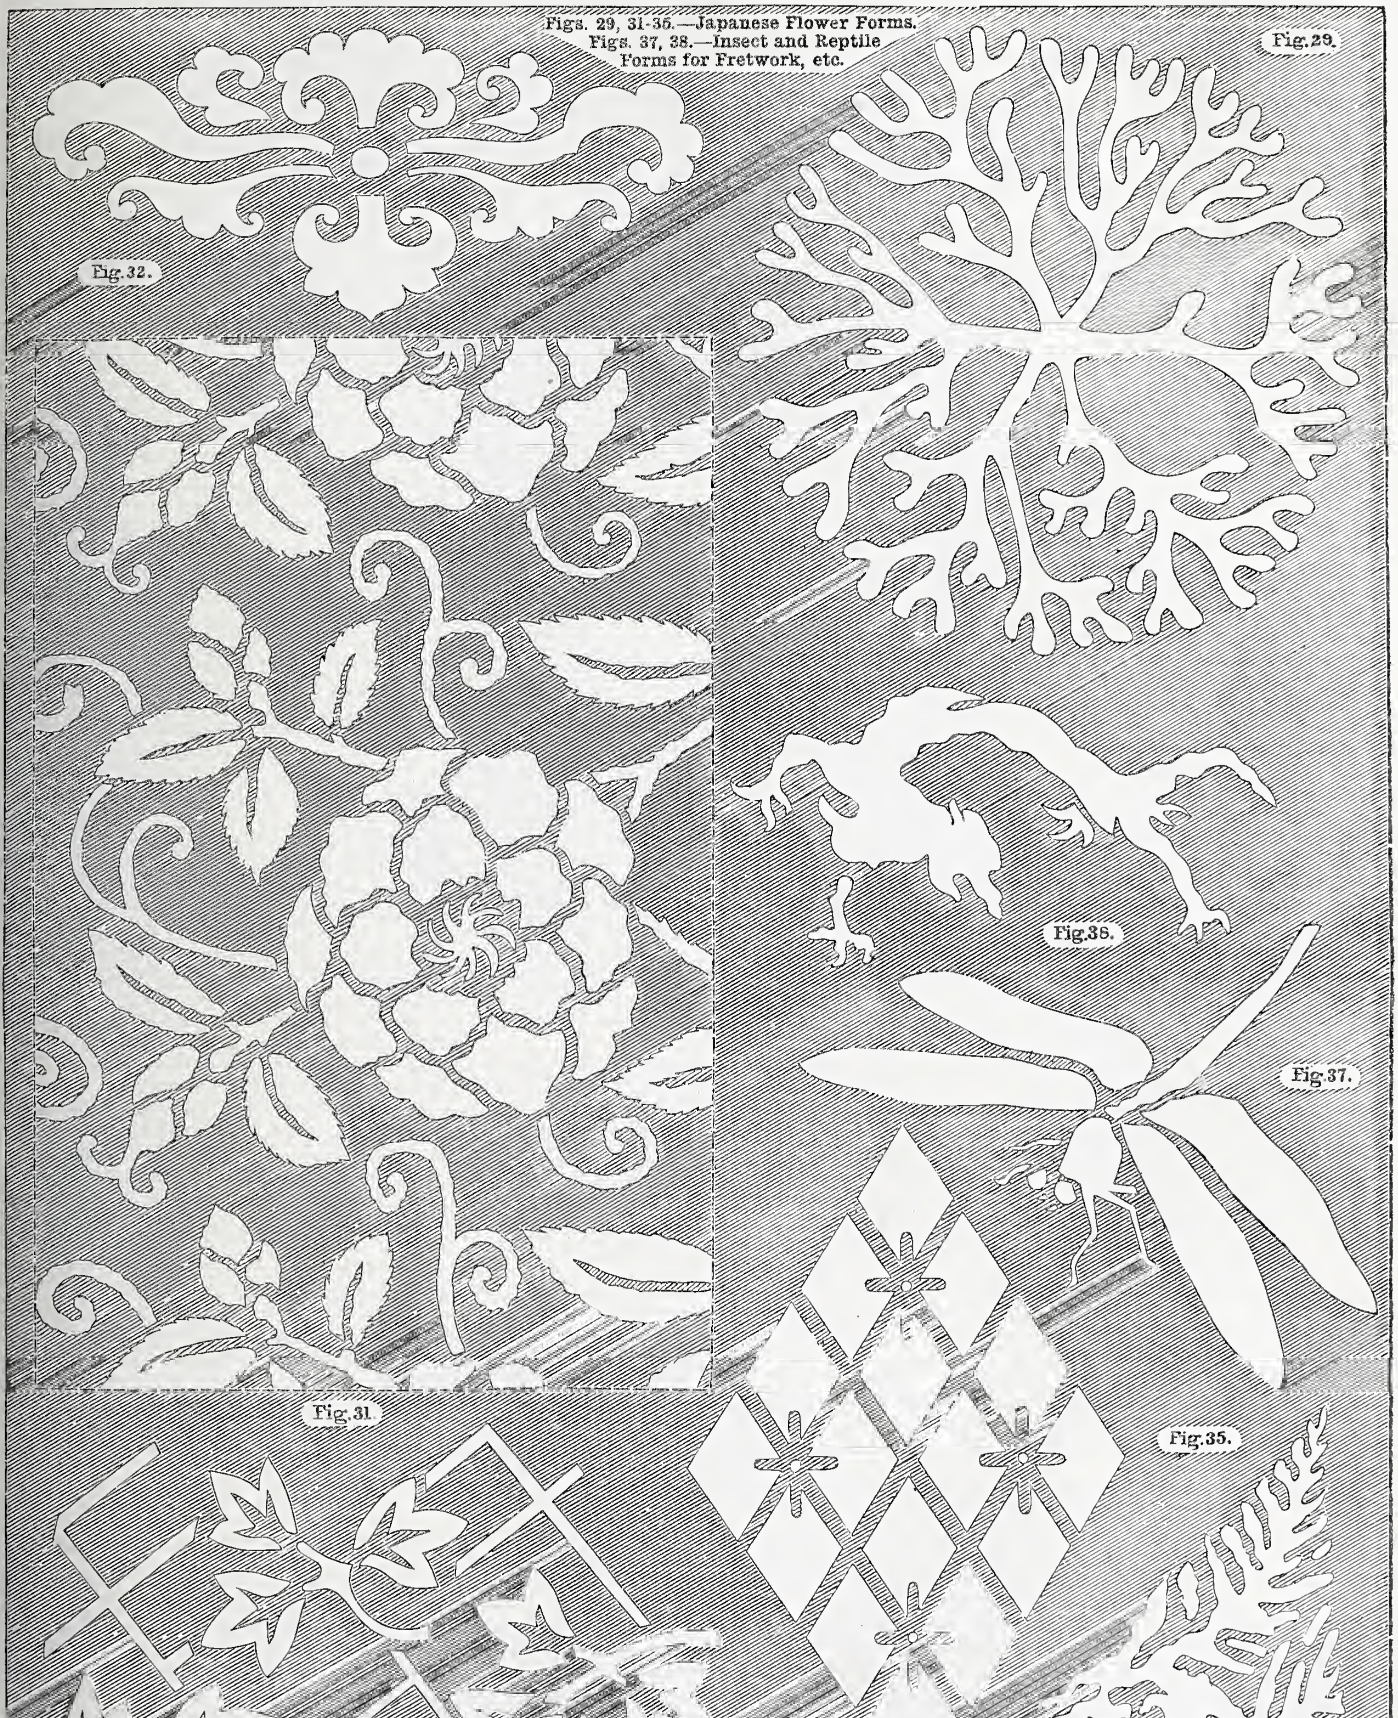
For the designs here shown are the piquant spots that decorate the mere construction, and to be of value must be used liberally, but with great care against excess. Of the two extremes, poverty of ornament is, on the whole, better than exuberance. A thing plain to meanness is less wearisome than overloaded with meretricious gewgaws. The tendency of late has been to exceed the bounds of good taste by ever-increasing mass of details. In many of our modern restaurants and hotels we groan for a square inch of plain restful surface. Floor, furniture, walls, ceiling, are all alike a mass of design, may be good in itself, but as different from really beautiful decoration as a meadow sprinkled with wild flowers is to a bedded-out lawn. This frugality of the use of ornament allows the thing introduced to be of better quality. It is better to have a square yard of fine carving than a square mile of machine-made pattern. Better to have just two or three masses of careful design to emphasise certain portions of the work than a cheaper style lavishly spread all over it.

One more point is needful to reiterate, namely, the distinction between ornament and picture. And this is a fault the Japanese rarely make. They are pre-eminently decorative artists, and realise the importance of the distinction. In no aspect of the craze for the imitation of Japanese style has the difference between the true and the false been more apparent.

Because the Japanese artist suggests a picture upon his panel, and only suggests it, too often the European workman has



Figs. 15-28, 30, 36.—Japanese Flower Forms for Fretwork and Stencilling.



Figs. 29, 31-35.—Japanese Flower Forms. Figs. 37, 38.—Insect and Reptile Forms for Fretwork, etc.

corrected what he took to be the result of mere incapacity of the Eastern craftsman, and translated the merely indicated background to a veritable landscape. But pictures are entirely distinct from decoration. Flatness is a valuable quality in conventional treatment of architectural spaces, distance an equally valuable one in a picture, and neither can interchange without detriment.

In these floral forms to-day it is instructive to note how carefully the Japanese artist has avoided pictorial representation of his subject. He has suggested all the salient points of the growth and shape of the plant, or been satisfied with a mere hint of the actual flower, but he has never tried to make it a picture.

Notice the floral ideas expressed in Figs. 15 to 31, especially the imperial crest of the Mikado, the horse-chestnut treated conventionally in Figs. 15 and 16; this beautiful object is perfectly suggested, and yet it becomes a conventional ornament, entirely decorative in itself. In Figs. 17 to 19, and 21 to 31, other flowers and leaves are expressed in similar way. Fig. 31 is an all-over design, capable of infinite extension to cover the required space. The amount of labour in a square foot of this pattern would be great, much more than in a square foot of American-Greeco-Gothic-Japanese-tag-rag-and-bobtail pattern. But the result would be also unlike. In one case a bit of good, if to some extent mechanical, art; in the other a monstrosity not worth having. Fig. 37 is a perfectly rational treatment of three simple leaves, but their geometrical arrangement makes the whole circle a masterpiece of design, easy and without effort, cut with no change of the fret saw; decorative either near or at a distance, it embodies all the good qualities of the art of design. Fig. 36 is a pattern almost meaningless in itself, yet repeated over a surface it becomes very telling in its effect. Of similar class is Fig. 35. If repeated it would be best to do it in chequer fashion, leaving alternate blank spaces the size of three sixteen smaller diamonds, thus saving the work, and gaining the larger decorative effect, the advice to secure which has already been repeated *ad nauseam* in this article. Fig. 34 is another all-over pattern, but the Japanese do not cover all the surface with such a design, as English use has it, but break up the mass by irregular portions of plain surface, vastly heightening the scheme of the whole.

And now, having noted down thirty-eight themes, how can they be best used?

For stencil plates they may be copied bodily. It is hardly needful to explain the way to cut these; but a very ingenious method, of Japanese origin, has been shown to me lately.

All stencil users know how often the bars left to strengthen the thin paper mar the design, so that in many cases the brush has to be used afterwards to fill up the breaks in the pattern caused by these said bars.

The Japanese solve this difficulty by cutting the stencil in two thicknesses of stiff but thin paper, then laying a network of the finest thread, as fine as hair, between the two papers. These being fixed together, the brush plays freely through the spaces of the net, which is of wide mesh in proportion to its size. Thus the sweep of the long line is kept, with no loss of strength in the stencil plate itself, and economy of future labour, since the one process completes the decoration.

For fretwork, there is no limit to the use of these motives; later on I hope to give working drawings of various structures adorned in this fashion, for this true fret cutting is worthy to be termed the classical method of its use. It appeals not to schoolboys or carpenters merely, but to artists. There is no reason why fretwork, properly used, should not rank among the minor arts. But to secure such a position it must be done without thought of the labour, and with care above that usually devoted to it. After many years of designing ordinary patterns, I should not like to maintain definitely that in this cut-out pattern the sole future is to be found; but I do hold distinctly, that much of the ordinary work is misapplied labour, and that if the pastime is doomed to remain only a pastime, it will be because of the low quality of its design. By this I do not, for one instant, say all designs produced are bad designs, but, as a rule, they are poorly adapted for use, and weaken the material under the pretence of beautifying it, making it less serviceable, less lasting, and, too often, in no way decorate the complete work, only ornament its several parts, and those in inadequate fashion. An inch of good decoration is better than a yard of poor ornament. A blot-book cover (to take an instance), with one of these Japanese designs worked carefully for its sole adornment, would be a thousand times better than many of the dozens of existing designs for that purpose; and as I am responsible for far more of these than perhaps my readers guess, such a statement comes at least unbiassed, and with the strength of a confession from one who has sinned even more than those to whom he is preaching.

Feeling strongly that a new future would be possible for fretwork if higher art were brought to bear on its designs, I have welcomed gladly this opportunity of showing one way to attain such a result. Here is good art and true, albeit it is foreign, and art of unusual style, in these thirty-eight examples.

For stencil work, these designs may be used to ornament panels, whether disposed as corner ornaments or centres, or produced in seeming irregularity over the surface at intervals. Nor need they all be worked in solid heavy colour; the Japanese obtain beautiful effects by shading off the colour in their stencil work, just as in their block printing they procure a result that is more akin to clever painting than printing, by this expedient of breaking into the European monotony of solid equal tint.

It may be said, to work successfully in this way needs the instinct of an artist. But every reader of WORK has more or less of that quality, if he would but make up his mind to use it. We have had artistic periods as a nation, and if now we can only encourage the individual to express himself individually, to cease to be a mere unit in a complex machine, there is hope for a new revival of genuine art. For art is not to be found in museums or picture galleries alone; when the cottage has a perception of beauty, seeking no mere prettiness, but a fit and seemly decoration, however simple it may be, that really beautifies its object, without in any way making it less useful or less serviceable, then the good day will be not far off.

The curse of the day is that each school, while proclaiming its own idols, disparages others. The Japanese lover will not love his hobby the less if he recognises the beauty of Flaxman's ornament, if he can appreciate Raphael's arabesques in the Vatican, and love and admire the attributes of periods directly opposed to his favourite Oriental models.

If those who look upon Japanese art as childish and barbaric, who think its worship a sign of degradation and decadence, are thereby impelled to revive their own admired styles, and diffuse new spirit and vitality into the well-worn mechanical repetitions of classic and later ornaments, well and good. But he loveth best who loveth well all things, both great and small; and the man who appreciates the value of a Japanese trifle at its true worth, will be better able to estimate the noble grandeur of those Elgin marbles we talk about so often aud gaze at so seldom.

Above all, "clear your minds of cant." This seems an aphorism far away from our title, yet cant is as easy to acquire in decoration as theology; and because I like Japanese, there is no reason why you, my reader, should not hold it contemptible! The danger is, that people follow each other blindly, adopt a new thing because it is new or popular, and degrade themselves in the attempt to assimulate hastily an indigestible thing that needs some amount of previous acquaintance and study.

To-day the would-be art lover has only too much at his disposal, and in the multitude of good things to see and read, is apt to lose his head and try all round. For the absolute canons of good taste and good art are familiar to us all, yet because they are so often insisted upon they fail to move us, and we let trivial things seduce us from our allegiance.

This paper has been a desultory one, and I fear irrelevant in its rambling digressions, but the study of a living school of design brings in every page painful memories of our own shortcomings; and if, in a paper like this one, that reaches so many, chance words inspire a "mute inglorious Milton" to try for himself, not to follow the advice here, but to strike out manfully by study of nature, to embody new features of design and new aspects of decoration, that one good, however problematical, must be pleaded to outweigh the tediousness of so long a chat upon and around and about—mostly the two latter—the subject of this paper.

And to hark back to our heading. As it is only by the study of the best work of others that all our work improves, and as in fretwork I know of no more worthy instances of good design than some of those here presented to our readers, to whom they will probably come for the first time, this grain of truth must be held in every way responsible for the verbiage in which it has been expressed.

"TIPS" FOR TYROS.

BY OPIFEX.

QUICK-DRYING FLAT OR DEAD BLACK.

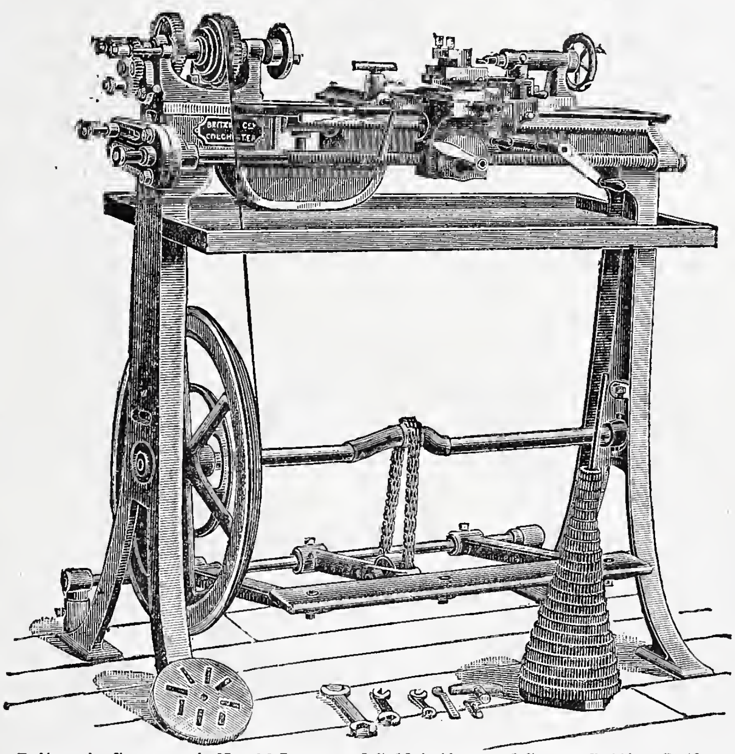
A GOOD "flat" or "dead" black which will dry in half an hour may be thus compounded:—Quarter lb. "drop" black; half pint of turpentine; a wine-glassful of black japan, well ground, aud mixed with stone and muller, or with a pestle and mortar.

This is most useful for ironwork to be japanned, as "black japan" is really a brown varnish, and requires a black ground. Articles of wood, furniture, panels, etc., when blackened with this mixture, if rubbed smartly with a cloth, assume a true ebony surface, which, in combination with gilding, is most effective.

OUR GUIDE TO GOOD THINGS.

50.—Britannia Company's No. 14 New and Improved Self-acting and Screw-cutting Lathe.

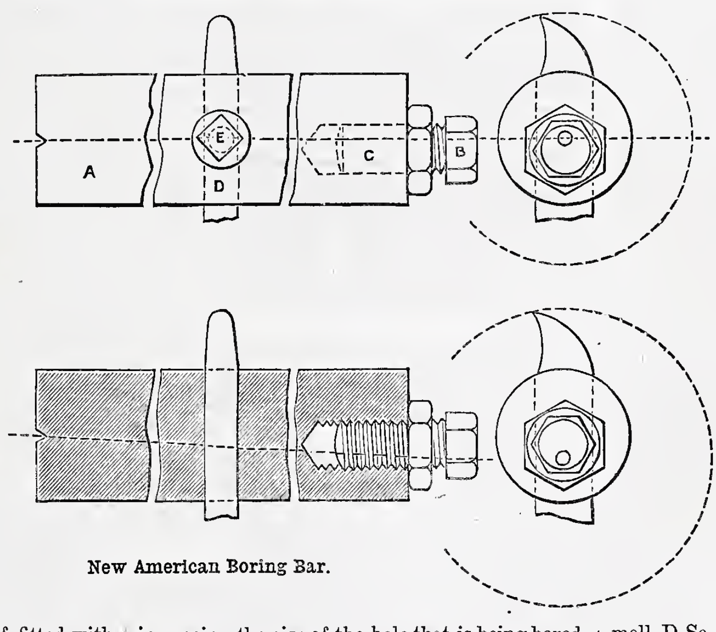
This is a well-made, compact, handy machine for amateurs, as well calculated for their purposes as the No. 16 Self-acting Sliding and Screw-cutting Lathe is for the workman to whose notice it may be fairly recommended. Similar in purpose to the No. 16 lathe, but in every respect smaller and less powerful, the No. 14 lathe is of new design of $3\frac{1}{2}$ in. centre and 3 ft. 6 in. gap bed. It will admit 25 in. between centres, $5\frac{1}{4}$ in. diameter over saddle, 7 in. over bed, and $14\frac{1}{4}$ in. in the gap. The fixed headstock is well made, with back gearing hard steel mandrel, conical neck, adjusting cone at back end to take up wear and running in hardened steel collars, three speed cone pulley for gut band, and fitted with reverting gear to cut right or left hand screws. The poppet head has a steel cylindrical mandrel, a left-hand square thread traverse screw, and bright turned hand wheel; the centres are of best steel, cone fitted. The saddle is strongly made, with flush top and T grooves for boring, well scraped and fitted to bed, with adjustable strip to take up wear, and carries a compound slide rest of modern design, swivelling and graduated to turn swivelling tool holder at any angle. The bed is of cast iron with V edges, all machine planed, 3 ft. 6 in. long, $4\frac{3}{4}$ in. on face, $3\frac{3}{4}$ in. deep, with gap 5 in. wide and $3\frac{3}{4}$ in. deep, with bridge piece properly fitted. The leading screw is of steel, accurately cut $\frac{1}{4}$ in. pitch and 1 in. diameter, with double gun-metal nuts, disengaging by eccentric motion, and the saddle is fitted with rack and pinion for quick return motion. The standards are A-shaped, and of cast iron, the top faces being planed; the bottom surface of the bed is also planed and bolted firmly to the standards. The crank shaft and treadle shaft run in self-adjusting swivelling bearings. The latter is made with three cast-iron arms and bright turned shaft, and connected with the crank shaft, which is also bright turned, by anti-friction cham and roller. The driving wheel is 24 in. in diameter, bright turned, with three top speeds and a small speed for slow motion. A polished tool tray is neatly fitted between the standards, extending back and front to hold tools, small work, etc. The lathe has a full set of twenty-two change wheels, fourteen pitch, $\frac{5}{8}$ in. face, face and catch plates, eccentric hand rest and two T's, spanners, keys, etc. The height from floor to centre is 3 ft. 8 in.; the approximate weight is 430 lbs. The price complete, as shown in the illustration, is £18 18s., or £19 19s. if fitted with cone speed and driving wheel with flat belt. If required for ornamental turning, as amateurs' lathes usually are, an overhead motion is supplied for £5 5s., making £25 4s. the total price if sent out with all the appliances named.



Britannia Company's No. 14 Improved Self-Acting and Screw-Cutting Lathe.

51.—New American Boring Bar.

As attention has been already called to various means for boring small cylinders in the pages of Work, it is desirable to introduce here, for the benefit of engineers, a brief notice and illustration of a new American boring bar of ingenious construction which has been recently described and figured in the *American Machinist*. It consists of the bar, A, in the end of which is the bolt, B, put in, as will be noticed, about $\frac{3}{16}$ in. out of centre. In the head of the bolt there is, as shown, a centre coinciding with that of the bar. The bolt enters into C, a chamber in the head of the bar which is threaded for its reception. By turning the bolt, therefore, a certain amount of eccentricity can be given to the cutter, D, for the purpose of gradually increasing the size of the hole that is being bored. The method is more accurate than the usual one of tapping the cutter outwards with the hammer. The amount of eccentricity given to the bolt may in most cases be less than $\frac{3}{16}$ in.; it would seldom be required more. A check nut, shown in the illustration, prevents spontaneous movement of the bolt during turning; E, in the upper illustration, is the set screw, by which the cutter, D, is pinched. To save trouble, I may as well say at once that I am not aware that the boring bar to which attention has been directed is to be purchased in the United Kingdom.



New American Boring Bar.

52.—The Boomerang: How to Make it and Throw it.

Any one who is at all curious on this subject may satisfy his curiosity by procuring a booklet, thus entitled, written, and, I presume, published by Mr. Alfred E. Beddow, 17, Cardigan Road, Richmond Hill. The boomerang is one of the weapons of the natives of Australia, and two kinds are used, one in war, which, when thrown, does not return to the owner, and the other in the chase and native games, which, after proceeding to the mark, will change the direction of its flight and return and fall at the feet of the thrower. Mr. Beddow first very clearly describes the mysteries of its manufacture, illustrating the method to be followed by carefully executed diagrams, and he then describes the mode of throwing it. He says that it has taken him several years of study and hundreds of experiments to acquire the information imparted in his pamphlet, and that any one wishing to make this singular weapon satisfactorily, without the aid of any instructions, would have to go through the same course.

53.—Calvert's Catalogue of Books on Practical and Scientific Subjects.

Many of us are frequently in want of a text-book on some practical or scientific subject, and find considerable difficulty in putting our hand on what we want. However, Mr. John Calvert, 99, Great Jackson Street, Manchester, has issued for 6d. a selected list of books on practical and scientific subjects, from the catalogues of all publishers, compiled by the editor of "Calvert's Mechanics' Almanack," a well-known and valuable annual. The list includes works on architecture and building; arts and sciences; bridge and ship building; civil engineering; decorating; education; gardening and agriculture; iron and steel manufacture; marine, mechanical, railway and sanitary engineering; mining and founding; navigation; textile manufactures; various tables and data; and miscellaneous trades and manufactures. Appended to the catalogue is a list of drawing instruments, revised to the present date. The entire catalogue is divided into sections, under each of which kindred or allied subjects are grouped together. As the catalogue cannot fail to be useful to the possessor, it should be found on the bookshelves of every workman, whether amateur or professional.

54.—Practical Mechanics.

This work forms one of the series issued under the general title of "Manuals of Technology" published by Messrs. Cassell & Company, Limited, La Belle Sauvage, Ludgate Hill, E.C., and edited by Prof. Ayrton, F.R.S., and Richard Wormell, D.Sc., M.A. The author is Mr. John Perry, M.E., Professor of Mechanical Engineering and Applied Mathematics at the City and Guilds of London Technical College, Finsbury. Its object is to put before non-mathematical readers a method of studying mechanics, that is to say, to afford an easier road to the acquirement of a knowledge of this subject than that which must be travelled by those who take up the ordinary mathematical text-books. It is written in clear and simple language, and is well illustrated by effective diagrams. It is a book that should be acquired by all young readers of Work. Its price is 3s. 6d.—The Editor.

SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

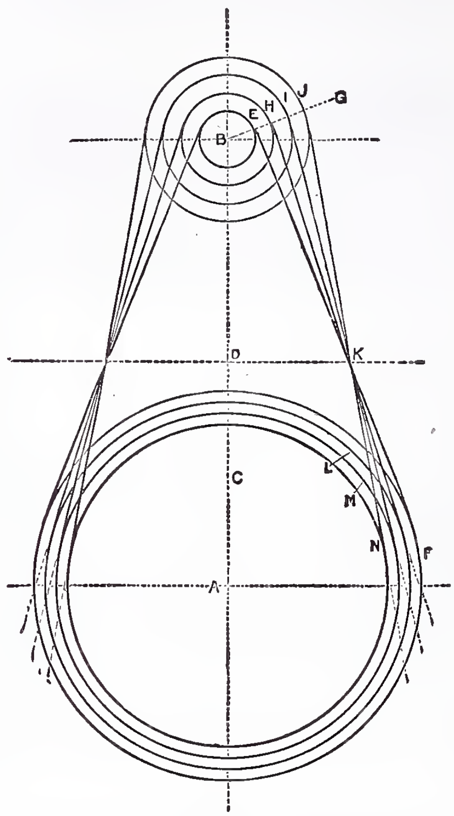
Building Construction. — PRACTICE AND THEORY BUILDING TRADES writes :—"Seeing your suggestion in 'Shop,' *re* plans, etc., for buildings, I write to say that I have been waiting for papers on this subject, and think that it cannot fail to interest a large portion of your subscribers. I think it would be well to bear in mind the fact that very few men would actually build from plans given in WORK, without structural alterations in a more or less degree, and so materials, modes, and appliances would be the principal part of the subject. I hope I shall soon see papers on this subject in WORK. I think stone masonry (monumental and building) is a subject which ought to have an early place in WORK, and I feel sure that a few papers on stone carving and letter cutting would interest many of your subscribers."

Small Cottage Construction.—J. R. G. (*Perth*) writes :—"I have taken in your paper since the commencement, and beg to state that my friends and myself are highly satisfied with it. It is undoubtedly the best paper published of its kind, and being so very moderate in price, many (who otherwise are debarred from purchasing more expensive books on different subjects) will welcome it. I myself have gained much valuable and useful information from its pages, and as I intend to build a little cottage some day in the country, I eagerly look forward to the sketches of cottages which I hope you will publish soon. I wish you (and the paper of course) every success, and trust I have not taken up too much of your valuable time."

Words from a Workman.—R. H. (*Preston*) writes :—"I have received the first monthly part of WORK, which I am very well pleased with indeed. Its style of composition, and construction generally, show that skill and talent are engaged upon it. A work of this description ought to have been out years ago; though never too late, it's none too soon. I wish you every success, and so will thousands of readers of Messrs. Cassell's publications, who know as well as I do that nothing ever emanated from La Belle Sauvage Yard but what was sound and good. I am sure it will prove beneficial, not only to the amateurs, but to the artisan that depends upon his skill for his daily bread. There must be a large demand for this work when it becomes more generally known, for I myself never knew of its existence before I saw the first monthly part exposed for sale. After reading the contents on the wrapper, through the window, and the name at the bottom, I had no hesitancy in becoming a subscriber. Any workman refusing to take a work relating to his business, stands as an obstacle to his further progress, and without progression he is left behind. But there are some very fair workmen who would feel affronted if another showed him a better method of proceeding with his work. A man of this sort considers himself perfect, and further improvement unnecessary. Granted he is perfect up to the present time (to-day); but is he the same to-morrow? To-morrow some inventor may bring out his idea that has taken years to develop, which may ruin his perfection, and send him to seek another employment. The old hand-loom weaver, in his happy (to-day) contentment, never thought of the morrow that brought out the steam-loom, and scattered him like chaff before the wind to seek any labouring job that was offered him. The same with the old millwright, with his square shafts and square-toothed wheels, before Watt and other geniuses were born. You will still find at the present day some remnant of the earlier craftsman in a few smiths' shops in the country, puffing at his asthmatical bellows, and using tools of the rudest description. What may be expected, be works for a low wage—not as much as a striker will get in a good shop—and where the competent average smith comes, he has to take a 'back seat.' I am particularly interested in this artificer, and shall have something more to say about him hereafter. Years ago I had the good fortune to invest a penny in a weekly periodical. It was the best pennyworth I ever got, for it not only gave me a thirst for knowledge, but it gave me the highest wage paid in any shop I have worked in, and that was the first issue of Cassell's 'Popular Educator.' That well-invested penny has given me constant employment without once being discharged, or loss of one single hour out of work for over twenty years. Had I never spent a penny on an instructive paper, I should undoubtedly be now receiving a less wage, less respected, and like many that never read, be paying the penalty by taking a 'back seat.' There are, nevertheless, a few good workmen with a very inferior education receiving the same wage as an intelligent workman, but with this difference: should a vacancy occur for a foreman, one is prepared, the other is not. And, moreover, if the uneducated workman can make a stand with his better-learned fellow workman, what would he have been if he had studied the same as they? Competition, and thousands of inventors working silently on something to astonish the world, make a man's trade like the fashions; there is always something coming out new."

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Proportion of Fly Wheel.—J. P. A. (*Walthamstow*).—To obtain the diameters of the steps of the driving cone, set out the centres, A, B, of the lathe spindle and driving crank, and connect them with the vertical centre line, C. Bisect C at D, and draw D at right angles therewith. Draw the smallest cone, E, and decide on the largest diameter of the fly wheel, F, and draw and connect the two



with the line, E, F. Draw E, G, at right angles with E, F; draw your remaining cone steps, H, I, J, and draw lines tangential therewith, that is, on the line, B G, to cut the line, D, in the same point, K, and prolong. Circles struck concentric with F, and touching these lines, will be the correct diameters of the speed-pulley steps, L, M, N. I may add that this should be done to full size, as a very slight inaccuracy in setting out will vitiate results.—J. H.

