The dip-pipe B is often fixed some distance from the band, as may be seen in the section Fig. 1, thus leaving a space for soil and any foul matter to collect, and it is generally either too short or too long; if the former, the trap soon ceases to act as one if there is the least syphonage; and if the latter, the soil and paper are more than ever impeded from leaving the trap.

The dotted line in the section shows where the foul matter chiefly settles and becomes hard and cement-like.

The air-pipe—if any—which is connected to this trap is usually either ¾ in. or 1 in. in diameter, and has so many turns and bends in it, that it is scarcely better than nothing at all.

And here, in passing, I may say that no soil air-pipe should be fixed less than 2 in. in diameter, for the plumber should know that the obstruction to the passage of the air caused by the friction, due to the velocity with which the air passes through a pipe, increases as the square of the velocity divided by the diameter of the pipe; thus the obstruction offered in a 1-in. pipe to a given volume of air passing through a given length in a given time is thirty-two times as great as in a 2-in. pipe.

By far the best plan is to carry a pipe the full bore of the soil-pipe up to the roof, and let it stand a little above the ridge, so as to keep all foul air escaping therefrom away from the windows.

Another trap whose sins are many is shown in section at Fig. 2, and is styled the "bell trap," on account of the bell which is fastened to the grating and which forms the "dip" or water-seal. It is used for sinks, and also for surface-water. The space all round the stand-pipe soon becomes filled with dirt, as the passage of the water through the trap is so sluggish that it cannot keep itself clean, and the inevitable result is the pulling up of the grating and knocking off the bell, when the water runs off merrily, and leaves a free vent for anything in the shape of bad air or gases which should chance that way.

Some makers have tried to improve this trap in many ways, but under whatever disguise they offer it to you, have nothing at all to do with it, for it soon ceases to be a trap and becomes a snare, while there are plenty of good traps to be had equally as cheap.

Figs. 3 and 4 show sections of traps which are as kings to the bell trap, but yet are far from perfect. They are both made on the same principle; one, however, empties itself at the side, while the other passes the water through the bottom. They are usually made of iron and are used for stone sinks, or on the ground-level for surface-water. They both suffer from one great defect, they are not self-cleansing, for in the angles marked A and B, dirt, soap, and slime will collect, impeding the passage of the water, and finally stopping it altogether, when the trap has to be lifted out and cleaned, and as it is very often merely dropped into its place and not cemented as it should be, this can easily be done, and to prevent a recurrence of the nuisance the trap is flung on one side, and a free exit for drain air is the consequence.

Since Messrs. Beard and Dent first introduced their patent cast lead traps, great strides have been made in this department of sanitary science. Figs. 5 and 6 show specimens of their S and P traps: they are made in any size from 1¼ in. to 4 in., and possess many advantages over the old D trap. They have no places in which filth can accumulate, they are smooth, without any joints or seams, and are very easily flushed. The "Dubois traps" are similar in appearance to Beard and Dent's; they are drawn by hydraulic machinery the same as lead soil-pipe, and to my mind are superior to the cast-lead traps, being absolutely of one thickness throughout, perfectly smooth, and there is no chance of finding any small holes in them as we sometimes do in cast goods. In using the smaller sizes of these traps, whether cast or drawn, it is always better to have them with a cleaning screw such as may be seen at A, Fig. 7, for facility in clearing, should they at any time become choked. Nothing less than a 4-in. trap should be used for fixing under a water-closet, and it should be soldered by a wiped joint to a lead branch pipe passing through the wall to the soil-pipe outside. If the closet be some distance away from the vertical soil-pipe, so that this branch exceeds 4 or 5 feet in length, it will be better to solder in a 2-in. lead pipe as shown in dotted lines at A, Fig. 5, for the purpose of ventilation. This pipe may be carried above the roof independently of the large soil-pipe ventilator, or may join that pipe at a point above the highest water-closet branch.

This minor air-pipe will prevent syphoning in the trap, and will also carry off any foul air which may accumulate in the branch pipe.

Not very unlike in appearance to these traps is Hellyer's "Anti-D trap," as may be seen at Fig. 8, but this has a square outgo, which renders the trap less liable to be unsyphoned.

Waste-pipes from baths, sinks, lavatories, etc., should pass at once, if possible, through the wall into the open air, and discharge—if they be fixed upstairs—into an open head, which in turn carries the water by means of an iron pipe to the ground level, where it is discharged into an open gully-trap; Fig. 9 illustrates plainly enough what I mean.

It will be seen that the short lead waste-pipe is trapped immediately under the bath. This is not absolutely necessary, as there is no danger to be feared from the air which might pass up through this pipe if left untrapped; but there is no doubt it will be very unpleasant to the sense of smell, for the soapy slime which will be sure to collect round the inside of the pipe smells very nasty.

Jennings has brought out a trap for baths, etc., which, in addition to the usual water-seal, has a ball which floats against the inlet pipe and prevents any back pressure of drain air from entering the house that way; but the security afforded by this trap is not needed if the waste-pipe discharges into the open air; and if it be feared that the wind will blow into the pipe, a copper hinged flap should be soldered to the end of it. If the waste-pipe has to be carried down inside the house, it should be entirely of lead, and an air-pipe of sufficient size should be carried from the highest point near the trap to the roof: at the foot a gully-trap should be fixed as before explained.

The traps which have been described up to now are only fit to be used in connection with the internal sanitary fittings of a house, and are, therefore, the only sort with which the plumber has really anything to do; but we often find that the plumber who has to fit up the interior, has also to superintend the laying of the drains outside, so it is well that he should thoroughly understand the work throughout.

In the first place, as regards the drain, the pipes should be made of stoneware well glazed, perfectly smooth within and accurately round.

All junctions or branches with the main house drain should be made at an acute angle running in the direction of the current. The joints are best made with cement, care being taken that the spigot end of one pipe goes tightly up to the end of the socket in the other, so as to leave no ridge or space inside to cause an obstruction. The drain should run straight from point to point, and at every change of direction some means of inspection should be provided.

This is best done by fixing an open channel bend as shown at Fig. 10, and carrying up a square brick manhole to the surface, covered by an iron grating or solid cover; such channels may be obtained of Messrs. Doulton & Co., Lambeth, who make them at a variety of angles.

As regards the size of house drains, as a general rule, 6-in. pipes for the main drain, and 4-in. pipes for the branches, are the most serviceable. In the case of a very large mansion, it may sometimes be desirable to lay 9-in. pipes, but it must be borne in mind that it takes a large quantity of water at a great velocity to thoroughly flush a drain of this size. For this purpose, an automatic flushing tank placed at the head of the drain answers capitally, as by this means rain-water, and the wastes from sinks, etc., may be collected and discharged with great force through the entire length of drainage. Every long drain with many branches should be thus flushed.

One of the best contrivances for this purpose is Mr. Field's tank, shown at Figs. 11, 11A. The wastes from the sinks, etc., should discharge over the grating into the small trap, A, which is movable, and thence to the body of the tank, B. The outgo is in the shape of a syphon, C, and, when the tank is full, the water overflows through the longer leg, starting the syphon and emptying the contents of the tank quickly into the drain. Messrs. Doulton & Co. also make a capital flushing tank, both in stoneware and galvanised wrought iron. These traps also act as grease-traps for preventing the kitchen grease from entering the drain in solution with hot water, as the cold water in the tank congeals the fat as it enters, and leaves it floating after each flush. The accumulated grease should be removed periodically, or the result will inevitably be a stoppage. A most serviceable trap for receiving surface-water, rain-water, and the various wastes from sinks, etc. (but not scullery sinks, as the water from these often carries grease with it, and which should be treated in the manner mentioned above), is the gully-trap shown at Fig. 12, and in section at Fig. 9. It should be provided with a galvanised iron grating, and, if possible, the rain-water and wastes should enter by means of a bend into an inlet at either the back or on one side of the trap. By this means the splashing, which is inevitable when they empty over the top of the grating, is prevented, and greater facility is offered for inspection and cleansing. The surface-water from the yard or area where it may be fixed can enter through the iron grating at the top of the trap.

The soil-pipe, or W.C. waste, should be connected with the drain by means of an obtuse bend at its foot, and the drain from this point should run in as direct a line as possible for the sewer. After the drain has passed all points of junction of branch drains, a syphon or trap should be fixed, to thoroughly disconnect all air communication between the house drains and sewer.

A large variety of traps are made for this purpose, but one of the best is Hellyer's "Drain Sentinel," shown at Fig. 13. The inlet is in the form of a channel, thus affording a large inlet for air to the house drains. This trap should be fixed in a disconnecting air chamber, as may be seen in section at Fig. 14. A manhole, or air chamber, of ample size is built up to the surface, of brickwork, and a channel-pipe, B, is laid at the bottom of it, receiving the house drain and emptying into the "Drain Sentinel," A.

This channel-pipe may be had with branches if necessary. The floor of the air chamber should be sloped from the sides to the middle, and the inspection arm, C, should be stopped with a plug or movable stopper. The arm at D may be similarly stopped, or a pipe may be carried from it to ventilate the drain on that side of the trap.

The top of the air chamber may be covered by an iron grating or a solid cover. In the latter case, one or two 4-in. pipes should be carried up from the air chamber as E (Fig. 14).

Messrs. Doulton & Co. have a trap which they call the "Kenon," in connection with which they make an air chamber floor of stoneware, well glazed, which has a 6-in. channel passing through the middle, with side inlets for branch drains, if necessary. It is very useful for places where the workman does not understand how to construct the floor himself.

Messrs. Dent & Hellyer have a trap, called the "Ventilating Drain Syphon and Sewer Interceptor," which will give great satisfaction, if properly fixed. It is shown at Fig. 15. It consists of a round pipe trap with a 2½-in. water-seal. The body of the trap is comparatively of much smaller diameter than the inlet, for the trap to hold as little water as practicable. The inlet is about 6 in. above the water in the trap, so that the discharges fall almost vertically, changing the water by a very small flush. The upper part of the trap is enlarged for the admission of air into the house drain, and is surmounted by an iron grating. When this syphon is situated near a window or door, it is better to replace the grating by a stopper, and a 4-in. air-pipe should be carried from the air chamber to a wall remote from the window or door.

It is not absolutely necessary to increase the size of the trap or syphon for the air inlet, and a very decent job and a cheap one may be made with a 6-in. stoneware P trap with an inlet at the back, using the upper inlet for ventilation.

In any case, the sanitary arrangements of a house should be so contrived and constructed in the best and simplest possible manner to use freely those deodorisers and disinfectants which Nature itself supplies: namely, water and air. These are, or ought to be, common to all in a pure state, though it too frequently happens that both the one and the other are contaminated by man's culpable agency.

LATHES FOR EVERYBODY

BY SELF-HELPER.

THE construction of the bed and frame will not be found to be difficult by anybody who has succeeded in making the heads, as I have described; but, to make a good job, none of the work must be carelessly executed, as want of steadiness in this part will prove fatal to all good work in the lathe.

For the bed and legs, it would be well to have the wood 4 in. × 3 in., but slightly lighter stuff could be made to act. It is well, however, to have everything rigid and very strong.

From Fig. 2 it will be seen that each leg consists of two pieces mortised together so as to form a T. To keep the legs as rigid as possible, I got stays forged from iron 1 in. × ⅜ in., and, having japanned them, fastened them to the woodwork with ⅜-in. bolts. These stays were made of one piece, bent into the shape of the letter V, and so high as to let the centre upon which the crank hangs pass through their apex. The tops of the legs must be carefully cut away from each side, leaving a shoulder, upon which the sides of the bed may rest.

Two bolts at each end will then secure the bed and legs in place. The top of the bed must now be perfectly flat and out of winding. Each cheek must be the same depth, so that the under part of the bed will be flat; and the shears must be exactly 2 in. apart, the same at each end, and at every point between. If the headstocks have been made exactly, the tenons will be found to fit nicely into the space for them in the bed.

The frame will now be found to be fairly steady, but it will require some stretchers connecting the legs together, so as to prevent the pressure of the centres on the crank axle from pushing them apart. The front one may be a piece of iron 1 in. × ¼ in., lying flat on the ground, and fastened to the bed with wood screws, as shown.

As the treadle will be hinged to the other stretcher, it will require to be somewhat stronger.

I used wood 1½ in. × 2½ in., and let it into the ends of the cross pieces of the legs, as seen in Fig. 2. A couple of little bolts secured it very firmly. The stand is now ready to mound the flywheel and crank shaft. That used for this lathe was bought, the flywheel being 27 in. diameter, with four speeds, and one small speed for metal work. The throw of the crank is 2½ in., which, doubled, makes 5 in. from the highest to the lowest point. Then the pitman comes to a point in the treadle halfway between the hinge and the place the foot rests on, so that the treadle rises 10 in. in front, which I find to be a fair allowance for a lathe of this size.

The centres on which the crank is hung can be purchased for about 1s. 6d. a pair, and it would not pay to make them at that rate. It is not a difficult job in any case. A piece of ⅝-in. steel is screwed, and a cone turned in the lathe. The point is then hardened. The centre holes in crank should be bored deeply with ⅛-in. drill, and it would be better if they were bushed with hard cast steel.

Instead of the bent crank shaft and pitman, a straight shaft and external cranks could be easily used. Bessemer steel 1⅜ in. diameter would do for the shaft. It should be hung on plummer blocks, which could be either purchased complete for 3s. 6d. each, having 1 in. bearing, to which the shaft would be turned down; or else cut from lignum vitæ, like Figs. 5 and 6; or else cast in patent metal like the same figures. Figs. 7 and 8 show the external cranks. They are best made in cast iron, but I have often used pieces of plain bar iron, about $\frac{5}{8}$ in. thick, for cranks.

If this plan is employed, the back stretcher should be so long as to project beyond the legs three or four inches at each end.

The treadles, one at each end, would be plain bars of wood, 3 in. × $1\frac{1}{2}$ in. × 2 ft. 6 in., hinged at one end to the stretcher, and attached to the pitmans at the middle. In this manner, both treadles would rise and fall simultaneously, and if a bar of sufficient length were screwed to both, we would have an efficient treadle the entire length of the lathe. Since the treadle thus formed would be supported at each end, there would be no tendency in it to get into winding by the pressure of the foot; but, when a treadle is supported by only one joint in the middle, the pressure of the foot on one corner tends to push down that corner and raise the one at the other end, and a treadle on this principle must be made very strong indeed to bear the irregular stresses upon it.

I supposed, in my former article, that the mandrels were not inserted in the headstocks until this stage of construction was reached, the reason being that it is difficult to ascertain their exact position in the headstocks. A templet of tin can now be made, like Fig. 2. The space in the lower part justs fits between the bed, and the point, C, is just over the middle and 5 in. from X.

To use this templet, the headstock is placed on the bed in the position which it is to occupy permanently, and the templet placed against one face. A point is then passed through a little hole at C, and marks in the headstock the position which the centre of the mandrel is to occupy finally.

The templet is then, *without turning it*, placed against the surface at the other end of the headstock, and the position of C transferred to that end likewise. The same operation is gone through with the other headstock, taking care to have the same surface of the templet always pointing towards the same end of the frame.

The treadle for the bent crank shaft is simply a frame like Fig. 1, about 18 in. shorter than the bed, and 2 ft. 3 in. wide. The position of the central member, M, is determined by that of the dip in crank axle. It should be directly under it. There is a mortise cut, through which the pitman passes, and a $\frac{3}{8}$-in. bolt across will serve as a pin, on which the latter hooks. The wood for this form of treadle would be $1\frac{1}{2}$ in. × 3 in. or 4 in.

The pitman I used was a plain rod of $\frac{1}{2}$-in. iron, bent at one end to embrace the crank, and, at the other, the pin I mentioned. It was filed flat at the bends, so as to afford a better bearing, and case-hardened. It was then japanned.

This lathe, as I have described it, worked remarkably well. It took a great deal of time, however, to make, as everything was finished in the best possible manner. If any of my readers wish to proceed more economically, all the woodwork may be made of beech, or even deal, and the lathe will still work well. Instead of the coned brass bush for the front mandrel bearing, I have used, on occasion, patent metal, pouring it into a hole in the headstock, the mandrel being held in its proper position. This is much easier to accomplish than boring a gun-metal bush, and works quite as well.

I trust that what I have said will induce many readers of Work to try their hands at lathe making, for, if they do, I am fully persuaded that it will be of the greatest possible benefit to them in their after life.

THE KALEIDOSCOPE: ITS CONSTRUCTION AND APPLICATION.

BY THOMAS RICHARDSON.

THE CASE AND INTERIOR MECHANISM OF THE COMPOUND KALEIDOSCOPE (*continued*).

(*For other Illustrations to which References are made in this Paper, see Pages 424, 425.*)

As arranged at the close of the last article, our next proceeding is to set out the fillets to which the sides of the case are to be screwed. They are $\frac{3}{8}$ in. thick, and are fixed flush with a line gauged all round $\frac{3}{16}$ in. from the edge, as shown in Fig. 2. As the interior of the plates are duplicates of each other, two sets are required, and the fillets at both ends are cut away in places, to clear the mechanism of the lower part of the arms (K K, Fig. 5), also on the front plate alone, to clear the lever, L. Having fixed the fillets, we next prepare the sides of the case, not forgetting a previous remark respecting the character of the wood to be used for the purpose. As this affords an opportunity for the display of good workmanship, I may here pause to remark that as, in many workshops, the same bench does duty for all classes of work, whether rough or smooth, it is just possible that the last job may have been of a coarse description—such as the repair of garden utensils or work of a like character—the consequence being that particles of a gritty nature have become embedded in the bench-top, rendering it extremely difficult to avoid scratching the surface of such work as that in hand. Presuming that the worker wishes to escape these troubles, he is hereby advised to procure a piece of deal, 3 ft. long, 11 in. wide, and 2 in. thick. Plane up one edge, and fix to the bench with screws at each end, the heads being sunk well beneath the surface, so as to clear the plane in trueing up for the present, and on any future occasion when necessary. Supposing the face to be true and level, we must provide a stop by cutting a dovetail, tapering groove $\frac{3}{8}$ in. deep across the grain about 2 in. from the end. Into this groove is to be tightly fitted a piece of hard beech, $\frac{5}{8}$ in. thick, $1\frac{1}{4}$ in. wide at one end and 1 in. at the other, the groove being dovetailed so that the bottom is $\frac{1}{4}$ in. wider than the top. When so fitted, the front edge of the stop against which the work is to abut must be rabbeted square with the front edge of the board, and perpendicular to its face.

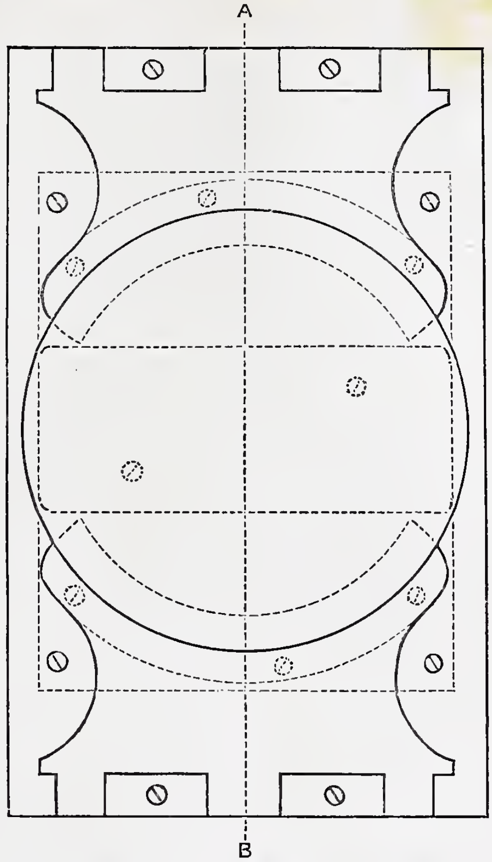

Fig. 6.—Diagram showing Method of Mounting Uprights and Segments in Lathe for turning them out of Solid Piece.

To proceed: The pieces composing the sides should not be less than 9 in. long and 4 in. wide; have a keen edge on the trying plane, with the back iron set close, and plane up each piece carefully to $\frac{1}{4}$ in. thick; then square one edge, and set off the rabbet at each end so as to support the ends of the case at a distance of $8\frac{1}{8}$ in. apart. As it is important to have all exactly of the same length, scribe a line across one end of each piece with the cutting end of the scriber; the distance from this to the second line is then gauged with a pair of compasses, and, having also gauged a line to the depth required, run a saw-cut across just outside the lines, and finish with a paring chisel. In order to shoot the edges to the correct angle, we must arrange matters as shown in Fig. 7, where the board already attached to the bench is utilised as a base on which to construct a suitable tool for the purpose. In the first place, observe that the stop is removed; the baseboard (A) is chamfered on its front edge, and to this is hinged a board (B), about 18 in. long, 5 in. wide, and $1\frac{1}{2}$ in. thick, the hinge being attached $\frac{1}{4}$ in. below the face of the board; over this another strip (C) is screwed, in order to raise the work within reach of the plane iron. In this latter piece a stop is required, similar to that in the baseboard; and the adjustment to the correct angle is effected by means of a pair of wedges (D, D), having each a mortise cut in the centre, so that they can be clamped to the bench by a round-headed screw and washer. The mode of using the above appliance will be obvious from the position of the hands as shown in the illustration, the work being held and pressed against the plane by the thumb of the left hand, whilst the plane is firmly kept to its work by the right as it slides in the angle formed by the bevelled edge of the board (C) and the base. In this way the sides can be truly planed to an angle of about 67°. As these will, probably, vary a trifle in width, it is only required, for the present, to bevel the edges which have already been straightened. They are

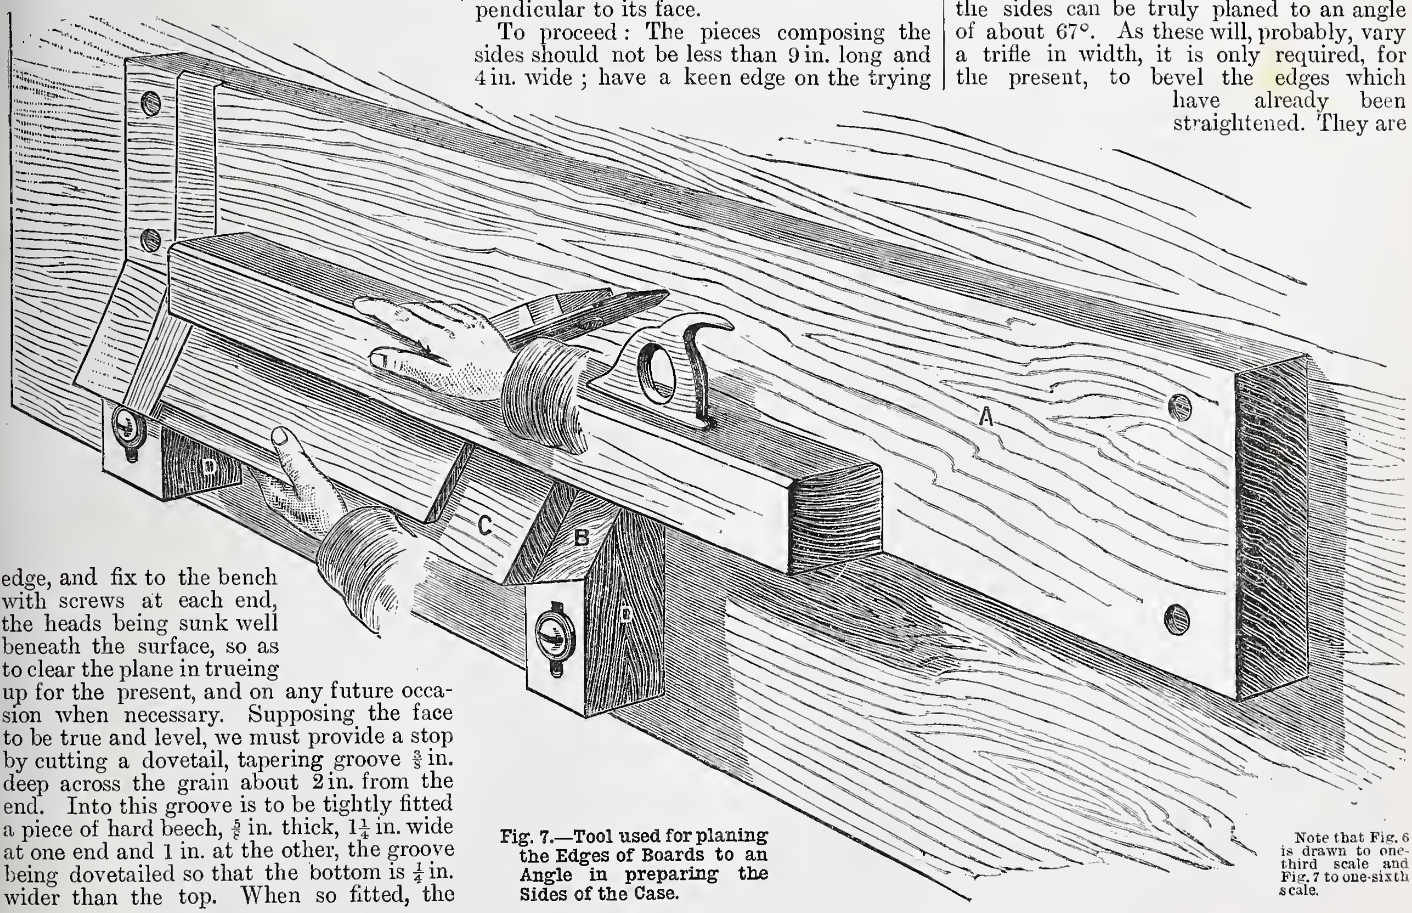

Fig. 7.—Tool used for planing the Edges of Boards to an Angle in preparing the Sides of the Case.

Note that Fig. 6 is drawn to one-third scale and Fig. 7 to one-sixth scale.

attached at each end by three round-headed brass screws, $\frac{1}{2}$ in. long, and it will ensure regularity, and greatly enhance the finished appearance, if the holes are set out with the square and compasses. In order to preserve the parallelism of the two plates while the sides are being fitted, we shall require a temporary piece to act as a stay; it is about 3 in. wide, rabbeted squarely at the ends to the correct length, and screwed to the flat at I (Fig. 2), its true edge being, of course, coincident with the angle of the plates. Now, secure the first side temporarily to the opposite flat with two screws at each end, its true edge being also carefully placed at the extreme angle on the right of Fig. 2. Here it will be noticed that an opportunity offers to rectify any little error or defect in the working of the slides, as hinted towards the close of the last article, seeing that the plates are now held parallel, and the interior is easy of access. When satisfied that each part works quite smooth and regular, we may pass on to fit another side below the first, with their true edges adjacent. Having produced a perfect joint, fix with a screw at each end next the true edge, and mark off the width at the angle below; then unwind the screws and bevel this edge to the mark. When this second side is secured in position we must return to the first, mark the width at the angle, and, having bevelled the edge, refix, and proceed in the same way with the third, and all the rest in turn until the last is reached, when, to make the joint between the seventh and eighth, it will be necessary to remove the first of the series out of the way until the joint between the last two sides is perfect; then replace it, and reduce the last edge very gradually, lest the piece be spoiled in the attempt, finishing by trimming the ends off flush and very slightly rounding the edges. As we still require access to the interior, the polishing, etc., must be deferred, and two sides each from the top and bottom of the case must be removed, the inside of each being marked with a $\frac{3}{8}$-in. chisel in Roman numerals to denote their respective places. Placing these out of reach of injury, the circles at X, X (Figs. 1, 2, and 5) now claim attention. They are prepared from half-inch close-grained mahogany, and the easiest method will be to turn them out of the solid, as shown, by mounting on a chuck with the screws passing through holes set out on a circle $6\frac{3}{8}$ in. diameter, the same being used eventually to attach them in position. All necessary holes are bored of the proper size before the surrounding substance is materially reduced, to avoid risk of splitting. To lessen waste of material, the interior portion may be removed with a thin parting tool, and reserved for constructing the eye-pieces later on. It is scarcely necessary to remind the worker that both sides of each ring should be trued up in the lathe, as it is of importance that they be of the same diameter externally and internally, and also of even thickness throughout, to ensure a smooth, even movement. By fitting a slip of wood in the opening at each end of the case, a centre may be found, and a circle described to coincide with the interior of the rings, and their correct appearance and position ascertained from Fig. 1.

The two uprights (V, V, Figs. 2 and 5) are turned out of one piece of mahogany, 12 in. long, 8 in. wide, and $\frac{1}{2}$ in. thick; one side is planed true and level, and also one edge; it is then secured to a chuck in the manner denoted by the *full* lines in Fig. 6, and a centre line (A B) scribed on the face parallel to the true edge through the centre found as it spins in the lathe. After being turned to the proper thickness, the opening is bored true and square to the same diameter as the outside of the rings, which may be used as gauges in the operation. In the preparation of the two segments (W, Fig. 2) we may economise the mahogany by attaching a piece of deal, $2\frac{1}{2}$ in. wide and 1 in. thick, across the centre of the opening in the uprights already on the chuck, and, on each side of this, a piece of mahogany $6\frac{1}{2}$ in. long, $2\frac{3}{4}$ in. wide, and $\frac{1}{2}$ in. thick, the position of each being indicated by the *dotted* lines in Fig. 6. The inner curve on these segments is the same as the rings, and the outer edge is rounded as in Fig. 5. When this is accomplished, two pieces of brass plate, $6\frac{1}{8}$ in. long, $\frac{3}{4}$ in. wide, and $\frac{1}{16}$ in. thick, are bent to the proper eurve, and fixed to the segments by fine $\frac{1}{2}$-in. screws, inserted about 1 in. apart. Now proceed with the base plate (U, Figs. 2 and 5): Plane to $\frac{1}{2}$ in. thick, and set out the mortises at each end, with the inner edges $\frac{1}{32}$ in. in excess of the length of the case; then the shoulders of the tenons are squared from the true edge of the piece and fitted to the base, to ensure their being firmly put together without fear of splitting; after which, a moulding is worked round the upper edge of the base, the case is laid on end on the bench, and the segments secured to the uprights, which have been well rubbed on the curves with blacklead, a slip of paper being interposed between the brass and the ring to avoid pinching. On removing the paper, the groove thus formed should slide smoothly over the rings. In providing the clamping action at F (Figs. 2 and 5), the instructions already given will apply to the milled head, which has a screw projecting about $\frac{1}{8}$ in. diameter, the small casting being tapped to suit, and the boss on the under-side let into the segment. The point of the screw bears on the free end of a thin spring of hard brass, $1\frac{1}{4}$ in. long and $\frac{3}{8}$ in. wide, secured in a recess by a small screw at the opposite end to that at which the pressure is applied. When all these little operations have been effected, the uprights can be cut to the outline in the figure, and finally glued to the base, especial care being exercised to be certain that they are exactly perpendicular to the base, after which, if deemed advisable, the joint may be further strengthened by passing a fine screw, about 1 in. long, obliquely upwards on each side of the central tenon, and $3\frac{1}{2}$ in. apart. This completes the stand and exterior of the case, with the exception of two brass clips, one of which is seen at Y (Fig. 2), which secure the object-box carrier to its seat; and four little handles, as at *m* (Fig. 1), having pins, which are fitted and glued in $\frac{1}{4}$-in. holes bored in the centre of the length and breadth of each alternate side.

We must now retrace our steps somewhat, and prepare the limbs (*a* and *b*) which compose the arms (K, K, Fig. 5). As there are four of each, we require for the lower set a piece of beech or hornbeam, 17 in. long, planed to $1\frac{3}{8}$ in. wide and $\frac{7}{8}$ in. thick; and, for the upper, a piece of the same thickness, but 14 in. long and $\frac{3}{4}$ in. wide. At $\frac{3}{8}$ in. from the front edge, a line is gauged on both sides, and on this the holes are set off and bored true and square, the upper set being bored to fit the tube which encloses the pinion, and those in the lower set to fit the tube enclosing the steel rods. One from each set must now be cut off, and pared to the form shown in the drawing, so that, on inserting a tube in the holes, they can be used as patterns from which the outlines of the rest can be marked, being careful to have each set of equal length, measuring from the edge of the hole to the point at which the two limbs are hinged together; and, in particular, the bevelled faces must be cut to the same angle; after which, grooves along the centre of these faces are set out, and cut $\frac{1}{2}$ in. wide, and a little over $\frac{3}{8}$ in. deep. Now halve the upper set at the top, as shown, removing sufficient to enable the inner edges to form an angle of 90°. A brass butt hinge connects the upper limb to the lower, and as the countersink is reversed in one set of holes, the screws must be replaced by those of a round or mushroom-headed pattern. If this is properly done, the upper limb will move freely round on the hinge when the lower is pressed flat on the bench, either side up. It will be well, therefore, to apply this test as each screw is inserted. Held against the lower edge of the hinge by a screw is a piece of brass having a slot cut the width of the screw at *d*, which is used to clamp the table (*c*, Fig. 5) to the arm after adjustment by the screw at *f*, the wood being mortised to match the slot in the plate, to allow of the necessary movement. To complete the arms, we require four brass brackets (*f*, *f*, Figs. 2 and 5), fitted with a screw $\frac{3}{4}$ in. long, and a spiral spring of hard drawn brass wire, about No. 18 B.W.G.

Our next business is the preparation of a table, or base, on which to mount the mirrors, and, at the same time, capable of slight motion up or down the inclined face of the arm, and of being securely clamped to the same. In dealing with this portion, we will take but one side, and assume that the two will proceed simultaneously, and we will further suppose that the stuff will be prepared in such a way that all similar pieces shall be cut from one length, which has been planed to a suitable width and thickness. The principal part of this mounting is the strip (*c*, Fig. 5). This is of mahogany, 8 in. long, 2 in. wide, and $\frac{3}{16}$ in. thick on the inner face, and at $\frac{5}{8}$ in. from each end a piece of mahogany $1\frac{15}{16}$ in. long, $2\frac{1}{2}$ in. wide, and $\frac{3}{16}$ in. thick, shown in section at *e*, and in elevation by the dotted lines in Fig. 5, is attached by four small screws. These latter pieces prevent warping and twisting of the table, to support which in a longitudinal direction, and also afford a hold for the screw at *f*, a strip of beech, $7\frac{1}{2}$ in. long, $\frac{1}{2}$ in. wide, and $\frac{5}{16}$ in. thick, is attached by eight screws, 1 in. apart, the outer screws being $\frac{1}{4}$ in. from the ends. Previous to fixing this in position, lines must be scribed square with the edge, and $\frac{11}{16}$ in. from each end of the strip *c*. Just within these lines, and abutting against the last-mentioned piece, are two slips of beech, $\frac{1}{8}$ in. thick, and of the same width as the grooves on the inclined face of the arm; these are held by a small screw at each end, and are slotted to match the mortises, and thus clear the screw at *d*. To support the lower edges of the reflectors, at *i*, *i*, are seen two pieces of beech, $\frac{3}{4}$ in. long, $\frac{7}{8}$ in. wide, and $\frac{1}{8}$ in. thick, which are screwed to the base (*c*), the upper edge being held by the slip of beech at *h*, 7 in. long, $\frac{9}{16}$ in. wide, and about $\frac{3}{32}$ in. thick. Any difficulty experienced in planing the edges of such thin pieces may be overcome by holding the slip of wood in the fingers and drawing it towards you over the sole of the trying plane, which is placed, bottom upwards, in the vice for the purpose. Blacklead must now be applied to the grooves and their corresponding guides, and the screws at *d* inserted, the relative position of the two portions being exactly denoted in Fig. 5. On clamping the screws, we can ascertain the lengths of the tubes and thickness of the washers which maintain the arms at the proper distance asunder; at the same time we can determine the thickness of the pieces of mahogany at *j*, *j* (Figs. 2 and 5), which occupy the space between the arms and the ends of the case. On reference to Fig. 5 it will be seen that the tubes and pinions are secured in their respective position by screws or rivets passing through them; after which, the back plate may be taken apart from the sides, and the milled heads can be attached to the pinions which pass through from the inside of the plate—not forgetting the brass washers, which bear on each side of the plate—before finally driving the heads on to the tapering ends of the pinions. The whole of the mechanism may now be connected in readiness for the reception of the optical portion, the preparation of which will be treated in my next paper.

ENGRAVING ON METAL.

BY NORMAN MACLEAN.

Engraving on Britannia Metal.

It will be, perhaps, of some assistance if I enumerate the various branches of engraving on metal. Brass, zinc, and pewter have already been alluded to. The easiest, perhaps, is Britannia metal engraving; but even this metal requires a certain style to make a little work look effective. The work, too, is done very cheaply, and at first sight would appear as if it were impossible to earn a living at the price; but as many engravers do nothing else but work on the above metal, if they have plenty of work they have nothing to complain of at the week's end. The principal articles made in Britannia metal are tea and coffee sets, hot and cold water jugs, biscuit boxes, etc. These are usually engraved, chased, and engine-turned.

At the present time there is not so much engraving, as chasing and embossed work, with fluting in the Queen Anne style, is most in fashion.

Then comes the "hollow ware" engraver, who ornaments trays and waiters, tea and coffee services, dish covers, ice pails and jugs, *entrée* dishes, soup tureens, all of which are made in silver and German silver.

Another branch is the engraving of small work, such as fish carvers and eaters, dessert knives and forks, forks and spoons (not lettering or cresting), and general "odd work," which is also made in silver and German silver. Heraldic engraving is a branch—the highest, I may say, as it requires a skilful and accurate draughtsman, a steady hand, and remarkable patience. It includes the engraving of coats of arms, crests, monograms, and inscriptions on metal, and lettering and cresting on pearl and ivory. There are also the watchcase and dial engraver and the jewellery engraver. The young workman will be able to select a branch of engraving from the foregoing, but I would strongly advise him to make an arrangement with some *boná-fide* workman who would be willing for a consideration to put him in the way of sound practice, or, what would be better still, to take him as an articled pupil for a time. There is no royal road to engraving; it is only to be learned by constant practice and competent tuition. These remarks apply, of course, to the more artistic branches.

I will now make a few remarks as to the form or condition of the work as it is given out to the workman to be engraved. In the case of Britannia metal goods, they are invariably "made up"—*i.e.*, the article is made throughout, as for a teapot, being fitted with handle, spout, lid, and is, with the exception of engraving, ready for electro-plating and finishing. Other articles, such as for chasing, embossing, and engine-turning, are not so "made up," the condition being the same as that in which they leave the spinning lathe, and otherwise rough polished or buffed. In German silver hollow ware, these are "made up" to a certain extent: thus, a teapot would have the spout, foot or feet, lid, and mounts for the reception of the ebony or ivory handle, which is fitted after plating; and where the handle is of metal, the necessity of non-conductors of ivory, etc., make it imperative that the handle should be fitted after plating, as the ivory will not stand the acid of the plating vat. With plated table cutlery, the blades and forks are sent to be engraved before they are handled, as they require to be electro-plated before the handles are attached. And with heraldic engraving, it is both finished and unfinished when it reaches the workman's hands. Presentation articles are usually made by the manufacturers, who generally receive the order and particulars of inscription at the same time; then the engraver's work is done before the article is finished. But in the case of a present having been bought from a silversmith, the workman has to do his work in a careful manner, so as not to spoil the finish of the article, and for which, by the way, he charges accordingly.

Probably the cheapest thing in the market for a workman to try his hand upon is a twelve-inch brass waiter, either round, oval, or octagon. These may be procured ready for engraving from Mr. Samuel Groves, Broad Street, Birmingham, at a low price. These waiters, well engraved, plated, and finished, *should* command a ready sale in bazaars, etc. Having procured the waiter, the next thing to be considered is the design, which should be pretty and effective, with just enough work in the design to well balance it. There are many styles to choose from, but at present the workman will perhaps prefer to try the one found in Fig. 32, and which may be engraved in five sections. To "set out" the waiter, first warm the centre of the waiter, and rub a little beeswax thereon, and place a small piece of zinc—say, one-half inch square—on the wax while it is hot. This will cause the zinc to adhere, and prevent any marks consequent on the action of the legs of the compasses.