Ticket Buckram for Easy Bookbinding (H. R. W., *Chiswick*) is procurable at every draper's I have tried. John Barker and Co., of High Street, Kensington, quote it at 8¾d. per yard 36 in. wide, who sell also the *vegetable parchment*, 20 in. × 30 in., from 9d. the dozen sheets. Whitcley's quote it at similar prices, but I have not their estimate at hand. It is quite possible that the thick parchment used would be at least double the price of that quoted. I have given 3d. and 4d. a sheet for it.—E. B. S.

Clockmaking.—F. H. M. (*Liverpool*).—I note your wish for instructions on the making of a clock and the supply of parts of a clock in the same manner as the castings of parts of lathes, steam engines, etc., are sent out. I will see what can be done to satisfy you.

Clockmaking and Shoemaking.—J. S.—See preceding reply with regard to clockmaking. I cannot say anything about shoemaking at present.

Zinco Process.—D. T. D. (*Cardiff*).—This process is engaging the attention of a contributor, who will write a paper or two on the subject.

Boiler Making.—E. J. (*Llandaff*).—WORK is a magazine intended, God permitting, to run on, like Tennyson's brook, "for ever," as wise men understand these words. There is no intention whatever of completing it in so many numbers or parts. You will have seen that "Smiths' Work" and "Wrought Iron and Steel Girder Work" have been commenced. "Boiler Making" is on the way, and special papers are in preparation on the construction of a steam launch and a half-horse power steam engine and a boiler suitable for it.

Jewellery Jobbing.—G. H. Y. (*Southwark*).—Solutions will be found in any text-book, but I can give no certificate as to their merits. I never use them. I sell the solutions with instructions on bottle; gold, 1s.; silver, 9d.; but as I do not make it I cannot say what it is. My own opinion of all processes without a battery is that very little dependence can be placed upon them; this is only an opinion, *not* the result of experience. Hard soldering requires more care and skill, because, as a rule, the temperature at which the solder runs is very near that at which the metal to be soldered will melt. It is quite impossible, in the limits of an answer, to deal with the subject thoroughly; so that only a simple example can be given to repair a ring broken at the back of the shank—that is, the point farthest away from the head, in the majority of cases. This can be soldered without drawing the stones, but care will be required. The two surfaces to be joined must be made clean by slightly filing, and then adjusted so that they press against each other. If this cannot be done without, the ring must be tied round with soft iron wire, called binding wire, and sold for that purpose of any thickness required. Then rub a piece of borax down with water on a piece of slate till you get a mixture about the thickness of cream, and with a small camel's-hair brush paint the part to be joined with the borax. Do this carefully, as you must remember that wherever the borax is put the solder will flow. The solder used is of a little lower quality than the article to be joined, and can be bought ready made to suit any kind of work; but for the majority of cases you will find it easier and safer to use a good silver solder. Of course, the joint will show white, but being very small it is not of much consequence, and can be gilt over; and in soldering cheap gold jewellery the quality is often so poor that it will not stand the heat necessary to flush gold solder. The solder is bought in thin sheets, and the surface should be cleaned by slightly scraping with the scraper or rubbing with a piece of glass-paper; then cut the solder up into little squares, the smaller the better, and, taking up one of these little squares with the point of the camel's-hair pencil, lay it carefully on the joint to be soldered. Lay as many as you think will be required, then gently warm the solder and the ring with blowpipe flame, first laying the ring on a piece of charcoal; the borax will dry and hold the solder in position. Heat should then be gradually increased until the solder melts and flushes into the join. The article to be soldered should always be heated on each side of the joint a little way, and then a sharp blow right on to the solder will usually cause it to flush and make a good joint. The solder left on the edges should be filed off when cool, and the ring polished with threads and crocus and rouge; or it may be finished by gilding; if much borax is left about the join put the ring while hot into a pickle of sulphuric acid 1 part, water 10 parts. This will dissolve the flux and clean the ring. Of course, this cannot be done when there are any stones in it that would be damaged by the acid.—J. W. K.

Brown Bronze Colours.—L. V. (*Norwich*).—I do not know the particular powder to which you allude, but the following give brown bronze colours: —Sal-ammoniac, ¾ oz.; carbonate of potash, 1½ dr.; vinegar, 1 quart. Apply with a sponge, and repeat several times until the proper tint is obtained. Or 5 dr. of nitrate of iron in 1 pint of water. This will give every shade to black. Chocolate colour can be obtained by steeping iron wire in nitric acid (aquafortis) for a quarter of an hour before dipping the brass. Florentine bronze: dissolve arsenious acid (arsenic) in hydrochloric acid, and apply. Or dissolve corrosive sublimate in acetic acid.—J. H.

Silver-Steel Hand Saw.—JOINER.—When I noticed this saw I gave the address of the manufacturers, Messrs. Spear and Jackson, Ætna Works, Sheffield. If you write to them they will tell you the name and address of any retail dealer in London or your own immediate neighbourhood where you may purchase one. Doubtless, you may obtain any variety of saw, whether rip saw, hand saw, panel saw, or tenon saw, in the same material, of Messrs. Spears and Jackson. The panel saw, I can easily imagine, would be more particularly useful to you. Saws shaped as the one described are called "skew-backed" saws. The American saw to which you refer was, without doubt, one made by Henry Disston & Sons. They are excellent saws, but I think you will find the English ones to be as good. I am told that Disston himself is an Englishman, and once worked for a Sheffield firm before he settled on the other side of the Atlantic. I cannot vouch for the correctness of the statement, but merely mention it to you as it was told to me.

Violin Necks.—WREN (*Glasgow*).—There are three ways in which a violin neck should be tested as to its being in right position, viz., by looking up to back joint, which should be in line with the centre ridge of the head; along the edges of the back, with which the eyes of the scroll should be in line, and also down the finger-board to the bottom nut. When fixed, the neck should project quarter of an inch above the belly. Instructions for bending ribs will be given in the papers on violin making, which will, I trust, soon appear. The price you quote (4d.) is a very reasonable one indeed for violin cramps. You would, no doubt, entertain the same opinion if you were to take the trouble of sawing up, turning, screwing, and tapping them. Your other "hobby" is certainly a novelty. It is a pleasure to be able to give information to so old a subscriber to Cassell & Co's. publications.—B.

Silvering and Gilding Solutions. — T. F. (*Manchester Square, W.*).—The best silver-plating solution is that made with the double cyanide of silver and potassium in distilled water. Dissolve nitrate of silver in distilled water, and add a solution of cyanide to throw down all the silver as silver cyanide. Wash this two or three times, and then dissolve with a strong solution of cyanide of potassium in distilled water. The best gold solution is made in a similar way from a neutral solution of gold terchloride. A weakly-charged Bunsen battery may be used, but it is not so good for this work as a Daniell or Smee. Further details will be given in my "Notes for Electro-platers," under the heads of "Gilding and Silvering Solutions." Information respecting the best batteries is already in the Editor's hands.—G. E. B.

Magneto Machine.—H. C. (*Newcastle*).—The two inside ends of the wire coils should be connected together. One of the two remaining ends should be connected to the insulated spindle of the coils, whilst the other is conneeted to the commutator or break. The braided wire from one of the handles must be attached to the frame of the machine, this being in connection with the coil spindle. The braid from the other handle must be connected to the insulated break-spring. No. 25 silk-covered wire is too large to give a sharp shock; No. 34 or No. 36 would give sharper shocks.—G. E. B.

Battery for Medical Coil.—BERNHARD.—This correspondent has made a medical coil after directions given by Mr. J. N. Urquhart, in *Design and Work.* You have given the wrong date; the article was published in Vol. IX., pp. 206-207, and first issued on September 11th, 1880, not 1881, as stated by you. If you have any difficulty in working this coil I would advise you to look up some correspondence on the subject between the author and "Diogenes" in Vol. X. of the same periodical. You do right in connecting the left-hand binding screw of the primary to the wire leading from carbon of battery. The coil may be worked with a small (½-pint size) bichromate, but a larger cell would give steadier and better results. 1. Carbons 3 in. × 2 in. exposed to the solution in cell. 2. Dissolve 3 ounces of bichromate of potash in hot rain-water, and add 3 ounces of sulphuric acid. 3. The carbons should not be further apart from the zincs than half an inch. 4. You will learn much respecting suitable electrodes from a pamphlet on the subject (price 4d.) from Messrs. F. Gent & Co., Faraday Works, Leicester. For replies to your last query, see correspondence above referred to in *Design and Work.*—G. E. B.

Glass for Aquarium.—TYRO (*Wheatley*).—The glass best suited to your aquarium is what is known in the trade as "32-oz." You do not, however, give the depth, which is the most important point in determining the strength of glass required, as the pressure of water upon the sides, etc., is as to its height and not to its bulk. For cementing the glass in, take 1 lb. of ordinary putty, ½ lb. of red lead, and thoroughly knead the two together into a soft mass with gold size rather thinner than ordinary putty. When of the right consisteney it should leave the hands without sticking. The wooden pillars should be given a coat of varnish before glazing; the edges of the glass where the putty will touch should be smeared with gold size to ensure perfect adhesion. An article embodying a design for a handsome aquarium is in hand, and will shortly be published.—C. M. W.

Moulding of Vulcanite in Dentistry.—BERNHARD.—The moulding of vulcanite is done in plaster casts secured in metal cases. It requires a heat of not less than 315° Fahrenheit, continued from 75 to 90 minutes, this being a pressure of about 85 lbs. to the inch. I do not see that an amateur could safely undertake it in any home-made boiler. Those I use are tested to 130 lbs. pressure; hence, in twenty years' practice, I have had no accident. In metals such as gold, platinum, etc., amateurs who can use a blowpipe might do very well.—R. B. [It will not be possible to give articles in WORK on making false teeth and all that appertain thereto. R. B. is kind enough to say that BERNHARD may write to him on the subject, if he wishes to do so. If BERNHARD, therefore, will send real name and address I will give him R. B.'s address.—ED.].

Mitre Box for Picture Framing.—SCOTO-IRISH.—You will see perspective view, plan, and section of a mitre box in No. 3 of WORK (p. 37), and instructions for making it in the same number (p. 35), in Mr. Adamson's second paper on "Artistic Furniture."

Treatment of Gold Rings after Soldering.—DEAN FOREST.—Referring to AUROLECTRIC'S reply to your query in WORK No. 8 (p. 125), he omits to say that the surplus solder has to be filed off and the joint regulated with the file, and the hammer too, perhaps. It would never do to gild or polish rings direct from soldering, except for the penny ones sold on hawkers' stalls. In properly-made gold articles such a way of finishing would never be allowed.—S.

Bureau Bedstead.—H. G.—It is not possible to satisfy your inquiry in "Shop," but a short paper shall be given showing the mode of procedure to be followed in making this piece of furniture.

Telescope Making.—J. G. (*Cambuslang*).—It will require a long series of papers to deal with telescope making, and we have so many subjects on hand at present that its treatment must be postponed for some future time.—ED.

Boxes with Sloping Sides.—W. K. S. (*Errol*).—Your inquiry is answered in the preceding reply to X. Y. Z. (*Orkney*), page 173. If there is anything in it that you do not perfectly comprehend, write again. The contents of future numbers will show you that your wishes and requests have been anticipated.

Bookbinding Materials.—ANXIOUS ONE (*Bingley*).—1. The proper size to be used for finishing cloth and leather work is glaire, *i.e.*, the white of fresh hens' eggs. They should be beaten up until the whole mass is converted into a snow-white, dry-looking froth, and allowed to stand for some time. The froth will entirely subside, and leave a clear liquid as thin as water. If not wanted for immediate use the beating can be dispensed with. Put it into a bottle, with a drop or two of vinegar for each egg. Cloth-bound books require only one coat of glaire; use a sponge, and apply lightly over the whole of the back or side of the book to be lettered. A little water may be added to the glaire with advantage; it will prevent the cloth getting streaked. For leather work use the glaire full strength. Apply to the parts to be gilded only, using a camel-hair pencil or sponge according as the surface is large or small. Two coats must be given, allowing the first to dry thoroughly before applying the second. Size prepared and used as directed with good solid gold, and the tools heated to the proper degree, should make the books shine like a new sovereign. 2. For collecting the surplus gold leaf a gold rag should be used, and not that soft messy composition which some finishers make and use (often dishonestly). A gold rag is a square piece of close unbleached calico with oil sprinkled over and well rubbed into it. If any gold leaf still adheres after using the gold rag it is cleaned off with a piece of pure bottle rubber. If the rag is properly used there will be little need for rubber, but it is best to have a bit, and the little pieces are picked off before the fall, and kept in a small box in the cushion drawer. The best marbling size is made by dissolving gum tragacanth in soft water; beat it well up with a bunch of birch or small canes, and strain through a hair sieve. In all cases use vegetable colours, as mineral colours are too heavy, and will not float on the size. Marbling colours are sold ready prepared, and it is not worth while preparing one's own as they are so cheap. However, in mixing marbling colours a stone slab and muller will be required for grinding. Put a little dry colour on the stone, and a paring of beeswax; mix it up with soft water, using a palette knife; then, with the muller, grind until it has become as fine and smooth as flour paste. Scrape it off the stone, put it in a small cup, and mix with water and a few drops of gall to make it spread when thrown in the trough. The colour intended for the top will work better if two or three drops of spirits of wine or linseed oil are mixed up with it. Keep the surface of the size free from bubbles and froth while marbling, and scrape the surplus colour off after each dipping.—G. C.

Bamboo Cane and Black Stain.—O. P. Q. (*Bow*).—Bamboos may be bent without danger of splitting by heating them at the parts to be bent over a gas flame or spirit lamp, taking care, of course, not to let the cane burn while doing so. The desired result may also be got by steaming the part. Mr. F. Westbury, 183, Great Dover Street, S.E., and Messrs. Benjamin & Co., 167, Great Dover Street, are dealers in all sorts of bamboos. The former quotes for retail as well as wholesale quantities; the latter may do so as well, but not having received any reply to an inquiry addressed to them I cannot say. I have bought bamboos from Mr. Brandenburg, Queen Street, Finsbury, E.C., and have always found him very obliging and painstaking in selection. I am not, however, sure that he is still there. If not, you will probably do better by purchasing such small lots as you are likely to require from bamboo workers instead of going to the large wholesale dealers. Messrs. W. T. Ellmore & Sons, 16, City Road, E.C., will probably oblige you with any bamboos you want. I have an article in preparation which will be helpful to you and other bamboo workers. Residing as you do in London, you will find it far more satisfactory to buy black stain ready made than to prepare it yourself, almost, if not quite, as cheap, and certainly better. However, if you wish to try, boil some logwood chips in water till all the colour is extracted from them; mix this with some vinegar in which pieces of iron or steel filings have lain for a time; copperas and water, instead of vinegar and iron, are recommended by some. Concentrate and apply to the wood till the necessary depth of tone is reached. Pine is not a good wood to ebonise or stain black. The subsequent polish or varnish should have a little gas black mixed with it.—D. A.

Transfer from Half-tone Negative, etc.—W. L. (*Newton-le-Willows*).—In making a transfer from a half-tone negative it is absolutely necessary to give a grain to the stone or zinc plate. This is obtained by a variety of methods; a very popular one is the use of a photograph of network or lines interposed between the negative and the sensitive film, which breaks up the image into minute dots or lines. Another plan is to cause reticulation by applying a solution of tannic acid to the bichromated gelatine film. Gum water may be made by dissolving about twenty-five grains of gum arabic in an ounce of water, and strain; this is applied with a soft sponge. Success, however, depends principally on the skilfulness of the worker rather than on the materials used. Consult any good handbook on photo-mechanical printing.—E. D.

Photographic Sketch Portraits.—W. J. F. (*Edinburgh*) will find a half-plate camera, with a lens of not less than 8 inches back focus, suitable; but a lens of much longer focus is to be preferred. This would, of course, require a camera of corresponding length, with a necessary increase in expense. The use of short focus lenses necessitate a less distance between the sitter and the camera, causing more or less distortion of the image. The other appliances are the same as for ordinary photography, and consist of measures, weights, dishes, printing frame, sensitised paper, and chemicals, with a non-actinic light to work in.—E. D.

Etching on Zinc.—P. J. (*Royston*).—A paper on etching on zinc, for printing purposes, is in preparation.

Limelight Lantern.—LANTERN (*Dartmouth*).—A set of signals may be easily arranged between lecturer and exhibitor, and carried out by means of simple electric apparatus. If you take off the gong of an electric bell, the armature will merely buzz when the push button is pressed; and this buzzing noise may be used as a signal. A Morse sounder may also be used for the same purpose, giving out a ticking or tapping sound when the key is struck. A cheap bell, battery, wire, and push will cost about 9s. Either Messrs. H. Dale & Co., 26, Ludgate Hill, or Messrs. Mayfield, Cobb, & Co., 41, Queen Victoria Street, E.C., will quote you prices for materials. As I do not clearly understand what you mean when you ask for "a pattern or dimensions of a good strong slide carrier," kindly ask again, and explain your wants more fully.—G. E. B.

Toning without Gold.—HALF PLATE (*Manchester*).—The results, as shown by your photos, are, as you suggest, not satisfactory; but from the look of the prints, I do not think this can altogether be attributed to the toning bath, as they appear to have been produced from very poor negatives. Of course, to get the best results with lead or any other toning bath, the prints must be good originally, and to get these good negatives are necessary. This, to a great extent, will supply the explanation you ask for. Never having obtained such bad results myself with lead toning, the rest is more or less surmise; but as I presume you are quite a beginner in photography, I give you, as a brother amateur, my opinions. From No. 1 having been so deeply printed it is almost a wonder you got anything discernible. It, as well as Nos. 2 and 3, was left far too long in the bath, and I think a good deal of the dirty look about them may be attributed to the too prolonged action of hypo, or possibly to insufficient washing. No. 4 is the best in tone, which is decidedly of a purple hue, and bears out the remark of the muddiness of the others being due to hypo, as the white in it is purer than in any of them. These, you say, were in all night, except No. 5, but even it was soaking in hypo for a couple of hours, or double the time for No. 4. This is decidedly the best of the lot, and to produce it you have apparently kept more closely to the instructions than you have done for the others. The colour of No. 5 is not nearly so good, in my opinion, but the print is clearer, though taken, apparently, from a desperately thin negative. There are no high lights to be seen. Judging from the stains on the back of it, I am afraid you are not a very clean operator; and no doubt you know chemical cleanliness is a very important matter in photography. I am pleased to give you these hints, but I scarcely think you would have got better results with any toning bath, unless closer attention were paid to the matters referred to. Your attempts with regard to lead toning seem to have been more of the nature of original experiments than an adherence to instructions, so that these are hardly to be blamed. You will remember lead toning was not suggested as being superior to gold; but for all that, far better results are to be got than shown in your specimens, and I hope in future you will meet with more success. Yes; camera making will receive attention.—L. J. P.

Polishing Desk.—J. T. (*London*).—Without knowing exactly wherein your difficulty in obtaining the desired polish lies, I may not be able to help you to overcome it. It would be of the greatest possible assistance in enabling questions about polishing to be answered satisfactorily, if inquirers would be kind enough to state wood and other particulars of any article they wish to finish, and, as in your case, if they would state clearly their *modus operandi.* One could then often tell the reason of failure, and what should be done. Without knowing more than I do, it is impossible, without writing a complete treatise on French polishing, which, of course, is out of the question in "Shop," to help you so fully as I should like; but perhaps the following outline of the process may be of some assistance:—Oil the work by rubbing in raw linseed oil; let it stand a sufficient time to dry in, say a day or two; then fill the grain of the wood with some filler, such as whitening, moistened with a little turps, and tinted to correspond with the colour of the wood. Clean off superfluous filling; body in with French polish, using rubber of cotton wool enclosed in a soft rag covering. Rub equally all over the surface till the wood absorbs no more polish and a fair amount of gloss is obtained, though the general appearance may be smeary. The final polish must be obtained by "spiriting off" the work, that is, continuing the rubbing and using a little spirit only on the rubber. Simple as this process reads, you may have made a dozen mistakes, any one of which would be fatal to a good result; so if you still cannot manage write more fully, and you may rely on my best efforts to help you.—D. A.

Choice of Lathe and Fret Saw.—J. H. S. (*Romsey*).—You ask whether it would be better for you to get the Britannia Company's No. 1 patent lathe and fret saw combined, or their No. 3 lathe and the separate fret saw appliance. The answer may be very much a matter of opinion. With

No. 1 you would have the best fret saw and a very small lathe; with No. 3 you would have a better lathe of more capacity and a less advantageous fret saw. I say less advantageous, because it would not have a vertical stroke. As for myself, I should certainly prefer the better lathe. A still better plan would be to have two separate machines. Have the No. 8 fret saw to begin with, and use that for a year or so; then get a lathe, and learn to turn. It is better to take up one thing at a time, and to have separate machines each perfect of their kind.—F. A. M.

Enamelling Fretwork.—CREAMY (*Gravesend*).—Of course, you can hardly expect your work to look "first-rate" when compared with the things you refer to, as you must remember they are finished by experts, while you, I presume, have not had much experience. Not knowing exactly what you have done, or wherein the work is unsatisfactory, I can only advise you in a general way. To begin with, the wood must be well smoothed; then, as it is soft, it would be well to size it, for which very thin glue will do. If this raises the grain, rub down again with very fine glass paper; this will prevent the paint being dull in parts while bright in others, though two coats of paint will have the same effect. Finally, apply the paint thinly and evenly, in more than one coat, if necessary, letting each be quite hard before another is added. If you still cannot manage, write again, and say what is amiss.—D. A.

Casting from Wood Carving.—F. S. (*Bethnal Green*).—We doubt if F. S. can find any way of moulding from wood carving more simple and harmless than by a "clay squeeze." Roll up a ball of thoroughly well-tempered modelling clay, soft enough to be completely plastic, but not so soft as to be in any way sticky, and squeeze it on the woodwork. If the carving is larger than can conveniently be taken at one squeeze, two or more may be used and fitted together before being employed as moulds. This will not give undercutting; if that has to be shown an "elastic mould" will be necessary. It is thus made:—Best gelatine, 1 lb.; beeswax, ½ oz.; water, ¼ pint, boiled together in a glue pot, and poured on warm, but not boiling. In either case the carving should be oiled before moulding.—M. M.

How to Judge Woods.—W. A. (*Leytonstone*).—The information you ask would take up a page of WORK to answer. Write to J. & W. Ryder, 11, Bartholomew Close, E.C., for their work on "Timber and Trees," by T. Laslett, 8s. 11d., post free.—A. J. H.

A Seeker.—(*Pontypool*).—Your way will be to write to Mr. Bolas, Central Institution, City and Guilds of London Institute, London, E.C., and ask him if his lectures will be published, enclosing a stamped envelope for reply.—F. J. C.

Pressure in Boiler.—LANKY TOM.—The pressure at the bottom of the boiler is in excess of that at the top by the weight of the water in it; the steam between the surface of the water and the top of the boiler presses equally upwards and downwards; therefore, for the pressure on the bottom the weight of the water must be added to the pressure of the steam. The feed-pipe is placed low down in the boiler in order that the feed water may enter at the coolest place, and fall naturally into the circulation.—F. C.

Reduction of Power by Pulleys.—LANKY TOM.—Your gearing is not described with sufficient clearness for us to answer your question. A sketch would be more satisfactory.—F. C.

Registration.—D. McR. (*Inverness*).—Register the "name" as a trade-mark.—F. C.

Window Fastener.—L. A. R. (*Mile End Road*).—The cost of provisional protection is £1, if you send your application direct to the Patent Office; but in your case you should certainly employ a patent agent, for your invention may be anticipated, and in any case the specification should be drawn by an experienced man.—F. C.

Gas Regulator.—R. M. C. (*Glasgow*).—Your contrivance is ingenious, but I do not think it would be financially successful as a patent. The fixing and unfixing are against its adoption. Thanks for the sketches.—F. C.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Barbotine Work in Gutta Percha.—PADDY MURPHY (*London, S. W.*) writes:—"Will some reader of WORK be so good as to afford me in 'Shop' some hints regarding the making of imitation barbotine work in gutta percha? What implements, paints, etc., are required for the work, where procurable, etc. etc.?"

Instruction in Wood Engraving.—TOM, who lives at Islington, desires to know where he may obtain practical instruction in wood engraving.

Tobacco-pipe Making.—SMOKE wishes to know if there is a good book to be got on the subject of tobacco-pipe making, giving full instructions with prices of materials.

Bevelled Cog Wheels.—POTTER asks:—"Where could I get a cheap pair of mitre cogs (*i.e.*, bevelled cog wheels?")

Gripping with the Vice.—CROSS-CUT writes:—"I sometimes want to grip in a front bench vice a piece of veneer against the edge of the bench, and also to grip a shutter or door edgeways with the same vice. How is it to be done in an instant by a cheap and simple vice for a strong wood bench?"

Marbling Washstand Tops.—W. H. J. (*Stratford*) writes:—"I should esteem it a great favour if any reader could give me some information as to a quick method of marbling common washstand tops, as I often have them to do at a short notice."

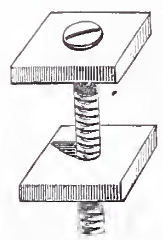
Bevels for Stair Rails.—CONE asks:—"What form of square or of bevel, different to the ordinary square and bevel, is used in trying the square or bevel faces and joints of staircase hand-rails?"

Steel.—PALL MALL says:—"Can you inform me how steel is blued for ornamental purposes for decoration of swords, etc.—namely, court swords, navy dirks, and other weapons? I only know of one firm where this kind of work is done, that is a German firm in Solingen, and if you, or any of our correspondents can inform me, I shall be much obliged."

Hand Circular Saw Bench.—G. H. L. (*Hull*) writes:—"An amateur who is desirous of making a circular saw bench (to be turned by hand) would be greatly obliged if any of your readers could give him a little information on the subject. Could I get sufficient power to cut 1 to 2-in. boards? If any of our friends could give me details how to construct a bench and the fixing of the saw, bushes, etc., I shall esteem it a great favour. My own idea is to fix the hand and wheel on the end of spindle; but I am afraid to venture this for fear I should spoil the spindle, and the whole not act."

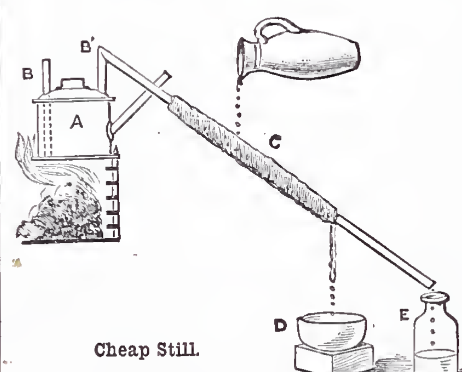
IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Violin Cramps.—J. G. (*Edinburgh*) writes in reply to E. P. W. (see page 125):—"In WORK No. 8, I observe E. P. W.'s inquiry as to violin cramps. The following is a very cheap method of making these, and gives satisfactory results:—Suppose two dozen cramps are wanted—which is about the usual number required in violin making—let him cut up a piece of ½-in. hard wood into forty-eight pieces, 2 in. square, then get twenty-four screw nails, say, 3½ or 4 in. long, and insert them up to the heads in twenty-four of the pieces; in the other twenty-four pieces, the hole must be sufficient only to allow the screws to work. The bottom piece can then be screwed up and down as required, while the other remains stationary. This drawing explains the process."



Cramp.

Cheap Still.—H. B. S. (*Liverpool*) writes in reply to BARRINGTON:—"Get a medium-sized tinplate saucepan, and bore two holes in the lid, each about 1 in. in diameter; if you can solder yourself (if not a tinman will do it for you), get a piece of tinplate tubing that will just pass through the holes; cut a piece long enough to reach to the bottom of the pan, and 2 or 3 inches through the lid when the latter is on; solder this in, so that it will nearly touch the bottom of the pan; get a longer piece of the same tubing, bent at a slight angle as shown; this will have to be done by soldering two pieces together; solder this into the other hole, only just allowing the tube to pass through the lid; when this is done solder on the lid. Your still is now ready. Put a funnel into the short tube, and pour water into it until the still is three-quarters full. Now put it on the fire, wrap a piece of tow or cotton round the long tube, allowing it to hang down a little; keep pouring water on during distillation, and it will run off into a basin at the loose end; it will be well, however, to grease the tube all round just below the cotton. Put a clean bottle at the end of the tube to collect the distilled water, and throw away the first portion that collects; the rest will be almost as pure as you can get it. If the condensing cloth is not sufficient, write, and I will describe a proper condensing arrangement."



Cheap Still.

A, Saucepan; B, B', Pin Tubes; C, Tow; D, Basin; E, Glass Bottle as Receiver.

Trade Notes and Memoranda.

THE question of the feasibility of telephonic communication between the postal authorities of London and Paris is under investigation.

A USEFUL little arrangement—"Mileson's improved screws" for drawing instruments—is well worth the attention of architects, draughtsmen, and all users of mathematical drawing instruments. By it the possibility of an instrument getting disabled through loss of the adjusting screw is entirely prevented, at the same time allowing the free use of the instrument in the ordinary way. Also, whereas with the ordinary screw the nibs of all jointed pens and inking points cannot be lifted for cleaning, etc., without removing the screw from top nib, the above arrangement ensures a saving of time in not having to remove the screw—a matter of some consideration. There is also another advantage—it acts as a sure and certain adjustment when the spring which is introduced between the nibs of jointed pens and inking points fails to perform its proper use; in fact, the spring may be done away with altogether.

THE Eiffel Tower is by far the tallest structure in the world, as the following table will show:—

	Feet.
The Eiffel Tower	984
The Obelisk, Washington	522
The Cathedral, Rouen	492
The Great Pyramid, Ghizeh ...	478
St. Stephen's, Vienna	452
St. Peter's, Rome	432
St. Paul's, London	420
The Panthcon, Paris...	259
The Monument, London	213

It is a remarkable fact, illustrative of the perfection attained in modern engineering works, that all the rivet holes were drilled before the work was brought to the ground, and not a single hole was allowed to be drilled, punched, or drifted in place. If we compare this structure with our own Forth Bridge—which stupendous work appears to interest few, except engineers—we shall see cause for a little self-gratulation. The amount of wrought iron used in the construction of the famous tower is about 6,500 tons; but the last quarterly report on the Forth Bridge by Major Marindin records a total of 39,000 tons of steel as having been fixed up to that date (Feb. 28). When the bridge is complete the total will be about 50,000 tons. In addition to this, 628,000 cubic feet of granite have been already set, besides 113,500 cubic feet of rubble, masonry, and concrete work built. In this herculean task an army of men, whose number averages 3,250 per diem, have been engaged.

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the ***Inventor and Manufacturer,***

PIT-FRAME FOR WHEEL MAKING.

BY PETER WILLIAMSON.

A WHEEL-FRAME or pit is a necessity to a wheelwright's or coachbuilder's shop. How a wheeler could make a wheel without this indispensable article it would not be easy to imagine. There are three differently made frames, but all are nearly similar in appearance, the only difference being the way in which they are fitted up. The primitive frame was, indeed (as its name implies), a pit-frame, and is still, I believe, used in some parts of the country yet. It is something similar to a sawyer's sawing-pit, only, of course, very narrow. A pit was dug 5 ft. long by 1 ft. wide, and 1 ft. deep; four posts were driven in, and the top was made exactly the same as the one I am going to describe 2 ft. high from the ground.

But this pit being a fixture in the shop or yard, it took up too much room, so, therefore, it has given way to a more convenient one, which I will describe, and show you how to make one exactly the same as I have, and on which I have made hundreds of wheels. It can be carried about by two men, and when not in use and there is no room to spare in the shop, it can be put outside in the yard, as I have kept mine out in all weathers, in summer and winter; and it appears to be as strong (although it is not painted) as it was when first I made it years ago.