Now, with the compasses strike *faintly* all the circles needed for the pattern, then accurately divide the waiter into fifteen equal parts by stepping it round with the compasses. This will leave two divisions for the panel, and one division for the ivy leaf spray. Next cut the outside lines of the panels, using the dividers to trace the second line of the panel, by means of the outside line. Cut all these second lines, and you will have the required space in which to sketch the scroll work. To do this, draw a straight line down the centre of the panel, and sketch in truly, and afterwards trace it in with the point (Fig. 23, page 596), and outline only. Now sketch in the spray to the right, point in and outline, and proceed in like manner with the outside and inside borders. On the line down the centre of the panel cut an almost imperceptible dot or speck, so that you may know the exact centre. Now that we have got a section outlined, the next thing to be done is the taking of an impression in paper, termed a "white" or "dry" print. This is done in the same manner as the taking of an ink print, with the simple exception that we must use no ink. Use a pretty good paper, such as good white or blue unruled foolscap. Take off the paper, after you think you have got a good impression, and dry it gradually and thoroughly. The pounce bag here comes in. It is simply made by crushing fine an ounce or so of common whiting—see that it is dry—and then enclose it in a piece of well-washed linen. Now cut from the print all superfluous paper, and cut an oval-shaped hole in the top and bottom of the paper print exactly down the centre. Now draw a centre line down the remaining four panels, and rub just the least bit of candle grease on the surface of each, and also where the ivy spray is to come. The print now being ready for laying down, dust the pounce bag smartly on the print with the impression upwards, and "lay down" all the panels in turn. If the workman has been successful in dividing the waiter accurately, the pattern will fit exactly. The workman will observe that the borders are little else than outlining, thickening, and colouring, which will form excellent practice, while the scroll and leaf work will be an agreeable change. Work slowly at first, frequently pausing to see that the work is uniform. The leaves of the ivy spray may be "blacked" out with the "shading" graver, and lightly veined, and the panels blacked out with either the graver or the shader, according to the time it is desired to spend upon the work. The scroll work will not want much shading, and only judicious thickening. I hope I have made this clear to the young workman, who is supposed to know something about the treatment of ornament as far as regards the shading, etc.

In Fig. 33 will be found a sketch of a Britannia metal teapot, of a very old-fashioned shape, but which is now very fashionable. This pattern may be done either in first-class style or in a cheap and effective manner.

As the latter style will better suit the young workman, I will give a few brief directions how to proceed with the work, leaving the engraver to supply the details according to his individual taste, which the workman will do well to practice.

The chief ornament is the wide border, with arches and drooping fleur-de-lis. For the double lines of the top and bottom borders a double wriggling tool (Fig. 34) is used, this tool being made in many different widths. It consists of a flat or ordinary wriggling tool, with a groove cut straight down the centre, slightly "set off" and whetted on the back in the usual way. In addition to the ordinary graver will be required a large round-nosed tool for the "bright" leaves of the top and bottom borders; also a smaller one for the small spots; and a narrow flat tool or wriggler for the waved lines of the bottom border, and the waved line of the spray in the hollow section at the top of the teapot.

The tools being ready, rule two single lines as truly as possible, using the dividers, and the angle of the join where the hollow at the top of the teapot commences. Rule similar lines of the required width for the bottom border, using the bottom of the teapot for a guide. Now take a double wriggling tool of the proper width, and with a regular rocking motion of the wrist, push forward the tool, which will, or ought to, make a continuous dotted double line. All these double lines are done before putting aside that particular tool. Now change the tool for the narrow wriggler, and cut the waved lines on each side of the bottom border, and a rather deeper and bolder wave for the spray at the top of the teapot. Then take a wide shading graver, a No. 12, and cut away the whole of the space between the lines of the bottom border, cutting lengthways, and then it is ready to receive the bold cutting of the large round-nosed tool (Fig. 35), which will eventually take the form of "bright" leaves. To do this, after whetting the round tool, rub the tool on a piece of thick leather on which a little rouge has been sprinkled; this will make the tool cut bright. Draw a pencil line down the exact centre of the teapot, and cut the four small bright spots. Now step out with the dividers the intervals for the bright leaves, and form them with two cuts—a deep and bold cut, followed by a light one in the first to clear the cut, and also to bring it to its proper size. It will be seen that the points of the leaves in both borders extend from the centre, and are carried round the teapot as far as the spout and handle respectively. After the round tool has done its work, cut the oval form left by the round tool into shape with an ordinary graver, flanching, or cutting with the point and right or left side of the graver, using two cuts on each side of the leaf. The ornament on the spout is done in a similar way, with the exception that the leaves are graduated. The bottom border and spout being finished, I will now show how the top border is done. Take the No. 12 shader, and cut the width of the graver *only* on the inner sides of the double lines already cut. Now rule a line along the centre of the border, and with the large round tool cut the four-leaved flower in the centre; next mark out the leaves with the point, setting out the angles of the leaves accurately and at equal distances, then rough the shape of the leaves out, as in the bottom border, with the round tool, and "cut them up" in a similar manner, giving the leaves a slight curve as shown in the sketch.

The spray in the hollow section now remains to be engraved; the leaves may be wriggled with the No. 12 shader, and "cut up" in three or four cuts on each side of the leaf, giving them their proper form as the work progresses. These leaves may be lightly veined and sprigged as shown.

The arches under the top border must be stepped out, and wriggled with the narrow tool used for the waved lines. The leaves at the points of the arches may be done (wriggled) with the No. 12 shader, and cut up in the same style as the spray in the hollow. A small spot between the arches, and a large spot with smaller one beneath in bend of arch, complete pattern. The work on lid is outlined with graver and finished with shader.

SIGN-WRITING AND LETTERING.

BY HENRY L. BENWELL.

OCKED LETTERS—THICKNESSES—CAST SHADOWS —SHADOWING—LIGHT AND SHADE—TUSCAN AND TABLET ALPHABETS, AND HOW TO TREAT THEM.

IE laws of light and shade play a very ominent part in the more advanced stages our art, especially to the more practical anch of ornamental lettering; therefore regards importance, this subject follows ry closely upon the heels of perspective. e will leave this matter, however, until the ter part of the chapter, and first of all nsider the raising and blocking of letters, d other work which always precedes the ading proper. I had better, perhaps, fore proceeding further, explain the mean- g of one or two technical terms, so that e novice may be able to thoroughly com- ehend their meaning whenever they are entioned in this chapter.

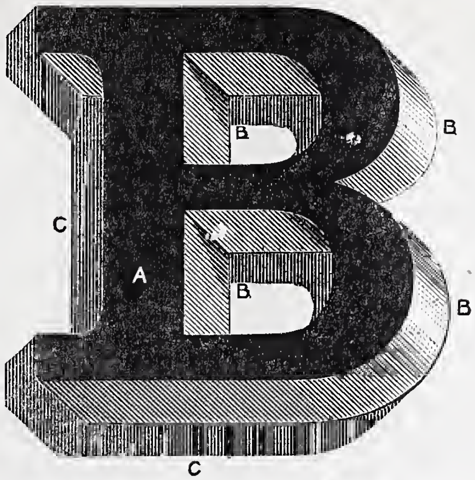

Fig. 66.—Diagram in Explanation of the Structural Formation of Letters.

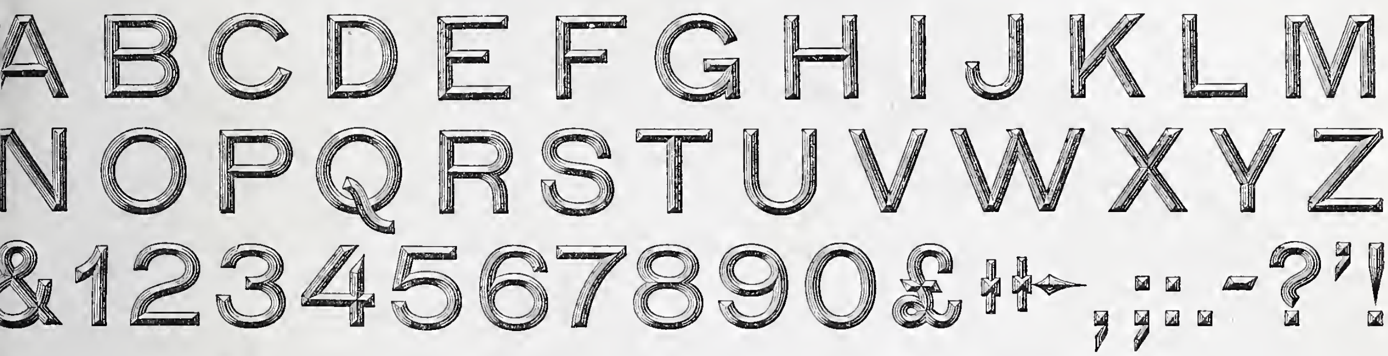

Fig. 67.—Tablet Alphabet, Capitals, Numerals, Points, etc., to Illustrate Method of Shading Letters.

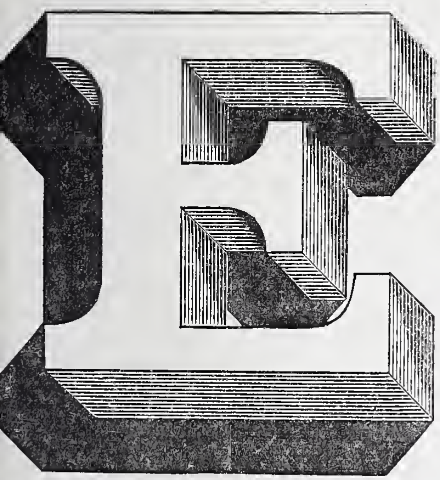
A "blocked" or "raised" letter is one ich appears, or stands out in relief, such the manufactured wood letters pre- ously referred to, and which it is the rk of the sign-writer to imitate on a flat rface by skilful perspective and colouring. "double blocked" letter is one which is ocked out on both sides, or internally and



g. 69.—Letter invested with Thickness underneath and towards Light. Cast Shadow on opposite side.

ternally. The "thickness" is the o sides or edges, and the two ends a blocked letter; but of course, om whichever way such a letter is oked at, only one side and one end e visible to the eye at one time, d as letters are generally looked at om below, and commonly shaded on e right, the bottom and right sides the letters are usually those where

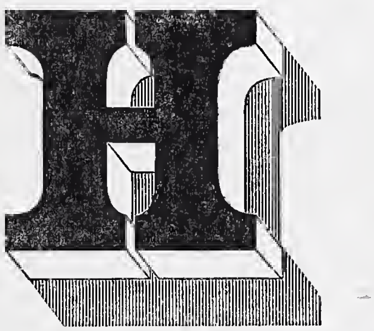


Fig. 68.—Letter with Thickness and Cast Shadow both on same side.

the thickness is given. Of course, it must be understood that we can put this thickness on either side of the letter, or at the top or bottom, but we cannot put it on both sides at once, because in a real raised letter it would be impossible for us to see both its edges at one and the same time. The same remark applies to the top and bottom edges. The "cast" shadow is the shadow which is thrown on to the background by a raised letter through the sun or strong rays of light shining upon it in an oblique direction: this shadow is of course on the opposite side to that upon which the rays of light fall. A graduated thickness is one with its colour of various tints softened into each other in order to represent more vividly the various degrees of light or the sun's rays as they fall on different portions of the thickness; these may be divided into the high light, the middle or secondary light, and the deepest shadow. A graduated thickness is often put in, however, for mere ornamental effect and showy colouring. The "face" of a letter is its front portion, which is generally painted to appear in the highest light, sunken letters excepted. The explanation of these terms will be better understood on referring to Fig. 66, where A is the face of the letter, B B the thickness or blocking, and C C the cast shadow, or, as it is termed in some parts, the back shadow.

Although no sign or inscription nowadays would be considered to possess any artistic merit unless the writing were executed in blocked letters, this system of blocking is of comparatively recent introduction: in fact, about the year 1840 it was only then just coming into vogue, but soon became immensely popular, and was considered to be a vast improvement on the "flat" lettering of the old style, and which we only now see on the commonest of work. In order to impress upon the mind of the novice the real meaning of these imitation raised letters, or, I should say, the effect or illusion they are intended to convey to the eye of the spectator, I may say that "blocking" was introduced by the sign-writing profession to imitate the raised cut-out letters in wood which I have previously spoken of, and which, no doubt, did the sign-writing profession at that date

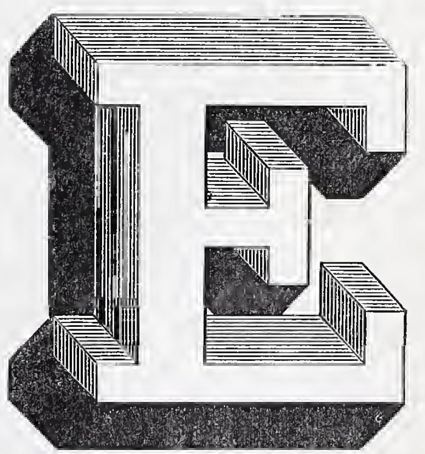

Fig. 70.—Letter with Thickness above and partly towards Light and partly against. Cast Shadow on opposite side.

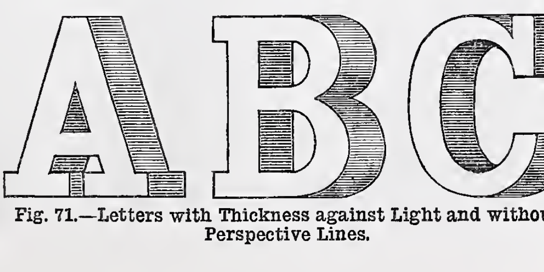

Fig. 71.—Letters with Thickness against Light and without Perspective Lines.

considerable injury by sudden and unexpected competition. A technical writer of the period indicated alludes to this subject in words which have still greater force and truth than they had formerly; he remarks: "The projecting letters, formed of wood or metal, have of late become so fashionable that the writers on shop fronts and signboards have had recourse to imitating them, and have produced letters *in such bold relief, that they look more real and much better than their wooden rivals.*" The italics are mine.

In "blocking-up," each letter must have its thickness outline in its own perspective, but the perspective must be at the same angle in each letter, say 45°, as being the angle usually adopted. For plain work, the colour of the thickness is usually darker than the ground colour, and also the colour used for the face or body of the letter, but there are plenty of exceptions even in the simple form of blocked letter, some of which are in very bad taste as regards colour. But when we go in for light and shade, then we must decide upon which side of the letter the light is to strike; if the thickness is away from the source of light, its colour will be darker in shade than both the face of the letter and the ground colour, but if it confronts the light, it will be lighter than the ground colour, but darker or of a more retiring colour than the face colour of the letter (see Figs. 68, 69, 70, and 71).

It must be remembered that writing on a shop front or on a signboard is generally looked at from below, so that it is a general rule to invest the bottom end of letters with a thickness, and not the top (Fig. 69). To see a letter with the thickness at the top and above its arms, as in Fig. 70, we must, if the letter be a real projecting one, stand above it and look down on it, but nevertheless, this lettering is often done even when it stands above the point of sight, and out of all true perspective. There is so much latitude allowed in sign-writing, that this anomaly is permitted to pass unchallenged, so that we may thereby obtain a somewhat picturesque effect. I can vouch for the example here given being perfectly correct, as it is a letter formed by one of the most successful writers this country has as yet seen. It is also permissible for one to do his thickness on straight lines instead of in perspective. In this system we have the whole of the work inside the two horizontal lines which contain the body of the letters, and there is not a single perspective line in any letter, yet they certainly have the appearance of projection, as will be seen on looking at Fig. 71. In a graduated thickness, the various tints or colours must not be blended into each other by guesswork; the principle of light and shade must be carefully thought out, and the science of optics studied before any successful result can be arrived at. In looking at some of the best specimens of sign-writing which we come across in the principal streets of some of our large towns, one cannot help being struck with the taste and ingenious talent displayed in the beautifully blended and coloured thicknesses which play such an important part in adding a positive air of grandeur to the work.

It is really wonderful how effectually we can imitate, upon a flat surface, a real raised letter of any description, or of whatever material, whether it be wood, stone, metal, or marble. To ensure success, we have only to be correct in drawing, colouring, and shading; in fact, the drawing must be true, the colouring bold and effective without being gaudy, and the shading and gradation appropriate to the whole, which gives to the subject an appearance of what it is not in reality. I can only add that the most beautiful softened thicknesses are only obtained with slow drying colours, and the judicious use of the blender. Thicknesses may, however, be of any colour, bright or otherwise, according to the scheme of colouring employed by the operator.

I must next turn to shadows; and here I may say at once that however bright in colour the body and thickness may be, if a cast shadow is added it must be quiet in tone, being, in fact, a mere glaze on the ground colour to make such colour darker where the shadow falls. It must not consist of a primary or secondary opaque colour unless the author of such work wishes to be accused of bad taste, and of being a bad colourist. The siennas, umbers, Vandyke brown, and asphaltum are good glazing colours for rendering cast shadows. Letters may be shadowed either on the same side as the thickness or on the opposite side; the latter, I think, will be the system generally adopted, and in this case the thickness receives the rays of light, and is therefore painted in a brighter colour than it otherwise would be, were it represented as in the shade. It is best, perhaps, if it is painted the same colour as that used for the face of the letter, but in a somewhat darker shade. When a thickness faces the source of light it is frequently put in with two or three gradations of tint or tone, the lightest being where the edge of the letter catches the most light, and the darkest in the underneath portions of the arms and bottom end of the letter; in fact, the bottom of a letter always gives better effect to the whole structure when it is painted in a darker shade, as this portion of a projecting letter must necessarily be in the deepest shadow. Of course, the bottom portion of all letters throws a cast shadow, and where these are inserted they follow beneath the thickness, so that the shadow always touches certain portions of such thickness, whether it is on the opposite side, or *vice versâ*. With a letter that has its cast shadow and its thickness both on one side, and against the source of light, the latter is naturally darker than the face of the letter, and the shadow is preferably of a shade not far removed from black. I have frequently alluded to the source of light in this chapter as being the guiding star upon which rests the correct colouring and shading of a letter. I suppose I need hardly say that this light can hardly be anything else than imaginary, in the mind of the writer, when carrying out work of this class; I am, of course, alluding to work in the open air, where the sun, that lights all things, good or bad, is constantly on the move. It would thus be impossible for the workman to so arrange his shadows that they may always be thrown in an opposite direction to that in which the sun is shining, or the light the brightest, because, if even correct in the morning, it would not be so in the afternoon. Most readers may say, every simpleton is aware of these simple facts, but I am writing more particularly for the younger generation, and boys are not apt, overflowing as they are with animal spirits and bumps of mischief, to give even these simple matters a thought. Once bring anything to their notice, however, and set them thinking, and clever lads will work the problem out for themselves; but I am digressing.

The best arrangement we can make, therefore, is to consult the position in which the sign is situated, notice from which direction the light is strongest during the best part of the day, and adapt the light and shade of our work so as to conform with nature, as far as it can, in a pleasing and truthful manner.

There are many specimens of the sign-writer's art to be seen abroad, which have been treated in a purely conventional manner: for instance, one may often see letters possessing a cast shadow, but without any blocking or thickness. The question arises, what is there to throw this shadow, considering that the letters appear to rest quite flat upon the surface; of course the only way out of the difficulty—if such it is—is to stretch the imagination and assume that they *do* project, and certainly by clever and tricky shading they may be given that appearance in some slight degree. After all, the sign-writer is a sort of "free lance," and even in blockless letters with a cast shadow, no very great harm is done if the work is handled judiciously.

Some styles of alphabets of the modern ornamental and mediæval design have the face of the letters shaded: this consists of sharp clear markings or linings. In some alphabets the thickness or breadth of these lines is symmetrical throughout, in others it is thickest in the middle, and graduates outwards to the top and bottom of the letter until it assumes a fine hair line. Those letters known as Tuscan are of this description, and when well done, they have a very gorgeous and rich appearance, especially if the letters are gilded. The student will find a complete Tuscan alphabet in any printer's specimen book; and to render the same more useful to him I would advise that in copying it for practice a full alphabet be enlarged to about the size of the large specimen letters given with this chapter, and they will then prove very useful for future guidance. They should be drawn on separate squares of Bristol boards, and kept in a strong home-made envelope or case, and to add to their usefulness, they may be coloured with water colour and gum in various designs, and will thus be handy for showing to customers for selection. I need hardly say this dodge applies to all alphabets, and is a good way of assuring oneself upon giving satisfaction even before commencing the work, yet, I presume, very few professional hands consult or study their customers' wishes in this way. Another alphabet is that known as the Tablet, and here the shading is all done upon the face of the letter, and to look well requires a skilled and decisive hand, besides a thorough knowledge of the art, otherwise the proper effect will not be gained. Those painted letters are supposed to represent cut-out marble or china tablets affixed to the shop facia—articles which are often seen in the reality, and common enough they look. Another style of letter very difficult to paint, and where the whole effect depends upon clever shading, is the sunken or incised letter, which is just the opposite to the Tablet.

If space permit I will try to give an alphabet of this in a later chapter, and will here only point out that the great difficulty in shading these letters is "*not to give a Tablet letter the* (*reverse*) *appearance of a sunken or incised letter, nor vice versâ.*" This is very often done, so "forewarned, forearmed," as the old proverb has it. A complete "Tablet" alphabet is given in Fig. 67, and here also should the letters be enlarged in order to learn and judge of the proper effect, and their suitability for various classes of work.

OUR GUIDE TO GOOD THINGS.

** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

19.—EATON'S "POSTABLE" FLOWER POT TRIPOD.

'HE accompanying illustration will, I think, e sufficient to show that the "Postable" Flower 'ot Tripod of Messrs. S. J. Eaton & Co., Inentors and Manufacturers of Specialities, 131, reat Titchfield Street, London, W., is a light nd pretty means of introducing plant decoraion into corners and other parts of rooms in hich it would be otherwise most difficult to get any adornment of this kind. The only thing about it to which I can take exception is its name "postable," which Messrs. Eaton & Co. have clearly invented for the occasion, as well as the speciality itself, and which is applied to it in virtue of its being made collapsible in one form, so that it can be closed up and forwarded by parcel post for 3d. or 4½d., thus rendering it an acceptable and useful present for transmission in this way, and to be readily obtained by anybody who may desire to have one if it does not appear among the stock of the fancy furniture dealer nearest to the residence of him or her who wishes to get it. As it will be readily

seen from the engraving, it consists of three bamboos arranged in the form of a tripod, with a larger triangular board inserted between them near the base, and a smaller one at the top, each board serving as a support for a flower pot or ornamental vase. Those that are sold fixed are 44 in. in height, and 15 in. wide at base; the "postable" are 41½ in. high, and 14 in. wide at base. They are sold plain at 1s. 3d. each, or 2s. 3d. per pair; enamelled in dark colours, or stained and varnished, at 2s. each, or 3s. 9d. per pair; enamelled white or in light colours at 2s. 6d. each, or 4s. 9d. per pair. I may suggest that the plain tripods would furnish a little congenial employment to ladies who are fond of "aspinalling," and who might thus bring them into accord with the prevailing tints and colours of the rooms in which they may wish to place them. Slender and pretty in appearance, the tripods are suitable for use in or out of doors, and make admirable stands for pendant and creeping plants above, and geraniums, etc., below. The stand is strong, rigid, and perfectly stable when ballasted with a heavy pot on the bottom board, and at the point where the bamboos cross each other is a ring to which a small coloured lamp or hanging vase may be suspended.

THE EDITOR.

A CORNER FOR THOSE WHO WANT TO TALK IT.

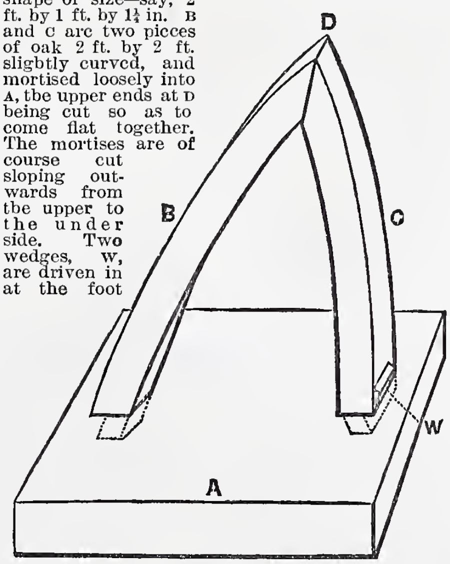
NOTICE TO CORRESPONDENTS.

**** In consequence of the great pressure upon the "Shop" columns of WORK, contributors are requested to be brief and concise in all future questions and replies.*

In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of WORK in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.

I.—LETTERS FROM CORRESPONDENTS.

Fretwork Clamp.—KILDONAN.—The contrivance here submitted is the invention of a friend of mine, a very skilful fret cutter, who in his leisure moments turns out the most beautiful work. It is so simple that any one can make it, and has the advantage of getting rid of the sawdust without any expenditure of breath, or adventitious aid of blower or other complicated arrangement. It is used, of course, by the artist who works with the ordinary bow. A is a heavy block of wood of any shape or size—say, 2 ft. by 1 ft. by 1½ in. B and C are two pieces of oak 2 ft. by 2 ft. slightly curved, and mortised loosely into A, the upper ends at D being cut so as to come flat together. The mortises are of course cut sloping outwards from the upper to the under side. Two wedges, W, are driven in at the foot



Fretwork Clamp.

of the uprights, thus increasing the gripping force of the jaws at D. Two similar wedges driven in from below serve to decrease the grip, and the tension of the jaws can thus be regulated to suit the convenience of the worker. The faces of the jaws are covered in leather, which keeps the work from slipping. If the wood is left bare it soon gets very slippery, and the work will not be held steady. The *modus operandi* is as follows:—Having drawn the design on the wood, the latter is placed between the jaws, the design towards the worker. It is held upright, and when the holes are bored the saw can also always be held upright, for the tension is sufficient to hold the wood in position. With the help of the left hand, the work can also be turned round, thus relieving the right arm of the fatigue of holding the saw at all sorts of angles. The dust falls down. The apparatus can thus be used in the house, for by spreading a newspaper below to catch the dust and pieces cut out, the cleanly housewife can look on complacently while the "guid man" cuts out some fancy article to beautify and adorn the home.

Tools.—H. J. L. J. M. (*Ealing*) writes:—"May I remark that Messrs. Melhuish, of Fetter Lane, E.C., offer facilities to purchasers of tools similar to those offered by the firm mentioned by H. C. on page 542? I have no doubt that Messrs. Buck, or any other tool makers, would give every information and instruction as to the use and capabilities of any tools supplied by them. I am not writing this from any desire to puff the wares of any one firm, but simply from a wish to let every one have his due. As I go in chiefly for chasing and repoussé work, I make the bulk of my tools myself, and am thus far independent of any firm."

Saw Hammering.—J. N. (*Sheffield*) writes in reply to T. O. (*Bootle*):—"I notice a reply from you to T. O. (*Bootle*) (see page 587), who makes an inquiry on the subject of Saw Hammering. I am junior partner in my firm, but am a practical workman. I spend a great portion of my time hammering saws, mostly circulars. I have only been a subscriber to your paper a few weeks, and I did not notice T. O's. (*Bootle*) question. If he will repeat it I shall be pleased to give him any information I can."

Boots and Shoes.—J. R. writes:—"I wish H. G. (*Bishopsgate*) would let me know through your columns how to cut out a pair of men's shoes laced, and a pair of women's laced plain for a light bottom hand-sewed; how to round the insole, the heel about 2 in. high and 2¼ in. broad for men's, and 1½ in. high and 1¾ in. broad for women's. Should there be two split lifts and one about with the lifts pegged together, or two split first? In all heels should they be slanted in heel seat what way to fit the welts, and dress up after sewn and level; how to make a broad welted boot and set up the stitch—should it be marked with a wheel; how to make a spring heel cork pump bottom, and a pair of slippers turned."

Ink for Posters.—M. D. C. (*Liverpool*) writes in reply to SMILING SMUDGER (*Manchester*) (see page 573):—"I would like to ask him how he calls oil paint ink for posters? From my point there is a vast difference between oil paints and inks. Also how is an amateur to fill up small letters with a pound brush? In reply to H. L. B. (see page 574), I would like to ask him if he ever wrote a poster of printers' ink and paraffin? as he says posters are only written with printers' ink and paraffin or benzoline. It is a nice thing to tell an amateur to use either paraffin or benzoline. Suppose a man bought enough colour to do what he wanted, and he used paraffin, I must inform H. L. B. that his colour would be useless after he had got it mixed. H. L. B., I must say, is a nice party to write an article on poster writing. I would like to ask H. L. B. if he knows how to mix colours for poster writing? If so, what would make a good chocolate or marone that will not fade on being exposed to the sun, also salmon colour, or flesh colour? Also, if he knows anything about poster writing, what would he put in printers' ink to keep it from working stickier, or leaving brush marks on his work. He says he is engaged by the Editor of WORK to write on poster writing. Well, if he is not an amateur I hope he will give us some good information, and I don't care how soon; but from my point he must be an amateur of the worst type, or he would not have mentioned paraffin to dilute printers' ink with. If A. Y. (*Ilkeston*) will send me his private address, I will give him all the information he requires on poster writing and ticket writing, although I am not a professional at ticket writing."

Book on Bookbinding.—B. R. C. (*East Finchley*) writes:—"Will you permit me to inform G. F. S. (*Nottingham*) (see G. C.'s reply to him, No. 36, page 572) that there is a thoroughly good and cheap book on bookbinding—viz., "Bookbinding for Amateurs"—by W. J. E. Crane, published by L. Upcott Gill, 170, Strand, London, price 2s. 6d. It contains full and clear instructions, with numerous helpful illustrations, on each process in the art from start to finish; together with descriptions and prices of the various tools and materials required, and the names and addresses of dealers in the same. Allow me to add that I am in no way interested in the sale of this or any other book, but write solely in the hope of giving a useful hint to a fellow reader of WORK."

Lathe Bits and Drills.—J. H. N. (*Malvern Wells*) writes:—"Seeing some forms of bits and drills for the lathe by OLLA PODRIDA, on page 321 of No. 21 of WORK, I could not resist sending you a suggestion for Fig. 7, an enlarging drill, for which I hope you will excuse me taking the liberty. The plan is, instead of having the wood on sides of drill, to cast in sand a plug of zinc, which is within the means of every one, rather larger than drill, to allow for turning down; then bisect plug down the middle, and cut down with a hack-saw; then fix on drill same way as shown in Fig. 7. The reason I propose a zinc plug is because it will wear better than wood, and not be so likely to be affected by the scrapings or chips cut by the drill."

English and American Tools.—WALSALL writes:—"I should like, through the pages of WORK, to call the attention of my fellow-readers to the price list issued by Mr. Lunt, 297, Hackney Road, London, E., which he will forward to any part of the United Kingdom on receipt of one penny stamp. I have one before me while I write this, and I can assure my fellow-workmen that it is the best list I have been able to procure, and I believe his price will compete with any other firm in the country. The list, which is illustrated, contains eighty pages of the best and most improved tools in the market, and tools suitable for almost every trade that is known. Also a large assortment of cutlery, etc. I feel sure my fellow-readers will not regret sending for Mr. Lunt's list. I myself have found tools in his list that I have wanted for several years, and could not obtain them, not knowing where to apply for them, and I have no doubt many others experience the same difficulty."

A Metal Worker's Complaint.—W. G. (*Gateshead-on-Tyne*) writes:—"In your issue of September 28th, on page 437, there is an article on Metal Spinning by F. Durrance, which I eagerly read, and looked forward for the next issue, as at the end of the article he says 'in our next we will try and have something more difficult,' but as yet I have not come across anything on the above subject."—[These papers will be continued as soon as possible. W. G. will readily understand, however, that contributors to WORK are practical men, who cannot always find leisure to turn from their work and to write. Moreover, other contributors than W. G. want their subjects considered, so that it becomes difficult to give weekly sequence to any one subject. All that can be promised is that all subjects commenced in Volume I. of WORK will be completed within that volume.]

Cuts and Bruises.—MECHANIC (*Rugby*) writes: —"Being a subscriber to your valuable paper, WORK, from its birth, and having read the correspondence from the writer in 'Means, Modes, and Methods,' and the replies, to and from, by MEDICUS and the writer (whose name does not appear), in reference to remedy for severe cuts and treatment of bruises (WORK, No. 26, page 411, and No. 35, page 555), I think, perhaps, you will not be against a few remarks thereon, having passed over twenty-six years in private and public engineering works of one sort or other, wherein I have seen, and in many cases attended upon, the injured parties. Prior to anything out of the way in 'Shop,' I would beg to say that when I was a boy of fifteen years old, my father, who was a brushmaker, had the misfortune to cut off his little finger on the left hand (about the centre of the middle joint) with the bench knife. This he picked up off the block, placed it where it came from, and walked to a chemist's shop, where it was strapped on again. This finger adhered to its old place, but it would not work with the others after. I know it had to be opened or shut by the aid of the other hand, but I could not now say which, and I have heard my father say many times that he had better have lost it at first, as it was often in the way. Still, I hope this goes to prove that parts of limbs will take root in their old places. As regards cuts and bruises I have seen many, from simple ones on the fingers to human bodies right through; and from nips from pincers, or cracks from hammers, to men hurled yards by blows from machinery. Of course neither of the latter cases would be likely to require the aids as prescribed by your writer in 'Means, Modes, and Methods,' as in such cases generally the sufferers rarely survive many hours, sometimes minutes, but for ordinary use I can assure MEDICUS that I have used gallons of turpentine for bruises, also for cuts. I never used leeches, but have seen them used; but for hammered finger or thumb nails, I have scraped and cut the middle of the nails away to release the blood underneath, which is equal to leeches sucking it out, I should suppose; and I know from experience which thumb or finger will get well first, the one cut, or the one left with the blood to rot under the nail. At sixteen years of age I had the inside flesh of my left-hand thumb torn off to the hone, from the nail end to the first bend. This was done at play. I went home, and asked my mother for a needle and white cotton, with which I put quite twenty stitches round the piece; after which I bandaged it up in old linen, and steeped the thumb end in Friar's balsam, and the thumb is as good to-day as when I was born with it; and I do not hesitate to say that good turpentine would have done the work equally as well. I have also used it in scores of cases of bruised flesh, having been ambulance man in one works over fifteen years. I am not now connected with any firm; but in addition to turpentine would recommend Friar's balsam, and a new article termed vaseline, and sold in boxes from one penny upwards. I have found the latter article very good for cuts and bruises; in fact, it heals and eases the pain like magic. I could give other cases and cures, but hope the foregoing will convince MEDICUS that he is not quite correct, and should space he allowed me at a future date I shall be pleased to give several tips upon treatment of injury to the limbs."

An Easily-Made Fret Machine.—EAST WINDOW (*Southport*) writes:—"Would W. R. S. (see page 332) explain what he means when he says that the throw of the machine will be double the distance from centre to centre of the piece marked C? What centre does he mean? and how does he arrive at the length of the piece marked C? for if it was not the proper length, I think there would be some difficulty in the working of the machine. I am sorry to trouble W. R. S., but I have never had anything to do with treadles or machines, so am ignorant of their working. I am much obliged to W. R. S. for his plain direction in the other parts of the machine, which has long been a desideratum."

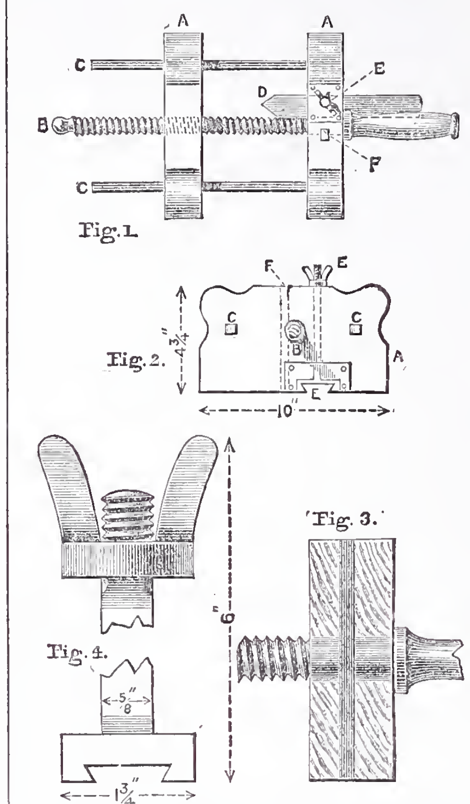
A Simple Incubator.—A. T. B. (*Walthamstow*) writes:—"Will W. L. (see page 557) kindly state what kind of lamp was used, also the degree of heat employed, and the means of ascertaining it, as no thermometer is mentioned?"

Hints to our Staff.—GNIMELF (*Dublin*) writes: —"Seeing in your issue of WORK for November 9, No. 34, a letter from W. B. (*Liverpool*) referring to writers for WORK shortening their descriptions, I beg to say that I quite agree with him. For instance, I wanted to make a camera. When I got the number it was in I was delighted, but after reading it I had quite to give up the idea of making one, as I could not understand it enough. I don't want to find fault with WORK, for I consider it the best paper I ever subscribed to, but if the writers would go into small details it would be much better. The article on Folding Stove is very vague."

A Simple Incubator.—A. R. (*Manchester*) writes:—"Will J. T. R. (see page 654) kindly answer through 'Shop' how and where does he use the lamp, and what kind? What position the drawer is, and how it opens if it has no bottom with eggs in? Has the damper to be bored through into the drawer, and what does he use for a damper?"

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Book Edge Cutting.—F. H. (*Walsall*).—There will shortly be published in these pages a series of articles on bookbinding proper, from which I hope you will learn all about "cutting edges," and not only this but everything in connection with the art. You are quite right about the plough. There is such an article, and it is used in conjunction with the press—the lying press as it is technically called. In the meantime I will give you instructions for making a plough, which I trust will be sufficiently plain. If you know anything about wood-working, I don't think it will be a very difficult task to execute. Fig. 1 shows the complete tool looking from above. Fig. 2 is a side view. The correct



Book Edge Cutting. Fig. 1.—Bookbinders' Plough looking from above. Fig. 2.—Side View. Fig. 3. —Detail of Wooden Screw, B. Fig. 4.—Enlarged View of Knife Bolt

A, A, Sides; B, Wooden screw; C, C, Square rods to act as stays; D, Steel knife; E, Knife bolt; F, Pin to keep screw in position.

sizes are given, and the letters in both figures refer to the same parts. The wood to be used should be well-seasoned beech, although for your purpose a commoner kind may be substituted, as I believe beech is difficult to procure. The two sides are made the same shape, and it is not necessary to adhere closely to the shape given in the diagram. They should be made of 1½-in. stuff, 10 in. by 4¾ in., and three holes in each—two square holes at equal distances from the ends, and a round hole in the centre; the hole in the left-hand side will require to be tapped to take the screw. The screw may be about 22 in. long, including the handle. A groove will need to be cut ¼ in. from shoulder (Fig. 3) to take a pin to keep it in its place. A square iron pin with a screw at the top, and provided with a wing nut, and a wedge-shaped piece cut out at the bottom to receive the knife, is passed up through the right-hand side (Fig. 4). On the top of the same side is an iron plate to prevent the wing nut from sinking into the wood; at the bottom also are two iron plates, against which the knife presses when the nut is tightened. The knife itself is a wedge-shaped piece of steel ground to a point at one end. To perform the operation of cutting with the plough, the book is screwed up tightly in the press, allowing the part to be cut off to be above the cheeks of the press. The plough is driven to and from the body; the screw is turned gradually until the cutting is completed. The left-hand side of the plough runs between two strips of wood screwed to the left-hand side of the press, and as the right-hand side is free to move, as the screw is turned the knife is brought over the entire edge. If you succeed in making your plough, and learn to cut books with it, you will not need to be ashamed to show your books to your friends, for edges cut with the plough are more satisfactory than those cut by the machine.—G. C.

Sanitary Inspector's Qualifications.—G. S. M. (*Hartlepool*).—The necessary information respecting qualifications, etc., for a sanitary inspector may be obtained by applying to the Secretary of the Sanitary Institute of Great Britain, 74A, Margaret Street, W.—E. S.

Making Fret Saw Machine.—JIG SAW.—I am sorry you are disappointed at this subject not having been treated yet, but everything cannot be treated at once, and there are many subjects of more general interest to the majority of readers. Let me advise you, instead of wasting the long winter nights because you have not a machine, to get one of the little fret saw frames which are worked by the hand, as you are much more likely to accomplish good work with it than with a machine of your own make under the circumstances to which you allude. Though the ambition of many fretcutters is to have a machine, I can assure you that unless it is of the best description a hand frame is better, and that for some work it is, to say the least, superior. Such thick wood cannot be cut with one as with a good machine, nor is it quite so rapid, but otherwise everything that can be done with a machine can be done with a frame. Your desire to make a machine seems to be on account of supposed saving in cost; but if you have to buy materials you would probably find that it would have been cheaper to have bought a machine. Perhaps these remarks will reconcile others who want descriptions of fret machines to absence of papers on the subject. You will find secondhand machines constantly advertised in *The Bazaar*, if you do not care to invest in a new one. It is impossible to answer your questions precisely without fuller particulars and detailed measurements of the parts you already have and intend using up.—D. A.

Watch Repairing.—PIVOT.—Your query has been sent to the proper quarter, and will doubtless soon elicit a reply. The contributor who takes charge of these special questions has been away from home on his annual holiday, and hence the reason that you are kept waiting. I have his promise that all these things shall receive immediate attention on his return. You may be sure that when an answer to a query is long in coming it is delayed for a good reason."

Matching Plane.—C. H. L.—If you will send me drawings and description of your matching plane, I shall be very pleased to look at them with the view to publish them. It would also be useful if you could let me have a look at your plane. It shall be quickly returned to you after I have examined and tested it.

Gilding and Mount Cutting.—J. A. McL. (*Glasgow*).—An article on mount cutting is in preparation. Gilding in all its branches will also be taken in hand shortly by a practical man.

Photo-Zinco Process.—PRINTER (*Edinburgh*). —The processes employed to obtain zinc relief blocks are varied, and some of them are secrets religiously kept by their proprietors. There are, however, two methods which any one is at liberty to experiment upon, if means and capabilities are agreeable, and I will briefly describe them. First, a drawing upon lithographic stone may be transferred upon a polished zinc plate, and afterwards etched by immersion in a bath of acid; secondly, a drawing or a print to be reproduced, if its detail be expressed by lines or dots, may be photographically rendered upon zinc which has been sensitised with bichromate coating (albumen or gelatine as the case may be), but the operator must use a rectilinear lens. The zinc is then treated thus:—A roller charged with litho ink is passed entirely over the surface, leaving behind a layer of ink, the thinness of which will be determined by experience only. The picture is developed by placing the plate in a vessel containing sufficient water to cover it, and while immersed gently clearing away with a dabber of cotton wool the coating which has not been affected by light. The plate is then fanned dry, and asphaltum powder is brushed over it, so as to adhere to all parts of the work; gently warming the plate, now causes the ink and asphaltum to unite. The biting away or etching in either case is managed somewhat after this fashion. The zinc plate with the subject upon it is covered with a protective agent capable of resisting the action of acid, and protecting the places where it is desirable, such as the back, edges, and large whites. The plate is then immersed in an acid—that is, a solvent of zinc, diluted, and a see-saw motion is given to the trough in which the bath is prepared. This rocking enables the acid to do its work more thoroughly than were it allowed to corrode the zinc gradually. This description is necessarily rough, but no doubt the book on "Zincography," published by Wyman, Great Queen Street, Lincoln's Inn Fields, will give information at greater length.—J. H. M.

Enlarging Camera.—MERVEILLEUX (*Peckham*).—Your sketch of the front of enlarging camera is quite correct, and shows that you have thoroughly grasped the details of construction. The inner box is movable, and slides out and in, for this reason, that the greater the size to which you enlarge the nearer must be the lens to the negative, while for small enlargements the distance has to be increased. If the box, therefore, were a fixture, as you seem to suppose, you could only enlarge to one given size, while, by moving it, you can make your picture any size up to 12½ in. by 10½ in. The lens you have will do very well for the purpose of enlarging, but you are in error in supposing it has only one "glass;" it has in reality two, which are cemented together, and so appear as one. As to your query as to the length of the baseboard, the fact that you only use quarter-plate negatives ll not affect its length, as that is regulated by the ;e of the enlargement, not the negative, so that you wish to have your pictures the full size that c camera is capable of making, the baseboard ust be kept to the size given. In No. 23 of WORK, page 360, you will find a method given for the aking of a camera bellows of a tapered form. ou should not use leather, as it is very expensive such a large size as you require; stout brown aper with black calico well glued down on each de makes a very good bellows, and possesses the ıerit of being easier to manipulate. If you decide n making a square bellows, you had better make rough box the size of the inside of the folds, and ork them over it, letting the glue dry thoroughly, nd then removing the box, which is simply to erve as a block to work upon while folding. hould you meet with any other difficulties I will e glad to smooth them away for you if in my ower, and as I reside near your locality could give ou a call, and a verbal explanation, if you comnunicate with me through the Editor.—G. LE B.

Batteries. — H. L. D. (*Heaton Norris*). — In ınswer to our querist, I am afraid he is rather ıazy about electricity and its terms. I suppose ›y what he terms penetrating power, he means the ›urrent in ampères. This depends upon the resistınce of the cells and the E.M.F. (electro-motive 'orce). A small bichromate cell such as he menions has an E.M.F. of 2·0 volts and 0·8 ohm inernal resistance, so that with 50 such cells in series ıe would have by Ohm's law:—

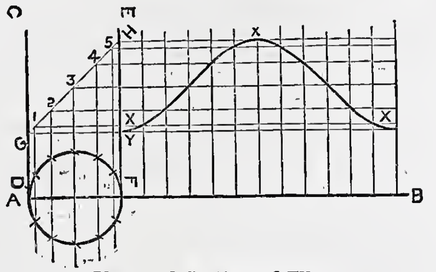
$$\frac{2{\cdot}0 \times 50}{0{\cdot}8 \times 50} = \frac{100}{40} = 2{\cdot}5 \text{ ampères}.$$

To measure this resistance he would need a resistance box and differential galvanometer, which I fancy our querist is not provided with; and another thing, even if he were, I very much question from the tone of his query whether he has the essential electrical knowledge that is required for all electrical measurements. If he has, however, the instruments, and thinks he can manage "Ohm's calculations," and likes to write again, I will advise him. Another thing that leads me to suspect our querist's knowledge of batteries lies in the fact of his using the bichromate cell for medical purposes. This is a bad thing from two points of view:—(1) That with the number of cells he has (especially in series) he is using a dangerous current, if using it on the human frame; and (2) the cell only gives a current from three to four hours, when it requires recharging. The cell that is recognised by electricians for medical purposes is the medical Leclanché. This consists of an outer cell of glass or ebonite, containing elements of a zinc plate, and a small carbon block. The zinc is wrapped round with a layer of canvas or flannel; these elements are placed in the cell, and are surrounded with a mixture of equal parts of small broken carbon and manganese. This is tightly packed in the cell, and thoroughly saturated with a strong solution of sal-ammoniac. This cell will give a current for five minutes, and then will require a little rest (to revive itself) and it is again ready for use. It is this cell that is always used for medical purposes, and so I should certainly advise our querist to change his bichromate cells for these. These cells are good for four or six months' work, and so it will clearly be noticed that it is a rather large step in advance of his now costly cells. Any further information I shall be very pleased to give.—F. W. M.

Paint for Glass Writing.—F. P. (*Bolton*).—Thanks for your letter; you may rest assured that our Editor is determined to make WORK the technical paper for all workers. "Rome wasn't built in a day!" you know. Scene painting will be, doubtless, taken in time; but it is a subject that requires some knowledge of painters' pigments and processes on the part of the student, to attain to any practical success. You are, therefore, advised to thoroughly master the papers on house painting, and these will prepare you for the other subject. We can't have "all paint" at once, you know. As to glass writing:—Mix your pigment or white lead, according to desired colour, with good copal oil varnish. Quick-drying varnish would be too brittle. Ordinary oil paint would take too long to harden right through, and there is a non-absorbent surface to consider. Carriage varnish will do. Keep your pencil free by rinsing in turps occasionally. Back your glass writing with varnish colour made in the same way, and give two thin coats in preference to one thick coat.—F. P.

Books on Photography.—AMATEUR had better purchase Burton's "Modern Photography," or T. C. Hepworth's "Photography for Amateurs" (Cassell and Co.), which will afford him all the information he will require as to the practice of the art; anything else is a matter of experience. With regard to the appliances necessary they are few, and may be thus enumerated:—Camera with dark slide, lens, tripod, developing dishes, measures, washing-pan, magnifier, and focussing cloth, dry plates, and chemicals for developing and fixing, varnish, printing frames, sensitised paper, and toning bath. As to how these are to be used, information will be obtained by carefully reading Burton's work. If AMATEUR gets into any difficulty after this, if he will communicate his trouble to WORK, I shall be pleased to help him along.—D.

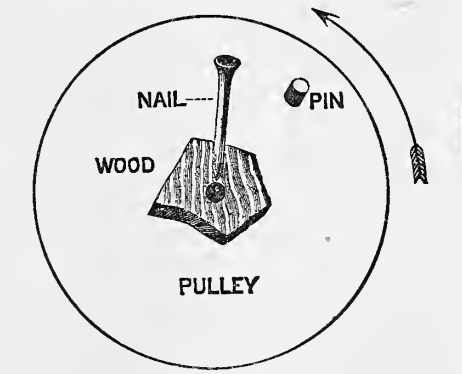
Iron Stove Pipes.—AN IMPROVER (*Arundel*).—To set out elbows in sheet iron, etc., proceed as under:—Take the piece of metal that is to form the pattern, and at the left-hand end of it describe a circle equal to the diameter of the pipe. Have the stuff long enough. Say you are cutting the pattern of a 4-in. elbow ordinary right angle or 90 degrees, cut the stuff 18 in. by 12 in. Having described the circle, draw a straight line, A B, through the centre of it. Next divide the circle into twelve parts; erect the two perpendicular lines, C D and E F, also the lines 1, 2, 3, 4, 5, cutting the divisions of the circle. Then set a bevel to half the angle required —in this case it will be 45 degrees, being half of 90 degrees—and draw the diagonal line, G H. Now along the line, A B, commencing from line, E F, set off the length required for the circumference of the pipe in twelve parts. For 4-in. pipe this will be 12⅝. Now draw twelve lines perpendicular to A B. Now



Plan and Section of Elbow.

from each point where the diagonal line, G H, cuts the lines, C, D, E, F, and 1, 2, 3, 4, 5, draw lines parallel with A B. Draw a curved line, X X X, starting from the point Y, and going from corner to corner. This gives the correct pattern; allow ⅜ in. each side for seam. Any angle can be set out like this, bearing in mind that the angle, G H F, must be half what you want the finished elbow. I hope this will be plain enough for you to understand. I think you will if you read it carefully and work it out two or three times. There are several other ways of getting these patterns, but I think this is about the best. I shall, however, have something to say about them when I arrive at that part in sheet metal work. To draw pipes in so that one length will fit the other is termed "tucking," and is done as follows:—After you have finished grooving the seam, draw the length of pipe nearly off the mandrel, and taking a thick pane hammer draw the end of the pipe in by lowering the left hand, that is holding the pipe, so that the other end is slightly raised from the tool; work right round the pipe with the hammer, taking care not to get solid blows on the tool, or you will stretch the pipe instead of making it smaller. When you have got round you will have made a kind of groove round the pipe. Now work round and round, gradually coming nearer to the edge, and working the puckers out. Strike with a kind of drawing motion, and finish off smooth with a mallet. Tin spouts, such as beer-can, tea-kettle, etc., are first turned straight, then filled with lead and bent, and the metal run out again. It is not worth your while to do them as they are so cheap, unless of course for any special job.—R. A.

Home-Made Lathe. — A READER (*Newcastle-under-Lyme*).—The wood is not driven by the bush of the cone pulley, but is simply put between the centres of the lathe. If now a screw or nail be driven into the end of the wood near the fixed headstock long enough to engage the pin mentioned in



Home-made Lathe.

your query, you will find that when the pulley is revolved it will bring the pin into contact with the nail or screw, and thus cause the wood to revolve likewise. In practice a carrier is generally employed instead of the nail or screw. In the end view annexed, when the pulley revolves as indicated by the arrow, it will bring the pin into contact with the nail, and cause the wood to revolve.—SELF-HELPER.

Microscope.—B. L. H. (*Glasgow*) has a microscope the power of which he wishes to increase, and asks how it can be done. I may say there are three ways of increasing the power: (1) By increasing the length of the power tube—this mode I should not advise; (2) by increasing the power of the eye piece — there are three powers often made and marked A, B, C; and (3) by changing the object glass. B. L. H. has a triplet which magnifies according to his measurement, 1—80, 2—100, 3—135, and he wishes to know, can the power be raised to 400 diameter? Certainly with the requisite O.G.; what that power should be it is impossible for me to say, as I do not know the magnifying power of the eye piece. What I would recommend B. L. H. to do is to send the microscope to an optician, and ask the cost. Mr. Lancaster, of Birmingham, would give him the information, I have no doubt. But before doing so, I would like to point out an important question or two. B. L. H. speaks of his instrument as a small microscope. It is for him to consider whether the other parts of the instrument than the power tube are good enough to spend much money on. Many amateurs forget that really the most important parts of a microscope are the stand and focussing arrangement; if these are all right, then higher powers can be added when one has the money. But to spend some pounds on a high power O.G. on a stand which is not perfectly steady, or where the focussing arrangement is not perfectly smooth and free from tremor, is simply a waste of money. Before I could advise any one to purchase high powers I should want to know the make of the instrument, as it seems to me that the powers attached are as high as could be used with advantage. B. L. H. asks, would an inch O.G. be suitable? Here we are on surer ground, and can answer in the affirmative. As a rule high powers are of little use to beginners, simply because they show but a small portion of an object at a time, whilst a low power, as an inch or 2 in., will take in a considerable field of view. But here, again, I cannot tell how much an inch would magnify, as that depends on the eye piece. Shall be glad to give further information, if possible, through "Shop."—O. B.

Lantern Slides.—G. B. says he has a lantern but no slides, and he wishes to know the cheapest way to procure some. By this and the statement made that he has some knowledge of photography, I presume he proposes to make his own. Beautiful and effective slides can be produced by copying—photographically—good wood engravings. As there are so many beautifully illustrated books and magazines now, there is no want of subjects. G. B. also asks where to get transfers for slides. I may say Mr. Lancaster, Optician, Birmingham, supplies the very thing. Personally, I can say nothing of them, as I have not seen them, but from what I know of Mr. L.—and I have had dealings with him many times—I am confident one would get their money's worth from him. The next and best plan of all is to paint slides. If there is a desire for the subject to be discussed, I shall, at the Editor's request, prepare a series of lessons on slide painting in oils and water.—O. B.

Bright Parts of Tricycles.—F. W. R. (*Harling*).—Coat them with some transparent enamel, of which several equally good kinds are sold for the purpose of preserving bright steel from rust.—D. A.

Twine Makers.—A. S. C. Y.—I am quite unfamiliar with the thing you ask for—viz., "a Cromer twin spinner," and I cannot find any one who knows what it is. At a venture I reply to your question. It may possibly refer to Macramé twine, of which you wish to know the name of a manufacturer. Write to Boardman Bros., Sharp Street Mills, Rochdale Road, Manchester; but if you only want a small quantity get it through some dealer in your own locality. If, instead of telling us you are "a constant reader of WORK," you had put your address, I might have been able to give you the name of some one in your own neighbourhood.—D. A.

Music Turnover.—EUGENE (*Castlejohn*).—There are several contrivances for turning over the leaves of music while playing, but I believe none of them have met with general acceptance. They are more of the nature of "fads" than of practical utility. The best forms are patented, so that you would be precluded from making and using. You may make a simple one with pieces of wire loosely hung at the top. Put a wire between the leaves you wish to turn over, the wire being sufficiently long to be caught at the lower end. With this or any other arrangement for the same purpose, you will be able to turn the music over nearly as quickly and conveniently as by the ordinary plan. To emboss headings to note paper, etc., you require a steel die, or rather, two of them, one having raised letters, etc., and the other sunk. These are fitted to a convenient press actuated by lever. The paper is put in between the dies, which are forced together, and the embossed imprint is formed. This, I think, will be intelligible to you without a sketch, and show you that the work, so far as the formation of the dies is concerned, is beyond your powers.—D. A.

Battery for Electric Light.—W. D. (*Blackfriars*).—The Bunsen battery is the strongest and most lasting for the electric light, but it gives a good deal of trouble in setting up and cleaning, and it gives off noxious nitrous fumes whilst working. If the same porous cells are charged with a solution of chromic acid instead of nitric acid, we get the next best battery, stronger at first but not so lasting in action. The whole subject of electric lighting in a small way is being dealt with in a series of articles now preparing for WORK.—G. E. B.

Electric Light for Photographic Dark Room.—F. D.—Respecting a former reply on this subject on page 445—both zinc plates and carbon plates should be of the size therein mentioned. The battery does not give off offensive fumes if charged with the solution of chromic acid. Of course, there is a certain acid odour about the apparatus, but that is not considered objectionable. Am glad you find WORK the paper you wanted.—G. E. B.

Bicycle Purchasing.—A WELL-WISHER (*Forest Hill*).—A WELL-WISHER would certainly find it cheaper to buy an ordinary bicycle finished ready for using, than to buy the parts ready for putting together. He gives no indication of the quality of the machine he wants. New ordinaries can be had from £4 10s. up to about £18. If he wants a cheap machine, and at the same time good value, he will get it from L. Deney, Berwick, from £4 10s. to £10. If he wants a tip-top, let him apply to Rudge, Singer, Bayliss and Thomas, or the Humber people, at prices from £15 to £18. There is no *best* maker; there are many of them, and to buy the parts finished of one of the best makers, fit them together, then get the machine enamelled and plated, would be costly, unsatisfactory, and altogether a mistake.—A. S.

Bending Wood Lawn-Tennis Racquets.—AMATEUR CARPENTER.—The wood used is English ash, and is boiled in a long tube or pipe for an hour and a half, when it is sufficiently pliable to be bent round a mould shaped like the inside of a racquet.—C. T. S.

Slate Mantelpiece.—OLD TIPTONIAN (*Tipton*).—The proper way, of course, is to enamel your mantelpiece, which, without proper appliances, you could not manage yourself. Failing this, you might certainly try the effect of one of the enamel paints; although it is not clear whether you simply want to touch up the mantelpiece here and there, or to go all over it.—D. A.

Music Canterbury.—A. T. F. (*Dover*).—Two novel and tasteful designs for a music canterbury or whatnot will shortly appear in WORK.

Knife Cleaner.—A. D. (*Wath-on-Dearne*).—Buff leather will be best, but almost any that is not too hard will do. Ordinary good sheet indiarubber. As for the rest of your suggestions, "Yes" will be sufficient answer. I am afraid you will find the job you contemplate is rather a difficult one.—D. A.

Worm in Furniture, etc.—P. H. C. (*Croydon*).—When once wood is attacked by parasites it is extremely difficult, if not impossible, to effect a radical cure. You may stop further ravages for a time, but sooner or later the "worms" will appear again in all probability. Benzoline is the best thing to use. Wash this freely into the infested parts. It will destroy existing worms. Of course you must not use the benzoline near a fire, as the vapour is exceedingly inflammable. To gild picture frames use the ordinary leaf gold as prepared for gilders' purposes. If an imitation will do use Dutch metal, which is got up and sold in similar form, or else a bronze powder mixed with varnish. Quite impossible to answer questions in our next issue after their receipt.—D. A.

Glaze.—F. W. R. (*Harling*).—Glaze is easily made by dissolving gum benzoin in methylated spirits. Proportions may vary, but a good general rule is to mix equal quantities—*i.e.*, half fill a bottle with the crushed benzoin, and fill up with spirit. You will require to strain the mixture before using. It is used to finish French polished wood instead of "spiriting off," to which it cannot be compared for durability of surface. By glazing, the polish or gloss is got quickly and without difficulty, but it is not to be compared with the legitimate method of finishing. It would be useless for you to apply glaze to bare wood, or over a varnished surface.—D. A.

Reviving Morocco.—F. W. R. (*Harling*).—Morocco seats may be freshened up by going over them lightly with a little thin French polish. Do not saturate the leather, and unless you are careful you will do more harm than good. Worn parts must be touched up with a little colour. White of egg is sometimes recommended as a reviver. It may be more convenient for you, but I have never used it personally.—D. A.

Stain for Light Wood.—F. W. R. (*Harling*).—Bismarck brown, mixed with warm water, makes a mahogany stain. A decoction of logwood chips will do the same. The nearest approach to a good rich mahogany, and not offensively red in colour, may be got by using a little weak walnut stain, composed of Vandyke brown, liquid ammonia and water to colour the wood, and then polishing it in the usual manner with red polish. This you can make yourself with ordinary French polish and a little Bismarck brown.—D. A.

Arms of Towns.—F. C. S. W. (*Birmingham*).—In Burke's "General Armoury" are verbal blazons of the arms of British towns and bodies corporate. The tinctures are, of course, given, so that any one who understands heraldic terms and heraldic painting will have in it all that he requires. The book may be found in most good libraries, or any bookseller will know and can get it. With any work containing coloured plates of the arms of all our towns we are not acquainted. A work of that nature, if produced with such care and exactness as to be of authority, must, from its nature, be very expensive.—M. M.

Outlines in Perspective.—R. Y. (*Norwich*).—There have been several inventions with the object of drawing correctly outlines in perspective, but we do not know of any which have been thoroughly practical and successful in working. It is beyond our province to compare the merits of one invention with another, having regard to their patent rights. If you give particulars of your invention to several firms you run the risk of having your ideas pirated, and it would be difficult for you to prove that your invention had been stolen. It is unwise to explain matters that have not received any protection. The most satisfactory way would be to search the records of the Patent Office, to ascertain if your idea has been anticipated. The Patent Office Library is open from 10 a.m. to 10 p.m., and is situated at 25, Southampton Buildings, Chancery Lane, London, W.C.—R. and C.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Adjusting a Compound Lathe Rest for Taper Turning.—IRON TURNER (*Bolton*) writes in answer to A READER (see page 382):—"I suppose A READER will have a mark on the base of his rest, to show when it is set right for parallel turning. Now, READER, take a pair of callipers, and get the diameter of the base of your rest, take half that diameter, and you have the radius. Rule—multiply one-half the taper required by the radius of the base of rest, and divide the result by the length of the taper part. Example—a piston rod end requires turning taper for crosshead to fit. Length of taper part, 8 in.; the two diameters, $2\frac{1}{2}$ and 3 in.: supposed radius of base of rest, 6 in. Now, by the above rule, one-half of taper $= \frac{1}{4} \times \frac{6}{1} = \frac{6}{4}$ and $\frac{6}{4}$ divided by $8 =$ length of taper part $= \frac{6}{4} \times \frac{1}{8} = \frac{6}{32}$ or $\frac{3}{16}$ of an inch distance to move rest. Take up this distance with a pair of compasses, place one compass leg on the mark on your rest for setting it parallel (your rest being set for parallel turning), and mark a faint line with other compass leg on the base of the rest. Move rest round until your centre mark coincides with this line, and your rest will be right for the taper you require, but remember whether by this or any other method, everything must be mathematically correct, otherwise you will not get your taper absolutely correct."

Machine for Current of Air.—J. A. P. (*Accrington*) writes:—"In looking through 'Shop,' I have noticed several replies to BELLOWS (see page 190). The fans sent have been out of shape and proportion in my mind. One with the wings bent the wrong way; and the one in No. 35, page 557, would blow very little, as the pulley on the fan is too big, and the driving wheel too small. It is made left-handed, and the hole in the pipe is not large enough. You cannot force a fan like you can bellows. It wants more play, as you will see by looking at Fig. 1. The pipe being much larger, the

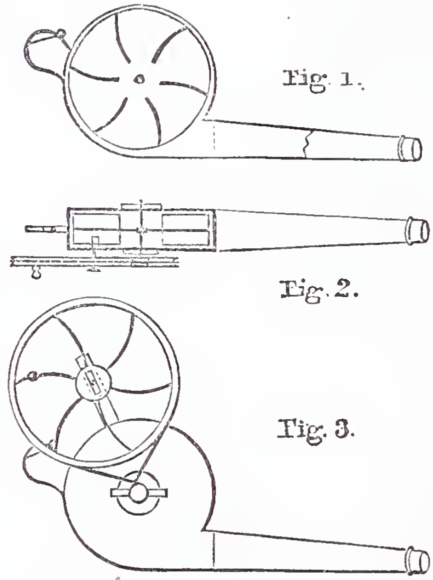


Fig. 1.

Fig. 2.

Fig. 3.

Machine for Current of Air.

spider should not run close to the case all the way round, but as marked in Fig. 1. Now as to making it. Do not use wood, as it dries in more one way than another, and I know cardboard is useless, as both have been tried many a time, and do not pay for the time in making. If they are worth making, make them well. I find tin to be best for these small fans. This is the handiest size that I know of. Fan 6 in. diameter, pipe 14 in. long, $2\frac{1}{4}$ in. square at fan, and $1\frac{1}{2}$ in. at end. Driving wheel 7 in. diameter fully on spindle, $\frac{3}{4}$ in. groove. If you have followed WORK up in soldering, and other things, BELLOWS should be able to make this."

Colouring Photographs.—S. H. C. (*Penzance*) writes in reply to EXPECTANT (see page 174):—"EXPECTANT finds difficulty of making water colour stick on the photo. If he would lick the photo over before painting, the saliva would render the surface fit to hold colour. There are preparations sold to work with, but I find the spittle best and handiest, if I may so apply the word. Gum arabic and water is a medium."

Trade Notes and Memoranda.

THE attempt which one of our great English railways is making on a small scale to use petroleum as fuel is being practically made in Russia on a large scale. All the steamboats in the Caspian Seas are using naphtha residuum and oil as the fuel. In Moscow, the factories are also taking to it; and on the Volga steamboats are beginning to use it. Cheap petroleum for some purposes may check the advance in the price of coal.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

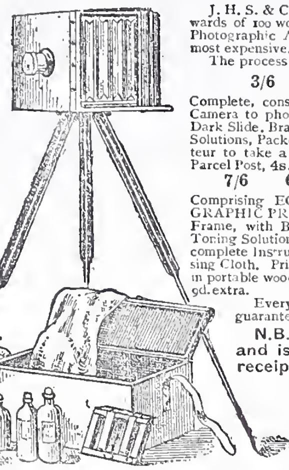
J. H. SKINNER & CO., EAST DEREHAM, NORFOLK,

Manufacturers and Importers of Photographic Apparatus and Fretwork Materials.



J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.

The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price 3s. 6d., or securely packed by Parcel Post, 4s.

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price 7s. 6d. Securely packed, post free, 8s. 6d. If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. **J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.**

Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

Catalogue of Machines, Designs, Wood, Tools, &c., with several Hundred Illustrations, and full Instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. Good Fret Saws, 1s 6d. per gross; best ditto 2s. per gross.

Eclipse Design, No. 102.

Wall Bracket. Price 5d.

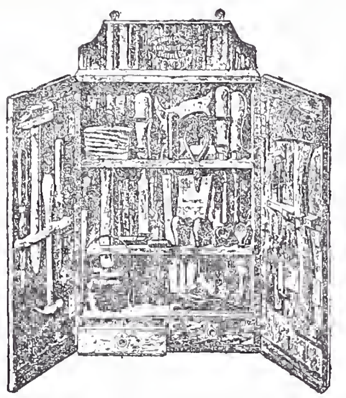
TOOLS.

BUY from the MAKERS, the Oldest Established and the Best House in London. Stock kept for Carpenters, Wood Carvers, Turners, Fretworkers, Amateurs, and Mechanics.

WRITE FOR PRICES OF WHAT YOU WANT.

OBSERVE THE FOLLOWING **GENTLEMAN'S** *Registered* **TOOL CABINET,** PRICE £2 2s. each.

Size, 21 in. high by 14 in. wide, made of Polished Oak, with Two Drawers, and with Lock and Key, and with two Loops to fasten it to a wall.



The above is a strong, well-made Cabinet of polished Oak, and every tool is full size, serviceable, and warranted. The contents comprise such tools as are usually required for repairs, &c., in a household, and the investment of its small cost will soon be saved by the work done with them.

IT **CONTAINS TOOLS** AS FOLLOWS:—

Mallet, Chisel, Gouge, Axe, Two Hammers, Saw, Three Files, Two Turnscrews, Square, Claw Wrench, Pliers, Two Gimlets, Two Bradawls, Pincers, Glue Pot and Brush, Plane, Compasses, Nails & Screws.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

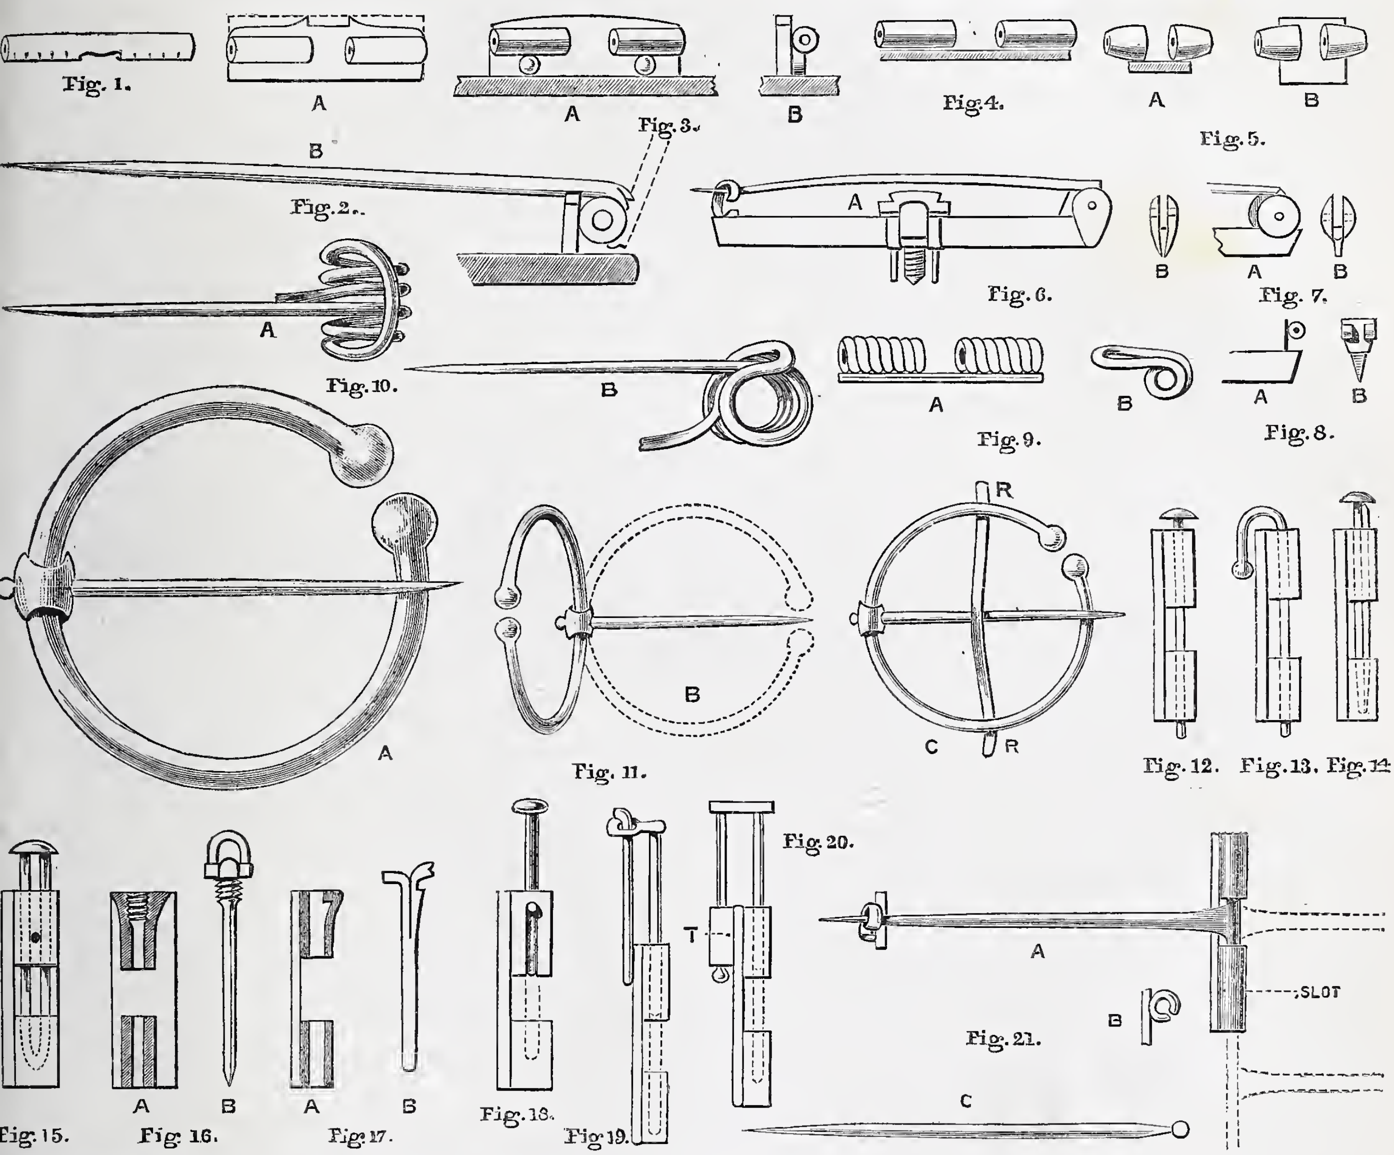
WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 46.] SATURDAY, FEBRUARY 1, 1890. [Price One Penny.



BROOCH JOINTS. Fig. 1.—Piece of Joint Chenier prepared for soldering on. Fig. 2.—A, Chenier soldered on and Centre Piece cut away ready to fit Tongue; B, Height Joint should be raised; also by Dotted Lines Convenient Distance for Tongue to turn back. Fig. 3.—Method of supporting Side Knuckles by Grain of Gold; B, ditto by means of Bar. Fig. 4.—Joint without Fly-up Plate. Fig. 5.—French or Barleycorn Joint. Fig. 6.—A, Side View of Ball-Joint made from Flat Plates, a Strong Form of Narrow Joint; B, End View of same. Fig. 7.—Ditto, but made from Grain of Gold with Centre cut away; B, End View. Fig. 8.—Weak and Bad Form of Narrow Joint—A, Side View; B, End View. Fig. 9.—A, Etruscan Joint formed from Coiled and Soldered Wire; B, Another Form of ditto formed from Wire. Fig. 10.—A, Top View of Antique Brooch Joint in British Museum; B, Side View of same. Fig. 11.—A, Type of Celtic Brooch-fastening without Catch; B, Showing by Solid Lines the Position for Insertion, and by Dotted Lines the First Move towards Fastening, *i.e.*, Point between the Ends; C, Position of Tongue when fastened: the Rod, R R, indicates way Material acts in securing Brooch. Figs. 12, 13, 14.—Joint with Simple Removable Joint-Pins. Fig. 15.—Joint with Pin that allows of Partial withdrawal. Fig. 16.—A, Section of Joint to take B, a Screw Joint-Pin. Fig. 17.—A, Section of Joint to take B, a Spring Joint-Pin. Fig. 18.—Another Form of Joint where Pin can only be partly withdrawn. Fig. 19.—Another Form of Joint acting on a Guiding-Bar. Fig. 20.—Another Form of Joint acting through a Tube. Fig. 21.—General View of Removable Tongue in Position: Dotted Lines show course of Removal or Insertion; A, Shows Position of Slot: B, Side View of Open (Lower) Knuckles; C, Side View of Tongue showing how it is thinned down to pass along Slot where soldered to the Joint-Pin.

THE BROOCH: HOW TO MAKE IT.

BY H. S. GOLDSMITH.

THE JOINTS OF BROOCHES.

THE joints of brooches are so evidently the next in order to tongues of brooches, that no reasons are wanted to explain the why and the wherefore of this paper coming next.

We shall have to see that they are made strong enough for a fair amount of wear, and that they are suitable to the size of the brooch, and in keeping with the character of the ornament.

We will first take up the most common form: *viz.*, those with the fly-up plate soldered to the joint for the tongue to obtain its spring from, for which tongues such as Fig. 5, A to D, in the previous paper, are suitable. Then those without the fly-up plate, for which the tongues, E, F, and G, are used.

Finally, the form of joint where the tongue is removable at pleasure.

Before we begin this matter, I particularly wish to call attention to the possible results of an unsoldered joint. It may cause a great amount of trouble and expense if it be not noticed before the work is finished, for I know—and if you do not know now, you will later on, to your own cost, too, I hope — that to reset and to polish and colour work a second time is running a great risk of the work not finishing, besides the loss of time and the delay in the delivery of the work to the customer, all of which can be prevented by a little care and attention on the part of the workman.

Now, to make the joint of a brooch we want a piece of chenier of suitable length and thickness, from the centre of which a portion has been cut away—of less than one-third in length, and only half-way through for the present, like Fig. 1. Then tie it on a plate of fair thickness, Fig. 2 A and B (I should say certainly not less than size 8; Shakespeare Guage 10 or 12 would be better), and solder it with the joining or soldering seam in actual contact with the plate, in order to get it firmly and soundly soldered: I mean so soldered that it cannot come open any more. The next thing to do is to remove the other half of the centre piece, and to fit the tongue in between these two knuckles or side pieces of the joint, and let it be fitted properly. If you want a pattern for your fitting, look at the hinge of the nearest door, and you will probably find that great affair fitted better than many tongues are, particularly in job work. Now, as our work is of a much finer and more delicate kind than that of a hinge maker, I trust that you will do your jointing as it should be done; it only wants a little care and practice—but it wants them both to turn out a properly made joint.

The other way of making a joint, by soldering each knuckle on separately, is rarely used for single brooches, and as that method more properly belongs to the joints of lockets and boxes, we will deal with that when we come to those particular articles.

We have now to solder the joint on to the brooch. But how? Some jewellers have the chenier fitting close down on to the brooch and soldered to it; but I prefer slightly raising it, as Fig. 2 A and B, Fig. 3 A and B, in order to let the tongue come back rather more than a right angle, which we cannot do without weakening the tongue, if the chenier be soldered close to the back of the brooch. Fig. 2 gives about the proportion of height required, and the dotted lines show the distance or angle to which the tongue should be able to move. If you raise the joint as advised, and you have made your fly-up plate too weak, you will have to support the side knuckles with grains, like Fig. 3 A, or a bar, like Fig. 3 B; but you ought not to require either.

You will, of course, file up the fly-up plate—something like Fig. 2 A or Fig. 3 A will do, or any other shape that you may prefer, providing that it is not liable to catch in lace that a lady might wish to wear with it.

We will suppose that the joint is soldered in its place (I will tell you about the place later on, when I summarise the first three papers on tongues, joints, and catches), and the tongue fitted. Now we will regulate the hole with a joint-brooch, and from the proper end, if you please. I don't suppose half the trade have thought about there being a proper end to put a joint-pin in—well, there is; and it is from the top end, and this is why—if it works loose, then it will work upwards, and may be noticed and replaced, while if it works loose after being inserted at the lower knuckle first, it will naturally work downwards and drop out; then the brooch will fall away, and either get damaged or lost. I can tell you that it is but a week ago that my firm gained a most valuable customer through this very defect on another firm's part, by which a diamond brooch was nearly lost.

The joint-pin itself should be of hard wire (metal or gold-wire I mean, not hard steel); it should taper gradually, if at all, and be finished with a smooth file; it should bind on the two outside knuckles so as not to rotate when the tongue moves; it should also be tight enough to keep the tongue perfectly steady, and on no account to let it wobble up and down, and from side to side anyhow; in short, it should *fit*.