The top of the frame which I have has apparently been the trunk of an ash sawn in two, as the under part and sides are just a little round, where the bark has been peeled off. I merely mention this to show that the top only is required to be straight and square, and also the sides a little, but, if the top be all of one width, so much the better.

In the first place we shall require two long lengths of ash or deal. If of ash, it should be $3\frac{1}{2}$ in. thick; if deal, 4 in. thick. These two pieces must be 6 ft. 4 in. long, 7 in. wide, and $3\frac{1}{2}$ in. thick; two swords 2 ft. by 3 in. by $1\frac{1}{8}$ in. of ash or oak; four legs, $2\frac{1}{2}$ ft. high by $2\frac{3}{4}$ in. square, also of oak or ash. These measurements are just as I have measured, so that you must allow for sawing and planing. Get your jack plane and smooth the two large pieces at the top and sides, also your swords. Then lay your large pieces or top on your bench both together in a line, put your swords upon the top, about 3 in. from each end of the large pieces, and mark with pencil each side of sword on the frame top.

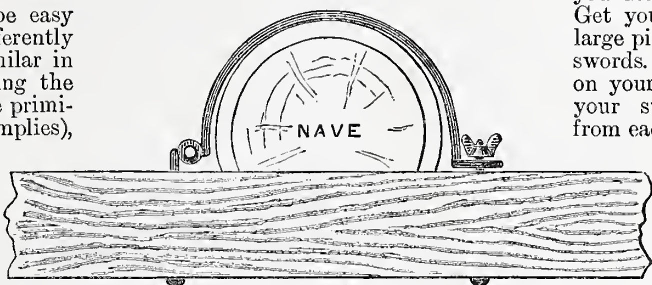

Fig. 3.

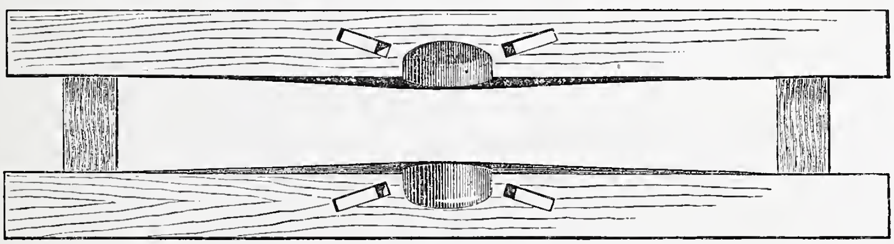

Fig. 1.

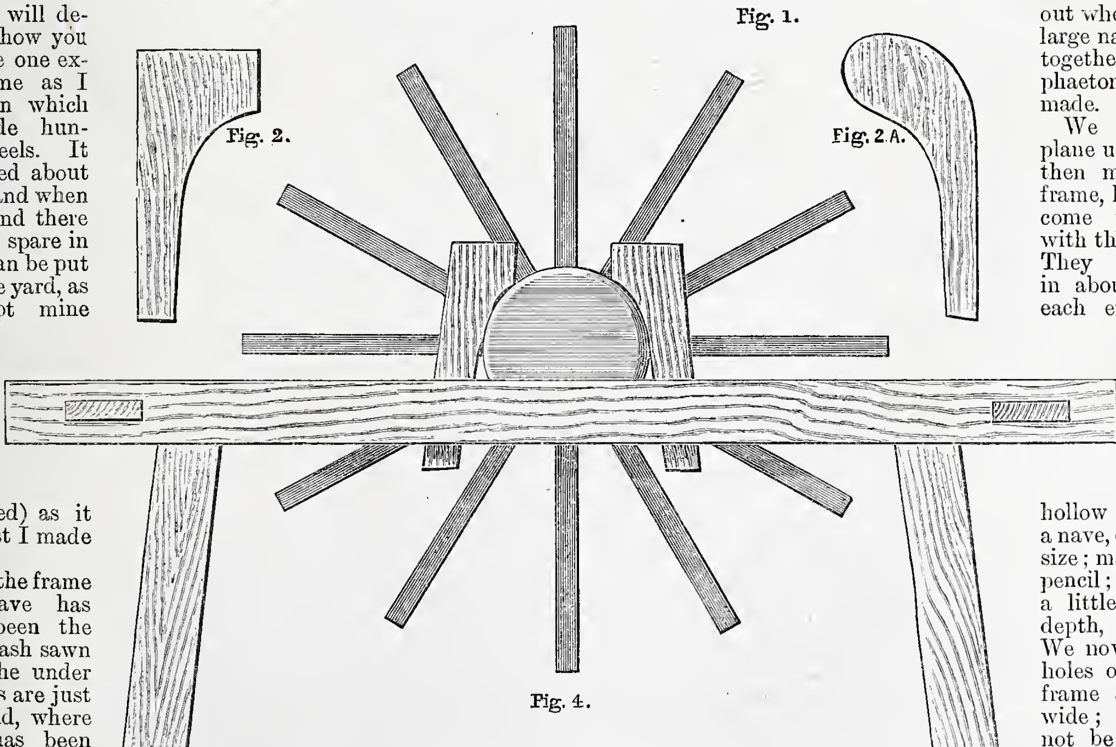

Fig. 2.

Fig. 2 A.

Fig. 4.

Fig. 1.—Plan of Top of Pit-Frame showing Mortises for Holdfasts. Figs. 2, 2a.—Wooden Holdfasts to hold Nave. Fig. 3.—Nave held on Frame with Iron Holdfast. Fig. 4.—Front Elevation of Pit-Frame, with Nave and Spokes in Position.

We now get the large piece and square down the sides from the pencil line. When we have served all the four sides alike, we set our gauge and mark for the mortise. This mortise must be 3 in. by $1\frac{1}{8}$ in. wide: bore first with $\frac{3}{4}$ in. bit, then mortise out with a sharp paring chisel. Knock in your swords; do not fit them in slack, and they must not be fastened in the frame, as it sometimes has to be drawn out when mortising a large nave, or pushed together when a small phaeton wheel is being made.

We now roughly plane up the four legs, then mortise in the frame, letting the legs come through level with the top of frame. They are mortised in about 15 in. from each end of frame. You will see that the legs stand out all round. Now find the centre of frame, and hollow it out; or get a nave, one of medium size; mark round with pencil; hollow this out a little at its lowest depth, say $1\frac{1}{4}$ inch. We now mortise four holes on the top of frame 3 in. by 1 in. wide; these must not be in a straight line, but slanting as Fig. 1. The space between the mortises must be $6\frac{1}{2}$ in. : these mortises are to be fitted with four holdfasts, as in Fig. 2, or 2A. These are of ash, the size of them being 20 in. long, full $\frac{3}{4}$ in. thick, $2\frac{1}{4}$ in. wide at the foot, getting thicker and wider at the top. Instead of these holdfasts, some wheelers have an iron band or hinged clamp which fits half way over the nave to hold it fast in its place whilst it is being mortised. At one end there is a thumb-screw which, when unfastened, allows the nave to be turned round. These iron holdfasts (Fig. 3) are fixed where the fret or hoop will be when in its place on the nave.

The pit-frame which I have been describing, and which is shown in Fig. 4, is, I think, the one which is most approved of, as the wheeler can get at the wheel all round. The third kind of frame is made exactly like Fig. 4, only half of it being fixed to the wheeler's bench. It is a piece of deal or hard wood, 6 or 7 ft. long, with two legs mortised into the top of frame. This half of frame must be quite level with top of bench. Two swords are then fixed upon the top of bench and frame. A 2-in. slot 1 in. from each end of sword is mortised for thumb-screws to work in, or holes can be bored in the sword every inch or so to allow the screws to be put in to tighten and keep the frame together. Two holes are mortised in the bench, and also a little wood hollowed out, to bed the back end of nave. This kind of a pit-frame certainly is a very convenient one, as it does not take up much room, and when not in use can be put at one side until again required.

SMITHS' WORK.

BY J. H.

(*Continued from page* 199.)

CAUSES OF LACK OF TALENT, ETC.—MISTAKES IN EDUCATION—LOWEST POINT OF SMITHS' WORK RENAISSANCE OF MECHANICS—AGE OF MACHINERY—CAPITAL AND LABOUR.

ONE main cause, as I think, of our lack of talent and originality in conception and execution is that our common methods of training do not sufficiently *educate*—draw out the latent faculty of the mind. Our training is imitative rather than originative ; it is mechanical, not creative. There is such a thing as mechanism of the intellect as well as of the hands. Instead of training the inventive faculties and encouraging the plastic minds of the young to follow the bent of their own individual genius, we give to them set tasks, too often destitute of animating life, divorced from ideals, and say in effect, "Learn these ; do these things, and you will become educated." But cramming with undigested and disjointed facts is not the way to evolve and nurture genius, art, beauty, and perfection in design and work. After centuries of pedagogy we are, so it seems to me, to learn the whole art and mystery of education over again. Interest, devotion, originality, must be awakened, fostered, and developed ere we shall behold the revivification of the fair ideals whose loss we unfeignedly deplore. Only in this way can the crushing effects of the use of machinery, and of the consequent division of labour into petty, paltry sections, be eliminated ; and only in this manner can the ruin of the old craftsmen be retrieved. In this lies much of the value of such journals as WORK and those of kindred character. Their mission is to awake brighter ambitions and aims than those at present existing, and to teach men those principles which underlie the practice of their crafts, and which in the modern workshop are not made a necessary part and parcel of their training.

I think we may regard the eighteenth century as being the nadir of industrial skill. The old race of craftsmen had mostly become extinct, the new race had not yet arisen. Hand-work had been neglected, machine-work was not come to the birth. The inventions of the last century demanded an excellence of workmanship which it was impossible to procure by any means. Bramah, Maudsley, Holtzapffel, and other contemporaries were in their infancy. Watt, writing to Dr. Roebuck, says: "You ask what is the principal hindrance in erecting engines? It is always the smith-work." His first cylinder was made by a white-smith, of hammered iron soldered together ; but having used quicksilver to keep the cylinder air-tight, it dropped through the inequalities into the interior, and "played the devil with the solder." Yet, inefficient though the whitesmith was, Watt could ill spare him, and we find him writing to Dr. Roebuck almost in despair, saying, "My old white iron man is dead," feeling his loss to be almost irreparable.

Watt continually complained of the failure of his engines through "villainous bad workmanship." Writing once to Dr. Small respecting a cylinder 18 in. diameter, he said at the worst place the long diameter exceeded the short by *only* $\frac{3}{8}$ in. Brunel could not for a long time get mechanics sufficiently skilful to construct his block-making machines.

But the great mechanicians of the eighteenth and nineteenth centuries have by their inventions completely revolutionised the character of our mechanical industries. Bramah, Maudsley, Penn, Clement, Nasmyth, Roberts, Fairbairn, and Whitworth are names to be held in everlasting honour They are the creators of the Renaissance of mechanics, names familiar to the cultured workmen as household words. Yet although we live in the Renaissance of mechanical skill, it is not skill of the same character as that which gave a lustre to the early and mediæval Christian centuries. The skill we boast of now is of an essentially different kind from that whose loss we deplore. We live in an age of machinery. With machinery there has come division of labour, perfection, and cheapness, at the sacrifice of individuality and of real artistic skill. The artist is crushed beneath the wheels of the car of our modern Juggernaut, the great god Mammon. A workman who sought conscientiously to emulate the old craftsmen would be undersold in the market, and starve by reason of the rage for cheapness.

The cause, therefore, of the decay of artistic craft lies deep down in the foundations of our social life. Master and man, with their living personal relations, have yielded place to "capital" and "labour," with their cold impersonalities. How much is involved in that ! In the great and silent revolution that has taken place, the artist craftsman, member of a proud guild, has given place to the mere "hand," the unionist, whose watchwords are the "three eights." Capital accumulates enormous fortunes; labour shuffles wearily through its tasks, and longs for the sound of the last bell ; capital has become synonymous with a proud abstraction ; labour is a portion of a huge machine by which capital is created. Labour is divorced alike from both wealth and art. The beauty of ideality has departed from every-day tasks ; and life's work is brutish without ideal, ambition, and glimpses of the spiritual and intellectual.

THE SAW: HOW TO USE IT.

BY J. H.

(*Continued from page* 162.)

TROUBLES IN SAWING—SAW STICKING IN WE WOOD—DIFFICULTY WITH HARD THIN WOO —SPECIAL SAWS FOR SPECIAL WORK—TENO SAW—DOVETAIL SAW—CROSS-CUT SAW- LINING OUT—TIMBER FOR CUTTING—ATTITUD IN SAWING WITH HAND SAW—ANGLE OF SA —KEEPING SAW UPRIGHT—REMEDY FOR EVIL —HOW TO USE TENON SAW.

HAVING now clear ideas respecting th proper form of tooth for the common han saw, we can presently pursue our subjec further, taking examples from the saws o other types. But first let us note the metho of action of the hand saw.

If we try to cut down a piece of we plank with a hand saw, we shall encounte great labour and difficulty in doing so. I we attempt to cut across the grain—that is transversely to the direction of the fibre —the difficulty will be much increased and if the stuff is of considerable thicknes the saw will stick fast, so that it will b impossible to move it in its kerf. If w attempt to use the same saw on thin an hard wood we shall meet with trouble o another character. The teeth will hitch i the wood, the saw will sway too loosely an freely in the kerf, and, if we cut across th grain, the timber will become broken o spalted out. Obviously, therefore, different materials require different forms of sa teeth, and the teeth of the hand saw ar only a kind of compromise between extrem forms, in order to enable the saw to do work of an average range.

There are two reasons why the saw stick in soft wet wood. One is that the kerf is not wide enough, the other is that the saw-dust cannot get away with sufficient rapidity. Hence the remedy is to increase the set and to enlarge the spacing, which means an increase of the pitch or centres of the teeth, with a consequent increase in the sizes of the teeth themselves.

The principal reason why the hand saw does not operate sweetly in hard thin wood is because there is too much set, and, in a lesser degree, because the teeth are too coarse and too wedge-like in form. Hence, diminish the set and spacing, and alter the rake. In hand saws which are used exclusively for soft or for hard woods, these modifications are made, a kind of intuitive knowledge begotten of experience and observation guiding the workman in the selection of the forms best adapted for any class of materials. When the limits of average work are passed, special saws are used, one saw being kept for ripping and another for cross cutting, each being of a different and distinctly marked type from the other. Then, again, according as a man works habitually in soft or in hard woods will the forms of these be slightly different. Fig. 8 shows the average forms of teeth of ripping saws used exclusively for cutting soft wood with the grain ; Fig. 9 those for hand saws for general use on hard wood ; Fig. 10 those of cross-cutting hand saws used chiefly on planks and boards of soft wood. In Fig. 8 the teeth are of an acute wedge-like form, having much penetrative power, and the teeth are so pitched that there is ample space between them to receive and carry away the coarse, fluffy sawdust. In Fig. 9 the teeth faces are set back, having little penetrative power, while there is yet sufficient interspace for the fine powdery dust removed from hard wood. In Fig. 10 the teeth are also set back, in order not to hitch in the grain fibres, and the amount of set is so large that the kerf is made sufficiently wide for the saw to pass freely between the severed and roughened-up fibres of the end grain.

Should any one question the effect of these apparently minute differences in form and set of teeth, let him try to cross cut any wood, soft or hard, with the ripping saw (Fig. 8), or to rip soft wood with the cross cut (Fig. 10). In the first case the saw would hitch perpetually, causing painful jar to the hands, and finally refuse to penetrate beyond a certain depth. In the second the labour to be expended would be excessive, and the saw would wobble about in a kerf of unnecessary width.

The remarks which apply in the main to saws of the hand-saw type will also apply in principle to all other forms. But in some the differences are more marked than in others.

The common tenon saw has more or less both of set and rake, according to the material upon which it is chiefly used. Usually it is set and sharpened in a medium or average style for general bench use. But according to the character of the

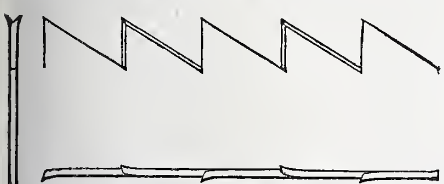

Fig. 8.—Teeth of Ripping Saw.

Fig. 9.—Teeth of Hand Saw for Hard Wood.

Fig. 10.—Teeth of Hand Saw for Cross Cutting.

work mainly done the size of the saw selected is from the 12-in. or 14-in. "tenon," to the 6-in. or 8-in. "dovetail," the teeth in the latter case being so fine that the thinnest wood and the most delicate joints can be cut without risk of tearing out the grain. In the large frame, pit, and circular saws, the tooth forms are often very much gulleted, to afford ample clearance space for the escape of the dust, while the angles, rake, and set are subject to much variation with the different qualities of timber operated on. In the two-handled "cross cut" the teeth are modified to cut in both directions, a form which is improved upon in the saws with M teeth.

A saw that is set and sharpened to be best adapted for its special work is much easier to use than one not so suitably adapted thereto. But, beyond this, there is art involved in the correct use of any saw, and the following notes thereon may be of service.

First, as to lining out. The chalk line, pencil, and scribe are variously used for the marking of the lines by which the saw is guided. The first-named is used for long pieces of timber, the second for ordinary and roughly approximate work, the third for the most accurate sawing.

In the first case a piece of fine cord is whitened with a lump of chalk, and being strained taut between two points whose positions are marked to correspond with the terminations of the line of cut, the chalk line is lifted vertically at or near the central portion, and being suddenly released, transfers to the timber a portion of the chalk, so marking a perfectly straight and fine line upon the timber, which thus furnishes a correct guide to the saw.

In the second, the pencil is used to mark lines for rough sawing, as when cutting short lengths from board, or cross cutting boards or planks.

In the third, lines are marked with the timber scribe, as in squaring the ends of planed stuff and in marking dovetails and tenons. The saw may then be made to cut close outside the scribed line, allowing just sufficient margin of material to be removed with the plane; or the saw may pass right along the scribed line, as in cutting dovetails and tenons, no after-finish being required. In either case the scribed line is preferable to the pencil-marked one, because the cutting can be done much more accurately in the first case than in the last. Also, when the end of a piece of timber has to be squared with the plane, there is, besides the greater accuracy, much less risk of spalting or breaking out of the grain occurring with scribed lines than with pencil-marked lines. In the case of planed ends, a careful workman will also contrive to saw extremely close to the scribed lines, in order to diminish as much as possible the labour of planing.

When cutting with the hand saw there is a certain orthodox kind of attitude generally assumed. The workman stands alongside the stuff, laid upon low sawing stools or trestles, steadying the board, if light, with his right knee, holding the saw in his right hand at an angle of about 65°, and steadying the edge of the board near the saw with his left hand. This position is, on the whole, the best, though many men are skilful in the use of the saw in another fashion. Sitting on the board, they hold the tool with both hands, in an approximately vertical position, and cut rapidly towards themselves, moving backwards with the advance of the saw. The general practice is, however, that first named, and is that in which the greatest power can be exerted and the most accurate sawing done.

The angle of about 65° at which the saw is held is also that which is best on the whole. If the saw is much more inclined, it cannot be advanced so rapidly through the wood; if much less inclined, the workman is forced to assume a somewhat constrained, bending-over kind of position, and the guidance is scarcely so good. Young apprentices usually err at the beginning by giving too much inclination to the saw.

Another point equally important is to keep the saw plumb in a direction transversely to the direction of the cut. Here the tendency is unconsciously to pull the saw towards oneself, causing the cut edge to become other than at right angles with the face of the board; and the canting over is usually not even uniform in unskilful cutting, but varies at every few inches, so that when the edges have to be planed, the timber may probably not hold up to the required width. Then, again, the cut will become wavy in the direction of its length, rendering a moderate allowance for planing insufficient.

The only remedy for these evils is care and practice at the commencement of sawing. The eye should be cast down the blade in order to judge whether or no it is plumb over the line. The attention must be specially directed to this point during the first few strokes of the saw, since to begin right is half the battle. A saw having an excess of set is more difficult of initial guidance than one having a proper amount.

When the saw has once fairly started the cut to a distance equal to the width of, say, its own blade, the risk of departure from linear accuracy is diminished. But even then the tool is apt to "run" by reason of momentary inattention, or by reason of a faulty setting or sharpening of the teeth more to one side than the other, and then the saw will have to be gradually and gently coerced into the right path, slight pressure and twist being imparted from the handle during cutting.

In ordinary sawing the workman bends over the board, not, however, in a too constrained position; and though the strokes of the saw are properly given to the full range permitted by its length, the workman does not sway his body to the same extent as the saw, which would be extremely tiresome, but directs the strokes mainly from the shoulder. The more free and unconstrained the attitude, the greater will be the amount of work got through.

Speaking generally, it will be found that the angle 65° given as the average angle for sawing will be varied with advantage in different materials. Of course, workmen do not measure the angle. I only give it as an approximate guide for beginners, who usually go wrong here. In thick stuff it will be found that there is advantage gained by keeping the saw slightly nearer the vertical, and in cutting thin stuff it may be slightly more inclined. In thin stuff the kerf affords less guidance to the saw than in deep stuff, and the wood is more likely to break out, especially in cross cutting. Hence the reason for the greater inclination.

The tenon saws are generally used at a very slight inclination only with the line of cut often almost parallel; there is then little risk of broken edges. A panel saw will cut much more rapidly than a tenon saw, and should be used in preference for cross cutting of ends and shoulders in quantity; and with fine teeth uniformly set and sharpened, there is practically no risk of broken edges.

After skill in the use of the hand saw and cognate types, facility in that of the smaller saws follows as a matter of course. Similar principles apply to each; matters of set, rake, sharpening, and guidance are pretty much alike, whether we use the large saws or the smaller bow, compass, or keyhole saws, and the principles of operation are alike in all.

THE TENANT'S GREENHOUSE.

UNATTACHED TO THE SOIL AND REMOVABLE AT PLEASURE.

BY GEORGE LE BRUN.

(*Continued from page* 212.)

Completion of Structure—Barge Boards at Ends—Alterations in Details—Filling up with Brickwork—Boarding Filled with Sawdust — Ventilation by Fanlights in Ends — Roof Ventilation — Ornamental Cresting for Ridge—Concealment of Sill —Stop Chamfering of Posts—Greenhouse on Flat Roof.

With the completion of the work, as described in the previous papers, the house is finished, at least, so far as the joiner's work is concerned, and only requires glazing and painting to fit it for the reception of the plants. It presents the appearance shown at Fig. 9 (see No. 12, p. 177), in which the alternative method of diagonal match-boards and Gothic-headed sashes are shown.

To further improve and ornament the structure, barge boards may be put on the ends, and their addition will much improve and beautify the greenhouse, while the extra labour involved is but little. A simple design for barge boards is given at Fig. 19, while Figs. 20 and 21 are of a more ornamental nature. There are many minor alterations in the details of construction that may be made to suit particular requirements, or as the fancy of the builder may dictate; as, for instance, instead of lining the lower part of the house with wood, bricks may be used to fill in with, in which case the sole and belt rails would require to be the width of the bricks used, and would

also be made in the roof if desired, and hinged at the upper end, but this is not so desirable, as there is a certain amount of difficulty in keeping roof openings water-tight, and, if ventilation is wanted high up, the end fanlights will serve every useful purpose.

Roof ventilation can be had, however, in a very simple manner, as will be seen on referring to Fig. 25, which gives a section of the roof, in which an opening board running the entire length of the roof is shown. For convenience in lifting, this board may be sawn across in the middle, and should have cross ends grooved on to prevent warping. In this style of construction it will be seen that the roof sashes do not come up to the ridge board (the stiles had better be kept the full length to afford a support for the ends of the ventilating board); they are kept about 5 in. short, and rest upon rafters, of which there should be three on each side of the house, one under the joint of the sashes, the other two at equal distances from it and the ends of the structure.

the sill lifted and knocked asunder, and the whole packed on a waggon and carried off, the garden ground remaining without so much as a stakehole in it, excepting, always, the drain pool two feet below the surface.

Two minor details I might draw attention to: the outer corners of the corner posts would be much improved by stop chamfering, or rounding; and it would also be advisable to bevel off the outer top edges of the top rails of the side framing for, say, 1 in., so as to allow the roof sashes to have a better hold. These things are not absolutely essential, but are desirable.

There are many houses in London, and other places, that have anterooms, kitchens, etc., projecting in the rear, and having flat roofs, often covered with asphalt or cement. On such a roof as this the greenhouse could be erected, and entrance to it be had either from a window or by means of a trap stair or even by a staircase or steps placed without if there were no means of access from within. In such a position the possession of it would be doubly desirable to the town resident who often has to content himself with a

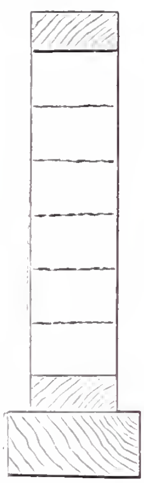

Fig. 22.

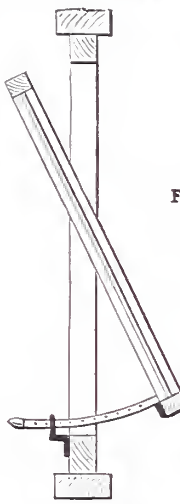

Fig. 24.—Section of Opening Pane or Ventilator in Side or End.

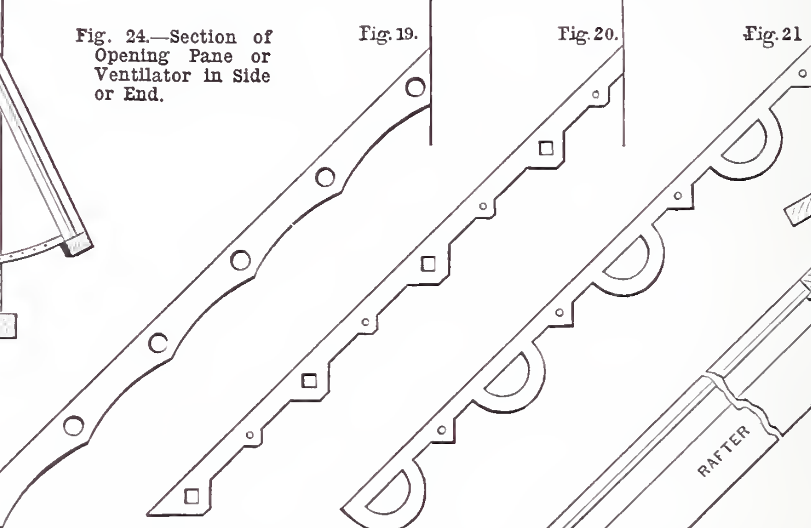

Figs. 19, 20, 21.—Designs for Barge Boards at Ends.

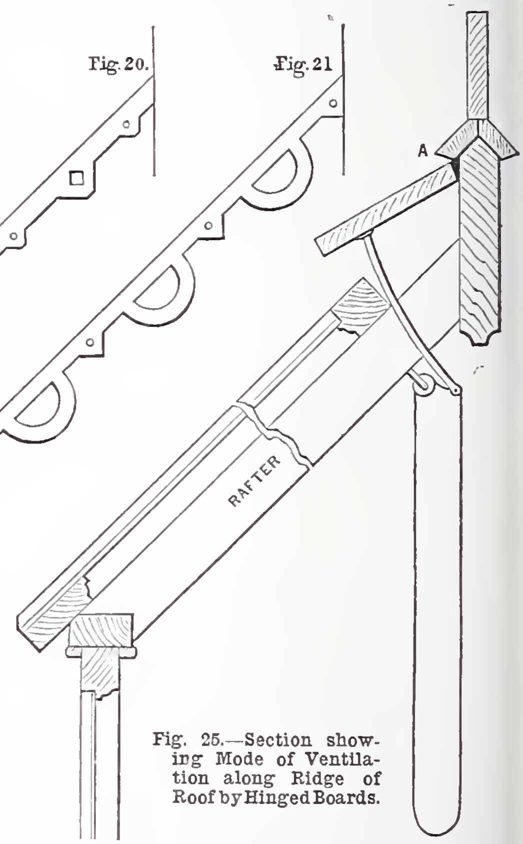

Fig. 25.—Section showing Mode of Ventilation along Ridge of Roof by Hinged Boards.

appear in section as in Fig. 22. Brickwork is certainly more conducive to the preservation of heat than wooden lining, and, in case that artificial heating were resorted to, would be very serviceable; but, then, bricks are not so handy in the event of a removal, so that another method might be had recourse to if heat were wanted, and the use of brickwork was objectionable. A double lining of wood could be put on, and the space between filled in with sawdust, or other material, in which case the details would be as in Fig. 23; both the inner and outer lining taking the form of panels, and being secured by screws only.

As to the opening of the fanlights in the ends, there are some florists who object to that mode of ventilation, and who prefer to have the opening panes at the sides of the house. In this case the alteration in structure is obvious; fix the square sashes in the ends, and make a pane in each of the side sashes to open. For this purpose two thicker sash bars must be put in to carry the opening pane (say $1\frac{1}{2}$ in. thick), which will be hung on pivots in the style of Fig. 24; keep the pivots nearer the top than the bottom, and put on an iron strap with holes in it to catch on a pin, as shown, so that the window can be opened and kept in position as wanted. Opening panes can

The ventilating board is hinged at A, and is opened and shut by means of a cord and pulley worked from below. Rain-water is prevented from entering at the hinged joint by a narrow board nailed on top of the ridge-board, the under edge of which is bevelled as shown in the drawing. The ornamental ridge is put on top of this board and covers the joint of it and its fellow on the other side.

The wooden sill on which the greenhouse rests can have the earth loosely banked up against it to hide its roughness, while the part at the door can either form a step upwards from the garden level, or the approach to it may be gradually raised so as to do away with the step entirely. There are many little details that will suggest themselves to any one who constructs a house of this kind, and the imperfections of the one described, though many, may be smoothed away. My aim has been to fix my attention more on the fact that the house must be removable at will, and so out of the power of the landlord to seize as a fixture, and at the same time be tolerably easy of construction, rather than that it should be perfect in either design or proportion. This aim I think I have accomplished, as every part can be unscrewed and taken separate,

paved backyard and a few pots of flowers, as by its aid he would be able to cultivate choice plants and enjoy his gardening hobby to a much greater extent than he could hope for without the aid of some such easily erected structure.

The amusement to be obtained from a small greenhouse, to say nothing of the profit, is considerable, and no man who can manage to put one up, however poor in general appearance it may be, should be without one. In a house with a good southern exposure, cucumbers may be grown readily, and the vines trained along the sash bars, or better, on wires a little below the sash bars or rafters. Tomatoes may also be grown to please the eye, first of all with the rich hue, deep scarlet or amber, as the case may be, of the clustering fruit, and then the palate, either cooked or in the form of salad.

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

(*Continued from page* 187.)

SMITHING, PLANING, PUNCHING, DRILLING.

IN some classes of girder work there is a great deal of smithing to be done in cranking angle and T irons, and joggling their

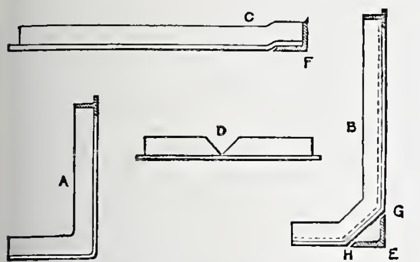

Fig. 6.—Principal Forms of Ends of Angle Bars, T Bars, etc.

ends, and there are two principal methods in use for effecting this: drawing the bars over a block by the hammer, and forming them in dies actuated by hydraulic pressure. In both cases the material is worked at a red heat, the temperature being lower for steel than for iron. In Fig. 6 are shown the principal forms to which the ends of T and angle bars are shaped; A shows one bent at right angles, frequently used in connecting cross girders to the webs of main girders; B is a cranked end used for stiffeners, which are riveted to both the web and flanges of plate girders; the cranking allows them to clear the longitudinal angle irons of the main girders. Such an angle iron is shown in section at E in the position it would occupy in the main girder. At C is an end of a bar joggled to pass on to the limb of an angle iron, on the same plate as that to which it is riveted itself. In some cases the bar ends have to be skewed, or bent sideways as well as vertically, but such forms should always be avoided where possible. To make the square bend, A, it is necessary to cut out a V-shaped piece as shown at D, then the bar is bent and the cut limb welded together again. A weld is always objectionable, doubts as to its soundness being very apt to arise, but in this case it cannot be avoided.