We may as well finish with the joint-pin here, although in practice it is the last thing we have to do before the work is sent home.

I have been taught that a joint-pin, if properly made and fitted, should stay in its place by itself, and it undoubtedly should in most cases; but with brooches I slightly rivet the ends of the joint-pin over—it gives so much extra security, and when carefully done, neither the brooch nor joint is touched or damaged. Mind, this riveting is in addition to a properly fitted joint-pin, and is not to be used in place of one fitted anyhow.

If the joint is not to have a fly-up plate, as Fig. 4 and Fig. 5 A, we prepare the chenier in the same way as before—that is, with part cut away from the centre—and proceed to solder it on the back of the brooch, or on a plate like Fig. 4 and Fig. 5 A; then we cut the remaining half of centre away as before, and fit the tongue. The tongues for this class of joint have to be made like Fig. 5, E, F, and G, in the previous paper, in order to obtain the requisite spring, which in the previous case we got from the fly-up plate.

The diagrams, Figs. 5, 6, 7, 8 and 9, give a few different forms of these classes; there is the Barleycorn, Fig. 5 A and B, made from thick chenier, and is filed into the shape it has. It is mostly used on French jewellery.

The ball-joint, Fig. 6 and Fig. 7, is the form usually found in the fittings for diamond work. It is either made from two pieces of thick gold, like Fig. 6 A and B, or else a grain of gold is melted, and the centre is cut out on Fig. 7 A and B, to take the tongue—which in these cases is formed with a flat plate instead of chenier — and the whole is drilled through together to take the joint-pin. Either way, we get an improvement on Fig. 8 A and B, with its weak knuckles; but Fig. 6 is decidedly the better of the two, inasmuch as each knuckle can be well and securely soldered to the side of the brooch mount.

Fig. 9 A is a joint whose chenier is made out of a coil of rings soldered together; it is sometimes called Etruscan.

It is undoubtedly one of the best, if not the very best, we can have—there is no danger of a soldering seam opening here, for the excellent reason that there is none to open. This is even stronger than the chenier without a soldering seam that has been introduced into the trade, for that might split if there were a flaw in the gold, while all the flaws would have shown themselves in drawing down the wire, and have caused it to break where they were, long before we had reduced our wire to the small size required for this work.

Fig. 9 B is another form of joint, used in the modern Etruscan or Roman gold work; it is made from one piece of wire, as I think the diagram clearly shows. One tongue for this is Fig 5 K, in the paper that precedes this. Generally a piece of tube takes the place of the joint-pin, and it is chamfered or burred over, so there is no fear of that dropping the tongue out. It is also worth noting as one of the narrow and strong class of joints.

The coiled wire that takes the place of a joint in a safety-pin brooch is much the same in all of them, except that we get three turns instead of two occasionally. You will see, by referring to Fig. 10 A and B, and Fig. 6 in the paper on Catches (both Fig. 6 and Fig. 10 being drawings of ancient brooches now in the British Museum), that this method of doing away with a joint is not in any way a new idea. Fig. 10 particularly has a very clever way of obtaining the spring, with the minimum risk of breaking the tongue short off, which sometimes happens to the safety-pin brooches, now so much worn. In this case, and in the type of brooch indicated by Fig. 11, no attempt is made to hide the means of fastening, as we always do, nowadays: in fact, the aim of these ancient jewellers undoubtedly was to turn a necessary part of the construction into an ornament, which is, I am told, the artistic way—and it can hardly be disputed, either—in these two cases, at any rate.

Do my young readers know how Fig. 11 is fastened? for it has no catch, as we generally understand the word, and the joint into which the tongue is soldered travels easily round the rim from end to end. What prevents it falling out? you may reasonably ask. The answer is the shawl, or whatever it fastens. That looks like a bull—and as this type of brooch chiefly comes from Ireland, a bull is surely admissible here, if at all—but it is a fact, nevertheless. First we will put the tongue through the shawl, etc., Fig. 11 B; then place the point between the ends shown by dotted lines, and bring it on to the top or front of the rim, like Fig. 11 A and C, and slide it round a little way, or a long way, just as you like, and that is all. We shall find that the shawl, etc., is acting in the way shown in the diagram, Fig. 11 C, by the rod, R R; and it is a good secure hold too, but it is only suitable for large brooches that have to fasten shawls and plaids, or such-like heavy woollen articles.

We will now have a few words on joints that allow of the temporary removal of the tongue, for this is often required in valuable ornaments that have to do duty for several articles, forming either brooch, pendant, or locket, bracelet-centre, hair-pin, etc., at the pleasure of the owner. Of course, joints and catches are made to remove altogether; however, at this early stage of my papers I do not think I will go into details, but will do so when I come to the fittings for diamond work, about which there will be plenty to say, and to illustrate.

In the meantime here are a few methods of getting rid of the sharp tongue, for no lady in evening dress could wear an ornament as a pendant, and have the point continually scratching her. And if the point were covered up by a protective catch, after the manner of Italian mounts for Mosaic work, there still remains all the brooch fittings to prevent the pendant or locket resting steadily and close to the figure; besides, as it is not wanted it is best away, so take your choice of doing it from what follows, or evolve something yourself which will be better practice for you, only using these as hints.

The simplest way of all is by making the joint-pin to take in and out; so just solder a top on like Fig. 12 or Fig. 13, and do not forget all these easily-fitting pins are to be inserted from the *top* end of the joint.

Fig. 14 is a split joint-pin, made out of two half-round pieces of wire soldered together at the two ends; this can be made to spring apart just a little, and so give some sort of a hold.

Fig. 15 is much the same, but it has a peg inserted and soldered to the knuckle; this allows of only the partial withdrawal of the joint-pin, and prevents its loss. It is a way much used to fasten Indian bracelets, for which it is much more suitable, as the size chenier required would look clumsy on a brooch; but as it can be used sometimes, I give it here.

Fig. 16 A has the top knuckle enlarged, and a plate or ring soldered in to take a screw. The joint-pin, Fig. 16 B, is made like the sketch, and generally with a fall-down handle, but that will have to be governed by circumstances; it has got to be unscrewed by the fingers, so take whatever means you best can to facilitate that.

Fig. 17 A and B is a spring in place of a screw, and there are doubtless many other ways that an ingenious workman will devise to obtain a desired result; and speaking for myself, there is nothing I like better than some good tough proposition in jewellery mechanics to work out.

These entirely withdrawing and removable joint-pins are always getting mislaid or lost, so I will follow on with one or two methods of retaining the joint-pin in its place.

Fig. 18 has a slot cut in the top knuckle, in which a peg can work up and down, and to the peg the joint-pin is soldered; it should not be made to withdraw further than to allow of the tongue's removal.

Fig. 19 has the joint-pin soldered to a cap, and the cap is pierced and fitted to run on a parallel guiding-bar, or else with the bar soldered parallel to the joint-pin and working through a tube (T), Fig. 20, soldered underneath the joint or behind, or wherever is most suitable for your particular job.

In the paper on Catches, which will follow this, you will find particulars of a fall-down catch that should be used with these removable tongues. Fig. 7 is its number.

Thus far only the withdrawal of the joint-pin to allow of the removal of the tongue has been considered, and for that purpose all has been worked from the top knuckle, so that if by accident or wear the joint-pin becomes loose, it will not drop down and disengage the tongue. Now, our next example, Fig. 21, is one in which the bottom knuckle plays a part, and for the same reason: namely, that it is the more secure of the two for the purpose.

This bottom knuckle has a slot cut right through it in the position indicated in Fig. 21 B.

The joint-pin is here soldered *to* the tongue, which is flattened and broadened out (Fig. 21 A and C); it is placed in position sliding along the slot, as indicated by the dotted lines; then when the tongue arrives in between the knuckles, it is turned down towards the catch in the usual way.

This is the one I mostly use, as it makes a neater joint, and reduces the number of pieces that have to be made and fitted, but it has two very important parts that want watching: first, the soldered connection of the joint-pin and tongue, which must be sound, and yet leave the round joint-pin quite clear where it joins the tongue, Fig. 21 C; the second point is the slot, which must be just wide enough to allow the joint-pin to come out sideways. I have enlarged all the diagrams on purpose to make things clear, and I hope I have succeeded.

This brings me to a finish of this paper; and before entirely closing it, I should like to say that all I have written here are what I have made or have seen, so there is nothing theoretical about them; but I must warn anybody that tries their hand at the more difficult ones, that patience, care, and skill will be required to carry them out properly, and even then it seems that it is not every man who is able to make them.

They should be taken in hand with a thorough intention to do the very best, and if done with a little thought, I do not fear the result.

As all of them depend on exactness of fitting, it is evidently of no use rushing at them in a careless, anyhow sort of way—slogging may do at cricket, but it won't do at jewellery. And if we aspire to be in the front rank of our trade, we must do all our work conscientiously, and I had almost written devotedly.

This capability of taking infinite pains, which somebody says is the sign of genius, will at the end give the requisite skill if intelligent practice is added; please notice that I have not written practice only, but practice and intelligence added, for practice (I mean making many things of the same sort) never will *alone* make a good workman. To become that depends to a very great extent indeed—in fact, almost entirely—on the man himself, and I hope that such a one may find a little now and then in these papers to help him on his upward road.

PLAIN AND DECORATIVE HOUSE PAINTING.

BY A LONDON DECORATOR.

MIXING OIL PAINTS AND COMPOUNDING TINTS AND SHADES OF COLOURS FOR PRACTICAL USE—SECOND AND THIRD COATS.

LET us now give a glance around the room before I make up the paint, and get some idea of what is required. We notice that, beyond the discoloration of the white plaster cornice, there is little evidence of oil paint on its surface, so that the oil has all been absorbed into it. The walls, however, having been well trowelled and finished, show some signs of the glossy paint on the surface, hence the suction is entirely stopped in those places, and, probably, nearly so all over. Under these circumstances, the previous kind of paint, but with a little more lead in it, is required for the second coat for the cornice, but, for the walls, I make it up considerably rounder, or thicker, and use, instead of all oil, two parts of linseed to one of turps.

Before straining this, I add sufficient Venetian red in oil to give my paint a decided pink cast, which not only enables us to see that nothing is missed, but also exerts an agreeable influence of colour upon the succeeding coats.

My second coat to cornice and walls being now manipulated as before, I return to the woodwork. Having lightly papered it down, I dust it, and stop the nail-holes in the panel mouldings, etc., with putty made from white lead stiffened up with best, or gilders', whiting. After stopping woodwork, it is advisable to let it stand a day, to enable the putty to harden on the surface; the second coat of paint can then be applied without affecting it, and should be of similar proportions to that last spread on walls, but in this case I use the paint without any stainer. We have now two coats upon all our work, the absorption in cornice, wall, and woodwork being thereby effectually stopped. Before, however, we consider the finishing *colour* of our paint work, we must turn our attention to the ceiling. This is now coated with a preparation of size and whiting, with the object of stopping some of the suction of its surface; and, having again become thoroughly dry, I finish my ceiling-light with three coats of white paint, and the flat, or bed, with a coat of faint pink distemper—a lesson on which process I postpone until the present one is completed.

At this point it is now necessary that you, my reader, as the supposed patron as well as learner, and I, the practical worker and adviser, should consult together as to the finish and appearance of our temporary job. May be you have received instructions from the partner of your joys and sorrows (who, probably, paints upon banjoes, tambourines, drain-pipes, etc., for the embellishment of your drawing-room, and is a member of the "Blankport Amateur Sketching Society") that such and such a "fashionable" shade of "electric" blue or peacock green will give the most artistic effect; or, perhaps, you have some striking colour-notion of your own, originating from a profound study of the charming kaleidoscope of colour obtained with a pot of Mr. Aspinall's enamel. This decision, we will suppose, is eventually arrived at—that the teacher's knowledge and experience shall be responsible for the artistic as well as the practical success of the work, the "why and wherefore" of my selection of colour being explained as we proceed.

In spreading a succession of coats of oil paint, upon plaster work especially, it is not advisable to use two coats of *all oil* colour upon each other, unless for the purpose of stopping the absorption; when, however, that end is gained, it is necessary to use the next coat with a larger proportion of turpentine than oil. If we continue using our paint very oily, each coat hardens, so to speak, in itself; but if we interpose sharp or turps colour between two coats of oil paint, the former acts as a cement, and the three coatings become firmly bound together. In *flatting*, or dead-painting, surfaces, this same principle underlies the whole process. A last coat of oily paint, nearly identical in colour to the desired tint of flatting, is very carefully spread, and upon this *ground*, as it is technically termed, the thin coating of purely turps colour is laid before the ground becomes properly hard—which is generally the next day or next but one. Providing the ground and flatting are properly prepared and manipulated, we find this action takes place: the oil of turpentine slightly opens the surface of the linseed oil ground beneath it, so that the latter takes hold of the particles of pigment contained in the flatting, whilst the gradual evaporation of the turps leaves the surface without gloss, the pigment being held from beneath by the oil, but uncased with any upon the surface. Woodwork and walls, if properly flatted, can be washed as safely as can oily paint, but the same knowledge of its nature is as necessary to successfully clean and preserve it as it is to prepare it. It is only when wrongly manipulated that flatting will not stand fair wear and tear.

This explanation will now help you the better to follow my methods. Having determined to flat the cornice, I must previously ground it with oil paint, somewhat akin to my finishing, flatting, colour. The wall space we will leave in a medium gloss of oil paint, so that my third coat must be of sharp colour and near the tint of finishing paint. The cement skirting I shall now first coat with the paint used on walls, and then finish that and the woodwork with two more coats of good oil paint. I here remind you that this decision is made with a view to present economy and the temporary nature of the job; permanent embellishment is to come later on.

In painting a billiard-room particularly, the range of suitable colour is governed, and limited considerably, by the appearance of *the* principal article used therein, namely, the vivid green mass of the billiard-table covering and the accompanying green shades to the usual gas-lighting arrangement. If, therefore, our selection of colours is of a common sense nature, it must not clash with or in the least detract from the appearance of the billiard table. The dominant colour-tone of a room is usually furnished by the walls, and being, here, the principal surface the eye will rest upon after leaving the green table, their appearance is a most important item.

Now every definite colour has its *contrast* and *complementary*: that is, a colour directly opposite it in appearance and sentiment; but which, when placed in juxtaposition therewith, not only improves and heightens the effect of it, but combines with the former in producing the sensation of *colour harmony*. In the selection of colour, *contrast* is therefore one scheme we may choose; the *alternative* in this case is to keep our walls more in *unison* of colour with the billiard table, namely, a subdued shade of green.

The complementary colour of the bright green in question is a rich purple red, the two combined giving a very brilliant appearance. Harmony of colour and brilliancy of contrast is not the principal object in this instance, however; my aim is rather to soften down the vivid green than to enhance its brightness, which any shade, however deep, of its complementary upon the walls would do. Our best wall colour will therefore be a dull and soft-toned green, and by introducing the warm complementary colours into cornice and woodwork we shall obtain pleasing and harmonious results.

From this short gossip on theory, we turn again to our practical operations. Preparing my third coating and ground first occupies our attention. The sharp wall colour is mixed—the proportions of lead and patent drier being twelve to one respectively—with nearly three-fourths of turps to the remaining part of linseed oil. There is no occasion to measure it out exactly, but if the solids are beat up in oil into thick batter consistency, it will require turps only for thinning it for use. I put enough of the thick paint aside as will suffice for the cornice, and before thinning the remainder for my walls, I stain it to warm green with the subjoined pigments, ground in oil: Prussian blue, yellow ochre, and burnt umber. In the colour mixing you manifest much interest, and since we feel the impossibility of adequately conveying, by signs or sounds, knowledge appertaining to the sense of colour only, I gladly bring to our aid the array contained on "Aspinall's enamel" card before mentioned.

I will here strongly advise all readers of WORK who take more than a passing interest in these papers to procure, if at all possible, one of the cards alluded to. Lessons on colour, without colour examples to work with, are of little avail; but with such a collection of some hundred different hues, tints, and shades of colour before both contributor and knowledge-seeking reader, the practical and artistic value of these papers should be increased tenfold.

To return to my wall paint, I find the exact shade is not contained on Aspinall's card, but its appearance is similar to "sage green" in colour, although of a much lighter tint. To ensure, however, a good solid wall when finished, I stain this "third coating" paint several shades *darker*, since a lighter, finishing shade of any one colour will cover much better when superimposed upon a darker shade than *vice versâ*—a point it is very necessary to remember in oil painting. In mixing both this and the finishing wall paint, I first stain the white to a medium blue, then add ochre and convert it into green, and lastly, the umber to soften and neutralise, or to warm the green mixture. Previous to spreading my "sharp," that is comparatively quick-drying wall paint, I must ground the cornice, but as I intend introducing thereon some warm tints in contrast to the "sage green" walls, it is best to first mix my finishing woodwork colours.

As some relief to the mass of wall colour, I determine to paint the woodwork in dark warm shades, and which, upon reference to the colour card, I find nearly identical to the globes thereon, marked, "Arabian brown" and "Terra-cotta, No. 3." The former, which is the darker of the two, I use upon the entire door frame and window frames, the doors, with the exception of panels and mouldings around same, and the deep bottom plinth of the skirting. The panels of the woodwork, the window-sashes and top plinth of skirting, I paint with "Terra-cotta, No. 3;" and, with a view to brightening up the doors in their entirety, I shall finish the panel mouldings and one member or division of the door frame with the soft sage green wall colour. From the method I proceed upon, there can be gathered the advantage of deciding and making-up the dominant colour given by the room, namely, the warm green, at the start, so that the remaining and contrasting colours may be compared therewith, and the most harmonious effect obtained. The paint for the woodwork I make from Venetian red and burnt umber chiefly, with the addition of a little ochre, lightened up with white for the panels and Indian red. In contrasting any shade of green against a warm colour, it should be remembered that the more yellow the green contains, it must be opposed by an equally blue or purple-toned red; the true contrast of *pure red* being, *not* as has been taught by some colourists, pure green, but a decidedly *blue hue* of *green*.

Notwithstanding the principles of colour-harmony are as definite as those which give us harmony of sound, a knowledge of the exact equivalents of a colour will not guarantee the successful colour-treatment of a room or building. The scientific equations alluded to should form the foundation of our colour-studies; but the amount of success we obtain will, however, depend upon our adaptation of these definite laws to each particular circumstance and undertaking. The climate and light, the position and interior lighting of the room, the scenery from the windows, are each and all prominent factors in determining the strength and weakness of the contrasting tints which compose a harmonious colour scheme—besides the more positive reasons I have explained herein—and it is then that scientific proportions fail the decorator, and he has to rely upon his own experience and faculty as a *colourist*.

Having given this explanation, you will agree that I cannot well describe to a novice the exact arrangement of my cornice colours. You notice, however, that I treat it in three main divisions: that portion next the wall I paint with a colour similar to the woodwork panels, but with the addition of a little more white and umber. The middle recessed division, or cove, I paint with a slightly more blue-grey and lighter tint of wall colour, made by adding a very little blue and white to the latter; whilst the third and top division of mouldings I ground a lighter and more golden hue of the base part. These cornice paints—which I have prepared from the "thick white" put aside previously for the purpose, and for staining or colouring which I have principally used a little of my woodwork and wall paints—are now well strained; and, being thinned with three parts oil and one of turps, are spread according to the above arrangement. The wall space being previously papered down, and any little indentations in the plaster faced up with the hard stopping made for woodwork, is now third-coated with the "soft" sage green, used darker than the desired finish and with fully two-thirds of turps to one of oil. The third coat requires to be rather rounder, thicker, than the two previous ones; must be well spread, laid off, and worked rather expeditiously, one flank or division of the wall at a time to avoid the joints "catching," as it is termed. The cement skirting is afterwards first-coated with the same colour spread *very barely*; and, as it is a comparatively non-absorbent surface, this sharp paint forms the best "key" for the dark red, finishing paint. Its present colour is no disadvantage, since the first coat of woodwork paint will effectually hide it.

I am again obliged to break off in my subject here, but I may add that few remarks are required to bring this part of my subject to a conclusion, and that they will be chiefly directed to the treatment of the cornice and flatting, and the colouring of the skirting and woodwork.

HOW TO MAKE A PIANO.

BY "NIL DESPERANDUM."

FINISHING OR FITTING INTERNAL MECHANISM—PEDAL ARRANGEMENT AND CELESTE PEDAL.

THE case having been completed, it is now ready to receive the internal mechanism, or labour to facilitate production. This made room for the key maker and action maker to supply the manufacturers, thus making the key maker and action maker two distinct trades. Although I am aware there are a few firms who make their actions and key-boards on the premises, these may be counted As for the piano we are making, we only need one; it will be enough for the present to describe this one. The action I have selected for this piano is what is known as the tape action, from the fact of it having a tape or bridle attached to the hammer butt. This action was patented in England as far

action. This branch of the trade is known as the finishing. The finisher prepares the keys and action for the case, and adjusts the different parts so as to bring the whole into working order, including the pedal action. Formerly, the pianoforte manufacturers made their own small-work, or action and keyboards; but as the demand for pianos became greater, it was found necessary to make more divisions in the on the fingers. The firm of Steinway, of New York, U.S.A., boast of making every part of their pianos, having several factories and an iron foundry, but they are an exception. There are a variety of actions in the market, each having its particular claims to merit, but the maker exercises his discretion as to the one he adopts. It does not come within the scope of this paper to notice the merits or demerits of the various actions. back as 1842 by Robert Wornum, who spent a large amount of time and money in perfecting the pianoforte, but it did not find the favour in this country that it deserved, illustrating the old proverb that no man is a prophet in his own country. But the French makers soon discovered the merits of this action, which was so much used in France that it acquired the name of the French action. Latterly, however, it has found more favour in the land of its birth.

The action forms a very important part in the construction of the piano, as without it the piano would merely be a large dulcimer. The action and keyboard form the link between the performer's hands and the strings. There exists much difference of opinion as to the weight or balance of a key or note, as when the key is pressed down and the finger taken off, it is returned to its former position by a weight at the extreme end of the key, and also the weight of the action. Some prefer a light touch or fingering of the keys, while others are in favour of a heavy touch; I think, without offering a decided opinion, it would be as well to accept the happy medium. For if a touch is too heavy, it renders playing for an hour or two more the nature of work, as it makes the fingers and wrists ache; while, if too light, you cannot feel enough weight under the fingers. The reader will find in very old pianos the touch is very light, while in the modern pianos they have a decided tendency to be heavy. The action I have selected for this piano will require a weight of two-and-a-half ounces to press the key down of each note, so that the hammer strikes the string. A person playing, for instance, the popular piece of music, "The Maiden's Prayer," presses a key down 1,220 times, which is equal to raising a weight of about 82 lbs. So the reader will readily understand that if a touch is heavy, and a person plays for some hours, how tiring it must be.

I will now enumerate the different parts of the keys and action as they are known in the trades. Beginning with the keys, we have the key frame on which the keys work, comprising front rail, balance or middle rail, and back rail; in the front and balance rail are key pins, those in the balance rail penetrating the keys, while those in the front rail partly do so. On these pins cloth is placed to prevent noise, the back rail also having cloth to form a cushion for the back of the key to rest on. The keys in a seven-octave piano are eighty-five in number, being fifty white or natural keys, and thirty-five black or sharp keys. The parts of the tape action are named standards, damper rail, hammer rest, set off or slide rail, hammer, damper, lever or crank, hopper or fly, hammer butt, check arm, check, bridle or tape, escapement button, bridle stay, and damper wire. You will now require your keys and action to commence work as the finisher; the keys you may obtain from F. Edwards, 63, Southampton Street, Pentonville, N. In ordering, ask for one set of keys (ordinary scale), ivory or celluloid according to your means, as ivory would cost more, 14 in., $7\frac{1}{2}$ in. balance. The action you can procure from V. A. Hallpike 213, Mare Street, Hackney, E.; order one tape check action (ordinary scale) 10 inch strike, with hammers complete.

Your first business will be to set up your action in the cases; take the two screws out of each end of your damper rail and put it aside for the present; now take the extreme bass and treble hammers out of the packet they are in, and file the ends of the shanks until they fit the holes in the hammer butts at each end of the action. In the bottom of each standard put a dowel, and make two blocks to fit them (see diagram); these are what the action rests on, and are glued on the key bottom when it is in position. Stand your action on the blocks, and put the hammers in the bass and treble holes of your action, and when the point of the hammer touches the string, see that the shank of the hammer is $\frac{1}{4}$ of an inch out of the upright or leaning back, both ends the same. Now keep the front edges of the standards upright or square, and mark the front of your standard blocks, and keep it in this position temporarily. You leave this for the present; put your keyboard on your bench; take the extreme treble and bass keys off the frame; take the treble one, and holding it $\frac{1}{16}$th of an inch from the front of the lock board, rub it under the treble note, and it having black lead on the bottom, makes a line on the top of your key; serve the bass end in the same way, and you have a line on each key. Put them in their places on the frame, and get a straight-edge and make a pencil line across the whole of the keys at the two marks, then take a centre-punch, and make a mark in the centre of each key on the line; in these punch marks holes are bored for $\frac{5}{8}$-in. No. 10 screws, and countersunk so that the head is level with the key: these are called pilot screws; put these in. Now make a pencil line across the keys $\frac{3}{4}$ of an inch behind the screws; now take the keys off the frame, and the next operation will be to load them. There are two methods of loading them: you can either bore the holes in the keys, and melt the lead in a ladle and pour into the hole while holding the key on a flat-iron with the handle in your bench screw, or you can buy the leads moulded ready to put in the holes and make tight with a hammer; you will require them $\frac{1}{2}$ an inch in diameter, one or two for each key, according to your balancing.

You now make a balance board: this is a piece of wood 3 in. wide, and the length of the key; mark one end for the back, then cut a kerf with your saw in the centre of the wood, and put a piece of thin brass or veneer in the kerf, allowing it to stand above a $\frac{1}{4}$ of an inch. Now bore two holes (for a wire nail with the head off, to fit in) $\frac{1}{8}$ and $\frac{1}{4}$ inches in the front of the kerf; have one of your moulded leads ready; put your wire in the $\frac{1}{8}$-in. hole, so that it stands above the level of the veneer an inch; put the centre hole of your key on, beginning at the bass end, then slide your lead towards the back of the key until it weighs it down. Now make a mark on your key at the place where the lead is, taking care that it does not come on the pilot screws: serve as many keys as there are dampers in this way; then you change your nail into the $\frac{1}{4}$-in. hole and weigh the remainder of the keys. In the treble the keys are a little heavier, to compensate for the weight of the dampers in the bass; you bore centre-bit holes in the keys right through the sides at the marks you made in balancing, and fill them up with lead; see that the lead does not move in the holes, to prevent rattling noises; as you hammer them in you can try if they are tight by pressing with the thumb.

You now want a strip of cloth $1\frac{1}{4}$ in. wide, and the length of the set of keys; let the cloth be of firm texture, such as box cloth or black cloth: this is glued on to the keys at the line behind the pilot screws, so that the cloth covers the screws; you only glue behind the screw, leaving the front of the cloth over the screws loose, as you may have to regulate these screws. After gluing, cut the keys apart with a knife; you will now require some baize or felt to put on your key frame—felt such as that used for putting under carpets will answer your purpose; put the two extreme end keys on the frame, and mark with a pencil the frame where it extends outside the keys; also see that the frame is level with the back of the keys: if it is not, plane it down, also cut the ends off the frame at the marks you made. You must now cut two strips of your baize or felt, one piece 1 in. wide, and the other $1\frac{1}{2}$ in. wide, and the length of the key frame: these strips of baize are to form a cushion for the back of the key to rest on, and are placed on the back rail of the key frame, directly under the pilot screw; you gauge a line and make a groove with your rabbet plane about a $\frac{1}{4}$ of an inch wide, holding the rabbet plane at an angle so that it makes the groove deep enough for your $1\frac{1}{2}$-in. piece of baize to lay in; the 1-in. piece is simply glued at its front edge and laid on the frame, and the $1\frac{1}{2}$-in. is glued in the groove and lays over it. You will now want on the centre pins of your key frame small pieces of cloth the same kind that you used for the top of the keys. In the trade, it is usual to punch these out with punches for the purpose; as the reader will not be provided with these, he must cut a strip of cloth the width and length of the balance rail, and stretch it across the top of the pins, then rub a file along the top of the pins, and it will make a hole for each pin; then press the cloth down level on the rail. For the front rail you will require two strips of felt: cut these the width of your rail, and make holes in the same way; the keys are now ready to be eased on the frame. For this you will require two small files, one round and the other square; if you cannot get the size you require at the tool shop in your locality, you may obtain them from G. Buck, Tottenham Court Road, W.C.; by rubbing a piece of thin paper over the round and square hole, you would be able to send the size; you use the round file first, easing the round hole so that the key drops easy on the pins, but do not make it loose. Now use the square file for the top hole, and ease so that it fits; serve the front holes in the same way: of course you ease every key on the frame. Now put the set of keys as they are on the frame into the case; the extreme bass and treble hammers are put in the butt at each end of the action, and while the lever is resting on the key you plane down your blocks that are under the standards until the point of the hammer is 2 in. from the string at each end: this is technically termed the blow, as it is the distance the hammer has to strike or give the blow to the string. When you have got the blow the right distance, you move one of your hammers, placing it in several butts, to see that your hammers will strike each note squarely, and the shanks upright; you must move the action either to the right or left until you have got it right. Now mark the place where the blocks or standard feet are, and these must be glued down on the key bottom; put a screw through when the glue is dry, then take your keys out, and unhook the tapes or bridles off the stays: this you can easily do by using a pair of pliers; notice how they come off, as you will have to hook them on later. Now lay your hammers out on a clean board: you will find they are numbered on the side of each one; then take your extreme treble hammer and cut a piece off the end of the shank, until the point of the hammer strikes the string close under the bridge pin: this gives you the length to cut the hammer shanks. You will need a block to cut these, so that from the top of the wood of the hammer to the end of the shank they are all the same length; you can make this block by rabbeting the edge of a piece of wood 8 in. long, and making a saw kerf across at the place you want to cut them. Having cut your hammers to the length required, you file the ends of the shanks so that they fit the butts; do not make them loose; begin at the treble, and take each one in rotation according to the numbers. While doing this you will have to lean the case back, as the hammers will have a tendency to fall forward.

After fitting them all in, take two small straight-edges about 8 in. long; begin at the treble, and place one on the top of the hammers and the other under the check arms, and see that the tops of the hammers and check arms are straight; if they are not so, file a little off the end of the shanks until they are. You now proceed to glue in the hammers: have your glue hot and of medium thickness, use a small stick to glue with, put a small portion on the shank, place in the first butt at the treble and turn the hammer round two or three times while it is in the butt: this forces the air out, and assists to set the glue. Now place the hammer up to the strings, and see that it strikes the note square; glue about a dozen in this way, then press one straight-edge under the check arms and the other on the top of the hammers, and see that they are straight; then draw the hammers back, and let them lean on your straight-edge about 2 in. from the strings: this is the distance of your blow. While they are in this position regulate the spaces so that they look even to the eye; serve the hammers right through the set in this way; now screw your hammer rest on with two screws. To find the place for this, lean the treble and bass hammer back, holding the hammer rest under them until the point of the hammer is 2 in. from the string: this will be the place for it to be fixed. When the hammers are all laying back on the rest, just look over them and see that they are to your satisfaction; when your hammers are dry, place all the tapes or bridles as before; now put your keys in the case, and take out the keys where the frame passes over the cross rails of the key bottom; then move your key frame to the right or left, until each key is under the lever of each note. Now mark the front, middle, and back rails of the frame for holes to be bored for screws to go into the rails of the key bottom. Having bored these holes, put your key frame in position, leaving a space of $\frac{1}{16}$th of an inch between the front of the keys and the lock front; screw down to your key bottom. At each side of the standards, blocks are fitted to fill up the space between them and the ends of the case: these are 1 in. in thickness, and are made of hard wood; the bass one has a piece cut out for a pedal stick to work through, the hole being lined with cloth; the pedal stick is tapered from an inch at the bottom to $\frac{1}{2}$ an inch square at the top. In a line with the front of the standard a $\frac{3}{16}$-in. slot is cut out of the blocks for a button to fit in which secures the action in its place; the position of these blocks on the ends of the case is 1 in. above the top of the hammer rest; put a screw through these into the ends, also glue them; now scratch a line under them on each standard and put a small dowel in, allowing it to stand out $\frac{1}{2}$ an inch: these press under the blocks and prevent the action from moving upwards; then screw one button on each standard to fit in the slots before mentioned: these you can make of beechwood $\frac{3}{16}$ths of an inch thick, 2 in. long, and $\frac{7}{8}$ in. wide round both ends and bore hole in centre for $\frac{1}{2}$-in. screw.

Having secured the action, you will probably find that your hammers do not lie evenly on the rest: some may be a shade high, while others may be low; by taking hold of the rest in the centre and pulling it forward, you will find some of the hammers follow the rest: these are low; take out the key and turn the pilot screw up a little until they remain stationary; if any stand a little above the rest, take the key out, put it on your bench, and give the cloth over the pilot screw a sharp blow with a hammer. The hammers being in line on the rest, the next operation will be to make the touch: that is, the depth the key presses down. Take two pieces of wood $\frac{5}{16}$ths of an inch thick, 2 in. long, and $\frac{7}{8}$ths of an inch wide; on the back of these is screwed a piece of lead sufficient to press the key down; these are named touch weights; one is placed on the front of a treble key, and the other is placed on a bass key, then a light straight-edge is placed from one touch weight to the other; if the keys are too high, and your straight-edge does not touch the weights, then your touch is too deep; you must alter this by placing a piece of cardboard under the front rail of your key frame; if your straight-edge rests on the touch weights and the keys do not touch it, then your touch is shallow: this can be altered by putting a piece of card-board or thick paper under the middle rail of the key frame at the places where it is screwed; get it as nearly right as possible to the straight-edge in this manner, then you must take a shaving off the bottom of the high keys, while a piece of paper must be put on the centre pins to raise the low ones; those keys that are out of square may be made square by tapping the centre pin either right or left, as required; the spaces of fronts of the keys are now made equal by a key spacer: this is a forked piece of steel which moves the key pin to one side or the other; you can do it with pliers, but do not scratch the pins.

Having spaced the fronts, now space the sharps, and by tapping the centre pin of the sharp, space it between the two naturals on the balance rail; the backs of the keys are spaced by striking the key on the side with a hammer on a flat iron the way you wish it to move; strike on that side. Now you will have to fit the damper rail when the dampers are on the strings; the largest damper is for the extreme bass note. Let the rail hang over the standards $\frac{1}{2}$ an inch each end; at the treble end a hole is bored through for a screw to go in the top of the standard, while at the bass end a slot is bored out for a round-headed screw to go through freely so that it does not touch the sides; on the front of the damper rail at the bass end a piece of wood 4 in. long is screwed and glued on, and extends beyond the damper rail to within $\frac{1}{8}$th of an inch of the end of the case; behind this projection, a crank (which is screwed on the end of the case) works; it presses the damper rail forward, while a spring screwed on the front of the standard presses it back, the screw at the treble end acting as a centre, and the bass one keeping it in position; the bottoms of the dampers should be $\frac{1}{2}$ an inch above the hammers when they touch the string; if they are too high, you must cut a piece off the tops of the standards until they are right, then screw the damper rail on, and screw a stop on the back of the standard to prevent the damper rail going back too far, placing a piece of felt between to act as a buffer; there must be a space of $\frac{3}{8}$ths of an inch between the top of the damper and rail. You must now take a pair of long-nosed pliers, and put the damper heads on the string, bending the wire to right or left as needed, and keeping the tops of dampers and heads in a straight line; then put the damper wires in, screw the top button down until there is $\frac{1}{8}$th of an inch space or play between the damper and lever when the wire is in, put them in, and then cut off the tops level with the damper with a pair of pliers.

You now proceed to pedal the piano; to do this, you must put the piano on its back on two trestles, so that you can get at the bottom of it; make two pedals of beechwood 16 in. long, and the shape they are in the sketch, $\frac{3}{4}$ of an inch thick; mark 4 in. from the front, and put two pins in temporarily; this is the distance they stand out in front of the plinth; from these pins bore a hole in the right or loud pedal, $2\frac{1}{4}$ in., and bore a hole in the left or soft pedal, $3\frac{5}{8}$ in., for the pedal bolt to pass through: these are made of stout wire with a nut to screw on the top; also bore a hole in each $1\frac{1}{2}$ in. from the back for a stout screw to go through; glue a piece of felt on the bottom of each to prevent noise. You now mark the centre of the plinth, and $2\frac{1}{4}$ in. each side of this mark you place the pedals, that will leave a space of $4\frac{1}{2}$ in. between the pedals; cut pieces out of the plinth for the pedals to fit in, cut up to the bottom board of the case, leaving space for a piece of felt to go round the hole; this felt is glued in the holes and tacked under the plinth; now let the pedals rest on the pins, and put them in their respective holes, and mark through the holes you made for the bolts; at these marks bore two $\frac{3}{4}$-in. holes through the bottom board; now put your pedals in their place and put a stout screw in the bottom of each. Next get out the rockers: these you can make of deal $1\frac{1}{4}$ in. square, and one piece will be 2 ft. long, and two pieces 2 ft. 6 in. long; on the 2 ft. 6 in. rockers a small block is glued at the bottom 10 in. from the end, while the 2 ft. rocker has a block 8 in. from the end; take one of the 2 ft. 6 in. rockers, and put it on the bottom board, extending 1 in. over the hole of the right pedal, the block being 10 in. from the pedal, then mark through the hole, and bore a hole at this mark for the pedal bolt to go through, the other end of the rocker being cut so that it is a $\frac{1}{4}$ of an inch from the bass end of the case; the rocker is bored with an $\frac{1}{2}$-in. centre-bit half-way through over the block; then bore the remainder with a spoon bit for a 2-in. screw; from the hole at the bottom round the block over, and put a pedal spring on so that the point of it comes near the bolt hole; now clean this nicely with glass paper, rub some soap on the block and spring, put your bolt through the pedal from the bottom and through the rocker, put your screw in through the block, and then pull your pedal and see that it works free, without noise; you do the same with the back rockers, except that they overlap each other, and the pedal bolt penetrates both; the short rocker is at the bass end and the long rocker at the treble; rub plenty of soap where there is friction. By referring to diagrams you will see how these are arranged; the soft pedal in this piano is what is known as the celeste: this is a strip of felt or flannel on a slip of wood, so that when the pedal is depressed the two ends of the slip rise simultaneously, and interpose the flannel between the hammers and strings, and so softens the tone; the loud pedal moves the crank, which gives the damper rail a forward movement, taking the dampers away from strings, and allowing free vibration, and so making the tone louder. By referring to diagram, you will see that the two sticks which hold the celeste have slots in them; also a piece cut out of the top for the celeste slip to ride in; screws penetrate the slots into each end of the case to keep the celeste in position, so that it is near but does not jar on the strings; fit it so that the top edge of the flannel is ½ in. below the strike line when the pedal is at rest. You now make a crank as per sketch, of beech ½ in. thick: this is screwed on the end of the case above the damper rail at the bass end, the front of the crank being over the pedal stick, the back being behind projection of damper rail.

MEANS, MODES, AND METHODS.

Stone-cleaving Tool for Small Specimens.

To the lapidary, the geologist, and the amateur mineralogist, a handy tool to cleave with more exactness and less waste than by the hammer has been much wanted. Some specimens that have to be opened are so valuable extrinsically, from their rarity, that the small cost of this tool would repay the owner at once using. Its value may be judged when jade has to be cloven so as to produce two surfaces without fracturing any but the part to be divided; and such rare stones as chrysolite, aurite, pectolite, fluorite, coral, etc., to be opened in a direction for special results.

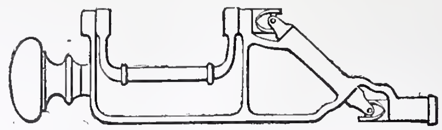
Such a tool was in use by one of the most scientific geologists in France, with the largest display of valuable minerals and fossils collected at the French Exposition—Mr. W. Foote, of Rue Desaix, Paris. It is an American invention of Mr. F. A. Clanfield, Dover, N.J., United States, for whom Mr. Foote is agent in France.

The illustration needs little description. It is nearly all cast steel, somewhat like the bed of a lathe, with two poppet-heads, each with a chisel in a socket-hole, with cross drift-holes, to enable the chisels to be driven out at any time. The head, A, is recessed into a slotted mortise in the bed-top, forming a movable joint, turning on the fulcrum-pin, B, by the purchase obtained by the screw, C. The shifting-head, E, has a tongue a third of the width of the bed-top, which is recessed into a long slot, F, shown by the dotted line. This is to take any side-rack. The movable "bridle," G, is the main stay to resist direct strain in cleaving stone. It consists of ½-inch square steel bond, fitting quite round outside of bed and poppet-head, secured only by the pressure in action, drawing it into angle-notches on the under-side of the bed. It requires no bench. A table serves to rest it on, as the resistance in cleaving is self-contained.

The force required for the hardest agates or gems is often less than for softer stones of the same bulk; but, so powerful is the leverage, that a lady can use it with ease. It is about 2 ft. long by 10 in. high.—J. C. K.

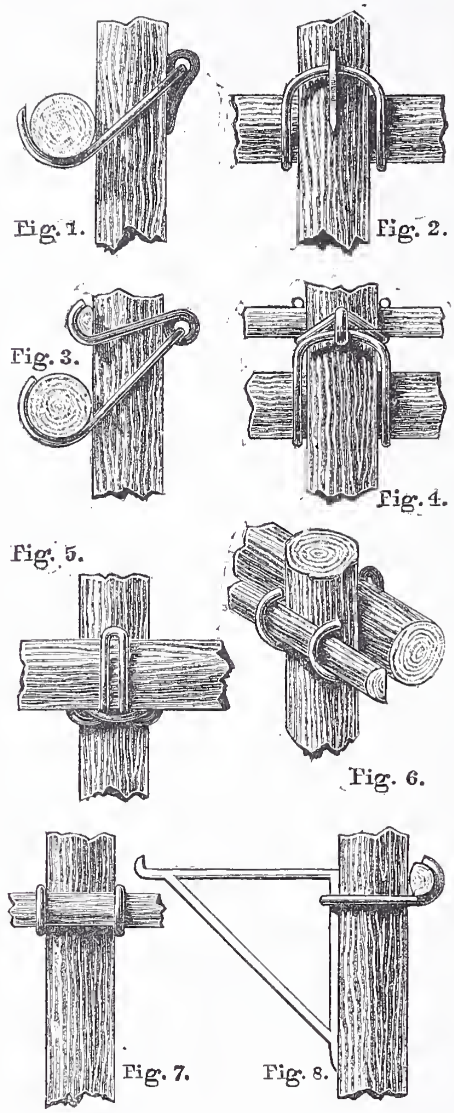
Science in Scaffolding.—Steel Ties.

To erect the scaffold from which a structure is reared is a skilful piece of handiwork. Recent improvements of elevated "stages," from which a building can be erected without the network of scaffolding, is a real scientific advance in building operations, but it is mostly restricted to very lofty buildings, so that scaffolding of the ordinary form will still be used for dwellings and factories of small altitude.



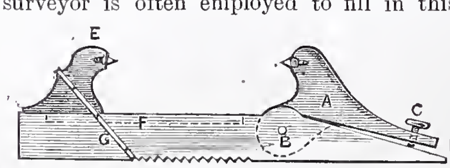
Brace for Boring in Angles.

Sometimes the new building falls to pieces "before there is time to get the paper on to hold it up," remarked a man on a jerry building that threatened to collapse when one of the doors slammed. The law is lenient to such malefactor builders, or it would not be attempted if the penalty was penal servitude for such delinquents. There



Scientific Scaffold Ties.

seems a hiatus in building science existing between the architect and the builder. One often is biassed by rules, the other often ignorant of the simplest laws of mechanics, and helpless to fulfil the main practical purposes of his trade—make a sound building as a comfortable dwelling-house. Any one who has been "clerk of the works" on any large building must have observed this. A surveyor is often employed to fill in this



Stone-Cleaving Tool for Small Specimens.

hiatus, and often very efficiently links architectural and building sciences.

The scaffold has to be got together often by the humblest craftsmen in the building trades, often with the most inadequate materials, the pole-bearers and putlogs being old and decayed, especially the ropes. To aid the builders, any plan which combines safety and economy would be welcomed. A Swiss invention for that purpose is now shown by the accompanying illustrations. T. G. Grossman, of Seefeld, Zurich, is the patentee. He substitutes steel for cord in securing putlogs to poles. It was shown at the Paris Exposition, and every opportunity of examining the scaffolding was given to those interested in such matters. The structure shown had all the firmness of a permanent building when heavily loaded to test its strength.

Fig. 1 shows the "dog-eye," with two "clutch-points" driven into the scaffold-pole, upholding a cross-pole. Fig. 2 is another view of the same. Fig. 3 is a scaffold iron with an extra double hook above the pole-hook for wedging the hook that holds the putlog tight. Fig. 4 is another view of the same. Figs. 5 and 6 show other forms. Figs. 7 and 8, the scaffold-iron used to hold an iron bracket wedged tight to the pole.

A practical builder would see at once the merits and disadvantages of the invention, and also see that the merits predominated for economy and security. He already practically employs a somewhat similar means in his "baulk-dogs," which require to stand exceptionally great strains. Such men are never slow to appreciate anything which is a practical and commercial economy in their trade. The way the scaffold was taken apart by two men was conclusive in the gain of time over using ropes to tie the poles together, and then wedging the tying tight, in scaffold-building.—J. C. K.

Brace for Boring in Angles.

All workmen, as well as amateurs, know how tedious it is drilling holes in the interior angles of furniture or buildings. The ordinary brace cannot be used for it. The geared brace, however small the mechanism, cannot drill one quite at the bottom of an angle and perfectly parallel to one of the sides.

A brace, similar to sketch, was shown at the Paris Exhibition, and seems to us to overcome this difficulty very well indeed. It is really a simple brace with the bit in a separate shaft, out of centre with the handle, but connected therewith by a double hook's joint.—H. B. P.

SOME MORE PHOTOGRAPHIC APPLIANCES.

BY AN OLD HAND.

Draining Rack for Plates—Copying Easel—Instantaneous Shutters.

The Draining Rack for Plates is a very convenient, and almost, so to say, necessary adjunct to the photographer's material. It is made of two kinds, rigid and folding. Since the introduction of gelatine plates, development of negatives is usually carried on at home. The *raison d'être* for the folding form is gone; the only advantage of this kind was portability. To make a rigid one, cut out two pieces of ¾-in. pine or any other wood—it is immaterial—7 in. by 5 in. (Fig. 1). In each make two grooves, Y Y, 3 in. long and a ¼ in. deep, at right

Fig. 5.—Modified Drop Shutter, working with Elastic Band—A, Case with Grooves; B, Ebonite Shutter; H, Pin; J, Elastic Band; K, Catch; L, Spring Catch; M, Aperture to remove Spring Catch.

ngles to each other, as in diagram. Pre-are two lengths of wood 3 in. wide and $\frac{3}{8}$ in. hick, as long as may be deemed convenient -12 in. is a good length. Nail and glue hem firmly into the grooves to form a kind f bottomless triangle, and on the inside ace of each attach some V grooving, made of either wood or zinc. The ordinary *straight* grooving of a plate box is sometimes used, but not to be recommended, as the edges of the grooves are likely to tear the film of negatives set in them to drain. The shape of the V avoids this fault. Care must be taken that the grooves are directly opposite each other. They are best fastened to their supporting sides by small screws, any projecting end carefully filed off. A coat of shellac varnish will complete it.

The Copying Easel.—In all studios where much copying is carried on some contrivance is requisite to support the picture, drawing, or whatever it may be, at a true right angle to the plate. The following easel (Fig. 2), although somewhat cumbersome, answers the purpose well. It will be seen to consist of two strong uprights on feet, framed together at the top and at a short distance from the floor, also centrally, a board working in grooves between them, kept in place by a rack and pin, and balanced by a heavy weight suspended in the rear. The difference in this from the ordinary artist's easel is that, instead of open framework, it consists practically of a large drawing board, on which can be pinned or fastened the drawings to be copied, an advantage that will be appreciated by those who have much of this class of work to do. To construct it, cut out two uprights, Z Z, 8 ft. long by $2\frac{1}{2}$ in. thick. The upper end of each may be somewhat ornamental, and the lower fixed into solid feet, Y Y. On the inside of one upright cut a groove 6 ft. long, G, and hollow the other out sufficiently deep to correspond with the opposite groove; and make up the outside with a hinged door, bolted top and bottom (Fig. 2 A), which, when closed, forms a groove for the projecting pins of the central board (Fig. 3, X X X X) to work in. To the centre of the bottom of the board fix an iron bar perforated with holes, half an inch apart, E, which passes through the lower connecting bar of the supporting frame, strengthened with an iron plate, and is retained at any height by the pin, F, being passed through and resting on the frame. On the lower face of the board is fixed a ledge, W, for the purpose of supporting framed pictures that would be too heavy to be supported by pins driven into the board, the usual way for light works. The diagrams will explain the construction in detail.

Instantaneous Shutters are, of all photographic appliances, perhaps, most varied in character, and may be numbered by the hundred, every maker having some pet design of his own that may embody some improvement on those that have been already constructed. The object in all cases is to give a brief exposure to the plate, always expressed in fractions of a second, in contradistinction to time exposures, which are generally understood to be from one second upwards. Some shutters claim to be under the control of the operator for any space of time, their speed being regulated by tension springs, and marked by a pointer on a scale. As to their accuracy for high speeds, it is somewhat doubtful. One of the first contrivances for instantaneous work, and which even now is not to be despised, is the drop shutter (Fig. 4), which we propose to describe. It essentially consists of a perforated screen, A, falling before the lens, the exposure taking place during the time the opening passes before the lens in the act of falling, the weight of the shutter being its only motive power. This speed may, however, be accelerated by the tension of an elastic band. This kind of shutter has several modifications, to work behind the lens, and through the lens mount itself in the position usually occupied by the diaphragms. The conditions essential for the satisfactory working of all shutters that are used in front of the lens, and attached to it, are, firstly, freedom from vibration during its action, and the absolute obscuration of light from the lens at other times. They should also be of as light weight as it is possible to make them, as they are generally used on small light cameras and lenses, that the additional weight of shutter on the lens hood tends to render less steady. Any shake produced at the *end* of the journey of the shutter is of no consequence, the exposure having been effected; but the *slightest* vibration during the time it is in transition is fatal to a sharp image. Such vibration is very difficult, if not impossible, to detect, except in the unsatisfactory result. A rough and ready method is by holding the lens in the hand whilst releasing the shutters, and noticing if there is any tremor during the movement. A very trifling jar may thus be detected. We will proceed to construct one. In the first place, the size of the lens for which it is to be made must be known, the diameter of the lens mount deciding the proportions of the shutter. A lens most frequently used for $8\frac{1}{2}$ by $6\frac{1}{2}$ pictures is the Rapid Rectilinear, the diameter of the lens hood being $2\frac{1}{4}$ in. We will take this as our guide. Plane and smooth some $\frac{1}{4}$-in. mahogany, or other light, close-grained wood, and make two pieces, $3\frac{1}{2}$ in. wide and 8 in. long. Glue a strip of wood $\frac{3}{8}$ in. thick and 3 in. wide across the centre of one of the pieces (Fig. 4 B), and when dry, cut an opening sufficiently large when lined round with a bit of cloth or velvet to fit the lens hood exactly and firmly; in the middle of the other, cut an opening $2\frac{3}{4}$ in. square, C. Blacken one side of each with black varnish or Stephens's ebony stain. The stain is, perhaps, the best. A strip of wood rather more than $\frac{1}{8}$ in. square is glued down each side to separate the pieces, and all glued and screwed together. We now have a shallow case, open at both ends (Fig. 4), with apertures in the centre of each, and facing each other. In a piece of ebonite preferably, although wood will do, $\frac{1}{8}$ in. thick and 14 in. long, the width of the inside of the case, make an oblong opening, D, 4 in. long and $2\frac{1}{4}$ in. wide, so that it will pass through the case with little or no friction. A strip of wood, E, is attached to the upper end to act as a stop, preventing the slide from passing through the case after the exposure has been made. In order to prevent any rebound, the strip at the top is made wedge-shaped, as Fig. 4, F. This completes the wooden portion of the shutter, and it may be actuated by hand, but it is better to fix a catch, G, on the side engaging with small saw-cuts in the edge of the shutter. In order to ascertain the proper position for these cuts, pull out the shutter until the lower part entirely covers the opening of the lens, holding it up to the light to make certain that none can pass; then make a saw-cut in it just above the top of the casing. Push down the shutter until the opening is fully disclosed, and make another cut. A simple pivoted catch (Fig. 4 G) is now fixed to the side of the case, the end of which will just engage the saw-cuts, and retain the shutter in either position with the lens disclosed for focussing or obscured ready for exposure. A slight pressure with the finger now on the catch will liberate it and the shutter will fall, the wedge-shaped stop, F, preventing any rebound. The favourite method of working all instantaneous shutters is by the pneumatic release, which is simply an indiarubber tube with an air-tight hollow ball at one end and an expanding tube at the other. Pressure applied to the ball expands the tube at the other end pressing against the catch, and so setting it in motion. The time of exposure of course depends on the rapidity of the fall and the length of the opening. With a shutter as described, about the twentieth part of a second is occupied; this may be decreased by slightly sloping the shutter, so that more friction is caused, or the speed increased by attaching an indiarubber band whose elasticity will give impetus to the fall. This is a very useful shutter, and free from vibration, and much good work has been done by it. Instantaneous shutters for very high speeds are altogether more elaborate affairs, and are made by the judicious combination of wheels, levers, and powerful springs. A modification of the drop shutter is constructed by substituting a groove, as in Fig 5, for one side of the casing. A small knob, H, is screwed into the shutter; an indiarubber band, J, passes over it, being fastened at each end to the sides of the case; the shutters being drawn out, the band is stretched, and, on being liberated, drives the shutter along the groove. A small spring catch is fixed to the lower edge of the slide that falls into a slot at the end of the journey, thus preventing any rebound. This shutter is used horizontally, and the speed entirely regulated by the strength of the elastic band.

The roller blind shutter is, as its name indicates, made on the principle of ordinary spring roller blinds, and may either be used behind the lens or before the plate, working either from right to left or from top to bottom. The blind itself is made of opaque material, with an opening cut across the centre of about half an inch in width and of the length of the plate, or diameter of the lens, according to the position it is intended to occupy in the camera.

Another very good form is the double drop shutter, designed by Mr. A. Cowan, and intended to work behind the lens, and is practically part of the camera front, working quite independently of the lens. This is constructed of two separate sliding pieces, one above the other. On applying the release, the lower part falls, disclosing the lens; and, on removing the pressure on the indiarubber ball, is rapidly followed by the other, which covers it again. It is not a very rapid working shutter, but sufficiently so for most purposes. Very free from vibration, the fact of its being attached to the camera instead of the lens is greatly in its favour, as any lens can be used, irrespective of size. The convenience of this form has made it a favourite with many leading photographers. Time exposures can be readily given with it, the exposure continuing so long as pressure is applied to the ball; remove the pressure, and the lens is at once closed.

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

120.—Patent Wire Thread Fret Saw.

I have replied more than once to correspondents in "Shop" that when I was in a position to state positively that the Patent Wire Thread Fret Saw was fairly on the market I would give the sizes in which it is made, and the prices current. I am now well able to do this, for I have received specimens from different quarters. A correspondent who gives no name sends two saws, and says, "The two saws enclosed are the finest, 00, and a thicker one, No. 5; they are made in sizes between. My correspondent signs himself "Bradley." Mr. Herbert Bolton, dealer in Fretwork Materials and Designs, 59, Burmantofts Street, Leeds, writes: "Herewith I beg to submit to your notice sample of the Patent Wire Thread Fret Saw that has been so much inquired for in 'Shop' for some time past. Will you mention in 'Our Guide to Good Things' that these are 7d. per dozen post free, or 6s. per gross? The sizes are from 0 to 5 inclusive." They are also kept on sale by the old-established firm of Messrs. Moseley & Son, 323, High Holborn, London, W.C., who wrote to me a short time since to say that they aro now prepared to supply them. These saws aro so constructed that the teeth project on all sides, and as the teeth run in a spiral from end to end it appears that the saw teeth are first cut in the ordinary way, and the blade is then twisted in order to give it its new form. The advantages claimed are: (1) That it will cut in any direction, so that it is unnecessary to turn the work; (2) that it never sticks fast but constantly frees itself; (3) that it is stronger than any other saw; (4) that it retains its cutting powers longer; and (5) that it cuts more rapidly than any other saw. Further it is said that the performance of this ingenious invention is most surprising in the way of cutting, and that the peculiar make renders it entirely free from all the faults peculiar to the ordinary fret saw, and capable of doing work that cannot be accomplished by the latter. A considerable saving of time is said to be effected by its use and its practice. Although its cost is somewhat higher it is found to be more economical than the straight fret saw, because a greater amount of work, on the average, can be done with each individual blade. Readers will find from their own experience, on making trial of them, whether this be so or not. For myself, I regret to say that I have not yet been able to find time or opportunity for testing them.

121.—"The Amateur."

I trust that amateurs who stand in need of more patterns for fret-cutting, wood-carving, and ornamental woodworking generally than can be given in Work will not forget the monthly magazine entitled "The Amateur," a serial publication of continental origin and production, published in this country by Mr. Henry Zilles, 24 and 26, Wilson Street, Finsbury, London, E.C. The third volume is commenced with the January part, and as the year is yet young a favourable opportunity for beginning presents itself to intending subscribers. In the December part, completing Vol. II., some excellent patterns were given for chip carving, or "notch cut work," as the Germans call it, a kind of surface ornamentation, with small carving tools, which is easily done, and is beginning to find much favour among ladies.

122.—Walker's Turning Patterns.

Mr. F. J. Walker, 41, St. Helen's Street, Ipswich, sends me a sheet of patterns for turning, comprising knobs, finials, spindles, pillars, etc., well proportioned and excellently drawn, and writes: — "Herewith I beg to hand you advance sheet of a set of turning patterns which I am preparing for publication. The set will consist of 50 distinct patterns in 5 sheets of 10 each. They will all be the same size, and equally well drawn as the enclosed, the only difference being that those for sale will be printed by the ferro-prussiate process direct from the tracings. I would beg to call your attention to the fact that these patterns are not stencilled copies of common mouldings, but originally and accurately drawn. I shall issue the first 100 sets to the readers of Work at 1s. per set, after which the price will be 2s." Let me warn my readers that there are only 99 sets to be had at the low figure named, as I have taken advantage of priority of knowledge, and secured set No. 1 by lodging the required coin of the realm with Mr. Walker. It is the best testimony I can give with regard to the excellence of his patterns from my point of view, judging from tracing of Sheet 1. The Editor.

SHOP:

A Corner for Those who Want to Talk It.

NOTICE TO CORRESPONDENTS.

*** *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Angles for Hoppers.—J. G. W. (*Glasgow*) writes:—"On page 414, No. 26, B. A. B. gives a sketch of how to get the angle of boards for hopper, which is quite clear. Instructions are still wanting how to find the angle for butt joints when the top and bottom edges of the hopper are square to the faces

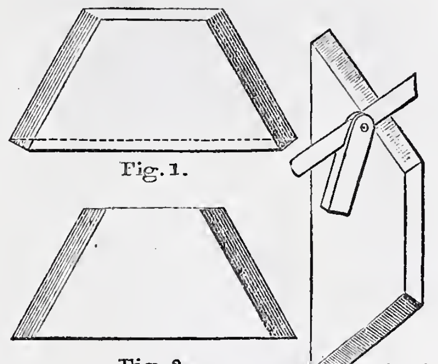


Fig. 1. Fig. 2 Fig. 3.

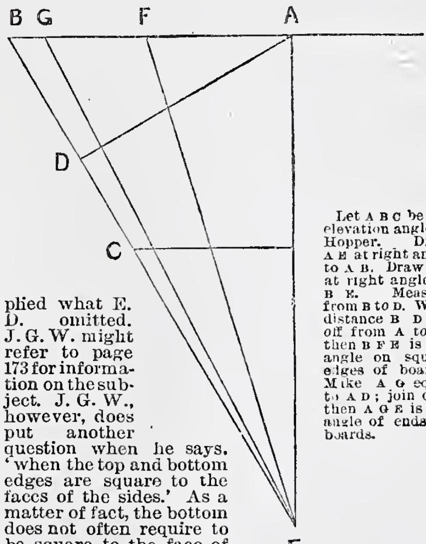
Angles for Hoppers.

of the sides, as in Fig. 1, not as in Fig. 2—that is to draw down the angle for the butt joints, and set a bevel to it, and apply to the butt edge, as in Fig. 3. I think this is the point which most of us can't get over. If you possibly can make this clear, I think the mystery will be solved."

"In answer to J. G. W. (*Glasgow*), may I be permitted to say that my reply, which he understands, was only supplementary to that written by E. D., and printed on page 173, June 1. I therefore only supplied what E. D. omitted. J. G. W. might refer to page 173 for information on the subject. J. G. W., however, does put another question when he says, 'when the top and bottom edges are square to the faces of the sides.' As a matter of fact, the bottom does not often require to be square to the face of sides. I will try to make it plain. He (J. G. W.) will also notice I give another but equally correct plan for getting angle of ends of boards. Scarcely any books give any help on this subject.—B. A. B."



Let A B C be the elevation angle of Hopper. Draw A E at right angle to A B. Draw A D at right angle to B E. Measure from B to D. With distance B D lay off from A to F, then B F E is the angle on square edges of boards. Make A G equal to A D; join G E, then A G E is the angle of ends of boards.

Angles for Hoppers.

Registration of Printers.—W. I. W. (*Banchory, N.B.*) writes:—"H. E. C. (*Wednesbury*) writes in 'Shop' (see page 509) about registration of printers. Being a printer in a small way I intended to follow his advice, and have myself registered with the Clerk of the Peace as stated. I applied to the Clerk for County of Kincardine, but he is not aware of on what conditions a printer may carry on his business, and if they have to be registered, he says, it is not with him. How does H. E. C. account for this?"

Taking out a Patent.—Loco (*Finsbury Park*) writes:—"As one greatly interested in Work from its commencement, I was glad to see an article on the above subject (see page 545), as I believe many would-be inventors are kept from availing themselves of the protection afforded by law, through their ignorance of the mode of obtaining a patent. To such as these your correspondent C. C. C. has afforded some valuable hints, while at the same time he seems to have fallen into the same error as, I might say, the majority of those for whom his article is intended—that is, that as soon as provisional protection is obtained the inventor is safe, or, to quote his own words, 'as safe (meanwhile) as if the patent had actually been granted.' Now, although provisional protection secures us against subsequent applicants, and also secures to us the right to publish and use the invention without prejudice to the patent to be obtained, it does not secure to us the full rights of a patentee—that is to say, the right to prevent others from making and using the invention to their own profit. For instance, suppose our imaginary friend, the inventor of the wheelbarrow, after getting provisional protection for his invention, forthwith starts to make and sell the same. A second individual or imitator (of which there are many), seeing that the invention is only provisionally protected, also starts to make and sell similar wheelbarrows. Then the original inventor has no remedy whatever, as he cannot sue the imitator for any act of infringement committed before the patent is actually granted. Any profits that the imitator may have gained are therefore legally his own. I do not see exactly why your correspondent should prefer to describe everything so fully by the aid of drawings, as when the complete specification comes to be filed he will then have to adhere pretty much to the description given in the provisional specification, as the examiners are sure to object to anything being inserted in the complete specification which was not indicated in the provisional specification. Your correspondent C. C. C. would have done better to have left out the claim which he makes at the end of his specification, as no such claim is necessary in a provisional specification. Where a complete patent is taken out in the first instance in addition to the two forms marked C, a form marked A or A¹, bearing a £1 stamp, as in the case of provisional protection, is also required. It will thus be seen that the forms for the complete patent will cost £4, the same as when a complete is filed after a provisional."—[With regard to Loco's comments on what has been said *à propos* of provisional protection, I must still be allowed to retain my former opinion. I know that the words of the official circular are that "Provisional protection entitles an applicant to use and publish his invention without prejudice to his patent rights, but does not protect him from the consequences of infringement," and that this would seem to credit it with a very limited value only. But it appears to me that the common opinion drawn from experience may givo a more truo appreciation of it. A rival maker may, as Loco suggests, make and sell a similar article. But he cannot well do so without its coming to the ears of the inventor, who thereupon completes his patent, and stops the sale, with probably a result of loss rather than gain to the pirate. Or, a second inventor may, in the interim, obtain protection for a similar invention. Such a caso has occurred within my own knowledge; but the first applicant having the right to complete first, did so, and the second inventor had simply to withdraw. Only a negligent inventor will, as it appears to me, be otherwise than virtually safe. As regards a claim in the provisional specification, it is immaterial; additional claims can be added in the complete specification. It is rather a matter for individual judgment. As to Loco's objections to the free use of drawings, let me say that an inventor ought to be able to adhere pretty much to his drawings; but he can, if he pleases, add others in his complete specification. I have added a converse method in one case, and no objection was made to it by the examiner. Loco will, I think, see therefore that his objection is of no great moment, whilst the following special advantage may be instanced. If he bears in mind that "pictures are the books of the illiterate," he will see how much better the working man understands the specification when it is read over to him, if it is freely explained by drawings. In most cases where a working man has come to me, he has first made a model, and the parts of this he recognises in the drawings at a glance, and is able to detect any little omission should there be any. I imagine also that explanation by drawings must save thought and time to the officials at the Patent Office.—C. C. C.]

Simple Incubator.—J. E. L. (*South Lambeth*) writes:—"In reference to B. F. (*Liverpool*) (see page 557), I beg to ask if he will kindly give us more explanation respecting the simple incubator, with garden pots, which he shows in his diagram, marked D, D. Do they both join together, or is there a passage through, and what is the supposed amount of heat from the lamp to produce satisfactory results? Has the box a door to it or is it left open?"

II.—Questions Answered by Editor and Staff.

A Baby's Crib.—Clydeside.—I do not think the construction of a baby's crib should be beyond your power. Of course, knowing nothing of your skill in joinery, or the size of the baby, which is a variable term—one has known babies of seventy-five—it is hard to give exact details or measurements. Speaking roughly, I should think a plan about 4 ft. by 2 ft. 6 in. would allow room for growth. I should take four upright posts, at the usual height from the floor, and mortise in cross pieces; or, if this be too technical, use thicker wood and simply screw each piece. A top rail at the usual height might be added, with a railing of either straight or turned wood to keep the precious contents from early nocturnal expeditions. The floor, so to speak, of the bed could be made of sacking nailed to the four pieces of the frame. If space permits, it may be possible to give a working drawing of such a thing, which would no doubt meet the wants of many. But for the sake of household peace, remember the old rhyme, and see that whatever may be made is strong, else down may come baby, crib, and all, and this member of the staff of Work become accessory, however innocently, to baby slaughter. Knowing the peculiarly destructive power of the young Briton, I should suggest cast iron or wrought steel as the best material, did not I fear the flippancy of the advice, no less than its impracticability, would be condemned. Seriously, no work could be more deserving of honest praise than such as you purpose, for the love of a strong man for his child is perhaps the most sacred thing of this life, and if the above remarks seem too jocular, I pray you pardon them, for I know no nobler instinct than this fatherly care for childhood.—J. G.-W.

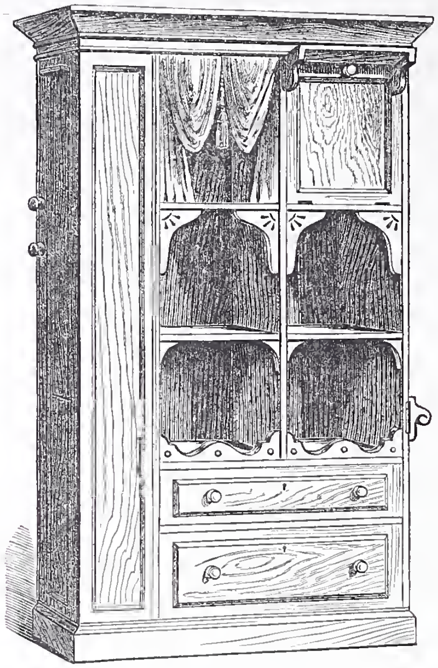
Organ Engine.—A Well-wisher (*Chichester*).—The Otto Silent Gas Engines are made from half horse-power upwards, and are adapted for organ blowing. If your single manual organ is not a large one, I should think the half horse-power engine would be sufficient for your purpose. I am unable to give you any information as to the price of the engine, but if you communicate with the vendors, they will no doubt be pleased to furnish you with full particulars. I believe the engines consume about 23 feet of gas per hour per indicated horse-power.—M. W.

Binding Single Plates. — Clydeside. — That "Bookbinding Made Easy" proved intelligible to you is somewhat of a relief to its author, for a dear friend who told him the sort of truth dear friends are apt to indulge me with, said he tried in vain to understand it. The great obstacle to binding single pages is that, try how you will, the book will not open flat, unless you paste each couple together with a strip of paper folded at the back, and thus make them, to all intents and purposes, ordinary folio sheets. If this course is not adopted, and it is a tedious and delicate task, the only other way I know is to lay all the pages in a pile with their edges exactly true, then taking a finely pointed bodkin or bradawl, bore a series of holes some quarter inch from the left-hand margin, and stitch them firmly with coarse thread or fine twine. So far it is plain sailing, but immediately the difficulty arises how best to fix them in a cover, and although I have tried a dozen makeshifts, I must own I never succeeded in doing so with a stiff cover, and now always fold a piece of limp cardboard, scored to fold with a sharp clean angle, just over the whole lot of prints, and bore the holes through it, stitching it with the pages themselves. If a piece of linen or buckram is pasted over the back to keep the stitching firm and safe, the book is well preserved, but it does not lie open as a book should. On the whole I should recommend, if the book is one likely to be used for reference, or still more if wanted for purposes of copying the plates—supposing them to be designs of some sort — that Clydeside should boldly face the trouble of affixing strips of paper to the backs and treat them as if they were ordinary pages.—J. G.-W.

The Mail Cart. — G. F. (*Nottingham*). — An article has been written on the mail cart with drawings of same, and appeared in Work, No. 30. There are three different designs, each possessing a novelty in the make. Since the article was written I have thought over a plan whereby a lifting hood might be made to fit the cart to protect the children from sun or rain.—W. P.

Ladies' Work Box, etc. — S. H. D. (*Newtown, Mont.*). — Every endeavour will be made as successive numbers appear to meet the desire of subscribers for small things, as well as large. In due time the wishes of yourself and your six friends shall be fully met, but it is not possible, as you must know from everyday experience, to do everything at once. Something, and indeed many things, must be kept waiting.

Combined Bed Suite.—J. H. H. (*Oldham*).—I venture to submit rough sketch of combined bed suite with less work in it than that published. I do not think it advisable to take away any more wood, if it is intended to make it a large job as per sketches. If a smaller article is required the bottom part might be taken away bodily, and the top part rest on four stout legs, the whole panel of the door falling down as flap, and being hinged to the bottom door stile. Concerning the thickness of wood I had more than one reason for giving it as $\frac{1}{2}$ in. Firstly, it will be apparent that if it is made as in No. 26 of Work, and the wood is even $\frac{1}{8}$ in. thicker throughout, it will increase the weight of job to nearly a quarter as much again. Secondly, this extra wood means extra expense. Thirdly, if made in comparatively thin wood, as there are so many boards connecting with each other, it will have a sufficiently firm and solid appearance. In the sketch, however, $\frac{1}{2}$-in. wood would scarcely be the thing, as there is so much space to counteract the effect of the wood. I should say have the sides and the long door $\frac{7}{8}$ in. thick, and the centre upright board and the horizontal ones $\frac{3}{4}$ in. thick. The glass door might be $\frac{5}{8}$ in., and the drawer fronts $\frac{1}{2}$ in. You will see that I show two knobs on the



Combined Bed Suite.

long door stile. One is to fasten the flap, the other the whole door. So far as I can recollect, I believe I showed this in my original drawing. Whether or no I cannot positively say, but if I did the engraver must have left it out, probably considering it was a mistake, or else concluding that one knob would fasten the flap to the stiles, and the door to the job. This latter could be done, but then the flap would always be loose, unless the door were shut. In the present sketch I have shown the glass door rests at the top, to come within the thicknesses of the two sideboards, and not on them as in Work No. 26. If the centre shelf is placed at the proper distance it will form a support for these rests, to keep the glass at the angle.—J. S.

Punching Dies. — R. G. (*Denham*). — Punches and dies are hardened by heating to a low red, and plunging in water. You ask for a few hints on hardening and tempering in general. This is almost entirely a matter of practice, but the following are of the nature of fundamental principles:—(1) Hardening almost invariably precedes tempering; the reason being that it is easier to lower a body to a definite grade of temperature than to raise it to that grade. (2) Since all articles are liable to warp in hardening, various practices are necessary to lessen this tendency, as heating articles in boxes to render the temperature equable, plunging vertically into the hardening mixture, cooling between plates when the articles are thin, and using lukewarm and oily or medicated mixtures. (3) The less often steel is passed through the fire the better, and overheating should be scrupulously avoided. A clear fire should be used, and charcoal is better than coal. (4) The scale should be ground off before heating, and the oxide produced by the fire rubbed off with a stone, and then with waste to render the changing colours visible. (5) Small objects are better heated on a hot bar of iron than in the fire, as the colours are then more readily observed, and the temperature under better regulation. The shank of the tool is often used as a reservoir of heat for the cutting point, communicating its heat thereto until the right colour is obtained for quenching.—J.

Siemens' Drum Armature.—Puzzled (*Burnley*).—The machine you saw was probably one of Siemens and Halske's continuous current dynamos. In these machines the ends of the armature coils do not each terminate in two segments of the commutator as in the form known as the Siemens H armature. In the machine you describe there are 12 coils on the armature, and 48 bars on the commutator. The ends of each coil, therefore, branch out to four different bars arranged on opposite sides of the commutator. Each coil of this armature is made to cut the lines of magnetic force four times during one revolution of the armature, and this gives a certain continuity and regularity to the current. If you care to go into the subject further, you will find a full description of these machines, illustrated by diagrams, on pages 299 to 302, part 5, of "Electricity in the Service of Man," now being published by Messrs. Cassell & Co., Limited, at 6d. each part. I can highly recommend this book to all students of electricity.—G. E. B.

Violin Bow-hairing.—Jeune Écolier.—I am preparing a paper, with illustrations, on the above subject, which will appear as soon as space permits. Organ and harmonium building will be thoroughly treated in Work.—B.

Violin Strings.—Sheffield Blade.—I cannot obtain the information you desire, but surely if you pay the price you will have no difficulty in getting the strings you require. Try Tarr, of Orchard Street, in your own town.—B.

Flux for Solder.—Blowpipe wants to know what is the flux used by silversmiths for silver solder, and how to prepare and use it. It is borax, and the necessary conditions of successful soldering are perfect cleanliness and freedom from grease and all other impurities in everything used in connection therewith. The solder and the work to be soldered must be scraped clean, and the borax slate and pencil must be washed clean. Generally borax—lump borax, not powdered—is rubbed up with water until it is as thick as cream, or until it stands in ridges. The article it is rubbed up on is a piece of clean slate, 4 to 6 inches in diameter, and to roughen it it is sometimes scored across with the edge of a file. Make plenty while you are about it for the job in hand, and apply it to the work with a borax pencil (camel-hair brush), taking particular care to get all the surfaces that the solder is to run over covered with it. The next thing to do is to prime your work with solder, and for silver it would most probably be small pieces called "pallions" that we should use, and they would be picked up by the borax pencil and laid along the soldering seam. All you now have to do is to gently heat it to drive off the moisture, and then, if these "pallions" have not moved away, you can apply the full heat and make the solder run. Another way, after boraxing the soldering seam, is to have a narrow strip of solder and apply it to the work at about the time you think it will run, and as it runs you move it along until you get to the end of your soldering seam. Should there be too little borax on your work, you can pass a piece of the lump borax along it, and it will hold if the work is hot. This is in place of leaving the work to get cool previous to applying more with the pencil. The strip of solder spoken of above must be held in pliers or something of that sort. Borax is sometimes burnt and powdered before mixing with water, but that is only for cases where it is of great importance that the solder does not move. I hope this answers you. If it does not, then please write again.—H. S. G.

Fern Case and Fountain.—D. M. (*Larbert, N.B.*). — I presume you mean that you want a fountain for the inside of fern case. If so, you had better not have one of the self-acting kind, as it is hardly likely that your case—not having been designed for that purpose—would be suitable. An article appears in No. 31 which contains details of a very simple plan of fountain, which you can easily adapt to your requirements.—C. M. W.

Chiming Clock. — H. E. B. (*Liverpool*).—It is not possible to deal with this subject at present.

Home-Made Lathe.—H. E. B. (*Liverpool*).—Instructions for making lathes of a simple character are given in the papers entitled "Lathes for Everybody."

Advertisement Pages.—J. G.—I am obliged to you for the correction, which I have forwarded to the writer of the paper. I am glad to know that you find Work helpful. There is no necessity, I think, for me to repeat what I have already said so often about the pages that contain advertisements.

Building Society.—Plumber.—It is altogether beyond my province to say anything with respect to existing building societies. I may add, however, that I am unacquainted with the one about which you write. You have the rules, I presume, and can ascertain from them if you can withdraw the money that you have already paid in.

Glass Staining and Lead Light Work. — Plumber.—It is not possible to commence a series of papers on these subjects in Volume I.

Painting Carriage.—W. M. (*Islington*).—You have omitted naming your carriage in your query. The two prettiest colours I know of to go in combination with silvered work are lemon yellow and black—the body panels and under-carriage painted yellow picked out and fine lined black, or picked out lilac and fine lined black. The monogram, if any, to be in the following colours, blue, red, black, green, and brown. If we have the body and under-carriage black, we pick out with a shading yellow graduating from a tan brown at the top to a chrome yellow at the bottom. Get a tube colour of chrome yellow, raw sienna, and burnt sienna; the last two must be mixed with white or yellow and gold size. Instead of placing the colours upon each other we can place them in close proximity to each other, taking care that the yellow is quite dry, or the colours will run into each other. Get your strongest fine liner you have and line, leaving a space of $\frac{3}{8}$ inch between. When dry get your raw sienna mixed with white, and line two lines within this space, these lines just touching the chrome lines. There will be a space left; this we fill up with tan colour made of burnt sienna and white mixed.

This has a very stylish appearance when finished. This lining looks well upon a dark brown. The monogram should be in silver or gold shaded, the body fine lined yellow. The following would also look well, which I will give for the benefit of other readers :—Rich blue body panels, fine lined yellow. Under-carriage yellow, picked out black or blue, fine lined black. Green body panels, fine lined vermilion. Under-carriage vermilion, picked out black. Rich olive green body panels, fine lined lake-glazed vermilion. Under-carriage lake, picked out black, fine lined vermilion. Brown body panels and under-carriage in any shade, fine lined with white, orange or tan, picked out black. The mouldings of the body in all cases painted black. I shall be pleased to supply you with further information.—W. P.

Hand-Railing and Staircasing.—Brutus.—I will endeavour to meet your wishes on this point as soon as I can. I have some drawings from the workman of whom I spoke in the early numbers of Work, but they are unaccompanied by descriptions, and he is now far away from London at work on a long job in the country. I must try to find someone else to write on the subject, but whoever may undertake it must not run in the old grooves. Readers seem to think that there is no trouble whatever to get good writers on special subjects. If they had had my experience, they would find it by no means as easy as they imagine, and would not wonder at the delays that frequently occur.—Ed.

Brass Ball Making.—E. J. B. (*Blakenhall*).—By all means send me the article referred to on "Brass Ball Making" on approval.