The whole difficulty in welding is in keeping the surfaces to be joined clear of scale and other extraneous matter, which might get closed up in the weld and so cause a flaw, which, being hidden, would escape detection. By the recently introduced methods of welding by the heat derived from gas, a greater degree of certainty as to the soundness of the welds produced should be created, and more satisfactory results still may accrue from electrical welding, if it proves easy of manipulation in the every-day routine of a workshop. In such operations as that of welding, the results of experiments specially made scarcely form any criterion of practical utility, especially where the piece-work system is in force. In the electrical welding, moreover, there must be an element of danger, from the magnitude of the currents necessary to produce a welding heat.

In making the square bend, A, there should be practically no alteration in the length of the bar, but in drawing the end over a block to form the cranked end, B, there will occur some lengthening, more or less considerable, according to the temperature at which it is worked, and the aptitude of the smith working it. In order to save waste, the bar should be cut off to such a length as will, when bent, be of the required dimensions. I have found in average work that it is about right to measure the drawing or template just clear of the root of the angle or T iron, as shown by the dotted line on bar, B. If the iron is very deep on the web, it may become necessary to cut and weld the bar even in making the crank end, B. In such cases it is better, instead of making the two distinct bends, to curve the bar uniformly from G to H; in this way none of the metal is lost; it goes in thickening the web of the T iron. In the joggled end, C, there is no element of difficulty; the bar requires slightly upsetting and then hammering down to shape, and a little extra length must be allowed in cutting off the bar for the joggle. The ends of the bars will require to be trimmed off square after they are worked, and for this about a quarter of an inch at each end is sufficient.

A much more satisfactory job is made by using hydraulic pressure to make these bends; then the bars are not lengthened, and therefore not thinned, but the slight excess of metal goes to thicken the web and make the bar stiffer at the bend, and, therefore, stronger for its particular duty in maintaining unaltered the angles of the parts of

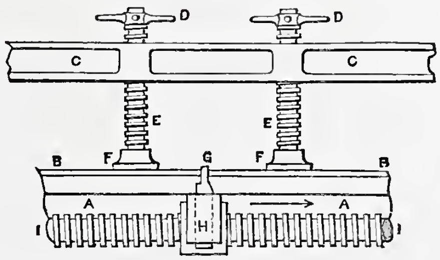

Fig. 7.—Front View of Plate Edge Planing Machine.

the girder to which it is riveted with each other. The fact that this thickening must take place, must be borne in mind during the preparation of the dies, and the requisite room allowed for it, otherwise they will not work. Another considerable advantage that is secured by the hydraulic method of making these knees, is that they are all turned out exactly alike—a result not to be hoped for with hand labour—and, therefore, the uniformity of the work is ensured, and the true bearing of all the stiffeners will materially aid in securing the rigidity of the structure. It may here be mentioned that in hand-bent bars the angle irons will be more troublesome than the tees, on account of their always tending to open out at the bend.

We must now follow our work to the machine shop, where the various parts are to be brought to their correct sizes and made to fit properly together. The planing of the plate edges and ends will first receive our attention. The plate-edge planing machine differs very materially from the planing machines of the engine shops, inasmuch as in the latter the bed of the machine—on which the work is fixed—moves while the cutting tool is at rest, but in the former the reverse is the case. Fig. 7 is a front view of a plate-edge planing machine, shown broken off, as they are made of considerable lengths in order to allow the edges of long plates to be planed throughout without having to shift and refix them on the bed of the machine, an operation of the greatest delicacy to ensure a straight edge throughout the length of the plate. A A is the bed of the machine upon which the plate to be planed, B B, is firmly held down by the heads, F, F, of the screws, E, E. These screws are adjusted by the cross handles, D, D, and work in threads cut in the longitudinal beam, C C. G is the cutting tool carried in the tool box, H, which is driven by a strong square-threaded screw, I I. The machine is fitted with an automatic tumbler to reverse the motion of the screw at the termination of a cut.

The plates having been planed on both edges, a number, of the same width, may be laid together and fixed on the end planing machine, and their ends all planed at one operation by a milling tool, which is essentially a revolving cutter working at right angles to the length of the machine bed. The revolving cutters as formerly made were far from being perfect, but during the past ten years very great advances have been made in the appurtenances of milling machines, and very good work is now turned out by them. In recent years, also, emery wheels have come into use, more especially on the continent, for finishing off certain parts such as the ends of cross braces and other parts that require to be accurately fitting at the joints, but I do not much incline towards their use.

The plates having been planed, or otherwise shaped, the making of the rivet holes comes next. If they are plain punched they will probably require some rymering, but with this I shall deal subsequently, merely pausing here to point out the disadvantage of using rymers under these circumstances. It is very important to get a clean hole so that the bearing of the rivet may be uniform, and to obtain this a tool with an accurate cutting edge must be employed, and the edge of an ordinary rymer is not a cutting but a scraping edge, the angle of its cutting edge being not less than 90°. The use of such a tool must tend to bulge the plate.

When the rivet holes are drilled, as in the best class of work, multiple drilling machines are used, and several plates may be drilled together, thus ensuring the exact coincidence of the rivet holes with one another, and abolishing the necessity of

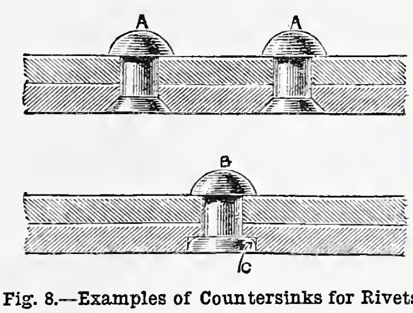

Fig. 8.—Examples of Countersinks for Rivets.

rymering out the holes afterwards; the only treatment the drilled holes require is the removal of the sharp rises around them, which might tend to start a crack under the rivet head during the cooling and contraction of the rivet.

The drills used should be carefully made with true cutting edges, the preference being given to what are known as twist drills, which, besides having true cutting edges, run very steadily, and, therefore, do good work, the chatter which occurs with scraping drills being avoided. I have referred to the difference in widths between the top and bottom of the web plates, caused by the practice of cambering girders; this will necessarily cause a difference of pitch between the top and bottom rows of rivets, unless the whole difference is taken up in the end pitches of each plate, which is certainly not so convenient as running a uniform pitch the whole length of the girder. The having to break pitch in certain places on the longitudinal angle irons has a tendency to lead to mistakes, and in any case it precludes the changing place of angle irons if it should be desired to alter the position of the joints for convenience of carriage or any other reason. Of course I know that all these points of detail should be definitely settled before the work is sent into the yard, but I also know from experience that it not unfrequently happens that a great many alterations are made during the progress of construction, and it is therefore advisable to be as far as possible prepared for any emergency that may arise. In the example taken, it was found that to give the requisite camber, the plates which were four feet wide at the bottom had a top width of 4 ft. $\frac{1}{16}$ in. At 4 in. pitch the number of rivets in the bottom edge would be twelve, and the same number should be put in the top edge, the pitch being found by taking a line 4 ft. $\frac{1}{16}$ in. and dividing it up into twelve parts with the compasses. When riveted girders rest upon plane bearings, it is necessary to sink the heads of the rivets in the plate on the side in contact with the bearings; therefore, in such positions, the rivet holes have to be countersunk as shown at A, in section, Fig. 8. The countersinks should be cleanly made with drills or rosebits, and where the thickness of the plate will allow, it should not be less in depth than one-third the diameter of the rivet, but it should not exceed one-half the thickness of the plate. Could the rivets be properly closed, a square sink, as shown at B, would be preferable, as it would give the rivet head a better hold upon the plates, but the sharp corner, C, running round the rivet would not get filled in. I am inclined to think that, at the hands of designers, the rivets do not receive the amount of consideration to which they are entitled. The whole safety of a structure depends upon its joints, and the most careful and elaborate calculations of main sections will be wasted if not followed up by correctly proportioning and placing the rivets. The strains to which rivets are subjected depend upon their positions; thus, if a load is held by a member hanging on the head of a rivet, the tendency is to pull the rivet asunder, or to strip the head off it. If the rivet is holding two plates together which are acted on by forces in the direction of their length, the effort will be to slide one plate upon the other and shear the rivet through the body or crush it by compression. When the rivet is intended to resist the first kind of strain, it is evident the head should be of sufficient thickness to afford as much strength against stripping off as its body does to tearing across. The stripping off of the head will evidently be a shearing strain, and the surface acted upon will be the circumference of the rivet multiplied by the thickness of the head. The surface resisting tearing is the cross sectional area of the rivet. The working strengths are for iron in shearing, 4 tons per square inch of sectional area; and for tensile strain, 5 tons. The cross sectional area is equal to the square of the diameter multiplied by 11 and divided by 14; and the stripping area is equal to the thickness of head multiplied by the diameter of the rivet and by 22 and divided by 7. These two sums being equal would give equal areas of resistance, in which case the thickness of the head would be one quarter of the diameter of the rivet; but the resistance to stripping is only four-fifths of that to tension, so one-fourth must be added to the stripping area, thus making the least thickness of the head equal to five-sixteenths the diameter of the rivet, and it is better practice to make it at least three-eighths the diameter. Now, in regard to the second kind of joint, the resistance to compression is the same as that to shearing, so the bearing area of the rivet in its hole should be equal to its cross sectional area. The bearing area measured square to the line of strain will be the diameter of the rivet multiplied by the thickness of the plate, and to this must be equal the square of the diameter multiplied by 11 and divided by 14, when the diameter of the rivet will be equal to the thickness of the plate multiplied by 14 and divided by 11.

THE PREPARATION OF PLATING SOLUTIONS.

BY F. W. MASON, CONSULTING ELECTRICIAN AND CHEMIST.

Classification—Gold Solution—Silver Solution—Platinum Plating—Copper Solution—Lead Solution—Nickel Solution—Brass Solution.

In the preparation of these, as most platers are aware, too much care cannot be given. Plating solutions may be roughly divided into two classes:—First, those of the rare or precious metals, as gold, silver, and platinum; second, those of the coarse or common metals, as copper, zinc, etc. Before proceeding further, it may not be out of place to state that all figures employed throughout this article are the results of practical experience, and not the mere figures attained by a few experiments. I will, first of all, give the preparation of solutions of the rare metals, as these are of the most consequence, and likewise the most frequent in use.

Gold Solution.—First in order let us consider the gold (*aurum*) solution, which is best made up to the strength of 8 dwt. to the gallon. To make it, proceed as follows: Take 8 dwt. of fine gold and put it in a porcelain dish of about 40 oz. capacity—an enamelled saucepan will do if this is not attainable—then pour upon this, gently, about 4 oz. of aqua regia (which is a mixture of hydrochloric and nitric acid, used in the proportion of two of the former to one of the latter), then gently heat the vessel containing the gold and aqua regia over a Bunsen burner — this to accelerate the chemical action. When the gold is dissolved, pour the solution of chloride of gold into another similar vessel and evaporate the acid off; a red mass will be the attainment thereby. If too much heat is used the gold will be reduced to the metallic state; if this should be the case, add a little more aqua regia to re-dissolve, and then re-evaporate. When the acid has been driven off, add to the resultant chloride of gold about one pint of distilled water, or failing this, use water that has been vigorously boiled and filtered. If, when the chloride of gold is added to the water, there exists a white precipitate, the chloride of gold solution should be carefully poured off it, and this precipitate is chloride of silver; it should never, on any account, be allowed to get into the gilding solution. Then to the solution of chloride of gold, a strong solution of cyanide of potassium should be added (this need not be of any specific strength); the result of this additiou of cyanide of potassium to the chloride of gold is a brown precipitate of cyanide of gold. The solution of cyanide should be carefully added, so that a drop at last should have no effect upon the clear solution. If you add too much cyanide, you will re-dissolve the cyanide of gold. This cyanide of gold should be allowed to stand for about fifteen minutes, and then the clear liquor poured off; the precipitate should then be washed two or three times with distilled water. This is done as follows: A quantity of distilled water is poured upon the precipitate; this is then allowed to settle and the water run off; this is done two or three times, as before stated. When the cyanide of gold is sufficiently washed, a solution of strong cyanide of potassium is added to dissolve it. When the gold cyanide is dissolved, a quantity of the solution of cyanide of potassium is added to it to form free cyanide. This is essential in the working of the solution; then a sufficient quantity of distilled water is added to make up to one gallon. This solution must be worked with a pure gold anode, and a battery power of two Bunsens, holding about a pint and a half each. If the solution works a bit slowly, a little fresh cyanide should be added, but you must be careful not to add too much, or the work will have a foxy colour. The solution must also be worked at a temperature of 125° Fahr. to 135° Fahr., with a solution same strength as above, and worked at a temperature of 132° Fahr., and two quart Bunsens the colour of the work has been first-class, far better than with other heats and strengths of solutions and currents.

Silver Solution.—This is prepared somewhat similar to the gold solution. Take 1 oz. of fine silver, and add to it about 3 oz. of nitric acid (this should be in a porcelain dish); stand this in a warm place; the silver is soon dissolved. As soon as the red fumes given off during the chemical process have ceased the silver is dissolved; the acid is then evaporated off, and the nitrate of silver treated exactly as the chloride of gold was treated. The solution is made up to one gallon, to be worked with a silver anode and two Bunsen cells, the same size as those used for the gilding. If the work is wanted to be of a bright colour, it can be obtained by the use of a little bisulphuret of carbon added to the solution; the way it should be added is as follows:—Take about half a Winchester of the silver solution and add to it 3½ F. oz. of bisulphuret of carbon; cork the Winchester and well shake it, and allow it to stand for a quarter of an hour, then shake again and allow it to stand. This should be very cautiously used; it should be added to the plating solution at the rate of 2 oz. per gallon of plating solution. This gives a bright, lustrous appearance to the work.

Platinum Plating.—This is generally done by means of a solution of bichloride of platinum ($PtCl_2$). Perchloride is the same as bichloride. This bichloride is prepared by dissolving the metallic platinum in aqua regia (equal mixture of nitric and hydrochloric acids). I myself prefer to use two parts of hydrochloric to one part of nitric acid. When the platinum is dissolved the reddish solution is evaporated down to a syrup, then re-dissolved in hydrochloric acid, and evaporated down to a syrup again. This is then cooled; it then solidifies to a solid mass. Care should be taken that the solution is not overheated in evaporating it down; as, if this is done, it will be found that the plating solution will be almost worthless. I myself also prefer (in the making of the bichloride) to use old platinum crucible lids in preference to new, or platinum wire. This old platinum, before being dissolved, should be boiled for about ten minutes in nitric acid, and afterwards dipped in a strong hot solution of caustic potash, washed, dipped again in nitric acid, and afterwards rewashed in distilled water; the platinum is then dissolved. If the platinum does not dissolve pretty quickly the application of a little heat will soon hasten it; I generally find, myself, that the solution requires a little heat. For the plating process I prefer to use a solution of the double salt of chloride of sodium and platinum, prepared by dissolving 268·4 parts of bichloride of platinum in distilled water containing 58·5 parts of chloride of sodium (common salt); to this add 55·96 parts of caustic potash. The solution should be made up so that it contains 400 grains of platinum in two quarts of water. Throughout these experiments distilled water was used; failing to obtain this my readers should use water that has been boiled for awhile and then filtered.

The following are the figures I employ for my bath:—Bichloride of platinum, 400 grains; chloride of sodium (common salt), 87·183 grains; caustic potash, 83·420 grains; distilled water, 2 quarts. The decimals can be rejected, and the whole numbers taken without any serious inconvenience. With this strength of solution I prefer to use a small anode and a weak current—about two Bunsens are the best. This current will, I think, be a little too strong; if so it should be regulated to the proper intensity by means of the ordinary plater's resistance board; the current I employ is 2·22 volts. This gives a very fair reguline deposit, far better than with any other strength of battery current employed; the article does not require much moving about in the bath, nor does it require (except in some cases) a very high temperature; between 65° and 70° Fahr. is very good. But a few words regarding the treatment of the articles themselves that are to be platinised. I cannot lay too much stress on having them scrupulously clean; in fact, experience proves to me that the cleaner they are the better the deposit takes place. For my method I use the ordinary acid dips, and then boil them in a strong solution of caustic potash, and then well wash them in distilled water, and then immerse them immediately in the bath. The only drawback to platinum plating is its troublesome working, which can be overcome by using the proportions named.

Having described the preparation of the rare solutions of gold, silver, and platinum, I will now proceed with the common metals, copper, lead, nickel, and brass.

Copper Solution.—First, we will take that of copper, as this is the preparation most frequently used. Take of copper sulphate 1 lb., dissolve this in boiling water, add 9 oz. of strong sulphuric acid, and add water to make up to one gallon; work with two Bunsens and large copper anode. Watt, in his book, prefers to use a little arsenious acid added to this solution, but I do not think that there is any absolute need for it.

Lead Solution.—One pound of acetate of lead in one gallon of water, and adding cyanide of potassium to precipitate the lead as lead cyanide, and then adding enough cyanide to re-dissolve this, and also to form free cyanide. Work with a pure lead anode and two Bunsens; but this has hardly ever been a commercial success, it has been mostly tried as an experiment.

Nickel Solution.—This is usually made of the double salt of nickel and ammonia. This should be made up to the strength of 15 oz. of the double salt to the gallon. Prepare the salt as follows (I believe this process was first invented by Mr. Unwin):—Take of nickel 14 oz., dissolve it in three parts of strong nitric acid and one part of strong sulphuric acid, and four parts water. When dissolved, which is known by the fumes (caused by chemical action) ceasing, add a little hot water and filter; the deep green liquid obtained is a strong solution of nickel sulphate. Then make up a strong solution of ammonium sulphate. This is done by dissolving 4 lb. of the salt in a gallon of water, then mix about half of this with the sulphate of nickel and make up with water to one gallon; work with a pure nickel anode and three Bunsens.

Brass Solution.—This is best done by the following solution:—Acetate of copper, 2 oz.; potash, 2 lb.; sulphate of zinc, 5 oz.; liquid ammonia, 1½ pint; cyanide of potassium, 4 oz. Dissolve the acetate of copper in a quart and a half of water, add half the ammonia, then dissolve the sulphate of zinc in two quarts of water at 190° Fahr. When the zinc is dissolved add the other half of the ammonia to it. This should be well stirred for a few minutes, then dissolve the potash in two quarts of water, and, lastly, dissolve the cyanide of potassium in another quart of water. Then add the solution of copper to the zinc solution, then the cyanide, and then the potash. Stir well, and allow solution to stand for two hours, then make up solution to 3½ gallons. Work with a milled brass anode (which should be well cleaned before immersion) and three Bunsen cells. A little ammonia and cyanide may be added when the solution works slowly. Watt, in his book, prefers to use a small amount of arsenious acid to the solution. If added, it should be at the rate of ¾ oz. to six gallons.

As before stated, these solutions must be prepared with care, cleanliness in the manipulation of the solutions, both in making and working, being strictly adhered to. If this is seen to, I have not the least doubt that success will follow, as all solutions given have been tested by long practical experience. Any information or advice any one may require, I shall be pleased to give.

SOME RATIONAL BOOKSHELVES.

WITH A FEW COMMON-SENSE HINTS ABOUT BOOKSHELVES GENERALLY.

BY MARK MALLETT.

MODE OF CONSTRUCTION—CAPACITY OF BOOKCASE—DIMENSIONS—ARRANGEMENT FOR VARIOUS SIZES OF BOOKS—SIDEBOARD IN CENTRE—MIRRORS AT BACK—CORNICE, FRIEZE, ETC.—MATERIAL MOST SUITABLE—EBONISING—PROTECTION FROM DUST—SHELVES, FIXED AND MOVABLE—"BRIDGE" FOR SHELVES—PROTECTION OF EDGES OF BOOKS—PRECAUTIONS AGAINST DAMP.

THE construction of bookshelves is a matter on which a little more common sense might often be brought to bear with advantage. Notwithstanding that books vary as much in breadth as in height, we see but little allowance made for that fact, and, as a rule, the shelves occupied by small books project into our rooms and take up space in a way that is quite needless; besides which the uniform projection from the wall of an ordinary bookcase of any considerable size renders it a heavy and disagreeable piece of furniture to the eye. The plan adopted by the writer, and which he now has to submit, is based on the rational old principle of making a big hole for the cat and a little hole for the kitten—a wide projection, that is, for the great folios, and a narrow projection for the octavos and all the smaller fry of volumes; he claims, also, some other advantages for his shelves, of which mention will be made in due course.

The bookcase shown in elevation in Fig. 1 is intended to accommodate some 700 volumes. An elevation of it has been given rather than a perspective view, because the former, being to scale, is available as a working drawing; yet it must be admitted that it does not do justice to the piece of furniture, artistically considered. Thus drawn it looks square and flat, which the thing itself does not look. In the actual thing the wings projecting in the upper part disguise the fact that the top is bounded by a straight line; the ranges of books are agreeably broken by the bright looking-glass in the middle; whilst the broad shelf beneath it, and the projecting centre of the lower part, convey anything but an idea of flatness.

Fig. 2 is a vertical section on the line, A B, of the above elevation, and Fig. 3 a second section through the centre of the shelves on the line, C D. Fig. 4 gives the central shelf (E, Fig. 1) as it might be seen on its lower side, with sections of the uprights which support the lower shelves; and Fig. 5 gives the upper side of this shelf, with the uprights of the upper portion. These five illustrations are on a scale of ¾ in. to the foot; the set of shelves being 9 ft. long by 6 ft. 4 in. high—that is, 3 ft. 6 in. to top of the wide central shelf, and 2 ft. 10 in. above. That damp—the old enemy who "foxes" books—may be the better avoided, the lowest shelf is kept 3 in. above the floor line.

In a collection of books the average numbers of the different sizes can be pretty accurately guessed, and the spaces for them are arranged accordingly. In the lower portion the central compartment is for *folios.* It is but narrow—only a foot in width—and has but two shelves, for not many folios fall to the lot of any ordinary reader of these days. That it should be narrow there is a second reason: folios are of great weight, and the bearings of a shelf that carries them should not be far apart. This compartment has a depth of 13 in. The lower shelf is some 18 in. high — high enough, that is, to hold *Blackie's Imperial Atlas,* or bound volumes of the *Graphic* or *Illustrated London News.* Ordinary human beings cannot be supposed to have bigger books; if they have they must provide special houses for them. The second shelf is 16 in. high, and above is a recess, 7 in. in height, intended as a receptacle for newspapers, etc.

On each side of this are compartments 15 in. wide, and having a depth of 11 in., which is ample for *quartos.* The six shelves in these are from 12¾ in. to 14 in. high.

But the great majority of our modern books are *octavos,* and to them (including smaller books) all the remaining space is apportioned. In the lower portion the compartments are 8 in. deep for the larger books of this class, while in the upper part they are only 6 in. deep; but that suffices for the lesser octavos, and for still smaller sizes. These compartments are 30 in. wide, and the sixteen shelves range from $10\frac{1}{2}$ in. to 6 in. high; the wings which hold them interfere but little with the space in the room, since at bottom they project but $8\frac{1}{2}$ in. from the wall, and in the upper part no more than $6\frac{1}{2}$ in.

Figs. 4 and 5, as well as affording horizontal sections of the lower and upper portions of the case, illustrate the peculiar shape of the central shelf (E, Fig. 1), which rests on the tops of the lower uprights. As it overhangs the uprights by an inch at each end, it is 9 ft. 2 in. long, and its breadth at the middle is 16 in., a width which allows it to serve as a kind of sideboard, which may be turned to useful or to ornamental purposes, or to both. Had the writer wished to show his design in an attractive rather than in a practical form, he would have represented some æsthetic pieces of crockery as ranged on this shelf and reflected in the glass behind them, but he leaves this to the imagination of his readers.

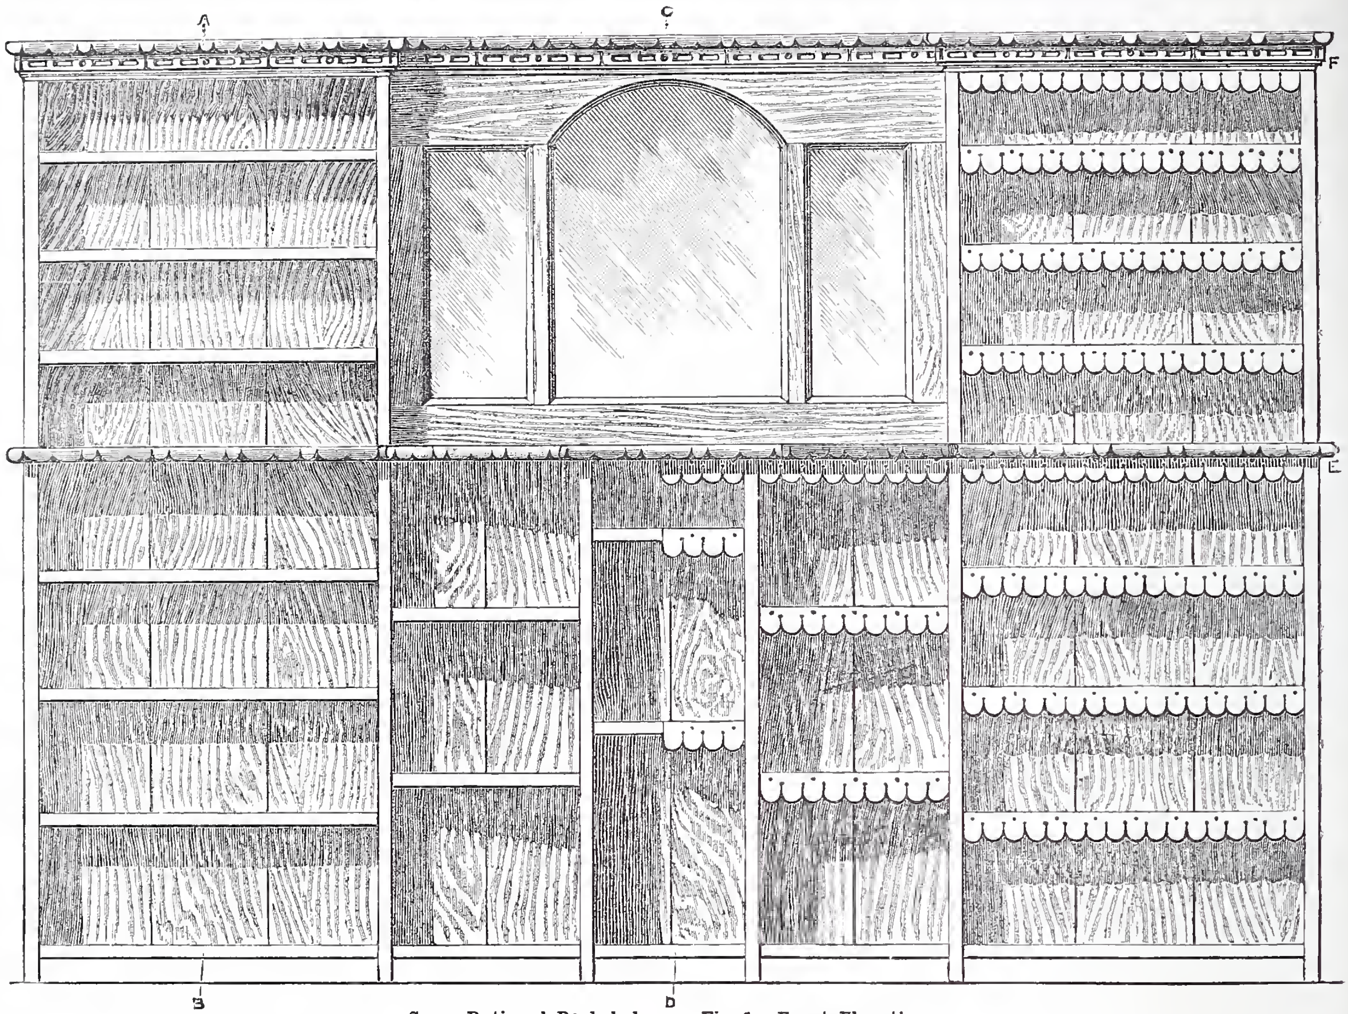
In a set of shelves built by the writer on this model, an old Vauxhall glass, with its characteristic gold frame, has been used. But all who may wish to work on the same lines may not have such a glass to their hands, and, therefore, in the present drawings three panels of ordinary looking-glass have been shown, as introduced. They are fixed in a very simple manner. The whole of the shelves are backed with $\frac{1}{2}$-in. matchboarding; this is continued over the space occupied by the glass, and to it the two horizontal and four vertical strips of $\frac{3}{4}$-in. wood, which form a frame to the panels, are screwed, the glass itself being held in place by a narrow strip of gold moulding fastened with needle points.

The cornice (F, Fig. 1), which, of course, runs along the ends of the wings as well as along the whole front, is, as shown in the elevation, relieved by a little simple gouge work, which is so simple that it can scarcely need a separate diagram for any one who would be likely to work it out. But most persons will probably consider this decoration, as well as the enrichment along the front edge of the central shelf, superfluous; and in the full-size section of this cornice (Fig. 6) the frieze, G, is left plain, and merely an ordinary moulded beading, H, is placed upon it, whilst I is a gilt beading. This and the other gold beadings are introduced on the supposition that the woodwork generally is ebonised, in which case a little gold will have an excellent effect, whilst it adds but a few pence to the cost.

With a view to ebonising, inch pine is recommended for the uprights, and $\frac{3}{4}$-in. pine for the shelves, etc.; the whole is backed, as has been already mentioned, with $\frac{1}{2}$-in. matchboarding. The top and bottom portions are made separately for convenience of removal, etc., the former being kept in place on the latter by four dowels driven into the central shelf, which fit into holes in the four uprights of the top. It is better to fit the work together with screws before ebonising the wood; then to take it to pieces, to brush it over with a strong, hot decoction of logwood, and afterwards with iron dissolved in vinegar. The boards can be kept from warping by letting them dry under sufficient weights. They have to be polished with beeswax and turpentine melted together; little wax and plenty of good hard rubbing is the secret of getting a good polish.

For the protection of the tops of the books from dust nothing looks so well as the stamped and gilded strips of leather, sold for the purpose, nailed along the front edges of the shelves. These are, however, costly, and one half of the elevation, Fig. 1, is shown as finished with a cheaper substitute in the shape of American leather cloth. With ebonised wood cloth of a dark green colour looks best, and the strips should be deeply cut between the scollops, as in Fig. 7, to allow of the easy taking out and replacement of books. The strips are fixed to the shelves with brass nails. The scollops may be quickly cut by laying the cloth on a lump of lead and cutting with a gouge of proper size.

The shelves in this design are not made adjustable, being screwed down to small strips, which, in their turn, are screwed across the uprights. So far as the experience of the writer goes, unless in a very solidly-built bookcase, adjustable shelves involve more loss in the shape of strength than gain in the shape of convenience. As has been already observed, the proportion of volumes of different sizes in a collection can be pretty accurately calculated, and no great difficulty will be found in providing sufficient accommodation for those of each size. Any arrangement



Some Rational Bookshelves. Fig. 1.—Front Elevation.

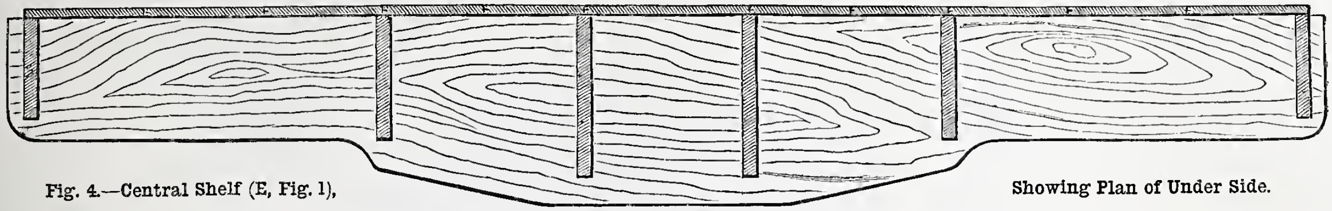


Fig. 4.—Central Shelf (E, Fig. 1), Showing Plan of Under Side.

for rendering shelves adjustable must do one of two things—it must either weaken the upright, or it must lessen the space for books. Yet, as some persons have a decided objection to fixed shelves, it may be well to mention one or two plans for supporting those that are movable. Perhaps as good as any of these is the double rack, Fig. 8. In this the movable slip, K, gives a firm support to the end of shelf, L, which has to be cut to fit upon it. This, of course, takes from the space for books a quantity equal to the thickness of the racks and slip, which can scarcely be less than a quarter of an inch. A slip of wood, near the ends of which are two projecting wooden pegs or pins of metal, made to fit into corresponding shallow holes in the upright, will save space, but it is less firm than the above plan; it is, however, to be preferred to the pair of short, stout, separate movable pegs which we sometimes see employed to carry a shelf end.

Whenever in fitting the non-adjustable shelves a want of proper books for the large compartments is found, and small books have instead to be placed in them, there is an easy method of obviating any unseemly gap between the tops of these small volumes and the dust strip. This is by nailing together three pieces of board in the manner shown in Fig. 9, and thus making a "bridge" of the length of the shelf. Its front edges should be coloured like the woodwork generally, and it will look better if fitted with a dust strip It can be made to bring the heads of the books placed upon it to any required height, whilst the space beneath will be useful for lie-down books, small portfolios, or magazines. If the height to be "bridged" is considerable, two low bridges, one placed upon the other, will be found better than one high one, as the two lie-down shelves will be much more handy than one. Such bridges are knocked together in a few minutes.

Heavy books of reference, which are frequently taken down from the shelves, are apt to suffer from rubbing on the lower edges of their covers. Hence in some elaborately-fitted libraries the shelves intended for such works are padded and leather covered. A cheaper and simpler method of protection has been found by the writer to work well; that is to give the shelf a covering of baize, or some such stuff, and above it one of smooth American leather cloth. This, though not so enduring as leather, causes even less friction, and consequent wear, of the book edges, and will last for very many years.

Whenever there is the slightest suspicion that the wall against which bookshelves are to be placed is not dry, it is always well to leave a space behind the back of the bookcase for the air to circulate freely. If there is cause for any fear beyond a suspicion, it is better, instead of matchboarding, to make the back of zinc. The cost will be much the same, and if the shelves are non-adjustable the zinc can be nailed to the back edge of every shelf. The front side will need to be brushed over with brunswick black, when it will go very well with the ebonised wood. Damp is a cruel enemy to books, and many a good collection is ruined as regards pecuniary value by not guarding against it. Simple precautions like those named above are, therefore, well worth attending to.

Everybody nowadays has books of one kind or another, since works of the highest class, that take rank as English classics, have been brought within the reach, even of those who can afford an outlay of no more than a few pence weekly on mental food in the form of books, by the issue of such works as "Cassell's National Library," in which the best works of the best writers are issued at a merely nominal price. But books, like other objects of utility, require a place to and for themselves, whether the collection be large or small. If large, the bookshelves described will afford a suitable abiding place. If small, the arrangement and spacing of the shelves may be taken advantage of for the construction of smaller

sets, which may be better adapted to the space at command and the number of books to be housed, so to speak: for example, the central compartment, with simple modifications, might be used for a recess, which might be appropriated to any of the numerous purposes for which recesses of this kind are often welcomed. There is no reason, indeed, why it should not be turned into a cupboard by the addition of a door, for it is not every one who requires the space for folio volumes, or who would care to go to the expense of binding the illustrated papers of the day.

"LINING UP."

WITH A FEW CONSIDERATIONS ON ART AND ITS TEACHERS.

(*Continued from page* 211.)

METHOD NECESSARY TO PROGRESS—LINING OF TOP OF TOILET TABLE—RELIABLE MODE OF PROCEDURE—GAUGE LINES AS GUIDES—BRADS ON LINES AS STOPS—HOLES FOR SCREWS—LINING OF BACK—ATTACHMENT BY SCREWS—SECURITY AGAINST "GOING."

IT must have occurred to every observer of work in progress how much time may be saved by a little method in the way the various operations are performed. One man will take half the time another requires to get exactly the same result, although they may both apparently be equally busy. The one who gets through with whatever he has in hand first does not seem to go about it hurriedly, nor does the other seem to dawdle and waste time. Why is it? Simply because one works by method, using the accumulated stores of experience, while the slower one does not, possibly only because he may not have done the particular piece of work so frequently that he is able to grasp all the facts in connection with it. The man who is constantly at one class of work acquires a manipulative skill which not only causes admiration in the onlooker, but conveys lessons which it is unwise to disregard.

Some such thoughts passed through my mind while standing beside a cabinet-maker's bench while a small toilet table top was being lined up. Not that there was anything novel in the way it was done. Every one who has been much in a cabinet-maker's workshop must have seen it often, if not precisely in the same manner, at least only differing according to the individual ideas of the worker. Having said this, it will be almost needless to explain that the following directions do not pretend to cover the whole subject of lining up. For instance, the vexed question of direction of the grain on the end lining is not alluded to, at least, not more than by inference. The aim is more to put on record, for the benefit of all whom it may concern, a reliable method of lining up, than to advocate a new one. Those who have followed any other method—or rather let me say have become skilful in other details of manipulation, and have found the result satisfactory—have no occasion to change their style of working. If, however, they find any hints in these directions which will be of benefit to them, so much the better for themselves and their work. I can answer for it that those who follow the course now laid down will have no reason to complain that time is lost, nor that the work when done is not reliable. In the latter respect, I refer to its freedom from liability to split, even if the wood be not thoroughly dry, or from the contraction and expansion which all woods, however dry they may be, are more or less subject to under varying conditions of the atmosphere.

On the bench let us suppose the unlined top lies, bottom upwards, properly squared, and cut exactly to size. The linings are to be set back from the edge, say, ½ in., the distance, of course, depending to some extent on the mouldings which are to be subsequently worked. Whatever the distance, however, run a pencil or gauge line of some kind as a guide to plant the linings down by along the front and two ends. The lining pieces will be of, roughly speaking, 3-in. width. One of them—that for the front—must be cut with mitred ends of exactly the required length; the other two only require one end of each to be mitred, and may be left a trifle full. If they project at the back they can easily be trimmed down afterwards. The front piece is to be glued down, and to regulate its edge to the guide line is certainly possible, but if a couple of brads or wire nails are driven in on the line, one near each end, they will serve as a stop for the front edge of the lining. It is only necessary then to put the piece, after it has been glued, on the top, pressing it both against this and the nails, to ensure its being absolutely in its right place. It is almost impossible for it to slip while the hand screws are being applied, and awkward fumbling to get it truly placed is avoided. As quickly as may be, the hand screws, which have been lying conveniently near, are applied.

If the nails as guides are serviceable for the front piece, they are equally so for the others; but, of course, none but the veriest tyro would in ordinary work think of gluing these to the top. They must be nailed on, or to put the matter more definitely, be screwed down. Very likely there may be some who, when they read this, think that it is not necessary to tell them how to drive the screws in. All they have to do is to bore a hole through the linings into the top and screw up. Quite so; that is all, and experienced workers will know the proper way to act in the circumstances; others will act as if instead of joining two pieces the screws were being used in one piece of solid wood. They will make the hole of the same diameter both in the lining and in the top, *i.e.*, the same bit or gimlet will be used throughout. The result may be satisfactory in the long run, but the chances are very much against it being so. No; if the work is to be reliable, the natural play of the top piece must be allowed for. On a narrow top it is not great, and provision may be made for it by boring the holes in the linings sufficiently large for the neck or plain part of the screw to fit quite loosely in them. The holes may, indeed, take the form of an oblong slot, but it is seldom necessary that so much precaution should be taken, and if not necessary time is wasted in forming them.

Let the hole be as large as it well can be; that is to say, just so that the head of the screw shall not be able to pass through it. Now it will probably occur to most workers that the holes can be bored through both pieces of lining at the same time with greater economy than through each separately. The size of the screws has necessarily been determined beforehand. Then take one of the pieces and lay it down in its proper place. Holding it firmly against the guide nails or pins with one hand, make the holes with a proper-sized gimlet for the screws into the top, taking care not to bore them through, a mishap which can easily be avoided by keeping the fingers underneath as the boring proceeds. Touch the mitred end with glue, place in position firmly, and screw up. A hand screw should be placed so that it grips the three pieces, top, front, and one end at the mitre.

The other end, of course, is treated in precisely the same manner, the hand screws being left on till it is judged safe to remove them, which will be when the glue has set.

The guide nails can be removed at any time after the pieces have been planted on.

There is still another piece of lining to be considered, viz., that at the back. It is cut with square ends, so that it lies within the two end linings, between which it should fit exactly, especially if the back is ever exposed to view, as it frequently is in dressing tables placed in a window. If the back of the job is to be against a wall, precision is not so necessary, though even then slovenly fitting should be avoided. The back edges of the top and the lining here will, in the vast majority of cases, be better if flush than if arranged with the top to overhang.

The back strip of lining may either be glued or screwed, according to the way the top is fastened to the stand or whatever it is to form part of. A moment's consideration will show the reason why. If the top is screwed or blocked down at back and front so firmly by the linings at these parts as to be bound and immovable, the provision which has been made by leaving the side linings free to allow of play in the top will be completely nullified—that is, supposing the back and front linings are both glued to the top. The conclusion, therefore, is that the back lining should be fastened to the top with screws, and that these should fit loosely at the necks; or, that if glue is used, the necks of the screws fastening the lined-up top to the job must fit loosely. To sum up about this part, it may be said that though the experienced worker may safely be left to decide for himself which course to pursue in any given case, the novice can hardly err by using screws instead of glue, always remembering that if screws are used to attach the lined-up top to the work, they must not penetrate beyond the lining into the top itself, unless their necks fit loosely. Enough has now been said to show how a lined-up top may almost to a certainty be insured against "going," which, for the benefit of those who do not understand the word in its technical sense, may be told is merely short for "going wrong." The grand secret to avoid this in lined-up tops the reader either is already aware from his own experience, or will have gathered from the foregoing instructions, is not to "bind" the top, but let it have free scope for natural play.

In describing the practice or way of going to work that ought to be followed, I have endeavoured to combine theory with it as far as possible, by showing, or at all events trying to show, the reason for taking each step in sequence in the operation from first to last.

OUR GUIDE TO GOOD THINGS.

55.—SYER'S JOINER'S CRAMP.

IN the present number of WORK I am enabled to call attention to some of the specialities of Messrs. Thomas I. Syer & Co., engineers, tool and work-bench makers, 45, Wilson Street, London, E.C., and I have all the more pleasure in doing this because it gives me an opportunity of saying that Mr. Thomas I. Syer himself is the principal of the Finsbury School of Practical Amateur Mechanics, whose workshops are in Finsbury Square Buildings, Chiswell Street, E.C., where classes are formed with the view of imparting practical instruction in elementary carpentry, cabinet work, wood carving and engraving, plain and ornamental wood turning, and metal working. Mr. Syer will also form classes for French polishing, upholstery, and fret cutting, as may be required, and will send prospectuses with terms and all particulars to any applicants. Private tuition is also given at any hour of the day in carpentry, cabinet making, turning, and carving. Mr. Syer is assisted in the several classes by competent instructors. The next term will commence in October, 1889, and I believe I am correct in saying that the class-rooms will then be found at 45, Wilson Street, Finsbury, E.C., Messrs. Syer & Co.'s new house of business. To return from this digression to

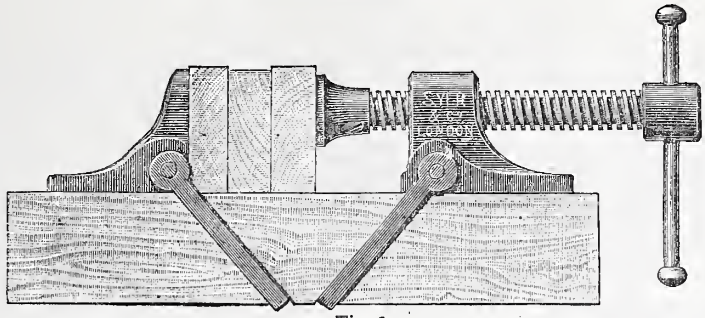

Fig. 1.

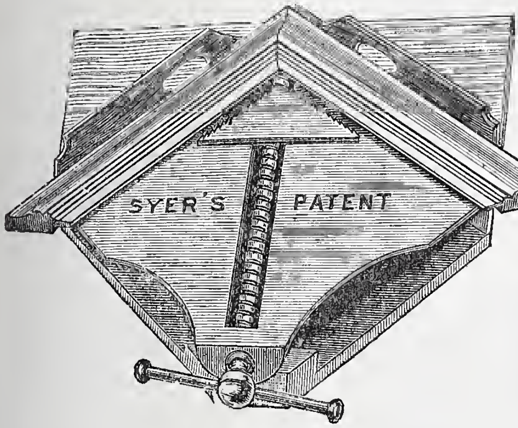

Fig. 2.

the joiner's cramp. The nature of this appliance will be understood from Fig. 1. It comprises a pair of metal heads made in three sizes:—No. 1, to fit over 3-in. by $1\frac{1}{2}$-in. wood bars, and capable of being used up to a length of 6 ft.; No. 2, to fit over 4-in. by $2\frac{1}{2}$-in. bars, and effective to a length of from 10 ft. to 12 ft.; and No. 3, to fit over $5\frac{1}{2}$-in. by 3-in. bars, and effective up to any length that the strain of the timber will stand—that is to say, speaking approximately, up to from 20 ft. to 24 ft. These are much used now by builders for very large work, as they are light and can be easily packed with the carpenter's kit. The prices of the three sizes—Nos. 1, 2, and 3—are respectively 8s. 6d., 11s. 6d., and 16s. 6d. per pair.

56.—Syer's Patent Universal Mitre Cramp.

This excellent appliance, useful alike to picture-frame makers, cabinet makers, and joiners, will secure any mitred joint true. Its principle is clearly shown by the illustration in Fig. 2. The cramp itself is first secured to the table or bench by G cramps or hand screws, and then the ends of two of the pieces that are to form the frame are planed up, if necessary, after being sawn or otherwise cut, and the pieces placed in the cramp as shown. The handle at the bottom of the cut is then turned, and by the action of the screw the triangular plate is pushed forward against the rebate of the moulding. The pressure of the plate is sufficient to close the joint and hold the adjacent pieces firmly enough to allow the nails to be inserted. It will be noticed that the pieces are held by the plate against the sides of the cramp, which do not approach each other so closely as to prevent the insertion of the nails. These cramps are sold at 21s. each, on wood stand; and at 23s. 6d., on well-finished stands of mahogany or oak.

57.—Syer's Patent Bench Knife or Back Stop.

The action of the Knife or Back Stop is shown in Fig. 3, which is placed in position on the bench, a pin on the other side of the plate and not seen in the illustration being dropped into

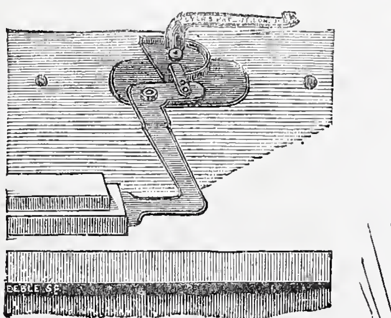

Fig. 3.

one of a series of holes made in the bench for its reception. The handle, which in this appliance is horizontal instead of vertical, as in the old pattern, is then pressed or pulled, and the bench knife is then pressed with force against anything that it is required to hold, the piece of wood, or whatever else it may be, being placed between the bench stop and the bench knife. These bench knives are sold at 3s. 6d. each.

58.—Brown's Patent Tool-Grinding Rest.

The Patent Tool-grinding Rest in Fig. 4 is suited for use on either hand or foot or power stones. As in the other appliances, the construction is apparent in the illustration. Two angle pieces of metal are fixed to the support or trough of the grindstone on opposite sides. Each of these carries a slotted arm, fixed to it by a fly nut. To the arms another iron framing is attached by the same means, and on the inclined piece in the centre of the framing the tool is supported during grinding. The slope can be fixed at any required angle, and the same slope can be easily obtained after examining the edge of the tool being ground, which cannot be guaranteed when tools are held by the hand only. It is made for and can be attached to any grindstone, wood or iron; and any person, however inexperienced, can use it. The price for wood trough and for stones up to 4 in. thick is 10s. 6d.; for iron troughs and stones of same width, 12s. 6d. A clamp for gripping tool on rest is supplied for 2s. 6d., in addition to the prices named.

59.—Syer's Registered Portable Work Bench.

This handy bench, which is illustrated in Fig. 5, is constructed in such a manner that it may be taken to pieces and quickly put together again with an ordinary spanner. The supports are of metal, which imparts extreme rigidity to the bench when all the parts are bolted together. The top is of deal, and is, in the bench illustrated, 6 ft. long and 22 in. wide, but other sizes may be had if desired. It is firmly bolted together from side to side, which prevents warping. The height is 30 in., and the bench at this height and size of top already mentioned is supplied at £3 12s., but 1s. extra is charged for every additional inch in

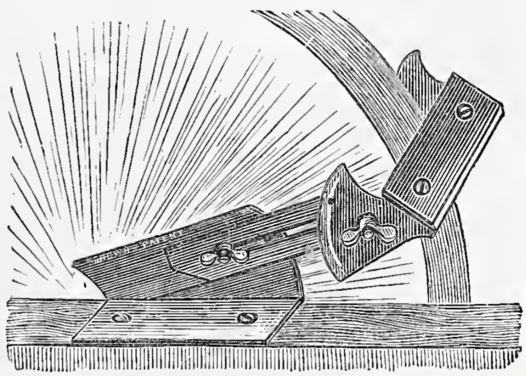

Fig. 4.

height. It is fitted with an instantaneous grip vice of the B pattern, with improved loose handle. With this vice, by a single movement, the wood can be immediately gripped and as speedily released. In front will be noticed a vertical board pierced to take pegs to support boards when in the vice. The bench is further fitted with a screw-rising wood stop of improved pattern, which can be easily raised or lowered to the required distance, and with the patent bench knife, already noticed, for which a series of holes is bored in the top to admit of its application to wood of any length. A strip of wood is shown in position on the bench between the bench stop and the bench knife.

The Editor.

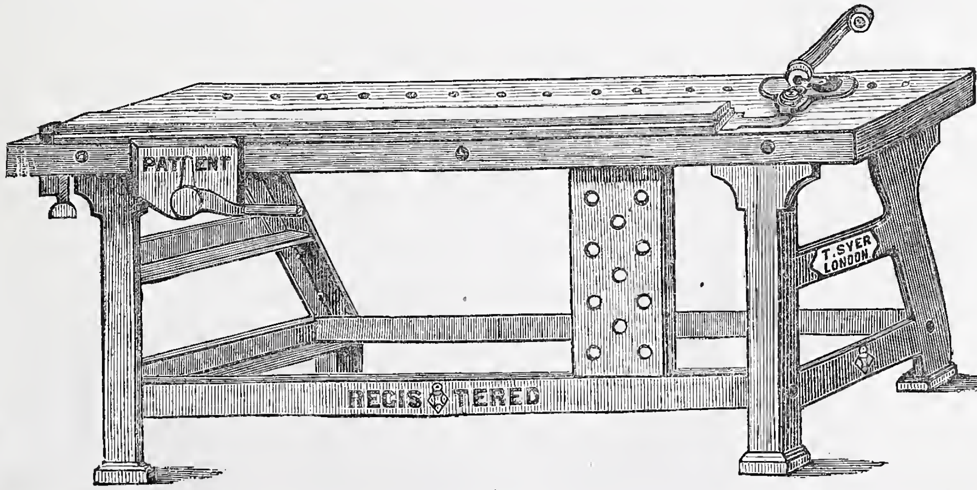

Fig. 5.

SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

Work.—S. H. E. (*Plymouth*) writes:—"As a workman I desire to thank you for the production of WORK. I believe that it supplies a long-felt want, and, therefore, I wish it all success. There are several features about it which are quite unique, two of which I may mention. One is its scope—treating, as it does, of all kinds of work done by man; and the other is its thoroughness of treatment of each individual subject, even down to the most minute details."

Subjects in Work.—SCRIPTOR writes:—"I beg to congratulate you on the success of your paper. It is a great favourite in this district, and most helpful."—[I am glad to hear this, especially as you write from Ireland.—ED.]

"I trust you will be able to give a few papers on the construction of good, honest furniture; not the gimcracks which find so much favour with a certain section of the community, under the name of artistic. What I want is good strong chairs and tables—such as are to be bought in shops. A sideboard is on the *tapis* just now."—[Furniture, plain and strong, and, I trust, not altogether ugly by reason of its plainness and strength, will not be neglected; but our "artistic" furniture is by no means to be classed with gimcracks.—ED.]

"Why is it that engine boilers are never described in magazines like WORK? Are they too difficult for amateurs to attempt, or is it dangerous for the stoker afterwards? If so, I think you might set up an insurance office for those who come near amateur boilers, and then it would be all right."—[You must make terms with some accident company for a policy of insurance, especially as a contributor has an engine boiler in hand.—ED.]

"French polishing would also be very acceptable to me."—[You shall have it.—ED.]

"Kindly remember, Mr. Editor, that I do not wish to have a few years of WORK suddenly published in one number for my special edification. These are merely suggestions, and I will wait for them with what patience I can; in the meantime giving place to more worthy readers. I will do what I can, however, to perpetuate your magazine, lest it should come to a sudden smash, and so deprive me of one of my pleasures on Thursday mornings."—[WORK is so firm on its legs that there is no fear of your Thursday morning pleasures being brought to an end by a burst up, unless the engine boiler happens to go that way.—ED.]

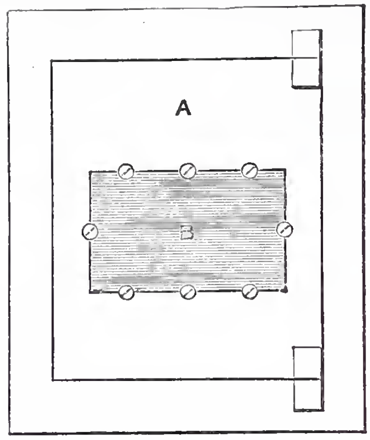
"When writing to friends I enclose one of your prospectuses, which I think a good plan. I am afraid they sometimes think I am an agent for its sale, which I am not."—[No, but being enthusiastic you do as much real good as any agent, and help the agents themselves. Please go on sending prospectuses.—ED.]

Wire Thread Fret Saw.—H. J. (*Shepherd's Bush*) writes:—"In accordance with your request in your appreciated paper, I have this day searched the indices of 26 vols. of the *Scientific American* at the Patent Office—viz., from 1870 to 1882—*re* the wire thread saw, and fail to see any mention of it. Perhaps O. F. could give a little more definite information as to the date he saw the article."—[I am truly obliged to you for taking so much trouble, and regret you should have had so much labour to no purpose. Possibly it may be mentioned in the *Scientific American* under some other name.—ED.]

Suggestions for Work.—H. J. (*Shepherd's Bush*) writes:—"I am very pleased to have such an organ on behalf of work as you are bringing out—such a thing being well needed; but I should be far better pleased, and I have no doubt many others would, if some of your correspondents would bear in mind that your title is WORK, *pure* and *simple*, neither for amateurs, professionals, nor apprentices; and frame their articles in a more simple matter-of-fact style, catering neither for one class nor the other, but for *workers* as a whole."

Home-Made Power Machine.—H. J. (*Shepherd's Bush*) writes:—"If you can see your way at any time to grant such, I would like to see an article (or series) on a *home-made* foot power machine that could be adapted to circular and scroll sawing, boring (wood), say, up to 1 in. in diameter; sawing, say, 3 in. or 4 in. of hard wood; and that could also be used for drilling and polishing metal, turning, etc. It seems to me that with different attachments all could be utilised with the same motive power (and which I would suggest, with its frame, should be described first, followed by its more important adjuncts in due order), though, of course, not all at once. An edge former or shaper might also be included—in fact, a sort of 'general joiner' for both wood and metal to a certain extent. Timber is cheap, and a handy man might rig up a machine at odd times that would, perhaps, turn out work to vie with a more highly finished affair costing £20 or £30 or more, and which he may never have if he has to wait till he can save up enough to pay cash down. I would also be glad to avail myself of J. H.'s kind offer and ask for a supplement to his valuable articles on home-made tools, describing how to make a metal smoothing plane with wood sole or base, as wood does not hang to the surface like iron, and therefore works easier; and if some means of adjusting the iron with a screw instead of by hammer, without infringing on other patents, so much the better."

Safes and Safe Locks.—INQUIRER (*Hull*) says:—"I am a whitesmith and locksmith by trade, and it often happens that some one has lost his safe key, and requires his safe opened and a new key. We used at one time to drill a hole through the door just where the bolt head of the lever lock comes, and force the bolt back; or, failing this, drill the head of the bolt clean away, and the door opens easy enough then; but now they are made with a hardened steel plate immediately behind the door, which we cannot drill; and the last one we did, we had to find the edge of the steel plate and drill it completely out, which, of course, means a new plate and a piece fitting in the door, which we fixed in its place by putting screws between the joints thus:—



I have taken WORK every week, and enjoy the 'Shop' corner very much; and I believe you are ever ready to help a young hand where you can; and what I want to ask your readers is, can they tell me a better way of opening a safe than the one described? The shop in which I work I served my apprenticeship, and there is only my master and I at work, and therefore I have had no opportunity of seeing any other man's ideas; and I should feel deeply indebted to you or any one who could tell me a good method of opening the safe. Also, I am told that in London they make safe keys to any key sent to them, which we do not do here in Hull, as we always take the lock off. Is there any book published that would give me any information on this subject?"

Another Encouraged One.—A. W. (*Liverpool*) writes:—"I had the good fortune to come across your excellent publication the first week it was issued, and have hailed every succeeding number with increased interest. This fact may surprise you when I say that I have never been a workman, either professional or amateur, circumstances, 'when I was much younger,' having turned my career into a channel which nowadays offers little inducement in the matter of remunerative occupation. I will tell you how I account for the interest I take in WORK. From my youth upwards I have always been fond of reading, and subjects connected with science, the arts, etc., were always the most attractive, among my first speculations in the way of books being Cassell's first series of Popular and Technical Educators; these, supplemented by evening classes in physics, mechanics, etc., whetted my appetite considerably. I have also visited workshops of various kinds, and always tried to learn something of tools, etc., when I could get the chance. You will see, therefore, that the foundation of my interest in WORK is not altogether built on sand. Now, the advent of WORK has raised a new hope within me—it has revived the latent yearning of years to be of more use to myself and those dependent on me; and I believe firmly that it will put me in the right direction. Your subjects are so clearly explained and illustrated that the average common-sense man can hardly fail to comprehend them. The advice and encouragement in which your journal abounds seem specially intended for such as myself; therefore I have ventured to address you at such length. Your reply, however, to H. D. (*Bury, Lanc.*), No. 6 issue, gives me a hope that I am not trespassing too much on your kindness. I also notice with particular satisfaction your reply ('New Inventions') to W. J. P., No. 8 issue; the position described is much the same as my own. I have had ideas from time to time which may or may not have been of value, but lack of means to develop them has always put the damper on. Your sympathetic remarks, however, to W. J. P. come like a gleam of sunshine. Some months ago I completed an idea in connection with domestic ventilation. I have not been able to learn, so far, whether my idea has been anticipated; therefore the principle and application of the appliance I shall submit is original to the best of my knowledge. With your kind permission I shall send a rough model with explanations when I hear from you, through WORK or otherwise. If through WORK, address A. W. Kirkdale, Liverpool. I am afraid this communication is too lengthy to merit your attention. In any future correspondence, however, I promise to confine my remarks to the subject in hand."

A Subscriber's Testimony.—C. S. (*Radford*) writes:—"I might say in passing I am highly pleased with your WORK. I waited for No. 1 with some impatience, and I consider it a long-felt want. It has come up fully to my expectations, and I wish it every success, which I am sure it deserves. I am doing some fretwork, and am going to compete at an industrial exhibition. I had so much on hand, I am sorry I had not time to make your cabinet for it."

Building Construction.—G. S. R. (*Tewkesbury*) writes:—"In reply to your request for the opinions of your readers, *re* plans, etc., for building, may I urge you with all my heart to carry out this suggestion? I know of others in my own profession who are placed as I am—that is, anxious and able to get their own house, but not able to meet with just what we want ready built. For months I have been thinking out and drawing plans for a residence—two-storey, with seven or eight rooms—and have drawn and redrawn them, as improvements came to me, but am still not satisfied. Now your splendid paper is just what I want in this direction. Its excellent articles on panelled walls and ceilings helped me greatly, and I intend having part at least of my new home left in the rough from the bricklayer's hands, so far as walls are concerned, and decorating by your valuable suggestions. In this connection may I ask whether a ceiling so treated would, or would not, look darker and heavier than the ordinary sort? Also, may I trouble you for your advice on this point? If the wall panels could be so made as to be covered with a sheet of glass, which should be kept in place by a removable fillet, would it look well or be bad taste to fill each panel with some picture, say a mount with photos, or a scene, etc.? If in accordance with good taste, I can see many developments of this idea. If you have room to reply, kindly do so to my initials. In conclusion, let me very heartily thank you for WORK. I can't say all I think of it, but if you knew how I treasure each number, and eagerly look for each new one, you would tell how truly valuable I feel it. On the completion of a volume, could you not prepare suitable covers for binding the numbers in? I intend having mine bound and preserved as one of my most valued books. When is the new kaleidoscope to be described?"—[The ceiling would of necessity look a little "darker and heavier" than the ordinary flat whitened expanse so called, because shadows would be cast by the beams or *quasi* beams. The description of the new kaleidoscope will appear shortly.—ED.]

Dyeing Osiers.—P. W. S. (*Poplar*) writes:—"On page 78 your conjecture that aniline dyes may be used for dyeing osiers is correct. That plan is preferred to staining for the more vivid colours."

Building Construction.—PLUMSTEAD writes:—"With very great pleasure I have read in 'Shop' of your last issue of WORK, in reference to plans, etc., for building, and would be extremely thankful to you to take up the same. I am about to lease a piece of ground of 40 rods, and want to superintend the building of a four-roomed house myself thereon with 15 ft. frontage. Seeing you would like to have the mind of your readers, I have ventured to write you. I am sure I have the same views as your correspondent: that according to the past and the valuable help WORK has been to me, your information would be most valuable."

Sale and Exchange Column.—CONSTANT READER (*Bristol*) writes:—"I think that all amateur workmen should be obliged to you for publishing WORK. I have got several men to take it in, and they are very pleased with it. I think if you would open an exchange column for readers it would pay you, and I hope you will shortly bring out a cheap way of electric bell-making for house purposes."

Japanese Fretwork, etc.—WAITING writes:—"I congratulate you on bringing out such a useful and interesting little paper as WORK. A teacher by profession, I spend a deal of my spare time in a workshop in the winter time, and in the summer I turn to brush and pencil. I have amused myself for the past five or six summers with water colours, but this year, with the return of the swallow, I began to try painting in oils. I find paints, brushes, and canvas rather heavy, having a very limited income, and have tried to make my own canvases. I cannot get a smooth surface, and it struck me I could get to know through WORK how the thing is done. I make a frame, stretch the canvas over it, size it, and then give it a coat or two of ordinary paint, but it does not turn out so well as bought ones, and I think I am perhaps wrong somewhere. If you would be good enough to give me this information through your paper, it may also help some other struggler. I hope you will soon bring out an article on painting. I am watching for it. I intend trying some of your fretwork patterns next winter. I like the Japanese patterns very much. The cornice design was beyond me. I haven't tools enough. I wanted one, but got three yards of tapestry, a length of felt moulding to go along the top, and cut some corner pieces in fretwork, which I covered with gold leaf, and made a capital one."—[Instructions on house painting will be given, but not on painting in oils for landscapes, figures, etc., as there are so many good text-books already in existence on this subject. You will find the Japanese patterns for fretwork, etc., very suggestive and useful. You have managed to make an attractive temporary cornice, but I am afraid you will not find it very durable.—ED.]