Tinning Cast Iron Diameters. — Tinner (*Hull*).—Your testimony as to the value and utility of Work is very gratifying. We are always pleased to hear that our efforts are appreciated by those for whom we write—viz., those who are willing to learn and anxious to improve their knowledge, not only of their own trades but of anything useful. To tin cast iron articles, they must first be pickled in a bath of mixed acid—hydrochloric acid 2 parts, sulphuric acid 1 part, water 7 parts. The stronger the pickle is made the quicker the articles will be ready. Heating the pickle also will cause it to act quicker. I used to use a large wooden tank lined with lead, and a steam pipe led to it from the boiler that drove the engine. When the things are sufficiently clean, rinse, and dip in a bath of "killed spirits" in which some lumps of sal-ammoniac have been dissolved. Pour this into the tinning bath, on which keep plenty of sal-ammoniac in a melting state. When tinned, take out and wipe or shake off the superfluous tin as required by the circumstances of the article. Cast iron is not so easy to tin as wrought iron, and some samples of iron are very difficult to tin at all. With regard to your second query—for a scale of circumferences for diameters of 1 in. to 24 in. I will tell you how to get the circumference of anything if the diameter is known. The rule is to multiply the diameter by 3·14569; thus an article 1 in. in diameter $1 \times 3{\cdot}14569 = 3{\cdot}14569$. If this is too difficult for you to calculate for the sizes you require, here is a very simple plan, which gives results quite accurate enough for any ordinary work. Divide the diameter into 7 parts, and take 22 of these parts for the circumference; thus, supposing a piece of pipe 7 in. across, $\frac{1}{7}$ of this is 1 in. multiplied by $22 = 22$ in. When the diameter runs into odd measurements, it is perhaps best to work it out with a pair of dividers instead of an arithmetical calculation, as you would have to go into decimals to get accuracy. If you want these sizes for stove pipe and similar work, you must add sufficient to allow for the seaming, or if riveted for the lap.—L. L.

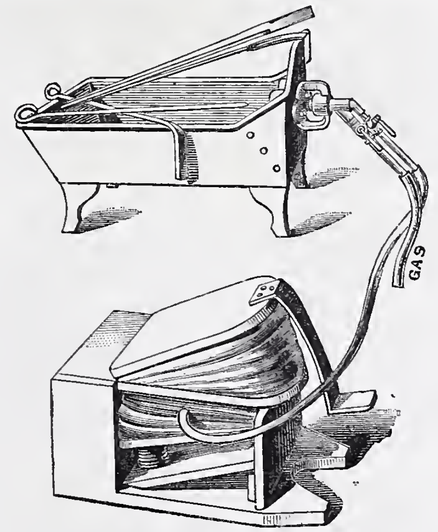
Duties of Telegraph Linesman. — W. W. (*Cupar*).—I do not know of a book detailing the duties of a telegraph linesman, and how to perform them. If any of our telegraphist friends know of such a book, will they kindly oblige us and W. W. by giving us the title, price, publisher's name, etc.?—G. E. B.

House Painting.—X. Y. Z. (*Liverpool*).—The following is a suitable book on house painting :—"House Painting," by Davidson, 5s., published by Lockwood & Co., Stationers' Hall Court, London.—F. J. C.

Drills.—C. E. (*Greenwich*).—Yes, you must soften the steel to form the drill, by heating it to a low red heat, and allowing it to cool gradually in air. When the drill is formed, and you want to temper it, proceed thus :—Heat it to a low red, and plunge the tip only in water. Withdraw it, and brighten the portion just immersed by rubbing a bit of soft stone upon it, and brush it quickly with a bit of waste. Now watch the changing colours imparted to the hardened point by the heat still remaining in the unhardened shank. When the point becomes of a plum colour, or dark purple, immerse it vertically in water until quite cold. I cannot see the reason of the method given in *Scientific American*, but turpentine is often used to assist the action of a drill through very hard substances.—J.

Sign-Writing Charges.—R. C. (*Chertsey*).—I am sorry to say I am unable to give R. C. any direct particulars as to the prices charged by sign-writers. Prices vary in almost all parts of the country, being highest in London, and other large towns; poor workmen also take work at a lower figure than their more skilled brethren would deign to accept, and the result of keen competition often leads to a lot of "cutting" in prices. R. C. may possibly, however, find this and other useful information in the following handbooks, which are published annually. Before purchasing these, though, I would advise him to write to the publishers, and ask if they contain prices of sign-writer's work. I know they contain prices of painters' and paperhangers' work, but am not sure as to sign-writing. (1) Lockwood's "Builders' and Contractors' Price Book for 1889" (3s. 6d.). (2) "Quantities and Measurements in Bricklayers', Masons', Plasterers', Plumbers,' Painters', Paperhangers', Gilders', Smiths', and Carpenters' Work" (1s. 6d.), Crosby Lockwood & Co., 7, Stationers' Hall Court, E.C. (3) Spon's "Builders' Price Book" (3s. 6d.), E. & F. Spon, 125, Strand, London. Perhaps, however, some reader of Work would kindly give a price list for sign-writers based on London wages.—H. L. B. N.B. I will endeavour to include a price list in my articles if possible.

Coke Forge.—Young Apprentice (*Kettering*).—I send you a sketch which will show you what you want: it is Fletcher's gas forge. You will see that a foot blower is necessary to work it; a bladder, as you suggest, would be of no use whatever, so don't waste valuable time experimenting with that. A fan would, perhaps, answer; but there is not the force and power in a fan that you would get from a foot blower, and these are recommended by the makers. The forge shown in sketch is a very useful article in a workshop for small odd forgings, doing



Coke Forge.

up lathe tools, etc. It is perfectly clean, no trouble in lighting, and is always ready for use. Starting all cold a slide rest tool can be repaired in about two minutes. The way to use it is as follows :—Fill the hearth with small coke, light the gas at the blowpipe, and use the blower. In a minute turn the gas out, and then turn on again, a very small quantity, not enough to burn at the blowpipe jet, but sufficient to visibly brighten the fire. When the heat is obtained the forge may be worked without the gas, but a little gas doubles the power. The gas must not burn at the blowpipe jet, except for the first minute. The parts may be had separately. Blower only, No. 590, £1 15s.; blowpipe, 10s. 6d.; hearth, 15s.; so what you do not succeed in making you will know the price of, and where to get it.—R. A.

Tin and Tinware.—No Name.—In speaking of tin as a metal, we do not mean the tin used for making up tinware. This is not tin at all, though it is often so named, but simply iron plates coated with tin. The pure metal tin is sold in blocks varying in weight from about 18 to 28 lb. This is called block or ingot tin. It is also sold in bundles of long strips; this is the kind termed grain tin. It is supposed to be better than the block tin, but I cannot say that I have noticed any difference; it is a convenient form for users of small quantities. Tin in the block or ingot gives a clear ringing sound like a bell when struck, and in strips can easily be recognised by a peculiar crackling sound when bent. Both tin and solders can be bought of any good ironmonger or coppersmith, value about 1s. per lb. retail. To melt, place it in an iron ladle or plumbers' metal pot; melt over a forge or kitchen fire, using a little resin as a flux.—L. L.

Electro-Gilding.—G. F. (*Birmingham*).—I hope shortly to be able to thoroughly deal with the subject of electro-gilding in an article in which I will endeavour to provide for your wants. The best solution for a novice or an amateur is one made up by the battery process, in which pure gold is dissolved in a solution of cyanide of potassium by the current from a strong battery.—G. E. B.

Model Yacht.—White (*Shipley*).—I know of no book, inexpensive or otherwise, which deals with the class of model which you are building. A model merchant sailing vessel, for which you require instructions in rigging, is seldom made by the ordinary model yachtsman, it being almost an impossibility to sail such a model on anything like a definite course. If (as I presume it is) your model is only ornamental, and not intended for sailing, your best course will be to notice and copy the arrangement of the rigging of any specimen of naval architecture you may happen to see, and then to find a good picture or engraving of the type of vessel you wish to make a model of. You will find some excellent cuts of all classes of vessels in the numbers of *The Illustrated London News*, particularly in the old numbers of that paper, and you will then get a very good idea of what your model should be. As to the actual rigging, there is very little required beyond care and plenty of patience, and as you do not specify whether your model is a brig or a full-rigged ship or what not, I cannot without fuller particulars give you definite instructions as to the proportions of the masts, spars, etc., for which, if you require them, you must write again giving the necessary information. I may say, however, that the masts and spars should be of straight-grained yellow pine, the sails of fine calico, edged with cord, and the cordage, shrouds, etc., of the best water cord, or fishing line, of various thicknesses.—G. J. E.

Printing Book. — Saraband (*Bridgwater*). — Printing is so universal a term, and embraces so many kindred arts, that I regret you did not define the particular kind of printing—*i.e*, letterpress, lithographic, copperplate, photographic, or process printing. The books on these arts are legion. You may, however, select from the following in the meantime, and address the editor again giving minute particulars, if my selection does not give you the precise information he requires: "Printing Machines and Machine Printing," 5s., Frederick J. F. Wilson; "Grammar of Lithography," 5s., W. D. Richmond; "Colour and Colour Printing as applied to Lithography," 5s., W. D. Richmond; "Zincography," 2s. 6d., Josef Bock.—J. W. H.

Tempering Tools – Long Chisels. — T. O. (*Liverpool*).—I answered this writer at your request fully, and sent it to you promptly with another question at the same time, I think. Briefly, he careful in forging to draw the steel regularly, not to smash the grain on one side, and work it unevenly. Steel-workers know there is science in the method of striking. It is explained in "Sword Making" in Work. Also in letting it cool in the ashes after forging. Heating in a "muffle" is essential. Use an oil bath—that is, two inches of linseed or other oil floating on the top of the water. Put the chisel straight down through the oil into the water. Do not move it sideways at all, but draw it straight up out of the oil and water bath.—J. C. K.

Jet Warehouse.—G. H. (*Hetton-le-Hole*).—G. H. will be able to get all the jet he wants from the Whitby Jet Association, 17, Hatton Garden, London, E.C. It will be advisable to clearly specify the purpose it is wanted for, as I am given to understand that there are some six or seven different sorts.—H. S. G.

Egyptian Articles.—H. C. T. (*Newcastle-on-Tyne*) and T. E. P. (*Cambridge*) will find Cavendish House, Cheltenham, a depôt for Egyptian goods.—C. H. O.

Book on Violin Making.—C. D. A. (*Glasgow*).—A good book is "Violin Making," by Allen, 10s. 6d., published by Ward, Lock & Co.—F. J. C.

Sign Writing.—A New Subscriber (*Hackney*).—Papers on this subject have appeared in Nos. 1, 2, 4, 11, 13, 17, 19, 23, 30, 34, 39, 43, and 44 of Work.

Spiral Spring.—Basil.—I should advise you not to attempt to make the springs; it is work requiring special knowledge and training, and you will find it cheaper and more satisfactory to buy them. The size you mention should be made of steel.—F. C.

Casting and Moulding.—A. W. A. (*Aylestone*). The subject of clay modelling will be noticed in turn in a series to be commenced by-and-by on foundry work.—J.

Moulding Papier-Mâché.—H. C. C. (*Hornsey*) will find that his first letter was duly answered. Some little time must necessarily elapse before the reply to any query can appear in "Shop."—S. W.

Ticket-Writers' Ink. — R. H. — Ticket-writing ink is called japan ink, and may be obtained at any large stationer's cheaper than it can be made at home—viz., 6d. per bottle. The following formula, however, is simple :—Evaporate some of the water from the best black writing ink in a moderately heated oven, then add liquid gum arabic to replace the water lost in evaporation. This will dry with a gloss.—H. L. B.

Fret Saw.—H. B. (*Manningham*). — Without having full particulars of the stand you wish to utilise it is impossible to give such directions as would be of the slightest use to you. Even with them I am afraid you would find "the game not worth the candle," for fret machines are to be bought so cheaply that, by the time you had made the necessary alterations and additions, the expenditure would probably be more than if you had bought a machine. You may often pick up a second-hand one by advertising at a very low figure. An umbrella stand will be described in an illustrated article in due course. Directions for cleaning up wood for polishing will also be given. I think you will find that you may learn much from every page of Work. As you say, the remarks on planing and planes are very interesting, but what is more to the purpose they are thoroughly practical and intelligible.—D. A.

TABLE GIVING PROPORTIONS OF WHITWORTH SCREWS AND NUTS, WITH CHANGE WHEELS TO CUT THE SAME.

Diameter of Thread.	Threads per inch.	Wheels required for lead screw of ½-in. pitch.				Diameter at bottom of thread.	Sectional area at bottom of thread.	Hexagon nuts.

Change Wheels.—F. W. H.—You describe the wheels of the two lathes you use, with the intention of asking "two questions," but you conclude without asking any question at all. As I am not a thought reader I can only guess what you may want to know. Here, then, is a list of useful pitches taken from a table of Whitworth bolts, and including gas threads:—40, 32, 28, 24, 20, 18, 13, 14, 12, 11, 10, 9, 8, 7, 6, 5, $4\frac{1}{2}$ threads per inch; 28 is "brass gas," 14 and 11 "iron gas." Probably you will want no others than these. Now for your first lathe, which has a screw of 2 threads, and 13 wheels of 16, 20, 22, 32, 36, 40, 40, 44, 48, 56, 64, 72, 80. Put the 16 wheel on the mandrel, and try each of the larger wheels on the screw, thus:—$\frac{16}{80}=\frac{1}{5}$, but as the lead screw has a pitch of $\frac{1}{2}$ we get by this arrangement a pitch of $\frac{1}{10}$, or ten threads per inch. This is the finest pitch the wheels will cut when arranged in single train. Trying other wheels on the screw we get—$\frac{16}{72\times2}=9$ threads, $\frac{16}{64\times2}=8$ threads, $\frac{16}{56\times2}=7$ threads, $\frac{16}{48\times2}=6$ threads. You see why the numbers 80, 72, 64, 56, 48 were chosen; the 16 becomes 8 when divided by the 2-pitch screw, and the numbers of the wheels are multiples of 8, so that they give 10, 9, 8, 7, 6 threads exactly, as required by the Whitworth rates. Continuing our investigation, $\frac{16}{44\times2}$ gives $5\frac{1}{2}$, $\frac{16}{40\times2}$ gives 5, $\frac{16}{36\times2}$ gives $4\frac{1}{2}$, and $\frac{16}{32\times2}$ gives 4 threads per inch. We need go no further in that direction, but only notice that the number of teeth in this part of the series rises by 4 instead of by 8, enabling us to get $5\frac{1}{2}$ and $4\frac{1}{2}$ threads per inch. However, thus far we have all the required rates from $4\frac{1}{2}$ to 10, and the remainder we must seek for by means of the compound train. Having already obtained 10, 9, 8, 7, 6, 5, $4\frac{1}{2}$ threads as before explained, it will be understood that if we put on the intermediate stud a pair of wheels which are as 1 to 2, say the 22 and 44, or 32 and 64, we can reduce the speed of the lead screw by one-half, and so multiply by 2 the pitch of the screw we shall cut. Now multiplying 6, 7, 8, 9, and 10 by 2 gives us 12, 14, 16, 18, 20 threads; by putting on intermediate wheels of 3 to 1, we might get 24 threads from 8; and by intermediate wheels of 4 to 1, from 7, 8, 10, we get 28, 32, 40 threads. The 16 and 48 wheels are the only ones which are as 1 to 3, therefore, as we have only one 16 wheel we must put for 16 and 64 to give 8, 20 and 80, so as to leave the 16 and 48 wheels free for the intermediate stud; 16 and 64 bear the same relation to each other as do 20 and 80. In placing the pair on the intermediate stud we must, of course, put them on so as to reduce the motion, the larger going on first to be driven from the mandrel, and the smaller next to drive the wheel on the screw. Looking over our list of pitches, we shall see we have obtained them all but 11 threads, quite an important one, since it is not only the rate of Whitworth bolts of $\frac{9}{16}$ in. and $\frac{5}{8}$ in., but it is also the rate used on iron pipes of 1-in. bore and over. Now we obtained $5\frac{1}{2}$, and, though that rate is not in the table, by doubling it we shall obtain the wished-for 11. Your second lathe has also the $\frac{1}{2}$-pitch lead screw, but it has, apparently, the usual set of 22 wheels rising by 5 from 20 to 120; you say, however, that the 35 wheel is "fixed" on the mandrel; I don't think so, but if it is, I would have it off somehow, if it had to be turned off, and put instead the 20 wheel, which is most often wanted with a 2-threaded screw.—F. A. M.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Safety Cages.—T. J. (*Dudley*) writes in reply to E. J. J. (*Notting Hill*) (see page 590):—"I shall be pleased to put before E. J. J. a new safety apparatus for mine and other cages, which for simplicity and certainty of action I claim to be the very best yet introduced."

Ink Bottles.—J. W. W. (*Hanley*) writes in reply to INQUIRER (see page 526):—"No doubt you can get the article you require if in store by applying to Calvert & Lovatt, Langley Mills, Nottingham."

Birdcage Fronts.—J. G. (*Nottingham*) writes:—"I beg to say if J. S. (*Coatbridge*) (see page 587) will communicate with me I will make him what fronts he wants, or I will put him in the best way to proceed in making them himself if agreed."

Tarring Fence.—W. D. (*Newcastle-on-Tyne*) writes in reply to C. M. (*Hornsey Park Road*) (see page 654):—"Coal tar is as good as any for this purpose. It should be mixed with pitch, boiled, and applied hot. It will dry hard and very glossy. If mixed with mineral naphtha it will soak into the wood and dry a dull black. The tar washing off by the rain may have been caused by the fencing being wet when it was applied."

Tarring Fence.—W. E. H. (*Bognor, Sussex*) writes in answer to C. M. (*Hornsey Park Road*) (see No. 41 of WORK) *re* tarring fence:—"He will find that to follow the plan adopted here by the fishermen in tarring their boats will be the best. They obtain the tar from the gas-house here, and add a pint of turpentine to the gallon of tar or more if required to make it thin enough. Then choose a warm sunny day, the wood being perfectly dry, and lay it on with an ordinary tar brush. Some add naphtha instead of turps on account of cheapness, but turps is best to add as it lasts longest. Once a year will be found sufficient for a fence. If new work, give two coats of tar, one week to elapse between each coat."

Tarring Fence.—FAL writes in reply to C. M. (*Hornsey Park Road*) (No 41, page 654):—"Black varnish, which is specially prepared for outdoor work, is much better for C. M.'s purpose than tar. Messrs. Bayliss, Jones, and Bayliss, Wolverhampton, make a very good quality at 1s. 6d. per gallon. Brushes, 1s. each. There are numerous other makers."

Wheels.—WHEELER writes in reply to R. B. (*Largoward*):—"In answer to your inquiry where you can buy machine-dressed materials for wheels, if you will write to any of the three makers named below you will receive a price list or a quotation for any requirements. The following names have been selected from a number of dealers in the same articles: William Cary, Red Bank, Manchester; James Chapman, 181, Chapel Street, Salford, Manchester; Joseph Owen & Sons, 21, Grosvenor Street, Manchester, and 67, St. Anne Street, Liverpool. You will be able to get what you want, even to the ready-made wheels ready for hooping and bushing, at Cary's."

Electric Motor.—B. F. (*Birkenhead*) writes in reply to J. C. (*Shipton, Yorks*):—"There is one of these working often in Avonberg's window, Manchester Street, Liverpool, driving the way you want. I have seen and bought the wheel of life with pictures for 6d. I have seen in Archer's, optician, Lord Street, electric motor with driving wheel on for 2s. 6d."

Trade Note.

ONE hundred and four societies reported to the request of the Board of Trade for returns, and these represented a total membership of 373,904, which Mr. Burnett considers are more than one-half the trade unionists of the whole kingdom.

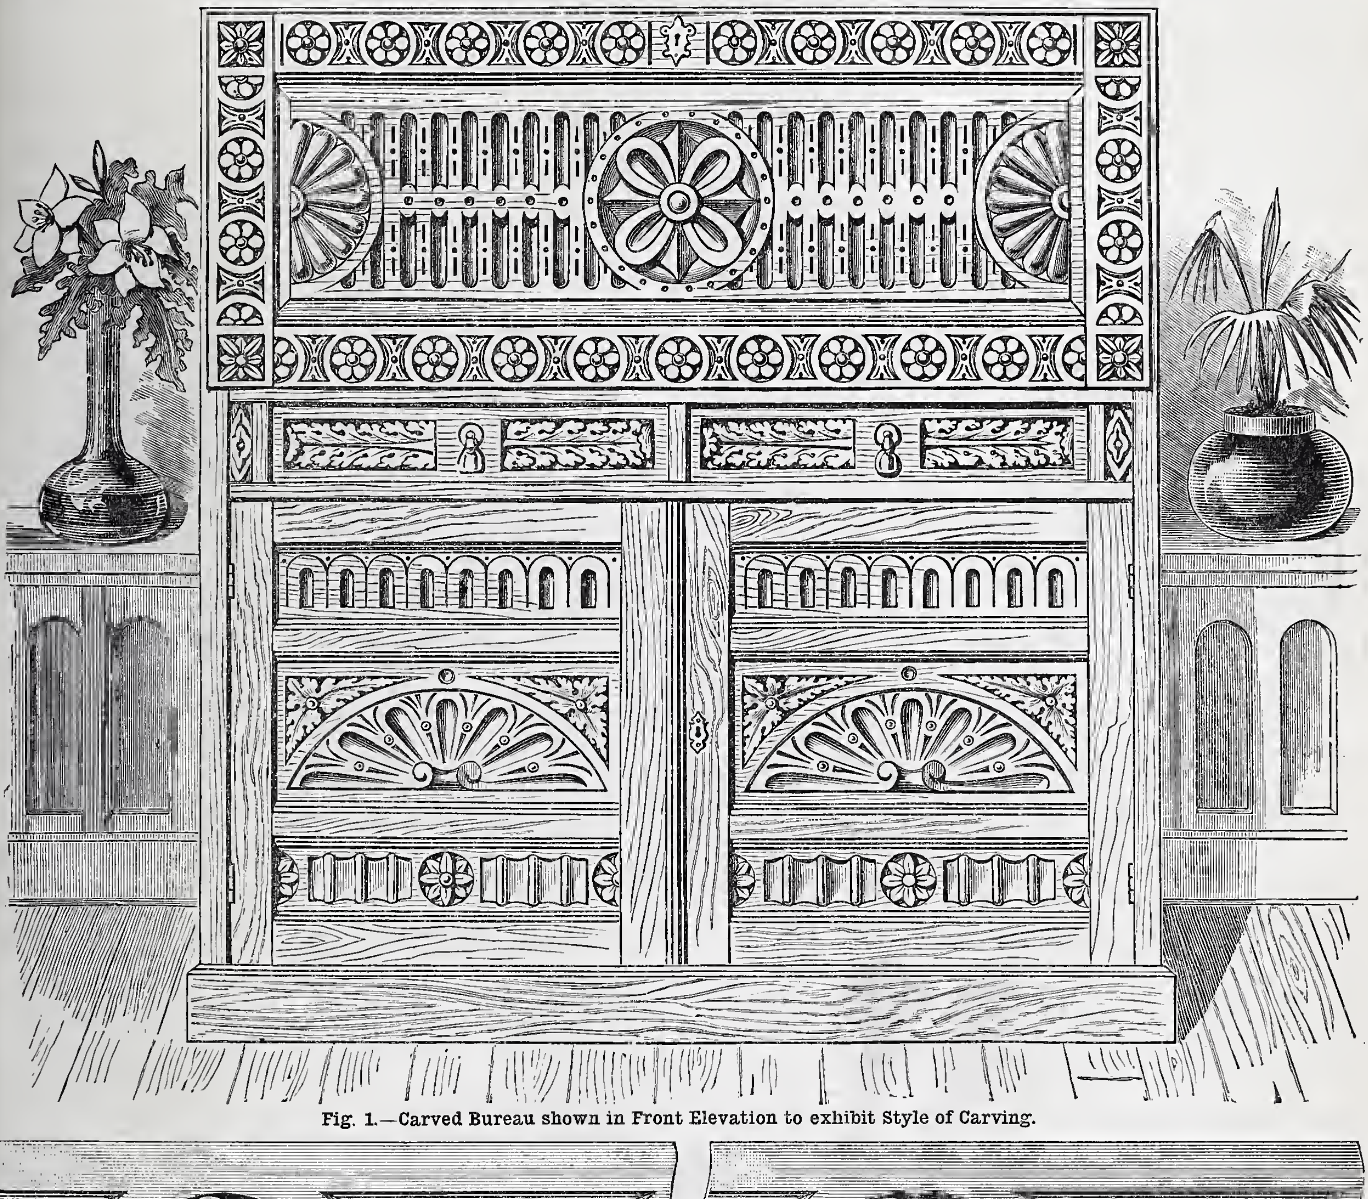

Fig. 1.—Carved Bureau shown in Front Elevation to exhibit Style of Carving.

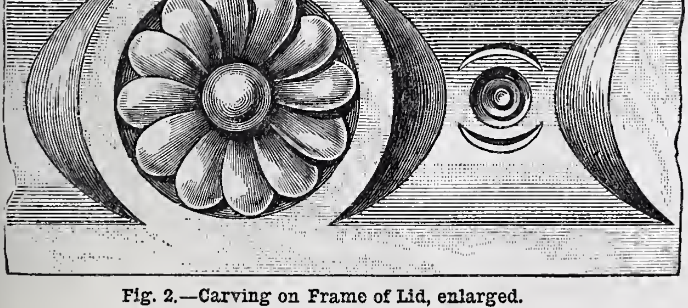

Fig. 2.—Carving on Frame of Lid, enlarged.

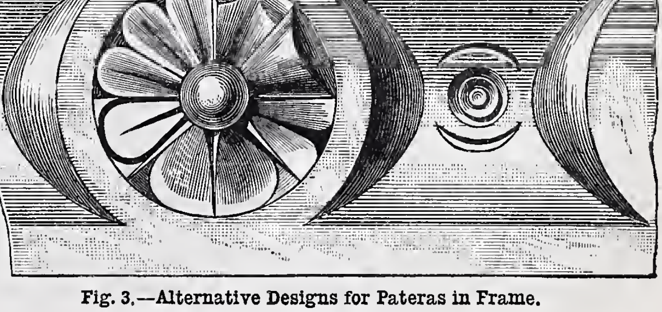

Fig. 3.—Alternative Designs for Pateras in Frame.

A CARVED BUREAU.

BY D. ADAMSON.

We have in previous papers considered the old bureau and a bureau in "Gothic" style. The next style of bureau which demands our attention is one which prevailed more or less during the latter part of the sixteenth and the greater part of the succeeding century. It must not, however, be supposed that art as applied to woodwork was at a standstill, and that no variety in style is discernible during this period; for there are differences in ornamental detail by which the Elizabethan or late Tudor style is distinguishable from the succeeding Jacobean. These comparatively trifling differences, however, need not be dilated on, for the prevailing characteristic of domestic woodwork decoration throughout them is much the same. If we examine any of the numerous specimens which have survived, we find the predominant feature to be bold, effective carving with little, if any, attempt at rendering natural forms. The designs are strictly conventional where foliage is represented, and simple geometrical forms are largely used. We thus see that the motives

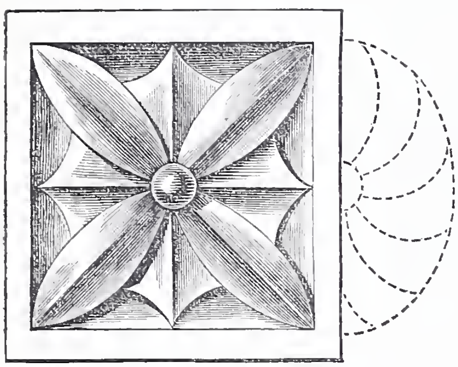

Fig. 4.—Pattern at Corners of Frame, enlarged.

which inspired the designers are in accordance with correct principles. There is no endeavour merely to imitate natural objects, and one has only to look at a piece of work of the period referred to to recognise the good general effect which was produced by the simplest means. Much of the work was crude in execution, but there was a boldness in its conception, an absence of all finnicking over-elaboration, which renders it so attractive not merely to students of woodwork but to the most casual observer. Please do not, however, suppose that this is intended to mean that it should be merely copied nowadays. Far from that, as the only result would be deterioration of the worker's powers. If we want to make a facsimile of some old work well and good, then copy from it; but if the intention is to make a given piece of furniture in a given style, all we have to do—so far as the design is concerned—is to seize some of its leading features, or, to use an expressive term, the feeling of the style, and embody the details in any article, whether of cabinet making or otherwise, which may best fulfil its intended purpose. It must be understood that the accompanying illustrations by no means exhaust the varieties of ornament which are to be found in Elizabethan woodwork. To do so would be impossible within a moderate space, and all that can be managed within the limit of these papers is little more than an indication of what may be done in the way of ornamenting woodwork by carving in what may be described as the English version of the Renaissance. We find a similar style prevalent throughout Europe, not identical in detail, each country giving a rendering of its own,

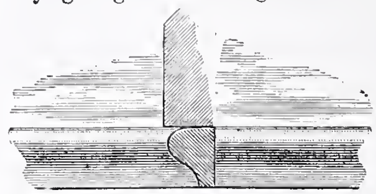

Fig. 5.—Moulding exhibiting Section.

but all emanating and expanding from the Renaissance originated in Italy.

So much for theory; now let us see how it is to be applied to the bureau. To begin with, for the encouragement of those who are not skilful carvers, it may be said that carving tools as now understood are not absolutely necessary. In the designs to be given there is nothing that may not be managed with ordinary carpenters' chisels and gouges. If carvers' tools are available, well and good, the work may more easily be performed, but certainly none of the more modern forms—the bent tools and others which carvers use nowadays—will be required. There is no undercutting, while all the work is bold and free. Those carvers—or should they not be described as carpenters, who used their chisels as freely for decoration as for construction?—of the days of good Queen Bess understood how to produce effect by the simplest means. Take the front of an old chest or cabinet, with its wealth of cutting as the old craftsman would probably have called it, how elaborate it seems, with perhaps scarcely an inch of its surface undecorated by carving, yet analysed it will be seen that there is in truth little that could not be attempted by the veriest tyro. Bold effective lines without much depth, which it requires only a slight acquaintance with the art of carving to discern, may be cut and shaped with the most rudimentary tools. But let not the beginner fall into the mistake of supposing that the breadth and general good effect can be produced by purposely leaving the work in a rough state. He is apt to do so, but let him instead give the highest finish he can to his work, taking care at the same time not to destroy the vigour and robustness which characterised the mediæval craftsman. Let the work be bold, but not necessarily rough. The former quality stamps its character with merit; the latter depreciates it. A bad, or, not to put it so strongly, an inferior design executed with vigour is preferable to one of superior merits weakly carried out. To combine robustness of work with proper finish is not so easy as it might at first appear, and as those who have attempted it well know. Still, this should be the aim of any wishing to excel in good carved work such as is under consideration. The illustration of the bureau shows a considerable quantity of carving, but it may be as well to state that there is no necessity for carrying out the design in its entirety. It will be noticed that a departure from the original construction is shown, two doors having taken the place of the three long drawers. This alteration is partly made as a suggestion that a cupboard may take the place of these, and partly because the carving of three drawers, or rather their fronts, might become monotonous.

This leads me to say that those who prefer to have the drawers may, if they do not wish to dispense with them, fit them inside the doors. Further, if they do not care for doors, it is not necessary that each drawer front should be of exactly the same pattern. The details of each rosette or patera, for example, may be varied, but this suggestion will be more of service to those who are fairly acquainted with the principles of design than to beginners, in whose hands there is a danger of the result being too patchy to be pleasing.

Well, now let us refer to the illustration, Fig. 1, which gives a general idea of the carved bureau, much of the detail being necessarily left out, or at most merely indicated. By the way, the front only is drawn in elevation, but there will be no difficulty in recognising the various parts. Let us take the lid first. This may be either made with the panel flush as in the original bureau, or sunk as suggested, when dealing with the Gothic design. As the panel is rather a large surface to carve, it may have a bevelled edge with advantage to those

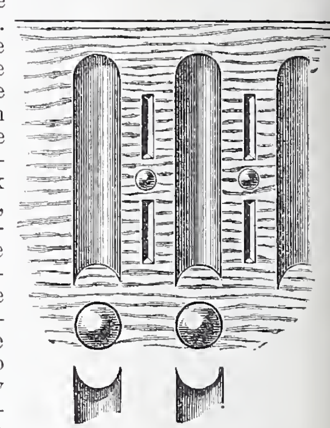

Fig. 6.—Carving on Panel.

who do not wish to bestow too much labour on it. Of course, the bevelling, which may be an inch or so wide, considerably reduces the surface to be carved, so that the effect of a panel covered with carved ornamentation may be produced without so much actual work. The framing around the panel may be either left plain or be carved as shown. To convey as far as possible the pattern, which, of course, must be drawn of a suitable size on the wood itself, illustrations on an enlarged scale are given, which, it is hoped, will make the ideas sufficiently clear to enable those who are not conversant with actual carvings of the kind represented to reproduce them. Fig. 4 shows the pattern at the four corners of the frame, and Fig. 2 the remainder. In case the cutting of so many pateras exactly the same may be monotonous, suggestions for varying them, while keeping them in harmony with each other and the rest of the work, are given in Fig. 3. The frame may also be left uncarved, like the door frames, if preferred, and, it is almost needless to add, these may be carved in a similar manner. It will be noticed that the long rails, those at the top and bottom, are moulded on the inner edges. To be in character with the style of

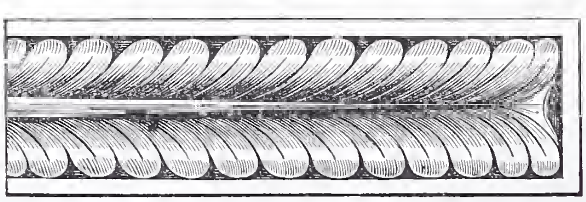

Fig. 7.—Carving on Drawers.

decoration, these mouldings should, strictly speaking, be worked on the solid, *i.e.*, instead of gluing them to the framing, they should be cut on the framing. This, however, may be rather more trouble than the amateur artisan would be disposed to take, and with care a very serviceable job may be made with mouldings stuck on. A suitable moulding is shown in section in Fig. 5, which also gives a portion of the flat frame. The carving on the panel itself is represented by Fig. 6, while that on the drawer fronts is shown by Fig. 7. The door panels are carried out much as the other carving, and no minute description can, therefore, be necessary. Each door, it will be seen, has three panels; the middle one being the principal, with fluted carving arranged in circular form, instead of being straight as on the lid. As the flutes converge towards a centre, they, of necessity, assume a tapering form. The top and bottom panels are simply flutes similar to those on the lid, but shown of a simpler form, with the addition of pateras on the bottom panel. The door framing should be fastened with the ordinary mortised and tenoned joints, the two intermediate rails being tenoned into the stiles. If the lower part is to have drawers behind the doors, it will be better to hinge these on, instead of within the ends,* as shown in Fig. 1. To do so, of course, the end pieces must be cut away to the thickness of the door framing, and the doors themselves be correspondingly wider. By hingeing the doors on the ends, it will be seen that the drawers can be the full length of the inside of the cupboard part; but if they are hinged within, the ends must be lined up, or thickened, that the drawers may work clear of the doors.

Much more might be written about the bureau in this old English style, which, undoubtedly, is a most interesting one, but space forbids. I may, however, say that many, if not most, of the old chests which one meets with, not to mention other articles of carved oak furniture, principally chairs and tables, are often rich in suggestions to the designer.

With this let us pass on, merely observing that the style known as "Queen Anne" was evolved from the one just considered, with which, for all practical purposes, it may be said to be almost identical, except that it indicates a closer adherence to classic forms, and, consequently, greater simplicity prevails in it. In the furniture of the Queen Anne period there is also much that shows Dutch ideas to have been largely borrowed; but as at present rendered in modern furniture, the term "Queen Anne style" is remarkably comprehensive, and, at its best, is founded on architectural details of the period which gives its name to it. For various reasons a "Queen Anne" bureau need not be given now, but it may be said that the style prevailed during the reigns of William of Orange, whence much of its Dutch character, and Queen Anne, to whom its name has been given, till well on into the eighteenth century, when domestic furniture, as we now understand it, assumed an importance it had not hitherto occupied. At the commencement of the second half of the eighteenth century the style known as Chippendale was all the fashion, and it may be interesting to note that, for the first time in the history of English furniture, this is distinguished by a name of its own apart from architectural nomenclature.

* See article on Hinges, etc., in No. 7.

PLAIN AND DECORATIVE HOUSE PAINTING.

BY A LONDON DECORATOR.

MIXING OIL PAINTS AND COMPOUNDING TINTS AND SHADES OF COLOURS FOR PRACTICAL USE (*continued*)—FOURTH COAT.

THE cornice is now ready for flatting, and the walls for the fourth and last coat of oil paint. I break up lead and paste driers with former proportions of solids, but all turpentine, into batter consistency. I then divide it into the amount required for the three divisions of cornice, stain them a few degrees lighter than the respective oil-ground colours, using the blue, red, ochre, and umber pigments for staining, then strain and thin with more turps for use. The nature of the flatting process I have already explained: but you must attentively notice that I must now take each colour right along each flank; first, the light terra-cotta next to ceiling; then the green-grey (recessed) portion; and lastly, the bottom division of warm colour. Were I to bring all three colours along at once, the joints would invariably appear shiny, the effect of which, at intervals of every five or six feet, would be most disagreeable, and would spoil the repose of the entire cornice.

Flatting requires to be *very* expeditiously manipulated, and the brush must not touch it a second time after leaving it and it once commences to set, which is within a few minutes. When a large mass of wall is flatted, the colour must be spread entirely over it at once; so that, single-handed, I do not attempt more than the cornice in this lesson. If any small portions of a large space are missed in the flatting, the wall is spoiled, not so much by the colour of the part missed, but by the bright oily gloss of the ground. Notice that I use the flatting much thinner than the oil paint—almost like milk—taking special care to coat all recessed as well as prominent portions, so that it all dries as dead and solid as the pink distempered ceiling.

All danger of splashing now being over, I give the walls a final rub down with No. 1½ glass-paper, and finish them with my lighter tint of sage green, prepared as before, but with two-thirds oil to one of turps, which dries with a good medium gloss, and gives me plenty of time to spread it and lay it off.

Ceiling, cornice, and walls are now finished and dry, so that the skirting and woodwork alone remain. My colour for the latter is already made, but requires the addition of terebine (which is preferable to white driers in compounding this paint), in proportions of one of terebine to twelve or fourteen of pigment. I thin sufficient of this with two parts turps to one of oil; then, having already carefully rubbed down and faced up the work (taking special care not to rub the previous coats off the sharp edges of the mouldings), I coat it on the system previously explained. The light, panel paint is first spread, covering mouldings also this time; and then the brushes are well worked into the dark, "Arabian brown" colour, and the remainder is painted, skirting included. On the following day we find our third coat quite hard, so I finish it right off with the remainder of our thick mixed paint, but made to working consistency with reversed quantities of liquids (namely, two-thirds linseed oil to one of turps), leaving until the next day the picking in of panel mouldings with the sage green wall-colour.

Let us now look around, and gather up the lessons this room should have taught you. There are the *proportions* of solids and liquids that go to compound both *oil*, *sharp*, and *flatting* paints for walls and woodwork. You have also a good notion of the *system* of working or manipulating them, as well as the methods of *thought* required i deciding colours, from which latter you have gathered that successful colour-results are *not* the outcome of a sort of inspiration—"taste" it is usually termed. Beyond this, you understand the *necessity* for clean and careful working, dusting the work, and well straining the paint, and thereby saving much time and glass-paper, on new wood particularly. As to the colour scheme of your billiard-room, perhaps its present appearance, after your being used to the rich variety (?) of black-and-umber drabs the builder has favoured you with, strikes you as being rather "loud." But wait, my friend, until the table is fixed in the room, with its pure green cloth, when our wall-colour will assume a warmer and much more sombre tone, making a fine background for a few good oil paintings in gilded frames; whilst the dark warm shades of the woodwork will correspond effectively with the mahogany framework of the table, and will suit equally well with any other articles of furniture usual to a billiard-room.