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Overhead Motion.—H. E. W.—If you have a fly wheel of 24 in. with a V groove I should recommend the overhead described in No. 8 of WORK; but if not, you might adopt that illustrated at Fig. 6, p. 92. The main shaft of the overhead may be about 1 in. in diameter, or ¾ in. if of steel. The drum is made of wood with brass caps at each end; it is built up like a barrel, and need not be more than 12 in. long to fix anywhere on the shaft; it may be 6 or 8 in. in diameter. The standards are of cast iron of elliptic section; the triangular section tie-bar at the top takes the thrust of the centre screws on which the main shaft turns, and it checks the fall of the weight if the band comes off. Weight may be about 4 in. in diameter. The overhead of the London Lathe and Tool Company, to be illustrated shortly, is a very good one. Adopt whichever of the three you like, and you will do well.—F. A. M.

Fret Cutting.—J. M. (*Perth*).—Trace the pattern with ink on ordinary tracing paper, and paste it on the wood; this avoids injury to the design itself, and is easier to work from. But if your knowledge of fret cutting is so slight I should not recommend the design referred to for some time yet.—J. G.-W.

Egyptian Trellis Work.—H. C. T. (*Newcastle-on-Tyne*).—I know of no firm in London selling this class of work. There is no great variety of pattern in the trellis work; the Egyptian is satisfied, as a rule, to repeat the same pattern continually. I have, I fancy, as many specimens of the work as are made; but, on looking round, I really do not think I have three distinctly different patterns. Variety is produced by the introduction of pillars alternating with the stars, the shape of the beads, etc., and the different colours of the woods used. The drawing you send is the staple pattern. I have, in papers about to appear in WORK, produced all the varieties of detail I have seen. The art is in the grouping of the patterns and in the designs of the brackets, etc., into which it is introduced. I hope, in the series of papers, to satisfy such inquirers as yourself. I am glad that my contribution has been the means of causing an interest in WORK. I am sending specimen copies to brothers in India, Australia, Demerara, and Yorkshire, all of which will, I hope, lead to new subscribers joining, as I shall ask each brother to show it to any likely friends. The fact of your doing work for a London firm in your own northern town would seem to prove that there is no firm in London who have taken up this style of work.—C. H. O.

[To this I may add that a caterer for furniture makers to whom I was speaking of the Egyptian trellis work the other day as a means of ornamentation that might be used with advantage in a variety of ways, threw, or tried to throw, cold water on the notion by saying that this kind of thing had been overdone in London, and that people were wearying of it. I still think, however, as I thought before the *douche* was applied. Having the principle of the work, it is possible to apply it in any number of forms by pressing differently shaped blocks and spindles into the service. For example, take a number of equilateral triangles as blocks, and connect these flat blocks by turned spindles, and see what a quaint but highly-effective trellis you will get, especially for outdoor work, for which this kind of ornamentation is very suitable, and a great improvement on the crossed lattice of every-day carpentry. If any of the readers of WORK, in making experiments in quest of patterns, hit on any combination of a striking and effective character I trust they will send their designs for publication.—ED.]

"Turning for Amateurs."—H. P. (*Canterbury*).—This elementary work, suitable for beginners, by the Rev. James Lukin, to which reference was made in No. 4, p. 51, is published and sold by the Britannia Company, Colchester.

Organ Building.—E.—In the papers on American Organ Building that are now in preparation everything that is of importance in the trade will be touched on, and made perfectly clear to the beginner.

Obtaining Patent.—J. S. (*Bristol*).—In making application for a patent it will be necessary for you to give your own name and address, and not to apply under an assumed name.

Brass-capped Bradawl.—D. W. M. (*Cork*).—These bradawls are supplied, carriage free, at 3s. per dozen, assorted.

Soda Water Machines.—W. H. C. (*Belfast*).—There is no intention at present of touching on the manufacture of machinery used in the preparation of aërated waters. Should it appear, however, that there is a widely spread demand for the description of such machinery, an effort would be made to meet it. I have said all I can say with regard to the advertisement pages in WORK, and can only repeat that if it be found possible to meet the wishes of yourself and many others with respect to these it shall be done.

Cleaner. — OIL. — The best oil for clocks or watches that I know—and I have now had eighteen years in the trade—is Kelley's, to be had of Grimshaw & Co., 33, Goswell Road, Clerkenwell, London, E.C., 1s. a bottle; or, I believe, by the box of a dozen, cheaper. State if clock or watch when ordering; it does not thicken, like most oils, after a few months. If unable to get it, I will gladly do so for you.—A. B. C.

Photographic Camera Making.—TRENCH.—This will not be neglected, but I think you will agree with me that this is best brought forward in the winter season, when photographers who can use tools can be at work for the ensuing spring and summer.

Tightening Chair Backs.—TRENCH.—Send a sketch of the kind of chair whose back has gone wrong, and show clearly what is amiss with it, and you shall have help. If directions are given in the dark, it is possible that they may in no way apply to the damage in your chairs. In asking advice in repairs it is always needful that the general build of the patient and symptoms, whether of fracture or of general debility, should be set clearly before the chair-doctor.

Column for Beginners.—TRENCH.—You want to get a knowledge of the first principles of carpentry rather than to have papers on making boxes, trays, and things of that sort. You will learn more by making the overmantel and secretary already described than in turning out a few simple things, for, after all, the sawing, planing, and putting together are the same in the one case as the other, or very nearly so. And in making your first article, pay a carpenter to show you how to use and sharpen your tools; you will find it money well spent. Nevertheless, your desire for a few small things shall not be forgotten.

Division Plate.—H. E. W.—You wish to fit one to your 5-in. lathe with back-gear, which has a wheel of only 5 in. in diameter; you say there is no room on the gear wheel, but that the wheel might have been 2 in. larger. I must conclude, then, that you are cramped sideways. I had a plate fitted in a similar situation by cutting away the casting of the headstock with the chisel, and so got in a division plate $\frac{3}{16}$ in. thick, made as a ring, so that the nut for securing the pulley to gear wheel could still be reached; a recess, or rabbet, was turned in the inner edge of the rim of the gear wheel, and the plate, or rather, ring, was turned to fit, and secured by rivets, which came between the rows of holes so as not to interfere. If you cannot possibly get your plate in thus, perhaps you could mount it on the tail end of mandrel, provided it comes through at the back of the headstock. As to the size and numbers of the holes, shape of division peg, etc., I think you will soon see an article on the subject. If you mean by "striking out" that you think you can set out the holes by compasses, I don't think you can make a division plate worth having that way.—F. A. M.

Wrought Iron and Steel Girder Work.—FEN MON.—You express a hope that the papers on this subject will be discontinued, because "there are plenty of journals devoted to the iron trade that better suit it, while more of the ornamental, the arts, and sciences seem more congenial to WORK." Yes; but how about the readers who ask for and like papers on the subject? It is impossible to ignore any subject because some are found who do not take an interest in it. Moreover, papers devoted to the iron trade are trade papers, and are purchased by masters and not by the men, and they do not enter so thoroughly into the construction, and explain the why and the wherefore of matters as completely and intelligibly to the young workman as the writer of these papers does. WORK is intended to be a good paper all round for masters and men, but more especially to enable workmen to get at the theory of their own trades through the practice described. To produce a paper that shall be equally interesting in all its parts to everybody is morally impossible, for nobody exists who has not his or her preference or proclivity both in work and play; so the next best thing is to endeavour to make a paper that is intended for all as interesting as possible to the majority of the readers. And if you are in the minority one week, you will be pretty safe to be in the majority the week after.

Patent.—AMATEUR (*New Southgate*). — To obtain a patent for your invention you must apply for it upon the prescribed forms at the Patent Office. These forms include a declaration, to be signed by the inventor, that he is the "first and true inventor," and the two other forms upon which the duplicate specifications must be commenced. These specifications must fully explain the meaning and the intention of the inventor, and be accompanied by sheets of drawings, when required, also in duplicate, and executed in Indian ink, with a very black line; and the specification must refer to these drawings, which are taken together to indicate the invention. No ambiguous language must be used, and the specification must commence with a *title*, and conclude with a distinct claim or claims, upon which the patent must stand. A provisional protection for an invention can be obtained which extends to nine months, when the specification need not be so full as for the patent, and no drawing is required. The English and French patents are quite distinct and separate matters, the only connecting-link being that, according to a law known as "the Convention," an English patentee has six months' priority should be elect to apply for a French patent. In the matter of foreign patents it is advisable to consult a patent agent.—R. & C.

Polishing and Soldering Aluminium. — ROUGE BUFF (*Battersea*).—Finished goods made of aluminium are polished on a dolly, or mop, revolved in a lathe, and charged with crocus; then finished with Sheffield lime, much in the same way as nickel. The dolly is made with soft linen or calico rags. The following white solders are said to be used for soldering pure aluminium:—(1) Aluminium, 20 parts; zinc, 80 parts. (2) Aluminium, 10 parts; grain tin, 90 parts. (3) Zinc, 5 parts; tin, 2 parts; lead, 1 part. The surfaces to be soldered must be scraped clean, and solid paraffin used as a flux. The following coloured solders are said to be used for soldering aluminium bronze: Hard.—Gold, 88·88; silver, 4·68; copper, 6·44 parts. Medium.—Gold, 54·40; silver, 28·60; copper, 18·00 parts. Soft.—Gold, 14·30; silver, 57·10; copper, 14·30; brass, 14·30 parts. The brass for this last solder is to be made of copper 70 parts and tin 30 parts.—G. E. B.

Electric Bell Battery.—SUPPLEMENT.—The Bunsen battery is altogether unsuitable for electric bell work. The Leclanché has been the battery in general use for this work for several years past. The Gassner dry battery deserves all the praise you may have heard about it. The cells are 4s. 6d. and 5s. each, obtainable in London from Messrs. Mayfield, Cobb, & Co., 41, Queen Victoria Street, E.C.; and in Leicester from Messrs. T. Gent & Co., Faraday Works, Braunstone Gate. An illustrated series of articles on electric bells is now in course of preparation for WORK.—G. E. B.

Bamboo Dealers.—BAMBOO (*Wolverhampton*).—F. Westbury and Benjamin & Co., Great Dover Street; Brandenburg, Queen Street, Finsbury; Ellmore & Sons, City Road—all in London—are dealers in bamboos. See answer to O. P. Q. in No. 14. I do not understand the part of your question asking how to order, I can only say it must be done in the same manner as any other business transaction, either personally or by letter.—D. A.

Oil in Planes.—J. B. (*Rochdale*).—You cannot get the oil out without spoiling them, or at least running great risk of doing so. The blocks are purposely oiled, both in order to improve them for working and to preserve the wood in perfect condition, so that I am at a loss to understand why you want to eliminate it. Few, if any, practical mechanics would regard a wooden smoothing plane as complete till it had been saturated with oil, a very common plan being to fill the hole with oil, after stopping it on the face, and leave it till absorbed. If the planes you wish to free from oil are new, and you find them too greasy to handle pleasantly, remember that time will effect the cure. I have said this to show the folly of trying to eliminate the oil; but if you are still determined to try you might keep the planes in a warm place to cause them to "sweat."—D. A.

Lettering Backs of Books.—J. S. (*Barnsley*). Assuming that your books are leather bound, beat the white of an egg and a few drops of vinegar to a froth; let stand some hours, and then draw off the clear glaire. Damp back of book with vinegar; when dry, give two coats of glaire; dry again, and place gold leaf carefully upon portions to be printed. Heat your letter stamps just so hot that water will not fizz, and apply with steady, firm pressure. Remove surplus gold with cotton wool.—OPIFEX.

Cleaning and Repolishing Dirty Tables.—HAIRDRESSER (*Great Dunmow*).—So much depends on the condition of the tables that one would almost require to see them before expressing a decided opinion on the best way to clean them; but I trust the following hints may be useful to you:—If the dirt and grease are merely superficial, and the wood has a fair amount of French polish on it, you cannot do better than make use of cleanser and reviver in one, composed of the following ingredients—vinegar, linseed oil, and glaze, or a small quantity of French polish. The exact proportions are not important; but, to guide you, say one pennyworth of each of the two first to half a pint of glaze, or half that quantity of French polish. A little of this cheap mixture goes a long way. Use it with a rag, and as often as you like, but continue the rubbing till the surface of the wood is glossy and dry. If the things have not been French polished, but merely oiled or waxed, you may wash them with warm water and soap; but don't saturate the wood. You must afterwards, when quite dry, either polish with a mixture of wax and turps or with French polish. The former is made by melting wax and adding turpentine, so that the mixture, when cold, is of a workable consistency. Use it sparingly, with an unlimited quantity of "elbow-grease." For French polishing proceed exactly as if the work were new, but unless you have some knowledge of the subject, you are hardly likely to make a good job with this finish. To tell you how to do so in the best manner for the various woods you name would require a page or two of WORK; but if you will tell me any one you particularly want to polish, I will direct you with pleasure. I may tell you that papers on French polishing will appear in due course. If the dirt and grease are thoroughly ingrained, the only way will be to plane or scrape off the surface till the clean wood is reached; but if any of your table tops are veneered be careful what you do, or you will go through the veneer.—D. A.

Column Support in Building.—THANKFUL (*Cinderford*).—The request made by a reader of WORK, under the *nom de plume* THANKFUL, is, I think, in part scarcely suitable for the paper. I take it that WORK is intended as a medium for general information; the main question involved in this query becomes personal. For general information I give the following figures, taken at random from various churches, giving the heights from floor to wall plate, the span of arch between nave and aisle, the height of columns and the diameter of columns, and, to a certain extent, must leave you to decide whether the arch you mention is supported by a column of sufficient strength or not:—

	Height to wall-plate.	Span of arch.	Height of column.	Diameter of column.
	ft. in.	ft. in.	ft. in.	ft. in.
1 ..	56 0	11 6	12 0	3 0
2 ..	36 6	22 6	7 0	3 6
3 ..	45 0	7 6	14 6	1 6
4 ..	34 0	11 0	11 0	1 9
5 ..	35 0	16 0	9 6	2 0
6 ..	42 0	12 6	10 9	2 6
7 ..	48 0	16 0	13 0	3 0
8 ..	47 0	14 0	13 0	3 0
9 ..	63 0	15 0	17 0	3 0
10 ..	33 0	13 0	16 0	2 6
11 ..	34 0	10 0	10 0	2 4

In the case you allude to the idea is, I suppose, to avoid creating too many or too ponderous obstructions in the structure, which must of necessity prevent some of the congregation from obtaining a general view. I can conceive of no other reason. From the above figures you will see that the column you mention has a diameter equal to No. 3, whilst the span is 16 ft. 9 in. as against 7 ft. 6 in. Strength of construction is made subservient to expediency; this is a mistake, certainly, in buildings which, like Shakespeare, are not for a time, but for all time. Personally, I should not run so close to possible danger; structural strength and stability should take first not second place. In answer to your second request, if the architect you employed has, to the best of his knowledge, fulfilled his part of the contract, how can you expect him to pay for an alteration you deem requisite, but which he, by his action, plainly does not? You must first prove a fault to exist. He evidently considers the building strong enough, for no sensible man would risk his reputation and practice by running a risk of which he was fully aware; and the collapse of a building under such circumstances must, in ninety-nine out of a hundred cases, mean collapse of business also. Nevertheless, he may, from want of sufficient data, make a mistake the result of which would be disastrous. The builder is in no way responsible for the work beyond fulfilling the scheduled requirements. The probabilities are that those who desire the alterations must also pay the piper.—J. M.

Binding Covers for Work.—W. S. W. (*Hunningley*).—A binding case will be prepared by the publishers of Work to contain a year's numbers, and the price of it will be about 1s. 3d.

Joiners' Composition.—There may be many in use, but the best I have tried is quite waterproof, and sets at once as hard as hard wood. It is called "choucha," and may be bought at Deed's leather warehouse, High Street, Bloomsbury, London. I think it is about 2d. or 4d. per ounce. It seems to be a mixture of gutta percha and shellac. I have used it in cabinet work, or to repair fractures. It is warmed over flame or by heat, and applied with a palette knife very thinly spread. Better also heat the parts to be joined.—J. C. K.

Plumbing Examinations.—J. G. (*Brighton*).—To answer fully the questions asked by J. G. would effectually destroy the chief object of these examinations, which are meant to test the capacity of candidates who wish to be enrolled as registered plumbers. My advice to J. G. is to apply to the clerk to the Plumbers' Company, No. 1, Adelaide Buildings, London Bridge, E.C., for the printed form furnished by the company to all plumbers who desire to be registered. This form contains all needful preliminary information.—G. S.

Painting on Zinc.—W. G. (*Brixton*).—I have painted on zinc both for indoor and outdoor decorative work, and would advise that for either the zinc should first be rubbed over or scoured with dry sandstone or grit, to create a roughness to hold the paint. For my indoor work (which I find stand remarkably well) I have used tube oil colours worked up with gum dammer varnish as a medium. The latter I prepare by dissolving the gum in turps and straining through muslin. A "dammar varnish" is sold which is probably much the same as mine. I have not found work thus done either peel off or blister. It is more difficult to make outdoor work stand than indoor. Some done by me seven years since without roughening the zinc and with gold size only as a medium has almost perished. The sun, and not rain or frost, is our worst enemy. I find that metallic colours, such as flake white, stand best. For merely useful outdoor work, such as spouting, the zinc is best *not* painted.—C. C. C. [As regards sizes and prices of rough articles in papier-mâché, W. G. is referred to Messrs. McCallum & Hodson, Summer Row, Birmingham.—S. W.]

Index to Work.—R. H. P. (*Broadstairs*).—Certainly an index will be issued at the completion of each volume of Work.

More Talk than Work.—Da Capo.—You ask if there is not more talk than work in Work. Assuredly not! How could you possibly learn any trade or art if your instructor held his tongue, and did nothing more than look at you and point and draw diagrams? In all teaching conveyed by the medium of paper, type, and ink, it is necessary to be as explicit as possible, even though the tuition given sometimes assumes the form of a lecture.

French Polishing.—A Constant Reader of "Work."—Information on French polishing will be given at no distant date.

III.—Questions Submitted to Correspondents.

E. M. (*Madrid*) writes:—"If you know of a practical book on the treatment of ivory, mother-of-pearl, tortoiseshell, and similar materials for such work as fan making, be kind enough to mention it and possible particulars in 'Shop.'"

Water Power.—J. L. (*London, W.*) says:—"Will any reader oblige by explaining in Work the reason why a turbine is of more power with the same amount of water available than an overshot or back-shot water-wheel? I can scarce understand its action."

Flour Paste Souring.—J. R. (*Skerries*) writes:—"Would any reader of Work kindly inform me of some means for keeping flour paste from souring and getting bad, so as to enable me to keep it on my office desk for use, instead of gum?"

IV.—Questions Answered by Correspondents.

Polishing Oak Floors.—D. A. writes in reply to H. N. (*Bexley Heath*), see page 174:—"Beeswax and turps, if properly applied, give a good polish, but not so brilliant as varnish. Probably the cause of failure is an insufficient application of elbow grease and a too liberal use of the wax polish. If a bright polish is wanted, use brown oak varnish."

Wood Colouring.—D. D. writes in reply to Ox Gall (see page 174):—"Take vandyke brown, ½ lb., ammonia, ½ pint. Mix and reduce with water."

Glaze for Finishing French Polishing.—D. D. writes in reply to W. H. B. (see page 174):—"Put 2 oz. of benzoin into ½ pint of methylated spirits. When the gum is dissolved strain through muslin."

French Polishing.—G. B. P. (*Birmingham*) writes in reply to T. A. (*Belfast*), see page 174:—"You should always varnish your fretwork, using no oil whatever, as the latter would work out in time. I polish my wood in the flat before cutting out, and then touch up with the brush. If you would let me know fully what you want to know, I would (with our editor's kind permission) let you know with pleasure, either privately or through Work. Editor has my address."

Solidifying Petroleum Oil.—H. B. S. (*Liverpool*) writes in reply to W. H. (*Liverpool*), page 110:—"It is not possible to solidify common commercial petroleum oil."

Solidifying Petroleum Oil.—P. W. S. (*Poplar*) writes:—"If W. H. (*Liverpool*) will name the purpose to which the solidified oil is to be put, I can help him, either in 'Shop' or privately." [Will W. H. (*Liverpool*) kindly notify if he desires the assistance offered by P. W. S. (*Poplar*), and in which way?—Ed.]

Joiner's Composition.—J. M. (*Louth*) writes:—"In answer to question by F. B. (*Guernsey*), page 158, I shall be very pleased to give him the receipt for which he asked, as follows:—Equal parts of beeswax and resin coloured with red ochre to suit the work. Red ochre for mahogany, brown umber for walnut; white wax use for ash, and other light woods. F. B. will have to be careful how he uses the red ochre, as a small quantity goes a long way; better melt the beeswax and resin, and add ochre to suit the job. Being a practical cabinet maker myself, shall be pleased to answer such correspondents as F. B. as far as lays in my power, not only because I am very pleased with Work, but because I am pleased to help any one that is anxious to improve himself. I, myself, am very pleased with 'Tips for Tyros,' the tip about picture-frame corners being very useful to me. I hope you will have a great success with Work, etc."

Etching on Steel.—Fen Mon writes, in reference to the reply given to Excelsior by G. E. B., in No. 8, page 125, under this heading:—"The powder Excelsior means will be, I have not the slightest doubt, sulphate of copper, commonly known as blue stone or blue vitriol. This, when dissolved in water, particularly if acid is present, will itself dissolve out iron or steel, and deposit in its place, as a spongy brown crust, metallic copper. The equation, leaving out the *water* of solution and crystallisation, is—

$$\left\{ \begin{array}{l} Cu\,SO_4 \quad + Fe \quad = Fe\,SO_4 \quad\quad + Cu \\ \text{Cop. Sulph.} + \text{Iron} = \text{Iron Sulphate} + \text{Copper.} \end{array} \right\}$$

Excelsior would get better results if, instead of soap, which is liable to dissolve away with water in fine parts, he heated the steel moderately, and rubbed it over with beeswax. Etchers have, instead, a complicated mixture for a novice to make. Then, with a sharp pointer or pen, be sure to expose the metal. If, when it has stood by, Excelsior does not think he has cut deep enough, before he takes off his wax he may change his solution for fresh, as it will only act so long as there is $Cu\,SO_4$ left in it. If he wants to etch other metals as well, nitric acid is best, as it will attack almost all metals, gold and platinum, etc., being about the only exceptions; but it is not a nice acid to use, staining the hands, and besides, very noxious fumes arise from it. I hope this will explain matters to the satisfaction of Excelsior."

Fretwork Patterns.—F. C. (*Cheadle*) writes in reply to W. E. M. (see page 174):—"Seeing in Work for June 1st an inquiry asking where the work on fretwork alluded to in that publication can be got, I have got the work, and have succeeded in getting some very pleasing patterns from it. It is published by Adams and Bishop, successors to Henry T. Williams, 46, Beekman Street, New York, price 50 cents. The copy that I have was bought at Messrs. Gleave and Sons, Oldham Street, Manchester.

Trade Notes and Memoranda.

The new battleships for the navy, eight in number, will each carry 4,550 tons of armour, whose maximum thickness will be 18 in. The principal armament will consist in each vessel of four 67-ton breechloading guns, having a calibre of 13½ in., and firing a shot of 1,250 lbs. weight, with a charge of 630 lbs. of powder. Besides these, each ship contains a secondary armament of ten 6-in. quick-firing guns, besides several smaller ones. We have it on the authority of Lord Armstrong that these 6-in. guns will pierce the armour of most of the warships now afloat.

A new line of railway between Liverpool and Manchester was opened on the 1st of June. There are already two lines, the Cheshire and the North-Western, connecting those cities, so that some rivalry may be anticipated. The new route runs from Victoria Station, Manchester, through Pendleton and Atherton, and passes just outside Wigan to join the present Lancashire and Yorkshire line from Wigan to Liverpool at Pemberton. Its total length will be 35 miles against 34 miles by the Cheshire line, and 31½ miles by the London and North-Western.

A paper on "The Origin of Bronze" was read at a recent meeting of the Paris Academy of Sciences by M. Berthelot. The author analysed specimens of metal from a statuette from Tello in Mesopotamia, and from the sceptre of the Egyptian King Pepi I., sixth dynasty, both dating back to about 4,000 B.C., and found them to be pure copper. He, therefore, argues the existence of a copper age between that of stone and of bronze, and thinks the latter is not more than fifty or sixty centuries old.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable every where throughout the United Kingdom on Friday at the latest.

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

AN ORNAMENTAL CLOCK CASE AND BRACKET.

BY J. H. MOODY.

Prefatory Remarks — Working Drawing — Demolishing Old Clock—New Top Piece —False Styles—Reconstruction.

The possession of ample means enables a man to indulge without stint in the purchase of things that are costly and massive, and to fill his house with articles that are pleasing and beautiful; but lack of the needful not only compels him to stifle his acquisitive longing, but sometimes induces him to resign himself to surroundings, the ugliness of which his impecuniosity renders him powerless to alter.

My readers will understand that I do not argue that apathetic satisfaction, amidst lack of beauty, is a natural consequence when a man's means are scanty; indeed, there are notable exceptions to be seen in frequent creditable efforts at decoration in humble domiciles; and some, also, that are even possessed of a high order of excellence; but if the efforts are only crude in execution and vague in design, as the work of an untutored savage, they are still to be commended for the good intention they manifest, and because they are evidence of a desire for a better state of things.

Now, it seems to me that it is part of the mission of Work to direct and order all these faltering well-meant efforts by showing how they may achieve good result; and they who are capable of good work may take counsel also; for even as it is said that everybody has something yet to learn, so it may be said that a man must be exacting indeed if he fail to find something to interest him in this magazine, or very undiscerning if he fail to perceive profit in the perusal of its pages.

It is quite possible for a man to attain mechanical skill if he earnestly strive for it; and if at the same time he apply himself to improvement in artistic ability, the time will not be far distant when the power to produce beautiful objects will be within his grasp; and if those objects be neither massive nor costly, I venture to say that their inspection will give pleasure, and likewise a vast amount of satisfaction to their constructor.

Fig. 1.—Ornamental Clock Case in Front Elevation (half full size).

But lest I be charged with misappropriation of space, I must hasten to introduce my subject, and it is imperative that I should quit the character of mentor and become for the nonce the aspirant who has accomplished a few easy jobs with *éclat*. Being big in the possession of a small stock of good tools, I looked around me, anxious, like another Alexander, for other jobs to conquer. I was, however, not long without work to do, and plenty of it—work wherein my proficiency would be tried. Here are one or two among the list:—An overmantel—to depose the one which had long done duty, and whose worn gilding had long been an eyesore—was my great ambition; then my books were becoming dilapidated for lack of shelves or case; the wife also suggests that a few brackets as receptacles for her treasures in the way of china would look well and assist in the embellishment of the walls of our best room. For my own part, I thought that sundry articles of domestic use might be improved and transformed in a way to suit modern ideas, and accordingly I gave preference to the following:—Among my belongings there was a clock that was a good servant in the household, and I determined that I would provide it with a case more important and ornamental than the insignificant one provided for it by its maker.

A description of this clock as it stood before alteration will give my readers some notion of the work I undertook, and will not tax space very considerably. The movement was a very ordinary brass one with pendulum, and the case was little more than a box with a plinth at front and sides, in which channels were cut to carry the bottom; the top was a flat piece of wood rounded on edge and bradded on; there was also a mitred framed door with glass panels; and the dial was printed on zinc plate. Altogether, my clock was such an one as our American cousins send away in shiploads.

The reader may express wonder that I took trouble over so paltry an article; but, as I have said, the clock had always kept steady time, and that, I apprehend, is as much as a clock, whatsoever its worth may be, is expected to do.

The ornamental case which forms my subject was the result of my deliberation, and when I took occasion to look about me for something to guide me, I could see no example in the clockmakers' windows to assist me. The inevitable marble clocks, said to be models of Pompeian relics or of Grecian temples, were too grand for me, and palled by their repetition. I turned then to the neat clocks in tastefully-designed wooden cases for relief; but their turned pillars and railed galleries did not quite satisfy me. At last I took my cue from some architectural detail, and I developed a very pretty cottage porch to suit my purpose. This is shown in Fig. 1.

The design for a new case being thus arranged, the first step was the making of a full-sized drawing of it. This enabled me the better to conceive how to alter my old friend's appearance, and I began work in earnest by demolishing the construction of the old case. This operation was performed with great care, in order that the severance of parts might be effected without abrasion or splinters; and my reason for preserving the parts from damage will, I think, be perceived, as the wisdom of such a course was apparent to me. When I came to review my clock's requirements, I saw that the same full allotment of width and height for length of pendulum and unwinding of spring were demanded in the new case as the old one had provided; and when the time came for reconstruction, my labours were greatly reduced, as much of the old work was used over again.

The old case thus, by disintegration, thoroughly lost its identity, and the *débris* remaining was examined as to how far the fragments might be adapted to contribute towards the building of the new design. Certain of the pieces, I found, were inapplicable; for instance, the old top piece not being large enough to provide the overhanging eaves, it was condemned, and a larger piece made; the door also was discarded as having no local habitation under new conditions. Among sundry other alterations, the doorway, which extended the whole width of the case, was narrowed by first planing the side pieces sufficiently to take away rebates that I found upon them; I then affixed false styles upon each side piece, to bring the aperture of the doorway within proper bounds. These styles also formed the backing for the two ornamental pillars. Planing the sides of course made them narrower, consequently it was necessary to plane away the side pieces of the plinth to match; and, that being done, the reconstruction was proceeded with. With slight alterations here and there, and a trifle of humouring, the case was soon ready for the attachment of ornament; and I must not omit to mention the cutting away of the front plinth for the top step, and for the setting back of the lower parts of the pillars, which also were cut with laps to bring their surfaces into close contact with the styles. In putting together, I ensured firm attachment of one part to another by using screws. I also used glue wherever its application would be attended by good results.

A PHOTOGRAPHIC CHANGING BOX.

BY L. IVOR POOLE.

Retrospective—Advantages of Changing Box—Dimensions—Materials—Stopping Light—Window—Holes for Hands—Hole in Front of Box—Sleeves for Hands and Head—Hooks for Lid, etc.—Eyes—Mode of Using Box—Preparing Plates—Utilisation of Box.

Now that summer is once more upon us, and hosts of photographic cyclists will be taking to the road with their wiry steeds and cameras, some description of an arrangement which I found of use may not be unacceptable to those readers of Work who are riders, though I can no longer call myself one of them. Still, remembering the glorious spins and occasional inglorious spills, the Saturday afternoon runs with their accompanying teas at the famous "Old Salisbury," or other well-known hostelry, I am one with them at heart. As I write how old memories come back: the sixteen assembled in the "Upper Chamber," which sounds better than "Attic," of Ironmonger Lane, there to settle the cycling affairs of the nation, or make as near an approach thereto as circumstances permitted. Portly, pleasant Tod, ably supported by dear old Sheppee, with the General, "Lord" Algy Darnley, Caledonian Craw, and others, who though "lost to sight are to memory dear." Then there's the Phairson with his celebrated song of "The Cat," Nairn (I wonder if he remembers his first ride up Muswell Hill on a sociable ?), MacCandlish, Lowe, "Sigma," and the rest of the cycling pressmen—ah! mentioning them reminds me of our "only Editor," him of the C. T. C. But to dwell on these reminiscences won't do; no further progress would be made than sometimes happened at, ahem, a council meeting of the N. C. U.; so mount and away, no more delaying at "Tally-ho Corner."

The changing box about to be described would be rather too cumbrous to be carried with ease on a bicycle, but on a tricycle I have taken it about without inconvenience. I do not say that it is more convenient than taking a number of dark slides with one on a ride, but on tour I have found it very useful, and at home it is hardly less so, when one wants to change a plate without going into the dark room. On occasion plates have been developed in it, though the space is rather too confined for comfort. Perhaps, to sum up its advantages, it may be said that it is very easily made, and that though not so good as some other forms of changing box, it is very inexpensive.

In size, it is 1 ft. 2 in. long by 9 in. wide by 10 in. deep, which I have found quite sufficient for changing quarter-plates. It is made of pine about ¼ in. thick, the various parts being fastened together with screws. The lid is hinged on to the top, or, as it becomes when the box is in use, the front. To prevent any light getting in round the edges of the box at the lid, these are lined on the inside with thick felt, just projecting above them. By this means a light tight joint is made without any difficulty. About the middle of the top piece a square hole measuring rather less each way, say, about ½ in., than a quarter-plate is cut. Round the edges of this hole a rabbet or recess is cut, within which a quarter-plate lies. This plate serves as the window for the box, and, it is almost needless to say, the light through it must be rendered non-actinic. This I managed by merely pasting some of the orange-coloured paper used by photographers over both sides of the glass, and subsequently oiling it to render it less opaque. The glass was then let into the rabbet, which, it should be stated, is on the inside of the lid, and not deeper than just enough to hold the glass. It will thus be seen that this is a good deal below the level of the outside of the lid, and is, therefore, to some extent, protected from injury. Without some other covering, it might seem likely to be frequently broken, and this objection has sometimes been made to it. All I can say to this is that the glass in mine has not once been broken, though I have used the box more or less for some years. Of course I have taken care of it, and protected it from rough usage. The glass is fixed in by tape glued both to it and the surrounding wood. This, I am bound to say, gave way once or twice, though it probably would not if the tape had been sufficiently wide. To prevent mishaps of this kind, I subsequently took a piece of calico, with a hole in it about the size of that in the top, and glued it down instead of the tape. This has been perfectly satisfactory.

In each end I cut a round hole to admit the hands. To suit me these holes are about 5 in. diameter, from which it may be inferred that No. 6 "kids" don't fit me, but in any case the holes should be quite large enough to admit the hand freely and allow of the sleeve-encompassed arms being moved about. These holes were cut with a fret saw, the pieces removed being kept and used subsequently as covers. This renders it almost unnecessary to say that when cutting them, the tilting table of the machine was adjusted so as to form bevelled edges. The thickness of the saw makes the covers fit in rather too loosely, a fault which is easily got over, however, by gluing slips of paper on the edges. By this means the covers may be made to fit perfectly, without any great skill in joinery.

On the front of the box a similar hole, but oval and measuring about 7 in. by 4½ in., is cut, the piece removed being also utilised as a cover. Through the holes in the ends the hands are passed to work inside the box, while the other one admits of what is done being seen. This latter is not absolutely necessary, as with a little practice it is quite possible to do what is wanted without the assistance of the eyes, though generally it is more convenient to use them. Of course, to prevent any light entering by these holes while plates are being changed, it is necessary to close them without in any way interfering with freedom of action. This may be easily managed by forming three sleeves or tubes of some flexible material, and I doubt if anything is more suitable than black holland and the "canary" coloured fabric sold by photographic dealers. A layer of each of these is used to form the sleeves, or, to express it differently, each sleeve is made of double material, one being black and the other the canary fabric. In diameter these sleeves, at one end at any rate, are rather larger than the holes they are to be fitted to. At the other end the size is not of so much consequence, provided that those for the arms admit the hands easily, and that the other one fits on the operator's head, or, rather, on his face. This latter may require some explanation, and I do not know that I can do better than state that the face is put in it and looks through it, as it were through a tunnel, into the interior of the box. The head sleeve passes under the chin, over the ears and the top of the head. To keep it in close, and also to prevent it slipping off, the edges are bound with a piece of braid-elastic. The outer ends of the arm pieces are also bound in a similar way, so that on the hands being passed through they closely grip the wrists, without, however, being so tight as to impede circulation. The elastic I have on my box is about 1 in. wide. The ring or garter of elastic is, of course, smaller than the full size of the diameter of the sleeves, which are what I think ladies call "gathered;" but this, no doubt, is part of the making, which will hardly be undertaken by men, and any member of the gentle sex will know how to do what is required without being told if the object is explained. In my own case it was so, and I can only hope others may be similarly fortunate, because I am quite unequal to the task of explaining the mysteries of the needle.

The other ends of the sleeves are fastened to the inside of the box with small tacks, so that when the covers are on they are not visible. The tacks should be pretty close together, and it is to allow of the sleeves being properly nailed down that it has been stated they should be a little wider than the holes. The length of the sleeves is not of much consequence: in my box, those for the arms are about 6 in., and that for the head about 1 ft. long.

To keep the lid close and the covers on when required I used nothing but small wire hooks. Something neater might be adopted, but they have served their purpose, and, by making them myself, I was able to get them just what I considered of a suitable size without any trouble. Four hooks are employed to secure each cover, and six for the lid, that is, two in front and two on each side. The hooks themselves are merely pieces of brass wire bent, with one end forming an eye or ring, through which a small screw nail is passed. To catch the hook over, the "eyes" are short round-headed screw nails. By first fastening the hooks, the exact position of these screws can easily be obtained; and if, at any time, the wire does not catch properly on them, a slight bend soon puts everything right. In this respect they are, perhaps, better than hooks bought ready prepared, as these might not be capable of such ready adjustment. In case any one does not understand the nature of these fastenings, it may be said that the side hooks shown in page 217 of Melhuish's catalogue will do admirably, the smallest size being preferable to the larger ones. Whatever sort are used, however, great care should be taken that they keep the lid close down to the box. As a matter of fact, however, it is seldom necessary to open the lid, as anything to be put in or taken out of the box can easily be passed through one or other of the sleeves. When the box has been stained black inside it is ready for use, but, of course, the appearance is much improved by staining and varnishing the outside.

The way of using the box may be explained as follows:—It is placed with the head sleeve upwards, the lid, containing the ruby window, away from the operator. The sleeves being drawn out, that for the head is first pulled over the face, and then the arms passed through their respective holes. To get the first arm through is not difficult, as the other hand can assist, but the other is more troublesome at first, though, with a little attention, it can soon be managed. Both hands being inside the box, and the eyes looking down into it, it will be found that the operations of undoing plate boxes, wrapping them up again, and all the movements incidental to changing plates, can be performed with the greatest ease. I have, however, found that plates were sometimes injured by the moisture of the breath, but having called attention to the liability to this mishap, it is not necessary to say more than that it can be avoided by not placing the face too close to the plate. Since I found out why the plates were injured it has not occurred. Naturally, owing to the confined space, the atmosphere soon becomes unpleasantly warm and close, but no great inconvenience need be incurred on this score.

In connection with this box, I may mention that I found it a great convenience to prepare the plates in pairs beforehand by putting them together with a piece of black paper between each. A small "dab" of gum or paste on the back of each plate kept them in contact with the paper, so that in changing, instead of having two separate plates with the loose backing to manipulate, there was practically only one. I may go a little further, and say that, by taking this precaution, I have changed many plates when out riding in a mackintosh legging for dark room. An elastic garter was slipped over each end of this, and the plates changed without looking at them. This, however, is only by the way, as it has nothing whatever to do with the construction of a changing box, any more than the mention of other kinds or of portable dark rooms.

The box described will hold camera besides other odds and ends, including the tourist's wardrobe when on tour, provided his impedimenta are not great, as they seldom need be for a few days' run, even though they consist of more than a comb and tooth-brush, and possibly a clean collar or two. When being carried about, the covers, which fit over the holes, hardly allow the box to be distinguished from an ordinary plain one.

Thus our box may be made useful in more ways than one, a desirable thing in these times, when so many things are "contrived a double debt to pay," and combination tools in which one article is made to do duty for three or four are so freely offered as an attraction to all workers on a small scale. And I do not think that many will be found who will quarrel with its adaptability on this score.

It is possible that some few, on reading the description that has been given above, and realising the fact that but little skill and labour are required in its construction, and that there is nothing about it to justify its introduction under some high sounding name, will ask why the subject has been brought under consideration at all. I trust, however, that in this case the result will justify the means, for it has been described in the hope that it may be as useful to cyclists and others as it was to the writer when he was one of "the sixteen"; for though, as already stated, no longer a rider, not the days "o' lang syne" nor "the auld acquaintance" are forgotten.

So "here's a hand my trusty frien',
And gie's a hand o' thine,
For auld lang syne."

A BLOCK PLANE AND PLANE WITH LEVER ADJUSTMENT.

BY A FOREMAN PATTERN MAKER.

A Word in Season—Shell of Block Plane—Patterns—Metal and Wooden Boss—Screw—Qualities of Shop Planes—Pin as Fulcrum for Lever—Lever Fittings—Cutting Iron—Merits of Wooden and Iron Planes—Metal Plate on Sole of Wooden Plane.

I have noticed once or twice in "Shop" expressions very nearly amounting to strictures with reference to instructions given on the methods to be followed in making certain tools at home, when the tools that are described may be purchased of most hardware merchants and dealers in tools. Others again show as much desire as others evince disinclination for papers such as I am now about to write, and declare that the information that they derive from them is alike useful and welcome. Doubtless there is much to be said on both sides, inasmuch as some have neither time nor inclination to do anything of the kind for themselves, and others are better pleased to use anything that has cost them both time and trouble to make better than the best of its kind that can be purchased at the tool shops. I think myself, however, that the time spent in reading the article is by no means lost, nor the space that is taken up by it in the magazine to be regarded as wasted, for due comprehension of the construction of a tool invariably leads up to better ability to use it. It is far from likely that every reader can find equal satisfaction or benefit from the perusal of every paper, but it is possible to rest contented even with that which may not be immediately profitable to himself when he remembers their importance and utility to others.

Figs. 1 and 2 represent in plan and section the shell of a block plane, which is made either in iron or in gun metal, in various sizes, and under various modifications. It is, however, only worth the trouble of making when not of very small size; useful dimensions would average from 6 in. to 8 in. in length.

I do not show the plane complete, because the wedge and screw are precisely like those shown in Fig. 3, and the same description will apply to both. The latter, Fig. 3, shows a very neat little plane with a lever adjustment for the setting of the iron, and one that can be made without much difficulty. These are to be bought in the shops, but any one possessing a moderate degree of skill in metal working can make two or three of different dimensions for home use.

In each case construct the patterns exactly like their castings, except, that in Fig. 3, the little socketed recess in the piece A will be left to be afterwards drilled and countersunk, as also will the small holes at B and C. Lest the very thin sides should become rammed inwards or outwards by the moulder, plane up a temporary bridge of wood to just fit between the sides. This will preserve their parallelism, and when the sand is rammed sufficiently around the sides the moulder will remove it, and complete the work without risk of getting the sides away from their correct positions.

In Fig. 2 a common wood screw is cast in the metal boss, B, to receive the circular wooden boss, C, which is struck with the hammer in order to release the iron. The pattern of the arched lever, D, Fig. 3, will be cut from a bit of hard close-grained wood, also like its casting. A pattern is also made for the screw, E, whose head is milled in the lathe. If made in gun metal the screw and head may be in one piece; if formed in cast iron the screw should be cast into the head. That portion of the screw around which the milled head is cast is made angular, square, or otherwise, to prevent it from working slack with use.

The planes sold in the shops are almost always cast in iron. But the iron is of a specially soft and tough quality such as cannot be always procured in ordinary foundries. In such cases it is much better to use gun metal which will not easily fracture. In such light castings the cost is very little in excess of iron because the labour counts for more than the metal. In any case I should have the lever, D, made in gun metal; even when made of good iron, these levers will often break when a slight excess of pressure is imparted in turning the screw for tightening the iron. I should also have the screw and milled head cast in one in gun metal, rather than cast the screw into the milled head, the screw being apt to work loose in its casting in the course of time.

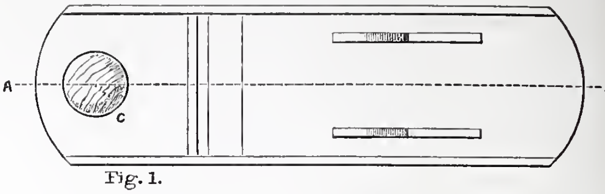
When cast, file the faces, and drill the various holes required.

A pin is made to bridge across the casting at B in order to afford the necessary fulcrum for the lever. This is riveted in holes which are slightly countersunk.

For the lever fittings in Fig. 3, get a bit of steel bent round, and file it to the outlines in F, Fig. 3, and Fig. 4, filing out also the recess through which the lever, G, operates. Drill the holes, C, H; prepare the lever, G, Figs. 3 and 4; pivot it in place, and then pass the pin, C, through, which attaches the rocking lever, F, to the plane.

The assistance of a smith must be obtained for the cutting iron, Fig. 5, which will be ground to size and serrated while yet untempered. These serrations, as well as those on the rocking piece, will have to be done very carefully and regularly. They number about five or six to the ⅛ in., and are sunk to about $\frac{1}{32}$ below the level of the under face of the plane iron.

To cut these serrations, get a cold chisel of the same width, and ground slightly keener than the ordinary chisel. Lay the iron on a piece of metal, and, holding the chisel transversely at right angles with the edge of the iron, strike it a smart but dead blow. That will not only indent the metal, but will raise a burr or ridge formed by the displaced metal. This ridge will guide the chisel for the next blow, and so on in succession like file cutting. If the chisel becomes only slightly dulled, re-grind. It will be as well to practise the cutting first on a bit of wrought iron or steel before tackling the actual plane iron. A shorter but otherwise similar series of serrations will be cut upon the top of the rocking piece, Fig. 4, and care must be taken that they are both at right angles, and at the proper pitch or distance, as otherwise they will not enter and mutually coincide.



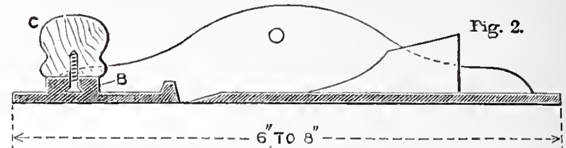


Fig. 1.—Casting for Block Plane. Fig. 2.—Section through A A.

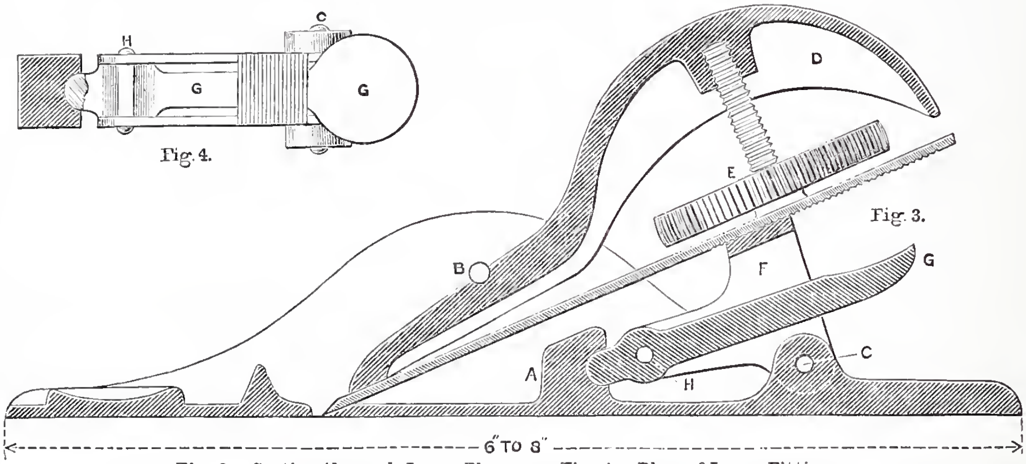

Fig. 3.—Section through Lever Plane. Fig. 4.—Plan of Lever Fittings.

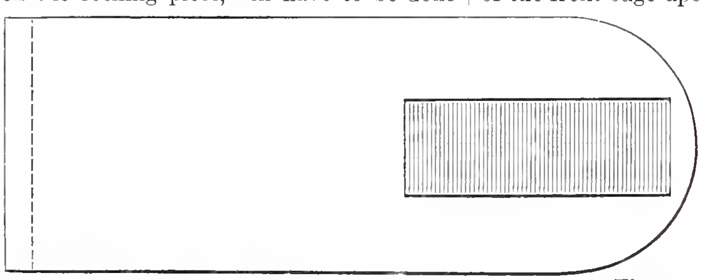
The only fitting about the lever is that involved in the coincidence of the groove, Fig. 3 B, Fig. 6 A, with the pin, and that of the front edge upon the iron.

When the iron is set approximately flush with the face of the plane, the milled wheel, E, is turned, tightening the iron. Then by the simple movement of the lever, C, upwards the iron is thrust forward, increasing the thickness of shaving: by its movement downwards the iron is drawn back for removing finer shavings. Thus no hammer is ever used on the plane.

A great deal of difference of opinion exists respecting the relative merits of wooden and of iron planes. The reason is not far to seek. Many of the planes sold are such utter rubbish that they will not stand ordinary wear and tear. A broken wedge, due to an extra turn of the screw, and a broken body due to a fall, are not unfrequent accidents. The reason is that they are too often made of the commonest cast iron; and so a tool having good inherent qualities has been consequently brought into some disrepute. But this certainly does not apply to the best iron planes, although, even in these, more care is necessary than in those of wood. An amateur also making his own planes will see to it that good metal is put into them, or will have them cast in brass. For the best indoor bench work, as cabinet making, joinery, pattern making, etc., iron planes have their own special value. Speaking of the writer's own trade, he would deem it quite exceptional to find a workman destitute of at least two or three metal planes. One of the advantages of these tools consists in their weight, another in the greater rigidity of metal over wood, by virtue of which they readily remove fine shavings and operate on cross-grained timber; another is that the sole does not become worn out of truth so rapidly as wood, and lastly they are not affected by heat or moisture. For the lighter and best classes of work, therefore, and for some special purposes, these planes are of service, and I have preferred to describe the making of planes of metal rather than those of wood, because the latter, as a rule, do not offer the same difficulties to amateurs and workmen as the former.

Sometimes a compromise is made in the case of wooden smoothing planes by screwing a plate of metal to the wooden sole, but this has obviously only a limited application.

Referring once more to the manufacture of home-made tools, it is, of course, infinitely easier for the majority of men to work in wood than in metal; and it is this facility in wood working, as compared with dealing with metal, that inclines most men to work in the former rather than in the latter. This, however, should not altogether tend to induce men to discard metal for wood because the former happens to be more intractable.



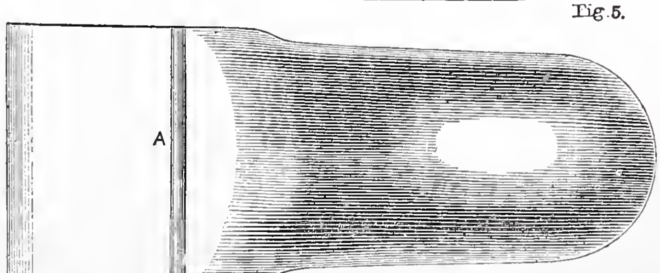


Fig. 5.—Cutting Iron. Fig. 6.—Plan of Lever.

SOME LESSONS FROM AN OLD BUREAU.

BY DAVID ADAMSON.

(*Continued from page* 182.)

ATTACHMENT OF TOP PIECE AND END—MORTISE AND TENON—GROOVE ACROSS ENDS—"RAGGLING" PLANE—FITTING TOGETHER—SUPPORTS FOR ENDS OF DRAWERS—KEEPING RUNNERS IN POSITION—INFLUENCE OF ATMOSPHERIC CHANGES ON WOOD—POLLARD OAK—SPLITTING OF OLD WOOD—DUST BOARDS—THEIR PREPARATION AND FITTING—LID BEARERS—THEIR FITTING.

No special instructions have yet been given regarding the attachment of the top piece (No. 3) to the ends, and it merits a few remarks.

The difficulty of cutting dovetails all along the ends of it and the grooves to match will no doubt have been anticipated while fitting the rails. To manage them neatly will likely tax all the skill of the amateur, while the longer spaces to be fitted to each other in the top will probably be more than he can accomplish. A loosely-made joint—that is to say, the one in which the dovetail slides in so that it does not fit tightly to its groove, is comparatively easy, but then the efficacy of the joint is largely nullified. Rather than have a badly-made joint of this description, it will be better, besides being simpler to construct, to take advantage of the ordinary mortise and tenon, being careful, of course, that the mortises are not cut through the ends. This must not be regarded as a makeshift, suggested by the supposed incapacity of the amateur, for it is a legitimate method, and one that would probably be adopted by the great majority of competent artisans in similar constructions. Many of them also use the same joint, the tenon, for the rails. The top, of course, ought, when the ends are cramped up and the tenons driven home, to fit closely up to the ends of the bureau, but it will probably be found more satisfactory to house each end of the top in a groove cut right across the ends. These grooves need not be deep; in fact, they should not be more than sufficient just to allow the top to enter them. Those who do not mind expense may cut the grooves with a plane constructed for the express purpose of cutting grooves across the grain. It is one not often found in even professional workers' outfits, and as there may be some who do not know that such a tool, though it is not a new one, exists, mention is made of it here. It is called a "trenching" plane, though possibly it is known by other names as well. In "Auld Reekie" it would probably be recognised more quickly if inquired after as a "raggling" plane. In its absence the groove, however, can readily be cut by ordinary tools, a chisel or two, used with care, being all that are absolutely necessary.

Mention has been made of the top being of thin wood, lined up in front of the desired thickness, but special instructions will scarcely be needed after what has been said about the bottom rail, which, if one may so call it, was a reversed lining up. When all the parts mentioned so far have been prepared, it will be as well to fit them together to see that everything is correct, but do not use any glue yet, as they will have to be pulled apart again. We have, as yet, only got bearers or supports for the drawers in front, but there must be other pieces from back to front to support the ends of the drawers, and on which they may slide backwards and forwards. The small upright divisions between the two top drawers, and between these and the lid bearers, should be fitted before proceeding further. They may best be fixed by tenoning them and cutting mortises in the top and in the rail below. The centre division needs no remark about its position, as it may be supposed that any one will be able to ascertain this without being told how; but about the others, those which are between the drawers and the bearers (No. 30),* there may be some hesitancy. The space between them and the inner sides of the ends should be just the thickness of the pieces (No. 30), so it will be as well to have these ready planed up, in order that it may be ascertained to a nicety, or else to keep the space small and plane down the bearers to fit, which is, perhaps, if anything, the better plan. I daresay it will be understood that these bearers are to work backwards and forwards like a drawer, so the importance of fitting them properly will be recognised at once. The pieces now required will be Nos. 31 and 37. The former must be fitted into grooves—say, ⅛ in. deep, running from behind the bearers to the back of the ends. They should be attached to the bearers by a tenon. But Fig. 9 will explain the construction better than any mere verbal description. A is the end of the bureau, B a drawer bearer, and C a drawer runner. These runners must be exactly the same thickness as the bearers to which they are attached, otherwise the drawers will not fit accurately however well they may be made. Not only must they be of the same thickness, but their upper and under surfaces must be level with those of the rails. Now, when all this has been done, it will be seen that the ends and fronts of the drawers will be supported, but some means must be employed to keep the runners in position. The grooves certainly prevent them from falling down when the weight of the drawers is on them, and the joint connecting them with the rails may be enough to keep them from shifting; but they will be further held in place by the boards, which next claim attention. But why not glue them to the ends, thinks the novice, for that, surely, would be strong enough, and save a lot of labour. Yes; certainly it would be *strong* enough, and at first sight it might seem a very feasible method, but a little consideration will show why it is not suitable. As this is one of those details of construction in which inexperienced workers are apt to go astray in their anxiety to glue up and screw up every part to the utmost of rigidity—I don't allude specially to amateurs only here—a few remarks may not be amiss by way of explanation. All wood is more or less susceptible to atmospheric changes. It swells in a moist atmosphere, contracts in a dry—not to any great extent, perhaps, but still appreciably, however well seasoned it may be, the balance of movement being towards shrinkage or contraction for a very considerable time, unless the wood has been thoroughly dried before working up. I allude, of course, principally to interior domestic fittings, not to wood out of doors, where, naturally, the changes are much more apparent. Watch a wooden gate or door, for example. During a long protracted season of dry weather it shrinks so much that it fits quite loosely. When winter comes, or a long spell of wet, cold weather, the same door could do very well with a shaving or two off it. Precisely similar changes, though in a modified degree, occur in all woods, and this natural play must be allowed for and provided against, or it will result in unpleasant consequences. Fortunately the difficulty of contending against it is greatly reduced by the fact that the movement is only lateral, not lengthwise—that is, a plank will only shrink in width, while its length remains the same. It is, perhaps, strictly speaking, not quite correct to say that wood does not contract or expand in length, but the alterations are so slight that, practically, they need not be taken into account. Take a very common instance of shrinkage in wood, viz., the machine-made imported door of a modern medium-class house, put up by that adept in meretricious work, the speculative builder. Look at the gaps between the parts, and remember they all arise from the rails and styles having become narrower, not shorter than they were originally cut, through shrinkage. The same action takes place in the unseen parts, such as the tenons, so that general ricketiness is the result. Now, in fitting the drawer runners to the bureau, it will be seen that their grain runs across that of the sides of the bureau. These sides are almost certain to expand and contract, but the runners will remain of their original length. Well, if the two are glued together, no play is permitted to the ends, which, in that case, are almost sure to split, so great is the tensile property of wood. If, on the other hand, the construction is such that they can expand or contract, the alteration being equally diffused over the width, no harm will ensue, and the slight alterations will pass unnoticed.

I have said that some woods are more uncertain in their action than others, and while we are on this subject I may say that oak, especially the variety known as "pollard," is one with which considerable allowance must be made. It may be some satisfaction to know that action can be largely stopped by stopping the grain up, as is done by polishing. But, say some, surely all this could be prevented by the use of properly seasoned timber. If this

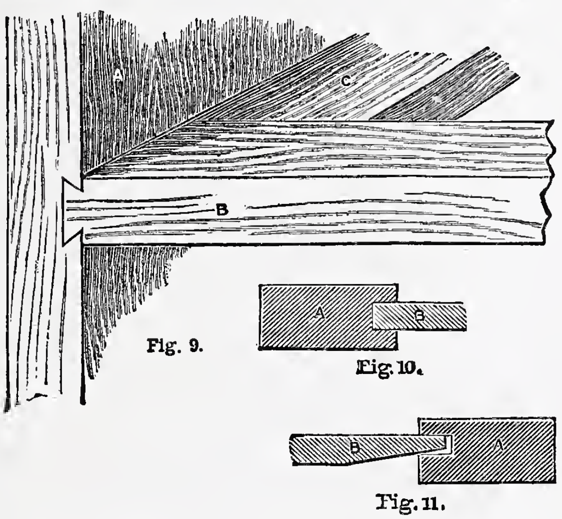

Fig. 9. Fig. 10. Fig. 11.

Fig. 9.—End Bearer and Runner. Figs. 10 and 11.—Fittings of Dust Board.

* For references to all numbers as above, see "List of Pieces of Timber required in Construction of Bureau," page 115.

were correct all cabinet makers would be delighted with the information, but, unfortunately, it is not more reliable than a good many more opinions of the same type. One who knows anything about the subject would not be surprised at the person making such a remark asking why a mahogany slab, 6 ft. wide, could not be made without a join. I would just like to ask those who have such great faith in old work and thorough seasoning, how it happened that one of the ends of the old bureau, which we are taking these ideas from, split from top to bottom, so lately as a couple of years ago. It could not be because the wood was unseasoned, so the explanation must be sought elsewhere. It is simply this. The bureau had been, for some time previously, in a cold, damp place, which had swelled the wood. It was removed to a room continually warm and dry. The wood consequently contracted and cracked, the immediate cause of the crack being a piece of wood fixed across improperly, and so preventing equal contraction.

I have been induced to dwell at some length on this, because it is rather an important lesson to be learned from our old bureau. Having noted it, the fixing of the runners may be proceeded with in the greater confidence of increased knowledge, and as the same principle applies in all similar construction, acquaintance with it will prevent many errors. Perhaps it may ere this have dawned on the reader that the intention of this article is not solely to teach how a bureau may be made, but that useful lessons in joinery may be gathered from it. The same principles are found in all good woodwork, and those that are correct in one piece of furniture are equally so in others. Details may, and must, vary, but the rules of construction do not. Why do I say this? Simply to help the amateur to devise and construct for himself without being obliged merely to copy or to follow minute instructions, giving him every detail of what to do without reasons. In short, the desire is that this article may be educational, leading the worker to think for himself, not simply to "cram" him. Even should he not be desirous of making, it will, at least, give him some ideas how to recognise and appreciate sound, reliable work, and to distinguish between that which is false and that which is correct. I speak now only of constructive not of ornamental details, for as sound construction is, or ought to be, the primary consideration, merely decorative effects must be left for future consideration. May I here say that if I omit to make any point of importance clear to novices, I shall be most happy to do what I can to rectify the defect by answering questions which the Editor may see fit to insert in "Shop."

The fact that wood does not shrink in length is taken advantage of in fixing the thin pieces, sometimes technically known as "dust boards," in such a way that they hold the drawer slides firmly in their places. These boards are sometimes omitted between drawers, and in that case the only way to fix the slides is to run a nail on the slant through their ends into the main piece, and it is just as well to adopt this plan even with dust boards. This still allows a certain amount of play in the end pieces, limited in extent, but generally enough. If the nails were driven straight through at frequent intervals the desired object would be nullified. In the specification these dust boards are given as ½ in. thick, but this thickness is by no means important, for if more easily obtained ¼-in. stuff will do equally well. Whatever the thickness a groove must be ploughed along the inner sides of the runners, and continued in the same line along the back edge of the bearers. Fig. 10 shows what is meant. The drawing is given in section, A being the runner or bearer, as the case may be, and B the thin board. It will readily be seen that on the thin board being pushed home into this groove, the runners are firmly held against the ends without risk of shifting, and that a very slight fastening is necessary. When finally putting all the parts together the dust boards may be fastened to the bearers with glue, but not to the drawer slides, in the grooves of which they are free to expand or contract without splitting. It is not meant that they should be loose, for unless they are immoderately tight, any reasonable degree of close fitting will not make them split. These boards, it may be stated, need not run to within a few inches of the back, but it makes a better job for them to go fairly close, and the same applies to the runners. To save unnecessary labour in planing over the whole surface of somewhat thick but otherwise suitable board to make it fit in any given groove that it may be most convenient to plough, the edge only may be planed to a bevel as shown in Fig. 11.

In another respect besides this method is advantageous. The board need not be so exactly cut to length, for the bevel-shaped edge acts as a wedge, and if at all fairly fitted tends to keep the slides firmly pressed against the ends. We have only to follow out the reasons why the dust boards are useful, so far as keeping the slides in position is concerned, to see that instead of nails driven in as previously suggested, a narrow strip, say, some 2 or 3 in. wide, driven into the runners at the back only would answer every purpose. Now, the plane called a "plough," used to cut grooves of this kind, very likely is not found in the possession of the worker, and though undoubtedly a most useful tool, it may be dispensed with in the present case by those who don't care to get it. The cutting gauge, with a little manipulation, will cut the sides of the grooves, and the waste wood between them may be removed by a small chisel. It is astonishing what may be done by the aid of simple tools used with dexterity, for though improvements may be very convenient, it by no means follows that they are necessary. In the present case the chisel may be regarded as a plane without the wooden stock, which serves to keep the blade in one relative position to the piece being cut, and at the same time by not allowing more than a thin shaving to be removed at a time prevents any tearing up. Bearing this in mind it will be seen that the proper way to hold the chisel is with the bevel underneath, and to be careful not to dig it too far into the wood. When the work is fitted up at this stage it will be noted if the lid bearers are put in that though they slide backwards and forwards, they are only prevented from lateral movements, on one side of each, by the ends. The small upright division separating each from the drawer next it is the only thing to prevent them being springy or strained inwards, and this is hardly sufficient, unless, indeed, the divisions have been made much wider than named. Instead of making this unduly wide, another plan will be found to answer better, and it is this. Immediately behind each division, and of exactly the same thickness, fix down with glue or screws to the runner a piece of wood—width not important, but ¾ in. or 1 in. will do very well—extending nearly to the back. Against this guide, on opposite sides of course, both the lid bearers and the drawer will slide, and any side shake in either of them be prevented. A similar guide will also be required between the two drawers, with the addition of a slide on which they may run, for it will be seen that the board is lower than the front rail, and there is nothing on which the inner ends of the drawers can rest. Now, there are several ways of fitting this part, but one can hardly do better than follow that adopted in the old bureau.