I promised in the opening lines of this lesson to deal generally with mixing colours for oil-painting, and to this end I will devote the remaining space allotted to my paper.

In these days of cheap paperhangings and materials it is the usual method for a client to choose a wall-paper, and then desire the woodwork to be painted to match—that is to say, in tints corresponding with the paper. In these cases, and for bedrooms especially, the painter will get good results by making the bulk of the woodwork a deeper shade of the predominant colour of paper. For instance, if the pattern is in soft green shades upon a cream ground, I should paint the panels cream, the remainder soft green to match the walls, and, as we should probably get a few touches of pink amongst the pattern, I should pick in the mouldings with a lighter tint of similar colour. Unless the paper is dark in appearance, it is generally advisable to put darker shades on the doors, etc. When such is the case, however, fairly light colours will suit a dark paper the best. The object in view is to make the doors and structural features of the room to stand out distinctly, but yet harmoniously, from the walls.

For practical house painters, the pigments I have previously described are the best, cheapest, and easiest to manage. Let me here point out the meaning of a few colour-terms, which are seldom properly understood even by operative house painters—namely, *tints*, *shades*, and *hues*. I take a little vermilion, for instance (which, you know, is a bright, rich, and rather costly red pigment), and to this add a little white lead. The resultant mixture forms a *tint* of vermilion—call it "coral," "blush rose," or any other fanciful name you please. If I further lighten the colour by adding white, it still remains a *tint*. Suppose, however, if, instead of adding white to the vermilion, I substitute a black pigment, the result is a darker mixture we should call a *shade*. By the term *hue* we understand what is predominant in a colour, such as a *blue hue* of green—that is, nearer the blue than the yellow, both of which it is made from. "The *roseate hues* of early morn" is a sentence that fully explains the word. It will, therefore, be understood that to speak of a colour as being a few *shades lighter*, or of a *darker tint* of colour, is altogether incorrect, and is certainly more than a matter of passing mention.

Before the painter can properly and confidently mix colours, he must be familiar and "carry in his eye" (so to term it) the appearance of all his pigments, so that when a colour has to be matched he can at once analyse it and judge what are the best pigments to use for it, subject to the other considerations of cost and permanence I have treated upon.

Suppose we try a few examples. I want to make a very bright and pure *tint* of red. Vermilion is my brightest red pigment, and this will, therefore, give me tints far purer than the cheap Venetian red. So also with blue tints: ultramarine gives the purest blue, and chromes the brightest yellow. The same method is used in mixed or compounded tints: we work with the brightest blue and yellow to obtain bright greens, although none such can approach to *emerald green* in this respect. All the useful variety of cream, buff, fawn, drab, stone-colour, ivory white, and terra-cotta colours, and so on *ad infinitum*, can easily be made from white lead and the yellow and red pigments of Venetian red and ochre, with burnt umber to tone or soften them down, and, occasionally, chrome and vermilion for the brightest kinds. Black with white gives us *grey*, neutral tints, and, with the further addition of blue, green, or red, we obtain all that class of cool *greys* known as French grey, silver-grey, green-grey, and so on, according to the dominant tint of colour displayed to us, and all of which a careful student of my papers should now be readily able to mix, providing his own vision is colour-perfect.

In my next paper the subject of distemper, or *tempera*, painting will be practically explained, this elementary series of papers being completed with a chapter on painters' tools and brushes.

SMITHS' WORK.

BY J. H.

About Grilles, Gates, and Screens.

A GRILLE is an open grating or lattice-work in metal, and is used as a protection to a tomb, relic, or shrine. In the Middle Ages a great deal of labour was expended on these works of art, so that they exist in very great diversity of form, and possess very often a great ornate development. A screen may be regarded as an assemblage of several grilles arranged in panellings; or it may be composed chiefly of foliage, with little or no duplication of parts. I cannot give an illustration of an entire grille or screen, but will only note in brief some of the details of their construction.

The illustrations here given (for some of which I am indebted to Wyatt's "Metal Work") represent some of the details of the construction of a screen from the Church of Santa Croce, in Florence. It is the most elaborate and perfect specimen of smiths' work in Italy. It was erected in 1371 by the Runuccini family, in honour of the Virgin. An examination of these figures will give a tolerably clear idea of the methods of union adopted. These methods of union are not apparent in front view; they must be looked for behind. The use of solid bars is well illustrated in each of these sectional figures. All the fastenings of bars and mouldings are not clearly seen, but the hinder views of portions of the gate clearly indicate the use of rivets. Thus the circles (A, Fig. 10) forming the panels are plain bars of iron, to which the mouldings are riveted (see section Fig. 11, A). The quatrefoils, B (seen in section Fig. 11, B), appear to form part and parcel of the circles, or they may possibly be attached by welding; but there are no rivets apparent. It would be possible, by slitting the bar forming the circle, to bend round strips to form the quatrefoils; or alternately the quatrefoils might be prepared, each separately, and welded at the cusps, C, or prepared as a whole and welded to the circles. Short scarfed joints might be made, or butt-welds, the metal, perhaps, being upset a little for the making of a good joint, and the superfluous metal filed off afterwards. The cusps, C (Fig. 10), are apparently welded on to the points of the quatrefoils.

The circles of the panels are united to each other and to the standards and transoms (Fig. 10) by means of dogs, D, which must evidently be riveted into holes countersunk on the front face. There is no attempt to conceal these fastenings at the back—all are visible; but in the front the points of junction are all hidden by little rosettes or star-like bosses (Fig. 12, A), prepared separately, and apparently welded or dabbed on. Thus the necessary method of union is made an occasion for the introduction of ornament. In this respect the panels would lack the rigidity of a cast-iron structure. But the screen does not depend for rigidity upon the panels, but upon the framework. The bars of which the structure is composed form an overlapping and crossing series, one bar binding others, and all riveted together in detail.

Some idea of this crossing of bars and mouldings may be gained from Fig. 11, C, which represents the building up of one of the vertical standards. Note also in the hinder view of a portion of the arch of the gateway (Fig. 13), which belongs to the screen of Santa Croce, how the various parts are bound securely with rivets and "fish-plates" (if we may use the term), while a stiff bar riveted right across ties the sides together, and affords a rigid backing for the mouldings.

We note also how the aim was to simplify the details of construction as far as possible consistently with the strength and beauty of the design. In no case is a moulding formed on a main bar where it can be formed equally well on a smaller supplementary bar. Not only in the larger sections, but also in the very smallest, such as those forming the tracery of the gate (a portion of the back of which is seen in Fig. 13), the mouldings are formed on bars distinct from those which constitute the skeleton, or light backing, or framework itself. This is the more noticeable as in all the tracery-work the mouldings have to be bent to such curvatures as would make them precisely concentric with their plates, so that the same margin of edge would show all around when the moulding and plain bar were bent and riveted together.

Thus in Fig. 12, B shows the section of the moulding of the portion A in Fig. 13, and Fig. 12, C, the section of the portion B in Fig. 13. To us, with our rolling-mills ready to turn out almost any sections to order, this method of bending mouldings and their bars distinct would appear a sad waste of time and labour. All the more reason why we should honour the men whose skill conquered the difficulties of hand work, and produced such beautiful examples of simple handicraft.

A beautiful example of a bit of work which must have occupied a vast deal of time is seen in the ribbon of the twisted shafts of the gates. A portion of one of these shafts is seen in Fig. 14. This twisting is prepared as a moulding, seen in section, Fig. 12, D. The centre piece of the shafts is a round bar, and the mouldings being bent around this, and meeting square edge to square edge, give the twisting whose effect is so beautiful. How many times one of these bars must have gone into the fire, how very many minute settings must have been required before the precise amount of twist was obtained, all kinks removed, and the ribbon-like moulding made not only to fit closely around the central bar, but also against the contiguous ribbons, three of which were required to complete the twisting, like a triple-threaded screw!

The more closely we look into these works, the more we see to admire. They are like great paintings: the more prolonged the study, the more vividly do their beauties impress themselves upon our mind.

It must have been a most tedious operation to build up an elaborate piece of work like the screen and gate, bits of which are seen in Figs. 10—14. Drawings, templets, swages, dies, must have been made, and every bit of iron must have been wrought upon the anvil, and between swages to its proper section, before any of the more artistic work was done. Probably some of these repetition tasks may have been allotted to subordinate and younger workmen. Though much of the beauty of some of these structures is largely due to their light appearance, yet a closer study reveals the fact that constructive strength has not been sacrificed. In some details we seem to meet with unnecessary mass. Many mouldings that we should stamp out of sheet-iron are formed in solid bars. And this, it must be remembered, was the practice at periods when iron was very precious, and every bit used was smelted with wood charcoal.

A curious illustration of the value of iron appears in a French book, written by one Mathurin Jousse, bearing date 1627, in which he advises the aspirant to begin to forge things in lead, so as not to waste coal and iron in his first attempts. By the way, I cannot see wherein the wisdom of this advice consists, or how the bending of lead can in any way aid in acquiring the knowlenge of how to bend iron. But in the Middle Ages iron was very dear, and was sold in bars of about four pounds weight each. Steel was about four times dearer than iron—in England at least, and probably also abroad. These bars were usually purchased at the great fairs; and on the farms the bailiff kept them in stock, and served out the quantity required by the local smith to fashion what was needed. It was owing to the great cost of iron that cart wheels were frequently cut out of a solid trunk of a tree and unprotected with iron, and that oaken pegs were substituted for those of iron in the rude harrows of that period. Spain was the principal source of foreign iron. Because of its cost it was chiefly reserved for ecclesiastical service, and for arms and armour.

There must necessarily have been many months of labour expended on such tasks as these screens and gates before any considerable show of erection was made.

Long time must have elapsed ere the conception of the artist began to grow into shape. Impatient these artists must have been sometimes to see the realisation of their ideas; but they were, nevertheless, severely careful not to let "raw haste" become "half-sister to delay." Every portion was carefully secured, each minute detail finished, as though that alone were the object of their care; and strength as well as beauty were regarded.

Identical methods were not followed in works of the same class. In some grilles the quatrefoils were made in bar-iron, bent and riveted together, as in that of Santa Croce just noticed. But in others a simple method was followed. Thus a grille in the railings which enclose the monuments of the Scaligers at Verona is made of sheet-iron. The quatrefoils are cut out of the sheets and riveted to each other. This was a cheap method, and lacks the strength of those made of twisted bars. The effect is, nevertheless, very pleasing. An excellent example of the method of building up with solid bars is shown in Fig. 15. This represents a portion of the framework of a grille of fourteenth-century date in the Chapel of the Palazzo Publico, Siena. The section (Fig. 15) is seen to be composed of five plates symmetrically arranged. In two the edges are notched for ornament.

There are some comparatively recent screens made by one

Figs. 16-21.—Various Details of Screens by Huntingdon Shaw.

Huntingdon Shaw, a blacksmith of Nottingham, about 1695, for dividing the gardens of Hampton Court Palace from the Home Park, which are now in South Kensington Museum. Their appearance is more attractive when viewed from a distance than when examined closely. There is a vast deal of work put into them; yet for excellence of finish they cannot compare with some of the mediæval screens. This is largely due to the action of the weather upon them, and to general neglect. The wealth of foliage with which they are covered is marvellous. From these screens I have taken a few illustrations, showing the method of union of parts, and with these I must conclude this article.

The heavy-looking horizontal bases, measuring about four inches square, are really made of comparatively light plates, bent round and riveted at opposite corners (Fig. 16, A). Upon these rest other plates, B, supporting the pillars, between which scroll-work is carried. Some of the larger scroll-work is united to the bases in the manner seen in Fig. 17. A broad thin tongue, or tenon, B, passes from the base through the scroll-bar, and is secured with a pin. In some cases the tenon only is used (Fig. 17, A), without the pin. Where a number of bars are running parallel for a little way previous to diverging into scrolls, they are united with a band or loop (Fig. 18, A). The loop, being large, is then made of four pieces, each of nearly semicircular section, and riveted at the four corners. Fig. 19 shows the union of three pieces with a riveted loop, A, B, and also the spreading outwards of the terminations of the scrolls. Fig. 20 shows leaves partly encircling the bars, and united thereto with rivets; and Fig. 21 shows broadly-expanded leaves spreading over the bars and riveted thereto, and fluted as *repoussé* work.

WHY MY GAS-ENGINE WON'T GO.

BY F. A. M.

Lubrication of Gas-Engines.

Is any one ambitious to make a gas-engine? Castings may be bought, and the work is not very difficult to one who understands and can make a steam-engine. The gas-engine, however, is not so well understood as the steam-engine, and many who have undertaken to make one have failed to get it to work, and have had to sell it as "partly fitted." I have made a model gas-engine, 1½ in. diameter, by 4 in. stroke, and it goes pretty well. I had to look up the subject, and found some difficulty in getting the information required, especially certain practical directions, simple enough when you know them, yet not contained in any book with which I am acquainted.

My first intention was to write a paper on "How to Make a One-man-power Gas-engine;" but I find the cylinder of this is rather large, and the crank shaft too large to be turned upon a 5-in. lathe; and, altogether, the amateur would probably have to get a good deal of the work done for him. Having applied to the maker of my engine for leave to publish working drawings, I could not obtain it; instead, therefore, of describing the construction of any particular gas-engine, I intend to try to give a few practical hints such as I found the want of myself, which may, perhaps, be useful, not only to those who have made gas-engines and cannot get them to work, but to those who have bought a gas-engine and find it "so uncertain."

Beginning at the beginning, I will deal only with the *non-compression*, or simplest form of engines; their action is briefly this: the fly-wheel must be turned by hand to draw the piston partly up the cylinder; the exhaustion underneath the piston opens valves over the air and gas inlets and sucks in both air and gas; besides the valve on the gas inlet, there is also a cock, which enables the quantity of gas to be regulated till it becomes about one-tenth of that of the air. Having thus drawn in the explosive mixture by raising the piston about two-fifths of the stroke, the piston, continuing to move, uncovers a hole made through the side of the cylinder, called the ignition orifice; from this moment the piston draws in at three places instead of two. Now, the ignition orifice is covered by a little hanging flap valve which opens inwards, and against the outside of this orifice there plays a constant flame. The moment, therefore, the piston passes the ignition, the suction of the piston opens the little hanging flap and draws in flame; the flame ignites the mixture of gas and air in the cylinder, which instantly becomes full of blue fire, the heat of which expands, momentarily, the contents of the cylinder and throws up the piston. All that remains of the cycle of operations to complete the revolution is, that as the crank turns the upper dead-centre and begins to come down, a valve must open to allow the burnt gases in the cylinder to escape; this is simply managed by an eccentric and slide valve.

For the sake of my younger readers, I may say that gas alone will not explode any more than pure air will; if you could strike a match inside a gasometer, it would simply go out! If you could introduce a jet of air into the gasometer, and light it, the air would burn in the gas, just as we now see gas burning in a jet in our rooms. What we call "burning," is simply the rapid combination under heat of anything with oxygen; thus the flame appears, and the burning takes place where gas and air meet and heat is applied. Air contains oxygen. Now, there are two ways of burning gas. One is to mix together the gas and air gradually, applying heat all the while; this is what takes place when you turn on the gas tap and apply a match to the burner; the gas mixes with the air of the room, the application of the lighted match supplies the heat sufficient to cause the rapid combination we call burning, and afterwards the combination is effected by the heat of the flame itself. The other way is to mix the air and gas in the proper proportion and then apply the heat by a light; this causes the combination to take place all over the mixture at once; it is just what occurs when a tap has been left on at night, or an escape has occurred, and the gas has gradually mixed with the air in a room; in the morning, the servant comes in with a candle and—you know the result, there is a fearful explosion. Now, what has taken place? Simply this: the room was full of air and gas ready mixed—the flame of the candle lighted the whole mixture at once; it became full of flame, and increased in a moment by reason of the heat to three or four times its former volume; no wonder if the window was blown out! The room was converted for the moment into the cylinder of a gas-engine, whilst the window or door was the piston. Now, in the gas-engine, we produce a gas accident on purpose every revolution; the explosion gives one strong, but almost momentary, impulse; it occurs about the middle of the up stroke, driving the piston to the top of the cylinder, the connecting rod acting something like the leg of a man who should give the crank a good strong kick just at mid-stroke; this will show why the cylinder of a simple or non-compression gas-engine requires to be so much larger than that of a steam-engine of equal power.

It is only when combined in certain proportions that gas and air will explode. About six of air to one of gas is the richest mixture that will give an explosion; if more gas than this is getting in, the engine will not work, and you can find it out by putting a lighted match to the exhaust while turning the wheel; if you can light the exhaust, the engine is getting too much gas. About ten or twelve of gas to one of air is the weakest mixture that will give an explosion when uncompressed, but the explosions of a weak mixture are less powerful than those of a stronger mixture, so that when a governor is applied, it can, by cutting off some of the gas, weaken the explosion, or by cutting off more, stop the explosion entirely for one revolution or two, so as to bring down the speed to normal rate.

Speaking of my own experience with the model gas-engine, many seemed to think it impossible to get so small an engine to work at all, and it appears to be admitted that it is more difficult to make a little one go than one of one-man-power. However, after a few minutes spent in regulating the gas tap to give the correct proportion of gas, my little model went off at the first trial. After running with the cylinder quite dry for ten minutes or so, I tried oiling the piston, and then my troubles began. Nevertheless, I am glad of this now, for it was the means of teaching me many things I should not have known if all had gone well from the beginning.

This leads naturally to the first reason why the gas-engine may fail to go. It will not go long if the piston is oiled. The reason for this is very simple: the heat in the cylinder at the time of the explosion is considerable, quite enough to carbonise the oil, so that instead of a lubricant you have a black sticky deposit; you put more oil and the piston is free for a few strokes, when, alas! the same thing occurs and you have a thicker coat of gum to deal with. The only way to deal with it is to draw the piston and clean both cylinder and piston with paraffin. Instead of oiling the piston make a paste of paraffin and black lead, and apply this with a paint brush to the inside of the cylinder; the heat will quickly evaporate the paraffin, and the black lead will lubricate the cylinder.

Now comes the second hint. On coming back the next day to make further experiments with the gas-engine, it was found to be set perfectly fast; the wheel could not be turned, and both the piston and slide valve proved to be firmly fixed. This was caused by rust; there was nothing for it but to soak in some paraffin to dissolve the rust, disconnect the parts, and continue rapping on the piston and valve, adding more paraffin, till the parts were again free. This accident can be very easily prevented by putting a very little oil, *after the engine has done working*, to both piston and slide valve, and then turning the engine round three or four times, just to spread the oil upon the rubbing surfaces; it is well to wait a little while, to allow the cylinder to cool somewhat, before adding the oil.

SIGN-WRITING AND LETTERING.

BY HENRY L. BENWELL.

PRISMATIC LETTERS — ORNAMENTAL LETTERING — CHURCH TEXT — ILLUMINATED CAPITALS — MEDIÆVAL ALPHABETS — SCROLLS — PULPIT PANELS—ZINC.

THE last chapter concluded with a reference to the sunk or incised form of letter, but it was merely mentioned there in its plain style only, *i.e.*, as a square sunk letter. I had forgotten to say that in these letters the "depth" is here the same, or the equivalent of the "thickness" in raised letters, but in addition to this, there are the shadows and reflections which must have careful "putting in" to obtain the desired effect. I should also add that the light is best made to fall on the side visible to the spectator, which will, of course, be in the highest light and the opposite in shadow. As the letters are also often viewed from below, the revealed parts at top and bottom should also be in shadow, and also because the light principally strikes down from above.

Prismatic letters are another class of the incised series, but are of a more elaborate nature, and, consequently, harder to produce successfully. The great aim of the writer is, or should be, to deceive the sense of vision, and as this is easily done, he is but a poor workman at his chosen art if he fails. This deception of the eye is the one great principle which underlies the sign-writer's art, and it entirely depends upon its successful or unsuccessful handling whether the art workman becomes *facile princeps* at his craft or otherwise. It should be the sign-writer's greatest endeavour to secure this faculty, which, with adroitness, decisive will, and skill, is the making of any man in this walk of the minor arts.

I now leave the plain alphabet with which we have hitherto concerned ourselves, and turn my attention to ornamental and ancient letters, church text, etc.

The letters which form the various styles of plain alphabets comprise the groundwork for most of the ornamental and other alphabets, and if the student has fully mastered the earlier series of letters, he should by this time be ready to approach with success the more difficult combinations which a first-class sign-writer is called upon to produce. Mr. Callingham thus discourses respecting this item :—"It is here that the genius of the painter is most severely tested. In order to execute the comparatively simple forms of the Roman, sans-seriff, and Egyptian alphabets satisfactorily, great neatness and finish are demanded. The angles should be clean and true, the various vertical and horizontal lines straight, the parallel lines regular, and the curves well poised. A considerable amount of dexterity is necessary to attain perfection in these particulars, and it can only be acquired by much practice. But, beyond this, when the learner comes to the more difficult accomplishment of ornamental writing, he must familiarise himself with the general principles of design ; for obviously a good painter will not always rest content with copying the productions of others, however much they may have in them that is worthy of imitation." What valuable information and advice is this, and how it stamps the man as one who has his work thoroughly within his grasp and knowing also by what means it is to be—and has been by himself—obtained.

The great point to aim at in ornamental lettering is originality, and in this matter the field is practically boundless, there being really no limit to the forms which may be given to the alphabetic characters. At the outset, however, it is necessary to guard the beginner against an extravagant use of ornament. As a general rule, it should be simple rather than complex. And whatever style of embellishment be decided upon, care should be taken that it does not detract from the legibility of the lettering ; for, if it have this tendency, the result can scarcely be deemed satisfactory, as it must be borne in mind that the writing has to serve a practical purpose, to which in the great majority of cases the decorative accessories are subordinate.

The style of the lettering, too, must in all cases be in harmony, and upon this matter Sir Matthew Digby Wyatt, who took such an active part in the decorative work of the great Exhibition of 1851, remarks with special reference to form and period, that "there are few faults more common in modern work or more offensive to the educated eye, than the association of styles of lettering and styles of ornamentation warring with each other in the properties of both time and form."

When the pupil has become an adept in the plain styles of lettering, he will find it anything but hard to strike out a fresh departure and introduce fresh and graceful lines into these letters, ornament their faces, etc., and thus beautify them by several degrees. He may get many suggestions in this way from a type-founder's specimen book, and it is from these that the writer has always worked out and adapted any ornamental alphabets he may have required. I must point out, however, that it is only a slight proportion of printers' type designs that are suitable for sign-writing purposes, and these are mostly to be found in the ornamental founts. The specimen books mentioned only contain a few letters, generally a couple or so of complete words, and for those who are so backward in self-reliance as to need every letter of the alphabet, I must recommend the books sold for the special purpose. I have heard that the books of alphabets by Delamotte, and published by Crosby Lockwood & Co., are very useful, but strange to say, I have never seen them, much as I should like to; still, they ought to be in every sign-writer's library, so here they are :—1, "Mediæval Alphabets and Initials"; 2, "Examples of Modern Alphabets"; and 3, "The Book of Ornamental Alphabets." Messrs. Brodie and Middleton have also several books of a similar kind, from one shilling upwards, but these also I have never seen, so cannot recommend them nor condemn them. The alphabets given in the last chapter are specimens of ornamental letters, but there is another and even more comprehensive style, which is known simply by the name of "Ornamented." Other varieties are known as Open Ornamented, Open Tuscan, Classic, Runic, Rustic, French, and Italian, and the alphabets incidental to every century; but enough have been mentioned to illustrate the wideness of the field of selection and the scope for a suitable display in every direction. I have found it impossible to give as many alphabets as I could wish, but those which I have given I have distributed throughout my series of papers as far as I have found it practicable to do so, knowing as I do their great utility to the aspirant for sign-writing honours.

I have purposely left church text out of the above list, because it requires separate treatment at my hands, and I will now endeavour to compress as much useful information as I can into the small space left at my disposal. We all know the vast amount of work which is done in this direction within the walls of our churches, and I believe it is work of the highest remunerative description. Much of it I know borders on what is a separate department of art, *i.e.*, the art of illuminating, but I presume a good sign-writer can and does take up certain classes of this work, and if he does not, one may well ask, Why not? His previous training should eminently fit him for such work with very little extra study and preparation, and he may surely rely upon self-help and self-tuition as far as it is needed. I can only say that if the young sign-writer takes up this branch of decorative art, it will be the means of considerably augmenting his income, and it is for this reason I am urging him to give it his most intelligent consideration.

For inscriptive texts in churches, etc., the use of illuminated capitals (see Fig. 74, G) and mediæval lettering (see alphabet, Figs. 72, 73) is now much in vogue. For ordinary purposes on plain painted walls, Scripture texts should be painted on the walls in two colours only, the capitals being red, red and black, or blue, and the small letters either red, blue, or black.

Of course, the colouring may be done in such suitable tints as would stand out best against the ground colour on the wall, but as stone colour is generally employed when a wall is painted, which is seldom, the plain colours look the most substantial and the best. I may say that walls are seldom painted; when they are, they are frequently treated in the polychromatic style of decoration, which is so noticeable a feature in many of the college chapels at Oxford and Cambridge. Here the lettering, of course, is more showy in order to be in keeping with the rest of the decoration. In employing the mediæval alphabets, it is necessary to make use of the various old style space ornaments and accessories (Fig. 74), such as quatrefoils, dots single and in clusters, stars, etc.

We frequently see in church texts each word divided with these ornaments or stops, which is, of course, a violation of punctuation, but as this was the method adopted by the olden time illuminators, it is still slavishly followed by modern members of the craft.

In this class of lettering, great care has to be taken not to mix the letters of one alphabet with another in the same inscription, or even in the same word, which is very apt to occur where the student has been practising with a great many alphabets of all dates and countries. To avoid this, he should always carry his specimen books —some of which should be of home manufacture—for ready reference.

I must warn the student against employing any alphabets antecedent to the twelfth century, as these are not intelligible to the majority of modern readers. Celtic and Anglo-Saxon characters the writer may have in his book, but only as curiosities and not for everyday use. He may, perhaps, require them when lettering some archæological object, and that is about all.

The great point to consider in church lettering is what alphabets to employ which shall be both readable and appropriate to the scheme of decoration in hand. Mr. W. Sutherland remarks that "Our ecclesiastical decorators are too much in the habit of stultifying themselves by using these unreadable letters simply because the same letters were used in certain manuscripts

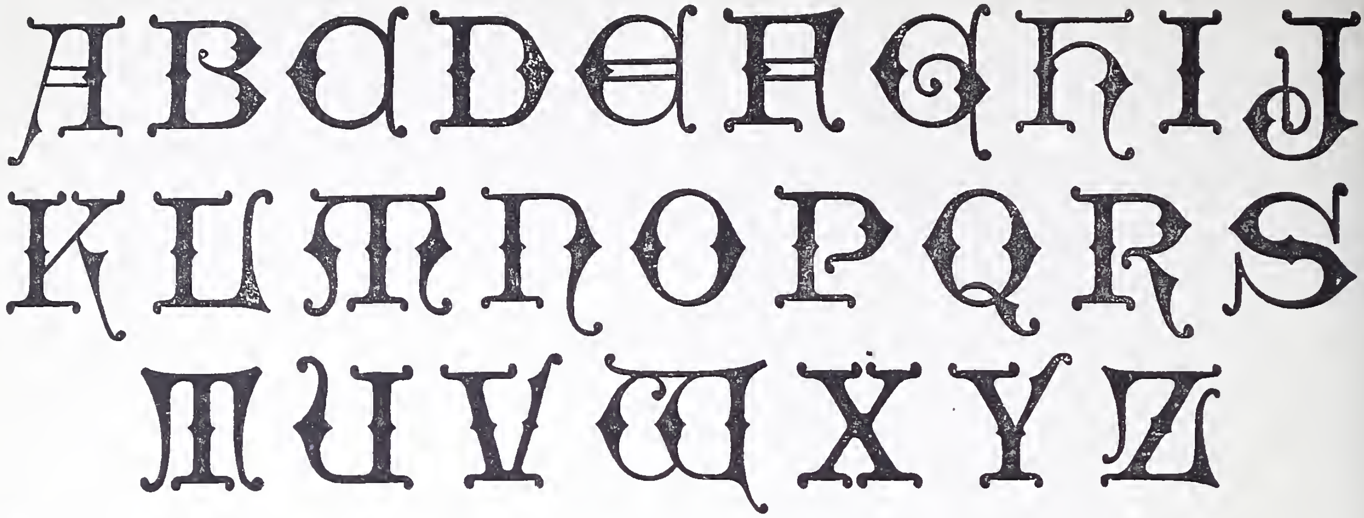

Fig. 72.—Mediæval or Church Alphabet: Capitals.

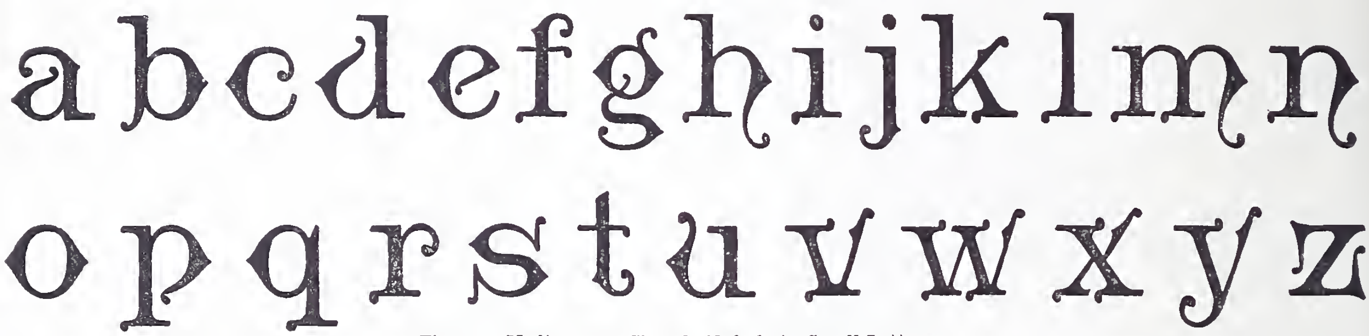

Fig. 73.—Mediæval or Church Alphabet: Small Letters.

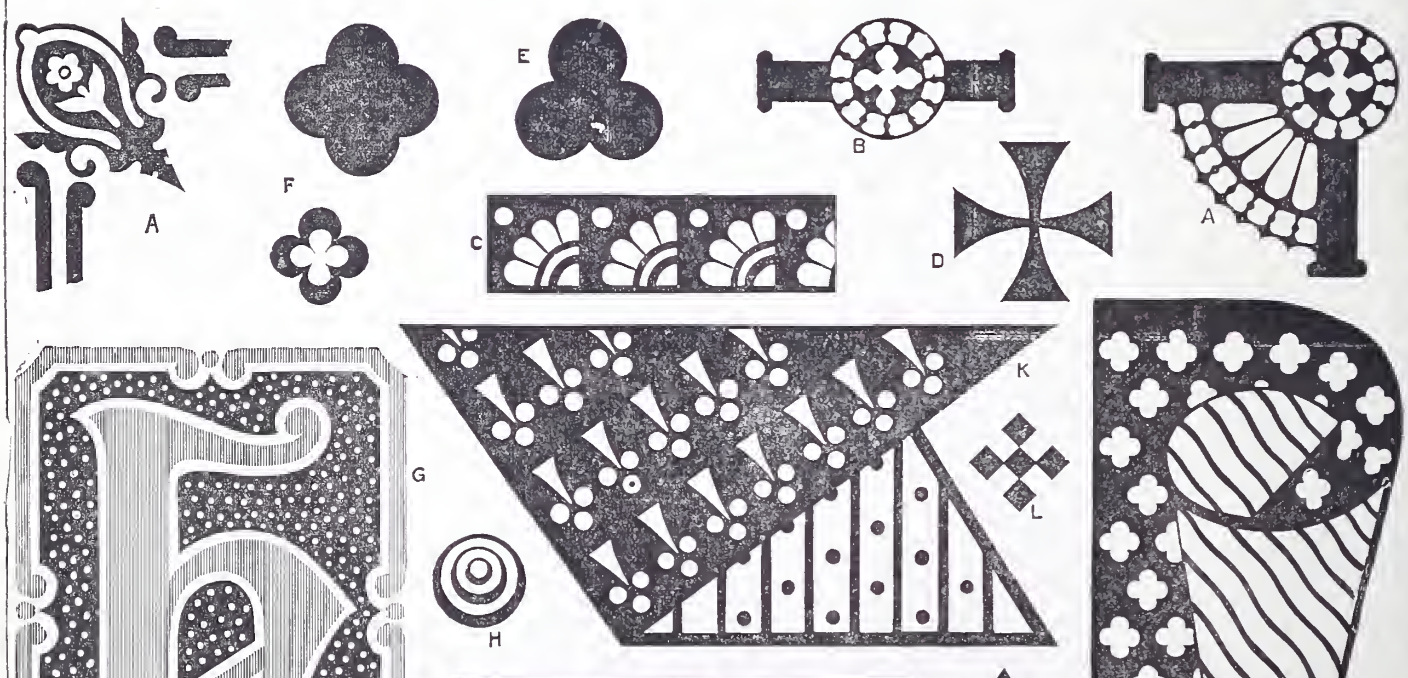

Fig. 74.—Ornamental Lettering and Ornaments for Church Work—A, Corners; B, Centre; C, Border; D, Maltese Cross; E, Trefoil; F, Quatrefoils; G, Initial Letter; H, Circles; K, Ribbon End; L, Diamond Cluster; M, Cross; N, Star (in Heraldry a Mullet); O, Tablet End; P, Scroll End.

and certain churches at a certain period, and they consider any departure from this plan as a move in the wrong direction, forgetting, or, if not forgetting, ignoring the fact that at the time these letters were used in our churches the mass of the people were ignorant of reading and writing, and that it was only the learned, who were few and far between, who could read or interpret these inscriptions." In these days, when all can read and write, we want inscriptions that are decipherable by all, and this these obsolete alphabets are certainly not.

As much text lettering is frequently done upon zinc in the shape of scrolls, pulpit panels, etc., I append a receipt for the preparation of the zinc previous to painting.

To prepare zinc for painting upon.—In sixty-four parts of water, dissolve one part of chloride of copper, one of nitrate of copper, and one of sal-ammoniac, and add one part of commercial hydrochloric acid; brush the zinc over with this mixture, which gives it a deep black; leave it to dry for twenty-four hours, when any oil colour will firmly adhere to it and withstand both heat and damp. I am sorry that space will not enable me to give examples of these scrolls and panels for church decoration.

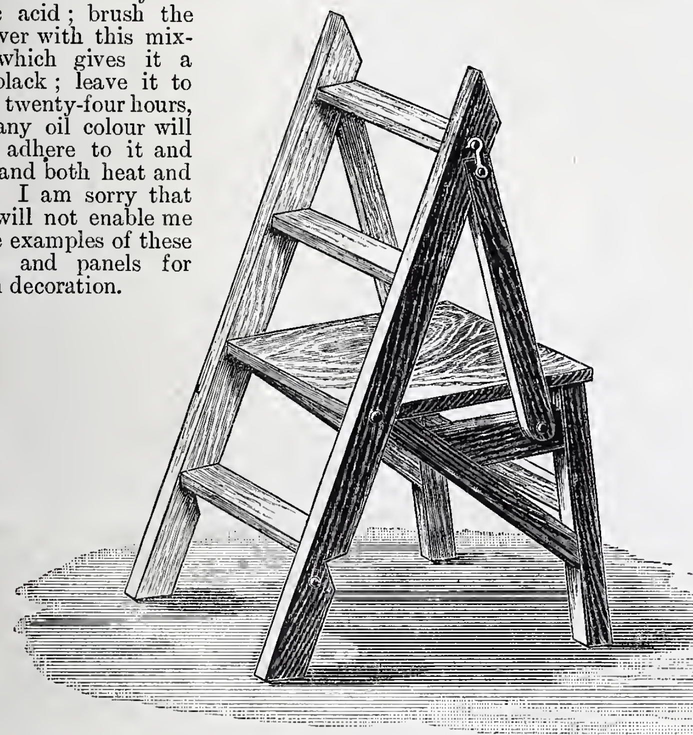

Fig. 1.—Step-Chair in Position for Use as Steps.

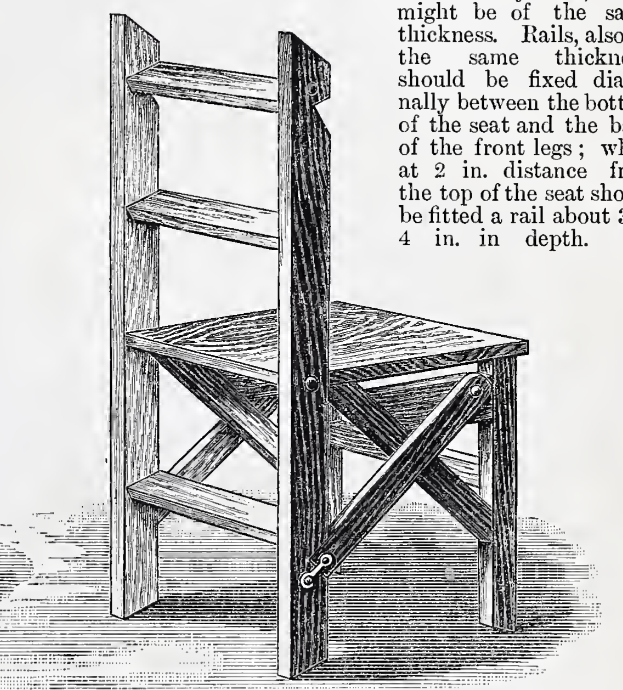

Fig. 2.—Step-Chair in Position for Use as Chair.

A STEP-CHAIR.

BY J. SCOTT.

EVERYONE knows what a step-chair is. It is a combined chair and pair of steps. For the library, such an article is of very great use, although much cannot be said in praise of its appearance, as the demands to be attended to in designing an article of this kind are such as prevent the introduction of curves; without which, beauty or prettiness can scarcely be obtained.

It is very often difficult to fathom whence a designer obtains his original ideas; they sometimes seem to spring from nothing whatever. In most of what are called original designs, nowadays, some feature or another is traceable to previous designs; and designing may now be said to consist of combining to advantage the improvements and most pleasing features that have developed from other men's minds, when there was a freer field for their imagination.

Whoever was the original designer of the ordinary step-chair—which is about the only one at present in the market—he could scarcely have had any suggestions from articles previously made, and the present result must have been one of those freaks of the mind that are frequently experienced by those who give up much of their time to designing.

My drawing shows a step-chair which, although I can claim a certain amount of originality for it, is merely a suggestion from that at present in the market. It has, however, a few advantages over its elder brother, and these are: that it requires hardly so much time, labour, and material to be spent upon it; and, although it may not be quite so compact and solid-looking an article as its relative, if made well, and in sound wood, it ought to be quite firm and substantial enough for its purpose. If any amateur reader intends to make one after this pattern, I should strongly advise him to go to some well-known and reliable wood-yard for his material, as, otherwise, some may be palmed off upon him which would be utterly worthless. I should, indeed, feel very sorry if I were to hear that one of our numerous friends had suddenly collapsed with the chair, while he was on the top of it reaching down some interesting book. I am afraid such a calamity would upset his desire for book information for some time, and also bring upon my head some undeserved accusations.

But it is not to be denied that great disappointment sometimes follows the purchase of what is apparently good sound wood. Not long ago I was watching a professional friend working up the back-foot of a chair with his spokeshave, when he suddenly came upon a very great defect, which was previously hidden from view. Of course, such things cannot be helped at times; but the chances of buying bad stuff are greatly lessened by going direct to a well-known firm.

In the article here shown, besides having good wood, it is a very essential thing to have thick and strong iron, steel, or brass pegs, to act as pivots upon which the back and side rails revolve.

Now for the sizes.