First of all a piece some 2 in. wide, wide enough to let the drawers rest on it, must be made just so thick that, when it is on the dust board, its upper surface will be flush with that of the bearer. Another piece, the counterpart of those separating the lid bearers from the drawers, will also be required to keep the drawers apart, and prevent them from being strained towards each other. Now, bearing in mind what was said about the play of wood, it will be quite clear that it will not do to glue the centre runner to the dust board, so that some means must be used which, while sufficiently efficacious in keeping the construction securely together, takes into account the properties of the material of which it is formed. Well, we have all that is desired in the method now proposed. Cut a tenon on one end of the piece that is to rest on the runner, and a corresponding mortise in the back of the upright division (the centre one), so that when the joint is complete, there shall be just the thickness of the runner between the dust board and the piece which is tenoned. Glue or nail the runner to this piece, put the tenon in the mortise, but not quite up to the shoulder, and then near the back run a brad through the runner into the board below it and we have all that is necessary. This, though possibly not the most common way, is thoroughly good; and it has the great merit, especially to the amateur, of being very simple, besides which, it is, as I have said, that taken by the maker of the old bureau. Proceeding from the top row of drawers to the bottom one, it will be seen that drawer runners or slides must be fitted there at the ends, for the front bearer is higher than the bottom board. Of course, the slides must be on a level with it, and it will suffice to fasten them with a touch of glue in front and a brad behind. Strictly speaking, this ought to be through a slot cut lengthwise in the runners, for similar reasons to those already given, when speaking of the properties of wood; but practically the brad driven in towards the back is generally found sufficient, and it is no use increasing labour for the sake of theory.

GOLD AND SILVER ASSAYS, ETC.

BY GEORGE EDWINSON BONNEY.

GOLD AND SILVER ASSAYS IN DRY WAY—ASSAYS OF METALS CONTAINING SILVER—ATOMS—ATOMIC WEIGHTS—TABLE OF ATOMIC WEIGHTS.

In concluding my last paper on matters of interest and importance to electro-platers, I intimated that it was impossible for me to complete in page 202 the subject of Assaying on which I had entered. I now resume my notes on this process.

Gold and Silver Assays in the dry way are more difficult, and they require the use of a muffle furnace. Those manufactured by Thomas Fletcher, of Warrington, give every satisfaction. The sample is weighed as for a gold assay, and the copper or other alloy is extracted from the gold and silver by cupellation in the muffle furnace. The weighed sample is wrapped in twelve times its weight of pure lead foil, and placed on a boneash cupel in the furnace. Here it is first melted with the pure lead, and then the molten lead is oxidised by admitting air to the muffle. The boneash of the cupel absorbs the liquid lead oxide, and with it the oxides of any oxidisable metals present in the sample, leaving on the cupel a bead of pure gold and silver. This bead is first weighed to ascertain how much of the combined metals it contains, then the silver and gold is parted in acid as for a gold assay, and the pure gold remaining is accurately weighed. By deducting the weight of gold from the weight of the bead left on the cupel, the weight of silver is ascertained, and the sum total of gold and silver, deducted from the weight of the sample, will show the remainder to be copper or some oxidisable alloy. Boneash cupels are small cups or crucibles made of boneash damped and compressed to the requisite form and consistence in a steel mould, then dried and baked. *Silver assays in a dry way* are performed in a similar manner by cupellation in a muffle furnace. A small portion of the silver of a sample is carried over with the oxidised metals on the cupel, and is lost. The ratio of this loss is ascertained by placing a check sample made up with a known weight of silver and copper on a cupel in the furnace with the samples to be assayed. As the silver in this sample is accurately weighed both before and after the process, the difference between these must represent the loss of silver during cupellation, not only on this but also the other samples cupelled with it.

Assays or Analysis of metals known to contain silver may be performed in the wet way. A weighed sample, as in other assays, is first dissolved in dilute nitric acid, and the solution thus obtained is evaporated until all the free acid has been driven off. The residue is then dissolved in distilled water in a large beaker, and to this is added a solution of common salt as long as a precipitate is formed. When this ceases, the quantity of salt solution used is accurately noted, and as this solution is made up of a known weight of salt in a known quantity of water, the exact weight of salt used to precipitate all the silver in a sample can be ascertained to a nicety. Knowing that the chlorine in a salt solution combines with silver in the proportion of 35·37 parts of chlorine to 107·66 parts of silver, we can easily calculate the weight of silver in a given sample of an alloy. This would seem to be a perfect method of assaying samples of silver alloys, but there are sources of loss and probable errors in this as in others. It is not easy to ascertain exactly when enough salt solution has been used, even when dropped from a burette. The addition of a solution of common salt (chloride of sodium) to a solution of nitrate of silver throws down the silver as a chloride, and leaves nitrate of sodium to form in the liquid, and this is able to dissolve some of the silver chloride, thus causing an unascertainable loss. The presence of silver in the supernatant liquid can always be ascertained by adding to it a drop of a solution of chromate of potassium, when if any silver be present it is thrown down in the form of a blood-red precipitate of silver chromate.

Atoms.—"Matter is made up of small indivisible portions which are called *atoms.* These atoms do not all possess the same weights, but the relation between their weights is represented by that of the combining weights of the elements; thus the atom of oxygen is taken to be sixteen times as heavy as the atom of hydrogen, and the weights of the atoms of nitrogen and oxygen as fourteen to sixteen." (Roscoe.) This law of combining weights was first enunciated by a chemist named John Dalton, who further based on this law the conclusion that chemical compounds must contain their constituents in the combining proportions, or in multiples of them, and in no intermediate proportion. For example—gold will combine with chlorine as a monochloride, that is, one equivalent of gold (196·2 atoms) added to one equivalent of chlorine (35·37 atoms) making a molecule of the molecular weight of 231·39 atoms. It will also combine with chlorine as a terchloride, consisting of one equivalent of gold (196·2 atoms) to three equivalents of chlorine ($35·37 \times 3 =$ 106·11 atoms), making a molecule of the molecular weight 302·13 atoms. But gold does not combine with any other proportion of chlorine.

Atomic Weights.—The following table of the atomic or combining weights of the more common and useful elements will show at a glance their value.

TABLE OF ATOMIC WEIGHTS.

Name.	*Symbol.*	*Atomic Weight.*	*Name.*	*Symbol.*	*Atomic Weight.*
Aluminium	Al.	27·3.	Lead	Pb.	206·4.
Antimony. .	Sb.	122·0.	Lithium . . .	Li.	7·01.
Arsenic . . .	As.	74·9.	Magnesium	Mg.	23·94.
Barium . . .	Ba.	136·8.	Manganese .	Mn.	54·8.
Bismuth . .	Bi.	210·0.	Mercury. . .	Hg.	199·8.
Boron	B.	11·0.	Nickel	Ni.	58·6.
Bromine . .	Br.	79·75.	Nitrogen . .	N.	14.01.
Cadmium . .	Cd.	111·6.	Osmium . . .	Os.	198·6.
Calcium . . .	Ca.	39·9.	Oxygen . . .	O.	15·96.
Carbon . . .	C.	11·97.	Palladium .	Pd.	106·2.
Chlorine . .	Cl.	35·37.	Phosphorus	P.	30·96.
Chromium .	Cr.	52·4.	Platinum . .	Pt.	196·7.
Cobalt	Co.	58·6.	Potassium .	K.	39·04.
Copper . . .	Cu.	63·0.	Silver	Ag.	107·66.
Fluorine . .	F.	19·1.	Silicon . . .	Si.	28·0.
Gold	Au.	196·2.	Sodium . . .	Na.	22·99.
Hydrogen . .	H.	1·0.	Sulphur . . .	S.	31·98.
Iodine	I.	126·53.	Tin	Tn.	117·8.
Iridium . . .	Ir.	196·7.	Tungsten . .	W.	184·0.
Iron	Fe.	55·9.	Zinc	Zn.	64·9.

Some of the rare elements are omitted from this table, but may be found in Roscoe's text-book of chemistry. In calculating the combining weights of elements, it is usual to take round numbers instead of the exact decimals, thus:—Silver, 108; gold, 196, etc. For further information, see notes on *Combining Weights, Equivalents, Molecular Weights, Valency,* etc. etc.

SOME RUSTIC CARPENTRY.

BY ARTHUR YORKE.

RUSTIC CARPENTRY SPECIALLY FITTED FOR GARDEN PURPOSES — WOODS SUITED TO RUSTIC WORK—LARCH—A RUSTIC GARDEN ENTRANCE —OAK FOR GARDEN CARPENTRY—THREE ADDITIONAL DESIGNS FOR RUSTIC FENCES — A SECOND GARDEN ARCH ON TWO PILLARS ONLY.

THERE are few of those who have gardens and who work in them who do not more or less dabble in some sort of garden carpentry. Unlike indoor work it demands no nice skill and no varied assortment of tools. Carpentry for the garden is everybody's work, whence it may reasonably be inferred that what I have to say about it, by pen and pencil, will have everybody's attention.

The description of carpentry of which I shall have more especially to speak is that known as rustic work; that, namely, which uses its materials in a natural state, and in that state endeavours to make them decorative. For this, as I take it, is the only style really suitable for garden purposes. Our sense of good taste points out that in our gardens all things ought to be in harmony with and suggestive of nature. Glass, metal, paint, which are suggestive only of the shop and of artificial life, we feel to be out of place. Anything of the nature of a greenhouse—whatever efforts may be made to render it ornamental—never appears to a cultivated eye as otherwise than ugly; whilst the rustic summer-house, with its wooden walls covered with natural bark, its low roof of thatch, and its decorations of moss and fir cones, gives unmixed satisfaction. And this style, whilst the most desirable in which to work, is at the same time the least costly and the most simple.

In the course of these papers I hope to do some service to my fellow-workers by pointing out, so far as I can, what is good taste in garden decorations of this class; by supplying designs, or what may furnish hints to them in designing, and by giving some little practical information with regard to material and construction. I shall hope before I finish to deal with a variety of summer-houses, seats, fences, and similar matters.

There is scarcely any kind of wood which may come to hand in a natural state which is not available for rustic work, though some sorts lend themselves to our purpose more readily than others. In most country districts one has generally a wide choice of materials, and not much more than a firewood price to pay for them; some little trouble has, however, to be taken to look out for and to secure them, as they are not like sawn deals, always to be found in stock at the timber yard, and bought at any time they may be wanted.

The example of rustic work shown in Fig. 11 will look and be best if constructed in larch only. Of all our common English woods this may be said to be most valuable for rustic purposes. Its straight growth specially fits it for the carrying out of decorative designs; it is enduring, lasting longer in exposed situations than any other ordinary wood—heart of oak only excepted—and wearing, perhaps, ten times longer than those portions of the oak which are available for garden purposes; and it is plentiful, for larch plantations now abound in most districts, and when they are thinned the rustic carpenter should look out for his supply. The larch poles grown in thick plantations are better for our purposes than such as grow singly, they taper more gradually and have fewer branches. The larch is a most accommodating tree, flourishing, apparently, almost as well in an old stone quarry or a disused clay pit as in the richest of soils, so it is no wonder that it is largely planted. The wood of spruce and other firs which have the same symmetrical growth may do almost as well for our work as regards appearance, but they do not last like the larch.

There are many modest gardens to which a fence and wicket entrance, like that shown in Fig. 11, might be found pleasing and appropriate; and it would be cheap even though a professed carpenter had to be engaged to construct it. But it is a point in favour of my rustic design that the owner, if he can use a saw and a hammer, and likes such amusement, can just as well put it up for himself. Rustic work looks none the worse because the workmanship may be rough; and I flatter myself that no great knowledge will be needed to understand my designs. I have done my best to make them simple, and purpose to give full explanations.

The general view, Fig. 11, is as nearly as may be drawn to a scale of ½ in. to the foot; the details shown in Figs. 4, 9, 3 are, for the sake of clearness, on a larger scale, ¾ in. to the foot, so that the exact dimensions of every part may be easily ascertained. The arch rises to a total height of 6 ft. 8 in.; its width from centre to centre of the side pillars is 3 ft. 6 in. The pillars, exclusive of tenons at their tops, show a height above ground of 5 ft., but another 2 ft. is supposed to be buried in the ground where it is rammed in with stones and earth like a gate post. The builder will, of course, set them upright by a plummet, and if he takes off the bark from those parts which go into the ground, and gives them a good coating of gas tar, he will find them last longer.

Rustic work, in a general way, is merely nailed together, but in the design before us the pillars are supposed to be mortised into the pieces which rest on their tops, the bars of the gate into the head and hinge tree, and the rails of the fence into the fencing posts. Fig. 1 shows how the shoulders of tenons are sawn so as to make them fit best to the rounded wood. But if this work is taken in hand by any non-professional, who does not feel himself equal to making mortises, he may make a joining, which will neither be quite so strong nor quite so well looking, by cutting each piece something in the manner indicated in Fig. 2, and driving a nail.

In Fig. 3 that side of the gate is shown to which the upright palings are nailed, but it should be noted that on the opposite side the diagonal pieces, A and B, must not be made of short lengths merely going from bar to bar, but must be in one length from top to bottom; they are not for ornament only, but act as braces, and are necessary to give the gate its required strength.

In the example of fencing shown in Fig. 11,

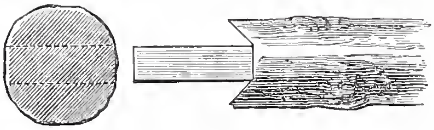

Fig. 1.—Rustic Mortise and Tenon.

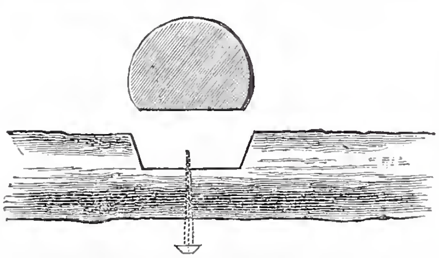

Fig. 2.—Rail and Post cut to Nail.

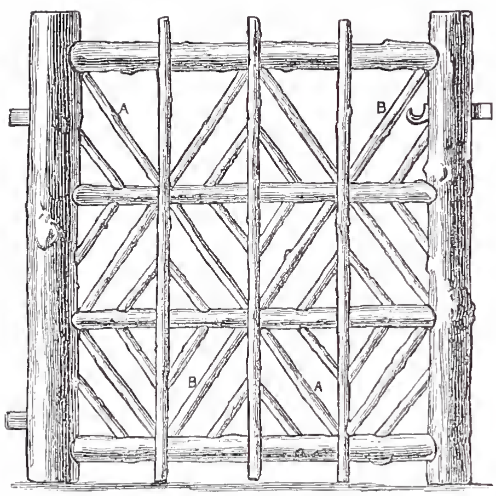

Fig. 3.—Rustic Gate.
(Scale, ¾ in. to 1 ft.)

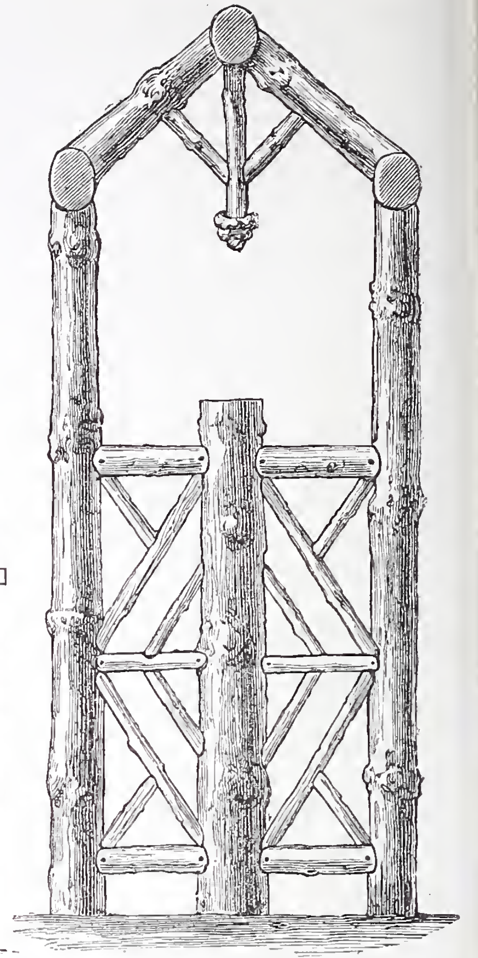

Fig. 4.—Side of Arch.
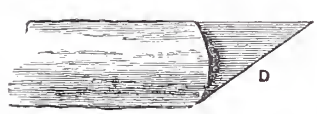
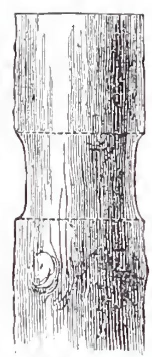
(Scale, ¾ in. to 1 ft.)





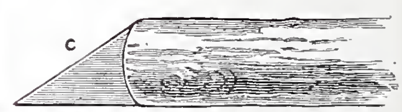


Fig. 5.—Rail Ends cut meet in Mortise.

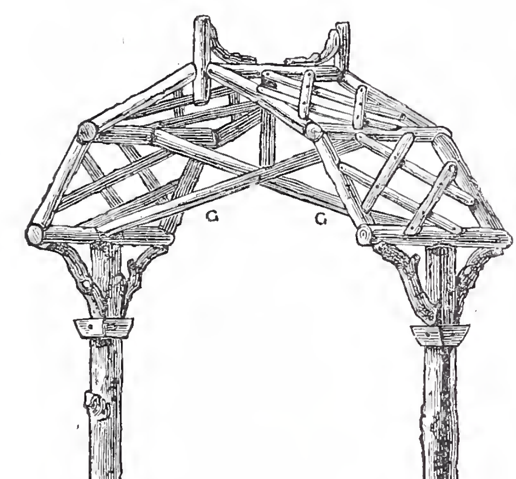

Fig. 6.—Garden Arch with Two Pillars only.
(Scale, ½ in. to 1 ft.)

the posts are set 7 ft. 6 in. apart. This is a short distance; fencing posts are frequently set at wider distances up to 10 ft.; in Figs. 7, 8, 10, they are drawn as 8 ft. apart. These posts, as also the gate posts, need to be set as deep in the earth as the pillars. Fig. 5 illustrates the manner in which the tenons of the rails fit together in the mortises of the posts. The end, C, is, of course, adjusted to the mortise before the post is fixed, the end, D, afterwards. The stuck, E, Fig. 8, which is let into the earth with a crowbar and then nailed to the rails, prevents the latter from having any motion in the mortises.

The smaller stuff, of which the palings and the lighter work generally are made, should properly be of larch as well as the heavier pieces, not only for the sake of appearance, but that the whole may wear together. With care such stuff may be provided from the tops and branches of the larger poles, and from the thinnings of young plantations. In the example before us, Fig. 11, the palings are nailed about 5 in. distant from centre to centre, and will exclude most small animals, but if special protection is desired against chickens, etc., the number of palings may be doubled, shorter palings, to rise about 1 in. above the centre rail, being nailed alternately with the present ones. The fence would then look a trifle heavier, but would keep out anything bigger than a sparrow.

The superiority of such a fence as the above to those in rustic work which we ordinarily see is very considerable. Those common in this country are almost invariably made of oak "bangles" set, as nearly as may be, to cross each other diagonally. Oak bangles, it may be explained, are the smaller branches of the oak, and as we get them they have been stripped of their bark for the uses of the tanner. Their knotted and twisted forms render them picturesque, and they have, therefore, a decided value for the rustic carpenter. But for fencing purposes they are not satisfactory; their crooked and uncertain growth forbids them being worked to any regular design; it also renders difficult the arrangement of them at such set intervals as will effectually exclude animals, but their worst point is that when exposed they decay very quickly. This is always a serious disadvantage, and especially so when, as is often the case, the rustic fence is intended as a support for roses or other climbers; for by the time the climbers are so grown as to be ornamental, the fence is apt to fall to pieces.

Possibly the reader has an idea that among English woods oak is pre-eminent for its powers of endurance. If so, he is in the main right; but the part of oak which lasts for centuries is the heart—that central growth which is always separated from the bark by a ring of softer and lighter timber known as "sap." Few kinds of wood rot more quickly than sap of oak. The smaller branches have little or no heart; they are nearly all sap, and hence their rapid decay. They last best in the dry, but even there they are more subject to suffer from grub than any wood of the fir kind. One point in their favour is, however, that they are cheap; for if not used for rustic work, their only value is for firewood.

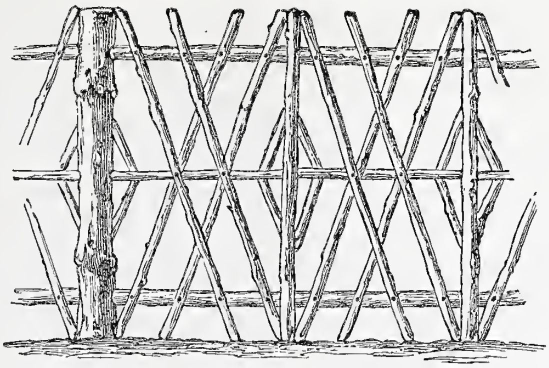

Fig. 7.—Rustic Fence in Rough Larch.

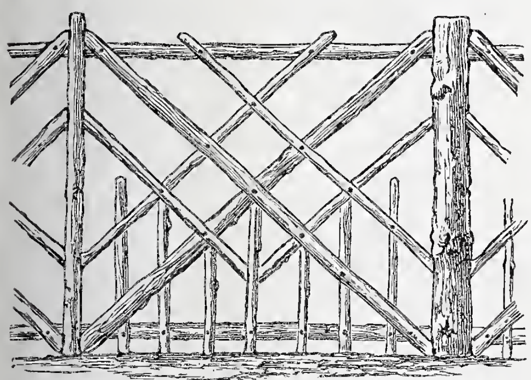

Fig. 8.

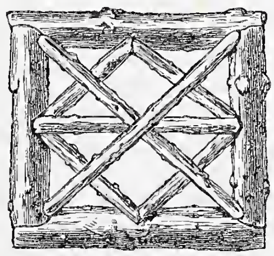

Fig. 9.—Panel of Arch.

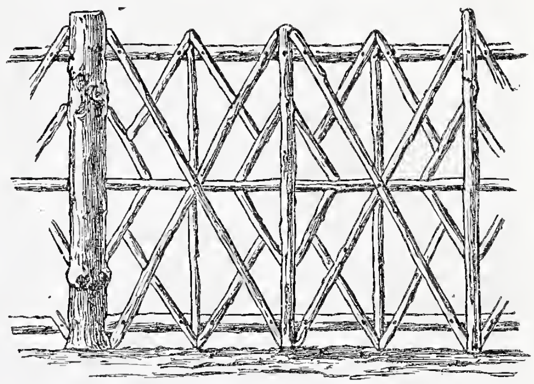

Fig. 10.

Figs. 8, 10.—Rustic Fences in Rough Larch.

Our larch fence will outlast two or three successive ones of oak bangles; as a safeguard it can be made more secure, and in appearance it will be more artistic. The arrangement of the stuff in ornamental patterns may be varied almost endlessly. In Figs. 7, 8, and 10, three additional designs are given (on the $\frac{1}{2}$-in. scale), and these will doubtless suggest still more varieties to the ingenious reader.

Fig. 6 is a second design for an arch, which may, if preferred, be made to take the place of that in Fig. 11 at an entrance. The two pillars, by which it is supported, might well carry such a gate as that in the last-named diagram, as any extra strain thus placed upon them would be compensated by the support given by the rails on either side. It would, however, be desirable to retain the bottom stucks (F, F, Fig. 6), since the weight of the upper part of the arch being considerable, it might, if not accurately balanced, tend to pull the structure out of the perpendicular if deprived of these supports. This arch in its upper part is, it will be observed, strongly tied together by the braces, G, G. This arch is on the same scale as Fig. 11 ($\frac{1}{2}$ in. to foot). It is the same width as the one there given, and 7 ft. 6 in. high.

In Fig. 11, every portion of the arch, with the very trifling exception of the apple-tree knots, with which the lower ends of the pendants are finished, is of larch; but in Fig. 6 are half a dozen pieces of some other wood, namely, in the struts at the tops of the pillars, and in the ties which connect the two pinnacles with the top of the ridge piece. In these a curved form is more pleasing than a straight one, and bits of apple tree have therefore been introduced.

Either arch will also do equally well for use within the garden to span a path and serve as a support for climbers, and will, I flatter myself, look effective in such a position. It is possible that some one may object that the wooden arch thus contrived and made has not the light appearance of, and takes up more room than, the light arches of iron now much used, in which the sides are made of substantial wire—or thin bar iron as I may almost call it—fitted to feet of some width terminating in spikes that enter the ground, and give stability to the structure when placed in position. The standards thus made are connected by trellis work of wire which fills the interval between them. In a trim town garden where everything is prim and rectangular, and laid out with line and rule, the iron arch may be preferred as a support for the roses or other climbing plants that are trained to its sides and top. In the country garden, however, the rustic arch will be more in keeping with the surroundings, and harmonise more effectively with the masses of old-fashioned flowers, long established favourites, that have not yet been sent into exile to make room for the contrasted colours of modern gardening, in which fragrance invariably gives place to brilliancy. With these few plain instructions a pleasant employment is introduced to those of our readers who enjoy garden woodwork.

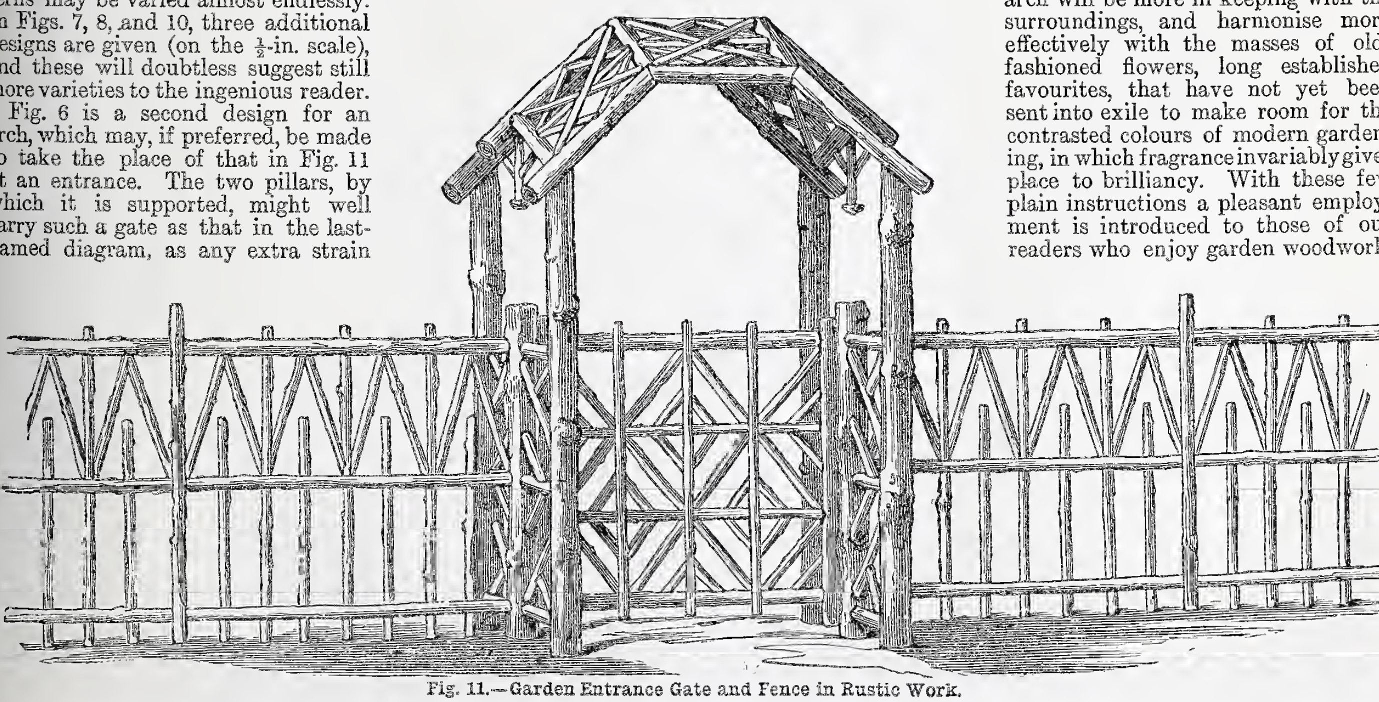

Fig. 11.—Garden Entrance Gate and Fence in Rustic Work.

JOINTING UP—FOR "'PRENTICE HANDS."

BY DAVID ADAMSON.

Plain Glued Joints.

Anything new? perhaps you may ask on reading the heading, and I have pleasure in at once telling you — No. So, therefore, good people who know all about it, your valuable time need not be further taken up with the present subject. I am addressing myself to novices, and not to experts. I can teach the former something, perhaps, but not the latter just now; and if any of these should grudge the space given to those who are, as it were, just feeling their way, will they, the said experts, kindly remember their own early days, and be generous to those who do not even know how to join two boards together?

Now, of course, as far as mere joining goes, boards may be joined together in many ways, the simplest being, perhaps, by laying one on top of the other and nailing them together. This method is seldom, if ever, required, and if the novice should ever have occasion to use it, the manipulation must be left to his native ingenuity. Not to make a long preamble and run through all the joints used in wood working, or from the multiplicity of them, as it is commonly called "joinery," let me say that I purpose confining myself to attaching boards by their edges so as to obtain any required width.

This work is what is known in many places as "jointing up." I say many places because terms are often only of local use, and an expression that may be perfectly well understood in one district, may convey no meaning in another part of the country. Still, I think "jointing up" is sufficiently understood to warrant its being used to express the kind of joint which is the subject of explanation, and, for aught I know to the contrary, it may be the general term all over England. Be that as it may, I do not think I have ever known a practical cabinet maker who did not know what was meant by it.

Possibly some — only those, however, who have never tried it—may fancy that any one can glue two boards together, and that directions may be superfluous. There can be few who are not physically capable of "jointing up," but the novice will find that he has a good deal to learn before he can do so satisfactorily, that is to say, satisfactorily to those who are able to distinguish between good and bad workmanship. So far as a few general directions can do so, I hope his difficulties may be diminished. Verbal instruction is, however, only of use to indicate to him how he should proceed, and it stands to reason if not practically applied will be useless. It cannot give the manual dexterity, and this is not to be acquired without care.

Just to show clearly and distinctly what a perfect joint is, or let me say rather, a perfectly fitted joint, let us compare two of a different quality. In one we see the line of the joint quite easily. There is no mistaking it for most of its length. There is a dark line, thicker in some places than in others, from end to end of the join. In some places it is interrupted every here and there for an inch or two, or, perhaps, even more; all the glue seems to have been pressed out. These places where the glue is not visible are the only ones at which the joint is thorough. Further, on examining the board, we find that instead of being perfectly flat there is an angle at the joint. Very slight if you like, but quite perceptible if a straightedge be laid across.

Now let us turn to the other piece which has been jointed. But stop, you say; for has it been jointed, or is it not one single piece? No line is discernible anywhere, but let us look closely and we shall find that the grain of the wood is stopped short off along a certain imaginary line; the figure seems abruptly broken, not only on one side of this line, but on both. That is all; there is nothing more to indicate a joint, and as the surface stands, as with such a good—I had almost written *invisible*—joint it is almost sure to, the test of the straightedge, it may be regarded as being an exact and perfect fit.