The length of each back-foot is 38 in., the width 3 in., the thickness 1 in. The bottom of each will have to be cut on the cant, so as to afford a firmer support for the job when used as steps; and for appearance' sake, the top as well might be so cut. The seat will be 18 in. from back to front, and 15 in. wide. It would be best, perhaps, if it were thicker at the back part than the front; say $1\frac{1}{2}$ in., and the front 1 in. It will then allow a sufficiently strong and stout peg to be driven into it. The front legs will be $1\frac{1}{2}$ in. square in thickness, and the sides of them must come flush with the sides of the seat; otherwise, the movable rail will not be able to work. It will not be necessary, however, to have them quite flush with the front of the seat. These two legs should be connected by a rail, which might be of the same thickness. Rails, also of the same thickness, should be fixed diagonally between the bottom of the seat and the back of the front legs; while at 2 in. distance from the top of the seat should be fitted a rail about 3 or 4 in. in depth. My reason for having this last-mentioned rail so deep is on account of the weight that will be brought to bear upon it. It will no doubt be seen that I show the pivot more towards the top than the centre or bottom, where it will be firmer.

Between the two back feet we have three steps, the seat forming the fourth. These steps should each be 15 in. long, and about 4 in. wide, by $\frac{3}{4}$ in. thick. They should be so fixed as to be in an horizontal position when the article is used as a pair of steps. Stout iron pegs should pass through the back feet, and penetrate the seat for a few inches; these are the pivots upon which the back feet work.

We now come to the movable side rails. These must be 16 in. long, $1\frac{3}{4}$ in. wide, and 1 in. thick. They work upon pivots which pass through them into the side piece, as I have shown in the drawings. Two notches must be cut in each back-foot, to admit the end of one of these rails. It will be best if the cutting of these notches be left until all the rails, etc., are cut out; their exact position can then be the better ascertained. A hook should be fastened, to work loosely, to the end of each of these rails; and an eye or nail fixed above the top notch, and one below the bottom. The steps will have a firmer support, perhaps, if the bottoms of the front legs are slightly canted inwards.

Allowance must be made in my measurements for joining, which will require a great deal of attention; as, unless well joined, it will soon become shaky.

Such a chair as I have just described is not a very comfortable one to sit in; but comparative ease can be obtained by using a cushion. This cushion should be made long enough to cover the back and seat together; and one end should be fastened to the top of the back feet, while the other is secured to the front of the seat, so that it hangs something like a hammock, only, of course, fitting more closely to the form of the chair. If this is done, it will be found that the cushion will in no way prevent the chair from working, as it will only be necessary to pull the middle of it up from the seat and back. Here, then, is another advantage, as a cushion cannot be so well adapted to an ordinary step-chair.

Thus I conclude my remarks of the step-chair; not "a thing of beauty, and a joy for ever," but a thing of ugliness, and of use for—not ever, but a long while.

PRACTICAL HINTS ON MOUNTING OBJECTS FOR THE MICROSCOPE.

BY A. T. SMITH.

Mounting in Cells — Semi-Opaque Objects.

Mounting transparent and semi-opaque objects in cells is the only subject which now remains for consideration. Cells, as we already know, are used for the purpose of preventing the object from being subjected to pressure, and so crushed out of shape; but, as in the case of dry mounts, so with transparent objects—it is especially essential that the cell chosen should be of the right thickness. This is even more important in the latter than in the former case, because if the mounting medium used is a fluid, the object is exceedingly apt to slide about in the cell if the cell is in the slightest degree too deep.

The choice of materials for the cell walls is also more limited, as it is always necessary to make the cell wall of a material which is not porous; if it is, the medium will, of course, leak through it.

Books on the microscope recommend, in many cases, "built up" cells—that is to say, cells built up of slips of glass cemented together on the slide, but for practical purposes these are never required, so we will not refer to them further. I have always found the ordinary vulcanite or glass rings amply sufficient for any ordinary purpose, and if I have found it necessary at any time to use an exceptionally large cell for any particular purpose, I have cut one out of a piece of good sheet indiarubber and cemented it to the slide.

For cementing the cell to the slide, marine glue is, perhaps, one of the best cements to use, and in order to make the cell walls quite impervious, they should be coated with a thin layer of gold size after the cell is fixed on to the slide. The coating should extend just over the outer and inner edges of the glue.

Marine glue is, however, at times, somewhat difficult to work with, and I have found very useful the cements sold for sticking glass together (compounded mostly of isinglass and acetic acid).

The media used for mounting in cells are the same as before: viz., Canada balsam, gum dammar, glycerine jelly, Farrant, glycerine, and dilute glycerine; but it is particularly necessary in using Canada balsam to dry the balsam very thoroughly before dissolving in chloroform. Again, in using balsam, it won't do to use cells fastened on with marine glue, because the chloroform will act on the gold size and glue and spoil the mount. Cells fastened on with isinglass cement should be used with this medium, and after placing the object in position, it should be covered with a watch-glass and put aside, to allow the chloroform to evaporate, then more balsam should be added until the cell is quite full of hard balsam, when the cover glass may be applied in the manner described hereafter. Balsam labours under a great disadvantage, in so far that it is difficult to get it sufficiently hard and dry before applying the cover glass, and the result is that, after the cell is nicely varnished and put aside as finished, some fine morning you will find that the cover glass has cracked across or collapsed in the middle, which mishap has been

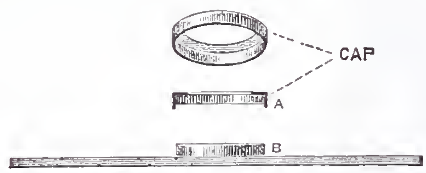

Fig. 4.—Cap for securing Cell.
A, Metal cap (in section), fitting exactly over cell wall, B.

brought about by the contraction, through further drying, of the Canada balsam.

Many of the fresh-water algæ, such as *Batrachospermum*, whose beauty is much impaired by pressure, look exceedingly well when mounted in a cell in glycerine jelly. They should be prepared by soaking in strong glycerine for a day or two previous to mounting, and as, in some cases, objects of this class are too fragile to stand even the slight amount of heat required to melt the jelly, they require to be mounted in glycerine alone, with a trace of carbolic acid, or even dilute glycerine, consisting of about equal parts of distilled water, pure glycerine, and a few drops of pure carbolic acid. It is here that the great difficulty comes in.

Glycerine, as we know, easily mixes with water, and therefore readily unites with most animal and vegetable secretions, but, for this very reason, has the disadvantage of interfering very materially with the effectual sealing up of a cell, because neither glycerine nor water will unite with anything of the nature of turpentine; consequently, if there is the slightest trace of glycerine or water in the top of the cell wall when you come to ring the slide with gold size, the gold size will not adhere at that point, and the result, sooner or later, will be a leak, which is undesirable. On the other hand, it is impossible to use a spirit varnish, because the spirit would run in at once.

The following very ingenious method of getting over the difficulty has been devised, I think, by Mr. Enoch :—

A small metal cap (see Fig. 4) is made to fit exactly over the top of the cell, and when the cover glass is in position, and as much of the medium as possible wiped away, particularly from the top and edges of the cover glass, a layer of gold size is applied to the edges of the same and the top of the cell wall, and then the little cap is placed over all. This holds the cover firmly in position, and the slide is placed on the turn-table, and a good layer of cement applied to the outside of the whole. If this is carefully done, and good gold size and indiarubber cements applied alternately, an exceedingly strong and neat cell is the result, and there need be no fear of breakage. As I have said before, the great thing is to see that all trace of glycerine or water is removed before applying the varnish.

Now concerning preparation and manipulation:

From the very nature of the case, objects suitable for mounting in cells cannot require much preparation. They must be altogether or almost transparent, to begin with, or, at any rate, quite capable of being easily rendered transparent by the ordinary methods of maceration in water, caustic potash, or soda.

Vegetable preparations will not, of course, stand much of this treatment; nor do they require it. Soaking in glycerine before mounting is usually sufficient, but preparations of insects, or portions of them, require careful and discriminating treatment.

Some of the very dark Coleoptera with hard carapaces require soaking, or even boiling, in strong potash or soda before being fit for mounting; others, again, with softer coverings, require only soaking. For some insects, again, the re-agents referred to are too strong, and pure carbolic acid must be used, and for others even this is too strong, and the carbolic acid has to be diluted with glycerine. This last method is the one used for preparing specimens of insects in their natural form and colour without pressure, and by it some very beautiful results may be obtained—the object being, after preparation, mounted in dilute glycerine.

It is often extremely difficult to get the object (say, the head of a bee or wasp) firmly fixed in the cell so that it will not move about, and this, no matter how careful we have been in selecting a cell of the right thickness. This defect may be remedied by taking a piece of glass tube and drawing it out to a thread. Now take a piece of this thread just the breadth of the inside of the cell, and stick it right through the object from side to side. If the ends of the glass thread are now placed against the inside of the cell walls, the object will be securely fixed in position, and a source of annoyance removed. The glass thread, when immersed in the medium, is not in the slightest degree unsightly, nor is it in the way.

It is far more necessary to be careful to exclude air-bubbles in mounting in cells than when mounting in the ordinary way, because they cannot be squeezed out. Hence, after filling the cell with the mounting medium, its interior should always be carefully examined, and if any air-bubbles are found adhering to the bottom or sides, they should be removed with the point of a needle. Again, as to filling the cell. There should be just enough medium in it to form a slightly convex surface when the object is immersed, and the object should be allowed to remain in the medium for a few minutes before applying the cover glass, in order to allow any air-bubbles that may be attached to it to rise to the surface. These should then be removed, and then the mount may be completed as follows:—

Take a clean cover glass—warmed, if the medium is Canada balsam—and, allowing the right-hand edge to rest gently on the p of the cell wall at the left-hand side, ish it gently forward until it touches the edium. If there is the right quantity of edium in the cell, the cover glass will now itself go into position by the force of pillary attraction, and all that is necessary rther is to squeeze out superfluous medium y gently pressing the top; clean it away, pply the varnish, then the cap, and after rther varnishing and drying, the mount is omplete. It is only necessary to add that a all microscopic work cleanliness and neatess are great desiderata.

OUR GUIDE TO GOOD THINGS.

** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

23.—Griffin's "Ideal" Combination Paper Knife, Eraser, and Envelope Opener.

Mr. Griffin, 5, Wisteria Terrace, Chapel Road, Stamford Hill, London, N., has sent me a very nice-looking and useful article which takes the form of a penknife, but whose handle is so cleverly contrived and fashioned that it will act also as a paper knife and an envelope opener. It is known as Griffin's "Ideal" Combination Paper Knife, Eraser, and Envelope Opener, and is sold at 2s. Its shape and make may be gathered from the illustrations given, Fig. 1 showing a back view and Fig. 2 a side view of the knife. Its length from end to end is 4 in., and its greatest width ⅝ in. The handle is made of a solid piece of ivory wedge-shaped in form, being sawn through from the top, which is rather more than $\frac{5}{16}$ in. thick, for 2¾ in. of its length to admit of the introduction of the blade and spring. The length of the handle admits of its being shaped at the thin end, as shown in Fig. 2, the form thus given to it being convenient for opening the envelopes of letters by inserting the point under the fold on one side, and pushing it along the top, which is

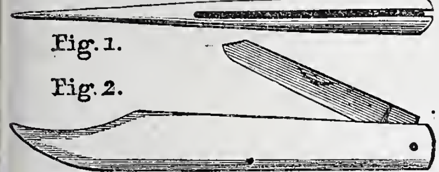

Fig. 1.—"Ideal" Paper Knife: Back View. Fig. 2.—Side View.

ripped open by the pressure of the wedge-shaped point. The blade is wide and stiff, and of a shape well adapted for erasing or scratching out. The handle of the knife is marked with a trade mark of peculiar form, consisting of a diamond surrounding a square on which is marked the word "Ideal," a black diamond being placed in each corner of the square, two sides of each of the small diamonds being coincident to a certain extent with the sides of the large diamond, the ground of which is white. This trade mark is the distinguishing feature of Mr. Griffin's inventions, all of which are therefore known as "Ideal" articles. Among them I may be permitted to mention the "Ideal" Patent Adjustable Perpetual Calendar, the "Ideal" Date Table, now preparing for publication, the "Ideal" Revolving Box Cover, and the "Ideal" Parallel Ruler. I have an early copy of the "Ideal" Date Table before me, a table showing the day of the week on which each month commences, and also giving a complete calendar for any month from A.D. 1797 to 1955. The Editor.

SHOP:

A Corner for Those who Want to Talk It.

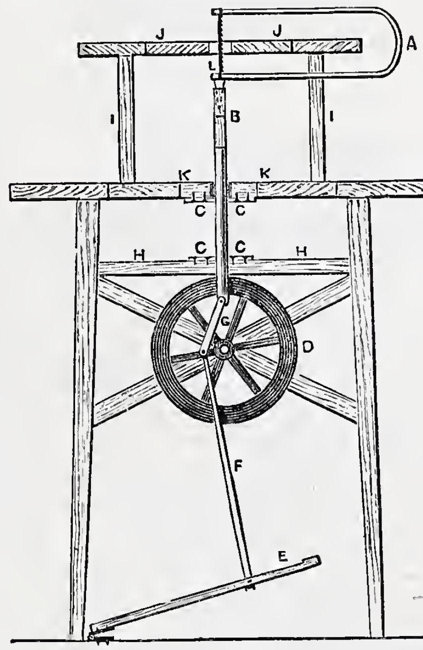
NOTICE TO CORRESPONDENTS.

** In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

An Easily-made Fret Machine. — F. D. (*Luton*) writes:—"In No. 21 of Work, on page 332, I noticed an easily-made fret machine (?), which claimed certain recommendations to the amateur—namely, a vertical stroke, easily constructed, and could be made for a few shillings. According to the design, they were all false claims, at least, in my opinion, and I should guess that from the letters which have recently appeared in 'Shop,' asking an explanation, I am not the only one of that mind. However that may be, I am glad it appeared, as I had long wanted a fret machine, and it



An Easily-made Fret Machine.

gave me an idea which I now propose to give in my turn to the readers of your paper. My easily-made fret machine has, I believe, a just claim to the above recommendations, as the illustration will show. First a table or bench is made, and it will be best to make it of such dimensions that it will be at once a bench and saw combined. The sawing apparatus will of course be at the end of the bench. The cross pieces which support the wheel will next be fixed, and then the shelf, H, which if run the entire length of the bench will serve as a shelf and bearing for the rod, B, at the same time. The shelf, H, and top of the bench, K, have each an iron plate fixed to them with a hole bored to let the rod, B, work in. The table, J, is next made, and fixed by means of four pieces of wood about 2 inches square to the top of the bench, so that it is quite firm. It has a hole about an inch in diameter bored in it to allow the saw to work in. The wheel is then fixed in such a way that it can revolve freely without rocking. Next the crank, F, is fixed. Suppose the saw is 5 in. long, and the thickness of the table, J, ¾ in., the screw of the top of the crank, F, must be 2 in. from the centre of the wheel. That will give 4 in. throw, and if the table, J, is ¾ in. thick, a quarter of an inch will be allowed between the top of the table and the under side of the top part of the saw frame. The crank, F, is not fixed direct to the rod, B, but is connected with it by a smaller crank, G. This apparatus gives a perfectly vertical stroke, and I believe is altogether what I claim for it—namely, a good machine at a moderate price. The rod, B, is a brass tube, and is flattened, drilled, and tapped to receive the screw which connects the crank, G, to it. The upper end is filled with a piece of wood to hold the end of the saw frame."

Cheap Hearth for Smithing.—Worker Bee (*Hertford*) writes:—"I would like to say a word of congratulation to A. H. (*Wolverhampton*) for the excellent hearth he has given us on page 556, and to point out to him, as well as A. S. (*Liverpool*), that his blast will be far more effective if the pipe marked 'A, Fig. 7,' is made slightly tapering all the way from the mouth of the fan to the nozzle of the tue-iron. I knew a chap who rigged up a nice little forge, but could not get it to go until he had made this alteration."

Band Saws Breaking. — Worker Bee (*Hertford*) writes:—"A. R.'s (*Scorrier Saw Mills*) remarks always attract my attention, because he not only knows what he writes about, but also, like myself, is a 'Cousin Jacker.' All the reasons he gives for band saws breaking are good and, I fear, too true, but in my experience the most fruitful cause of breakages is when the wood from various causes (such as the plank being warped or hollow, as it frequently is) does not lay 'dead' on the table at the exact spot where the saw passes through it. The plank vibrates or 'chatters,' as we term it in the mill, more or less, and the probability is the saw snaps before it has cut sufficiently far to allow the plank to lay flat on the table again. I was about to say a few words on polishing cutlery, and one or two other matters, but must refrain, or I shall be dubbed a *multum-in-parvo* critic."

Model Yachts, etc. — Nautical (*Waterford*) writes:—"As Oxygen surmises, articles in designing and building model yachts that will sail well will interest others besides him, and will, I think, extend the circulation among the younger members of the fraternity. Model yachting is not such child's play as it may seem, and is a healthy as well as pleasant pastime—a consideration to some who are engaged in workshops, etc., during a long day. I hope to see designs and hints for building or making a good racing model soon, and wish you every success with your magazine."

Cabinet for Fretwork.—F. P. (*Bath*) writes:—"I was forcibly struck with the beauty of Mr. Gleeson-White's design for a cabinet in fretwork in your first issue of Work, and determined, sooner or later, to attempt its construction, but as no hint was given as to the thickness of the wood to be used for the purpose, I decided to wait awhile, hoping that some brother amateur would lay before you the result of his labour so that I might glean some information for my guidance. In a subsequent number (6) T. F. seems to have undertaken it, but failed to produce the desired effect, owing to his having employed too thick a wood. Having some very old dark oak panelling by me, I had them planed down to ⅛ of an inch thick, and then commenced cutting out the pattern carefully traced from Mr. Gleeson-White's design. On the completion of the pieces for two cupboard and four drawer fronts, I procured some mahogany ⅛ in. thick for backing, and, adopting Mr. White's suggestion, gave each piece of mahogany three coats of white enamel paint, laying my work on the last coat whilst wet, and then subjected the several pieces to pressure until the paint was dry and hard. This was continued for three days, and on removal from the press the fretwork was found to be firmly embedded in the paint, and in a solid condition for cleaning up and polishing. I should have acted wisely had I followed your advice and have used thinner wood (say $\frac{1}{16}$), but notwithstanding my self-will, the cabinet is much admired as a fair substitute for marquetry. I must add that the body of the cabinet was constructed of mahogany, ebonised, by a skilled cabinet maker, and now forms a goodly ornament in my wife's drawing-room. Thanks to Work."

Fret Saw.—A. J. A. (*Malvern*) writes:—"I notice that A. A. (*Coventry*) (see page 636) whilst finding fault with methods of fitting up saws for fret cutting contributed by Artist in Wood and W. R. S., has in his own sketch for fret saw totally omitted to give any idea as to how he obtains the necessary motion without a fly wheel. I presume this was an oversight."

Tuition in Carpentry.—R. A. P. (*South Kensington*) writes recommending in strong terms the classes held by Mr. S. Robertson, 11, Augustus Road, Goldhawk Road, Shepherd's Bush, London, W.

American Organ and Harmonium Building, Book on.—J. B. (*Ashton-under-Lyne*) writes:—"In Vol. I, page 673, G. N. says he does not know of any book on the above subject. May I inform G. N. and the readers of Work that much information may be gathered from two books published by Metzler & Co., 42, Great Marlborough Street, London, W.—'The Alexandre Harmonium: Its Mechanism, Stops, Tuning, Regulating, etc.,' clearly explained, with drawings and plates of various instruments; and 'The American Organ: Directions for Tuning and Regulating Mason's and Hamlin's Organs,' preceded by a description of their mechanism, stops, etc.; also *Musical Times*, No. 421, Vol. 19. I, like many more of your readers, am waiting for the long-promised papers on American organ manufacture. Hoping your readers will help each other when opportunity presents itself is the wish of Musical. Please say if back numbers can be had. I am about two numbers short since Work started."—[Yes, all the back numbers are obtainable through your bookseller or Messrs. Cassell & Company, Limited, London, E.C.]

Cork Heels, etc.—T. R. (*Ripon*) writes:—"If H. G. (*Bishopsgate*) (see page 526) would tell me how many irons are used in finishing the shanks of boots and shoes, such as waist, fore part, etc., and whether the shank irons do for men's and women's alike, I should be obliged. The description of the "Wurtemburg" is what I wanted, but should like to know if the screw nails are driven in slant outwards or inwards, and how to make the breast level with the sole? Should there be a piece of leather under the heel of the insole or across the balls? This part in particular I hope will not be looked over. Please say also in a heel of a boot or shoe 2 in. high and 1¾ in. broad at top piece how may split and lifts be sloped in; if the pegs or rivets should be slanted in the same way—the split lift from the edge of seat for men's light boots or shoes bandsewn on wooden lasts; how to dress a pair of welts, and how to make a close-welted boot, and broad, and medium?"

Band Saws.—A. R. (*Scorrier*) writes:—"In my remarks on band saw machines and band saws in No. 35 of WORK (see page 556) I said the top wheel should rise and fall freely. This will allow for the expansion and contraction of saw. I might add that I have worked saws ⅜ in., ¾ in., and 1 in. wide with 5 and even 6 brazes in them, and they seldom break in the braze, and with as many as 4 and 5 flaws half-way across the saw by punching a small hole at the end of flaw. I was rather amused with some remarks on band saw brazing on page 621. I never heard of a stone or brick wall being used for brazing band saws on before. I should judge it to be a very clumsy way to braze a band saw. It may be all right."

Clocks in Fretwork Cases.—A. B. C. (*Christchurch*) writes:—"On page 606, column i, line 11, word 'left' should be 'right.'"

A Word in Season.—J. W. H. (*London, S.E.*) writes to querists in "Shop":—"(1) Do not ask us for information, vaguely expecting to be taught a trade or process by a few magic lines. It stands to reason that the short allowance of space at our disposal cannot be made a finger-post to any royal road to learning. (2) Don't be discouraged by failure in attempting anything well begun! Give us the fullest detailed account you can of any difficulties you may encounter; give us a fair chance of coming to a logical conclusion as to the causes of failure by stating your case fully, and you will have no cause of complaint in our answers, but if you only tell us half the circumstances, how can you expect to be more than half counselled? (3) Write at full length; we must be brief in reply. (4) If you ask more than one question at a time, pray use a separate piece of paper for each query."

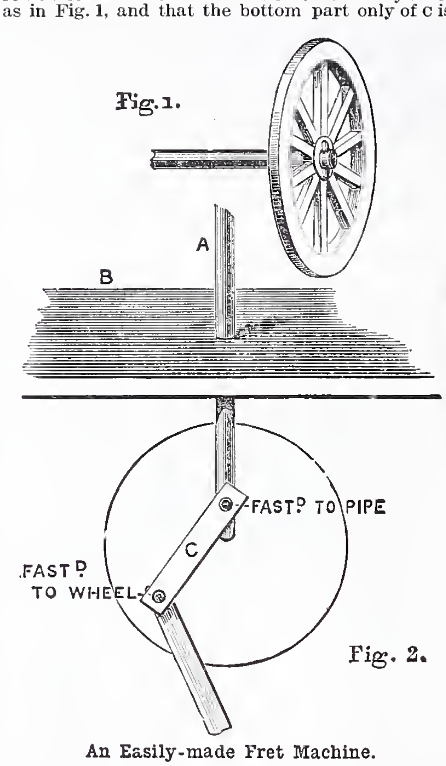
II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Staining Floor.—DECORATOR.—The floor of the room you refer to having been painted, you cannot treat it as if the boards were still in the natural state. Your questions are rather involved, but as far as I understand you want to know how to polish the existing painted surface, or how you can get the paint off in order that you may stain, and the answer to your letter is given accordingly. It certainly would be hardly worth while for you to take the trouble of "polishing," if by this is meant French polishing the floor. A sufficient brilliancy may be got with far less trouble and expense by varnishing it in the usual way, which, as a decorator, you are, no doubt, practically acquainted with. Of course, if the paint is much disfigured by wear there is no reason why you should not repaint, in which case there is no necessity for removing the present coat. This, I think, would be a far better way than staining, for before this can be done you must remove the paint, which you will probably find a very tedious and troublesome operation. It seems almost unnecessary to remind a decorator that the paint may either be burnt or washed off with one or other of the many well-known preparations, and that the paint on the skirting board is very apt to be injured. Without knowing all the circumstances of the case, I am inclined to think that if the floor is to be stained it will be advisable to have it planed over. So much, however, depends on its condition that I cannot do better than advise you to use your own judgment, for you will readily see that an amount of trouble, which might well be bestowed on a fine oak or pitch pine floor, would be thrown away on one of the ordinary kind. Finally, neither I nor any one else can tell you how to "stain with the paint on," as it can't be done.—D. A.

Dry Battery for Electric Lights.—ASCA (*Newcastle-on-Tyne*).—I do not know of any dry battery giving an E.M.F. of 4 volts from two cells in series. The silver chloride battery has an E.M.F. of 1·02 volts per cell, or each pair of elements, so that you would require four cells and four pairs of elements to give you the needed E.M.F. from this battery. This is the nearest I know of likely to suit you, as it is quite free from liquid, and very light and compact if made up with ebonite cells. The elements of the battery are:—Negative, a silver plate coated with silver chloride paste kept in position by blotting-paper pad; positive, a zinc plate enveloped in blotting paper, moistened with a solution of zinc chloride. The zinc plates may be 4 in. by 2 in. by ⅛ in., and the silver plates may be of silver foil, having the same surface area. Connect three of the pairs together by soldering strips of copper to their tops; this will leave one zinc plate to form one pole of the battery, and one silver plate to form the other pole. The cells should only be large enough to admit the plates with their folds of blotting paper, so that the intervening paper may be pressed between the zinc and silver plates in each cell.—G. E. B.

Coppering Blackleaded Moulds.—COPPERED PLUMBAGO (*Malton*).—Knight's process of coppering blackleaded moulds previous to placing them in the electrotype solution is as follows:—First, blacklead the mould in the usual way. Then wash off superfluous plumbago with a jet of water. Next flood the face of the mould with a concentrated solution of sulphate of copper. Over this sift some very fine iron filings through a very fine sieve, or dust the mould with finely-sifted iron filings from a kind of pepper-box. Brush the face of the mould with a soft brush, and wash off excess copper and iron with a rose jet. By this means finely-divided copper is precipitated by chemical action on the blackleaded surface of the mould, with the result that a superior conducting surface is presented to the electrotyping solution. I do not know where you are likely to get the "impalbably fine iron filings" ready to use. They are easily got by sifting ordinary iron filings through a very fine sieve, or rubbing them through a fine wire mesh.—G. E. B.

Fret Machine.—C. J. D. (*Glasgow*).—You say that you made a model of this, but could not get the pipe to move up or down. I think that the fault is that you have not got the pipe exactly over the centre of the wheel (if you turn to page 332 you will see that I specially mentioned this), or else the bearings are not bored straight. You must please remember that the wheel runs on an ordinary axle, as in Fig. 1, and that the bottom part only of C is



An Easily-made Fret Machine.

fastened to the wheel, and the top part to the pipe, as in Fig. 2. You also say that you wish me to give you a correct drawing of the machine. The illustration on page 332 is perfectly correct, and is the same as the machine I have here, which I shall be pleased to show you if at any time you are in London. I might add that your letter is not a very complimentary one, as it seems that because you are not able to make the machine you think that the best thing to do is to abuse it.—W. R. S.

Replating Brass Caps.—R. C. (*Wood Green*).—Strip all the old silver from the brass caps by boiling them in sulphuric acid, and adding, whilst the acid is hot, a few crystals of saltpetre. The acid should be heated in a porcelain crucible, or glazed carthenware pipkin. Add the saltpetre until all the silver has dissolved off, then take the caps out of the acid with a pair of brass or copper tongs, and throw them into clean water. After this, brush off all loose silver with a wire brush, scour the caps with bath brick in water, well wash them, and quick them in a nitrate of mercury solution ready for silver-plating in the bath. I must ask you to be good enough to look up other replies to correspondents relating to electro-plating for further information respecting how to make up and work the silver-plating solution. I hope to take up the subjects soon in a series of articles, and then you will be able to learn all about it. Dynamos, motors, and other "electrical hobbies" will receive attention in due course, and you will then, I hope, be abundantly satisfied.—G. E. B.

Oxford Picture.—F. M.—In answer to yours, a small circular saw is used for cutting rebate in Oxford frames, fixed in bench sufficient to cut depth in wood desired. A cutting gauge is used sometimes, but is very hard work. Spokeshave is used for chamfers and chisel. You can buy the wood ready rebated, and can neatly fill the ends in. If carefully done, it is as good as cutting out of solid. Almost any moulding can be treated in this way, black and gold, etc.—G. R.

Charging Batteries for Electric Lighting.—J. T. (*Walham Green*).—Charge your battery with a solution of chromic acid, made by dissolving 3 oz. of chromic acid in 1 pint of water, acidulated with 3 oz. of sulphuric acid. With this solution your three-celled battery will give a current of 1½ ampères at a pressure of 6 volts for some four or five hours with one charge of solution. If you select a 6 volt 2½ c.p. lamp, this current will light it up nicely during that time.—G. E. B.

Leaf and Flower Printing.—LEAFLET.—Impression of leaves, etc., can be taken on wax or cast in plaster of Paris, but the process is too long to describe here. I shall, however, be happy to contribute an article on the subject if of sufficient interest, as this was a favourite hobby of mine in my younger days. LEAFLET may also try the blue printing process recently described in WORK, as it is often used for the purpose of copying leaves and plants.—H. L. B.

Mounts and Cardboard for Ticket Writers.—TICKET.—Write to Messrs. Surflen & Clarke, 3, Bucknall Street, New Oxford Street, W.C., and ask for their price list, which will be sent post free.—H. L. B.

Transfer to Metal Plate, etc.—F. J. L. (*Bristol*).—I know nothing about the process of the first query. The only ink that can be used on zinc to withstand the action of acid is of a greasy nature, such as that used by lithographers, which can be ground up thinly and used with a pen on stone, transfer paper, etc. The drawing would have to be transferred to the zinc from the transfer paper, unless drawn on the metal with a fine brush. The pen would scratch the zinc. See a manual on lithography.—F. M.

Clock Cleaners.—W. E. S. (*London, E.C.*).—Take off cylinder cock, and with a pinion gauge measure from jewel hole to middle of curb pins. Select a hairspring the same size. take hold of outer end of the spring, pass the cylinder bottom end up through the centre of it, and let it hang by the notch. Then measure as near as you can the distance the cylinder and balance draws the spring down. If about a length and a half of the cylinder it may possibly do (if you have the old spring you can get near the right strength by comparing the old and new). Now take the collet off the cylinder, and take the pin out that fixes the inner end of spring to collet. See if the collet will go inside with a little room to spare. If not, break out coil till it will go, then bend a small portion of the inner coil straight so that it will make a half-circle. Then pass the straight piece in the hole of collet and pin it in tight. See that the spring and collet are quite flat, replace the collet on balance or cylinder, lay the cock on the bench on its back, put cylinder cock pivot in the hole, pass the outer end of spring through the stud in the cock, and pin it in. See that the spring is free everywhere, and that the watch is in beat, set going, and note time. If it gains, you must go all over the work and put a weaker spring; if it loses, try breaking off a turn or half-turn first of the outer end; re-pin and try, but if after taking off one or at most two turns and it still loses time, why you must put a stronger spring, but unless you have a good selection of good springs, I should advise you to send or take to any watch tool shop, the cost of springing and timing being only about two shillings.—A. B. C.

Book on Heating.—MECHANIC (*Lewisham*).—Hood's "Warming and Ventilating," Spon & Co., 12s. 6d., is a good book.—F. J. C.

Book on Cooper's Work.—Δημᾶς.—A suitable work is "The Cooper," price 1s., in Houlston's Industrial Library.—F. J. C.

Moulding Indiarubber.—C. P. C. (*New Kent Road*).—This substance, which is the dried sap of the *Hevea Guianensis*, etc., cannot be moulded whilst in the pure state, although the sap as it runs from the tree may be used to coat the external surface of any article selected as a mould, which, indeed, is the method adopted in the collection of the gum in its crude commercial form of "bottle rubber," but such a process is evidently of extremely limited application, and has no commercial value. Moulded articles of so-called indiarubber are formed of an intimate admixture of indiarubber and sulphur with various adulterants, the mixture being pressed into hollow moulds of suitable shape, and simultaneously subjected to a temperature varying according to the amount of sulphur contained in the raw mixture, and the degree of hardness required in the finished article. The heat not only softens the compound, and so enables it to conform to the exact outline of the mould, but also effects the vulcanisation of the rubber by chemically uniting the sulphur therewith, the result being a more or less elastic object capable of retaining permanently the form of the mould in which it was vulcanised. The pressure is needed to counteract the expansion which would otherwise be caused by the liberation of sulphurous gas, the result of such expansion being rubber of a spongy texture similar to that sometimes used for cleaning gloves. The adulterant is added to give "body" to the mass, and to reduce cost at the same time. It may consist of any inert substance capable of resisting the heat employed in the vulcanising process. Unvulcanised sheet rubber of various qualities and thickness may be obtained

. almost any shop for the sale of rubber goods.—
ui Vive.

Cracks in Oven.—J. D. (*Hanley*).—Try one of e following cements. You will find them all ood for the purpose you require:—(1) Flour of ilphur ½ oz., sal-ammoniac ½ oz., finely sifted iron orings 20 oz. Mix to a stiff paste, and apply im- ediately to the crack. (2) Five parts of fire-clay ell dried and powdered, 3 parts of fine iron orings or filings, 1 part peroxide of manganese, part of salt, and ½ part of borax. Mix these ioroughly, and make a paste with the necessary ater, mixing well. The parts cemented with this iixture should be heated gradually. This will stand red heat. (3) Dried and powdered fire-clay ¾ lb., on filings ½ lb. Make into a paste with boiled nseed oil. If you could get to drill a hole or two ı your oven, and put on a plate with a few small ındcr bolts, with some portion of one of the above amed cements, that would make the best job of .—R. A.

Rifle.—Derry.—I am inclined to think it is not) much because your rifle is not often used as ecause it is badly and carelessly kept when not in se that it "gets a sort of rusty, etc." Keep it ean, well oiled, and in a dry place, and you will ot find it rust either inside or outside. There is no ay by which you could "blue" the barrel satis- ıctorily without risk of injuring it, unless you are ccustomed to the work. It is done by heat. I uite agree with you that Work is a splendid paper or instruction, and I am only sorry that I cannot nswer your question more definitely. Thank you or your good wishes.—D. A.

Upholstery.—S. M. (*Battersea*).—Your hope will ot be misplaced, as we shall not print your letter, 'hich has been written under an imperfect appre- iation of facts, and reminds one of the old tale of ie peaceably inclined Hibernian who trailed his oat on the ground for some one to tread on. Your erception of the contents of a former corrspon- ent's letter is wonderful, the only point on which ou are wrong being that he did not ask for in- ormation on the subject to which you allude, and, f course, this slight error disposes of the utility of ıe major portion of your remarks. We do not ee how you can have taken up the idea that we ıink drapery cutting is woman's work, for the entence on which you found your assumption egins thus:—"With the exception of planning, tc., draperies, the actual making up is done mostly y women." As one who is very much in the up- olstery trade, I cannot find in this anything to ıdicate that women are engaged in cutting. An pholsterer was replied to, and knowing his question e would understand the answer. You, not know- ıg his question, have misinterpreted the answer.)f course I am glad to have your opinion as to what ·ould be useful to readers, but I am not convinced hat the cutting of draperies would be a subject of ufficient interest to warrant much space being evoted to it. Here and there a reader might find benefit, and you may be sure the matter will re- eive all the attention it deserves, if there should e anything like a general wish for papers on up- olstery drapery. Perhaps those who agree with ou that these should be given will write saying so, or the desire of all concerned is to make Work s generally useful as possible to all classes and rafts. It is news to me that cutting is not taught a trade except for an extra premium and in ex- eptional cases. Of course you know that in aany shops, especially in London, drapery is not ttempted, and that the men are only stuffers, a vord which you have possibly heard rhymes with 'duffers." You will usually find that cutting lraperies is not specially taught, but is acquired, if may express it so, gradually. The foreman takes n interest in the smartest boys who show some ptitude, and they by degrees become conversant vith the "fine art" of the upholsterer's work. There are several old books dealing with draperies, out I do not think you would find any of them of nuch use. If you are inclined to study them you vill find many in the South Kensington Library. t is very likely that before long an article on lrapery, with an illustration, will be given in Vork, whose pages, I quite agree with you, will ıot be degraded by it. Your remark that "one ;ood design," accompanied by full directions how o cut out same, "would be sufficient for all pur- ıoses," simply amazes me. How can directions for estooning a chair, for example, teach you or any ıne else how to drape a window or a bedhead? No, ny friend, you will find that each article, each lesign, must be specially studied with due regard o material, quantity, colour, cost, etc., and that it s absolutely impossible to formulate a few rules vhich shall be applicable and sufficient under all ircumstances. A namesake of yours was at one ime, perhaps is still, foreman in one of the largest ıpholstery shops in London. Ask him, or any other ıpholsterer, if he can kindly tell you of any one lesign and instructions which will enable any ıne to master the art of cutting and arranging lraperies, for if you can get to know, and will send ıs word, you will confer a benefit on all young up- ıolsterers, for whose benefit the directions—with our permission—will be printed in full.—D. A.

Etching with Nitric Acid.—Spot (*Lancashire*). —In answer to Spot, the first thing you should do is o see that your metal is quite clean, then heat it sufficiently to melt a composition of asphaltum and Burgundy pitch, called etching ground; or of as- ohaltum, gum mastic, and resin. This should be olaced on very thinly, and allowed to cool, when it will be found to be of a hard consistence, and ready to receive the subject to be etched, which is drawn on transparent paper with a blacklead pencil, and then laid face downwards on the etching ground, and pressed or rubbed with such force that the im- pression is left on the ground when the paper is removed. Next apply your tool over the lines, care- fully removing the ground, at the same time press- ing sufficiently hard to scratch the surface of the metal. A wall of wax is now placed round the margin of the plate, and some aquafortis poured in the inclosure. Let this stand for about an hour while it bites in, then wash the plate with water, and let dry.—S.

Counter Case. — W. P. (*Liverpool*). — As an amateur you will not find the construction of a show or counter case an easy matter, and all that can be done is to indicate the course you should pursue, or, rather, the course I should advise you to take, for possibly an expert show-case maker, especially if lightness of appearance were a *sine quâ non*, would go about the work in a somewhat different manner. I think you will succeed better by not making the framework too light, and I sup- pose you want something serviceable. I fancy you are under the impression that the wooden framing, or what you call the beading, is added to the glass. If so, let me put you right. The skeleton case, or framework, is made up first, and the glass fitted into it. Regard the case as so many frames, which are to be glazed much the same as a window would be, and you will understand what is wanted. Now, to give you a few hints about making the case. The bottom board you will not need to be told about, but you may as well get it out first, as it

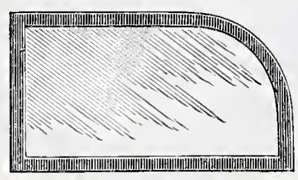


Fig. 1.

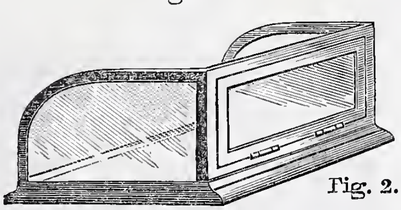

Fig. 2.

A Counter Case.

will guide you when making the rest. For the framing into which the glass is to be fitted, use ¾-in. square stuff. Make two frames for the ends as Fig. 1, and a similar one, only rectangular, for the back. Within this latter, fit another to serve for the door. Hinge this to the lower portion of the back frame. Fasten the back frame and ends together with glue, if necessary running a bead to break the joint, and using a few screws. Fasten the entire framing to the bottom board by the same means, the screws being driven through from below. The framing must be rabbeted to receive the glass, which can be kept in place either with putty or small beading. Along the front fasten a rabbeted piece for the bottom of the glass to rest on. See that you get the glass bent, so that it lies within the rabbet without straining; in other words, it must be a perfect fit or it is sure to break, and I daresay you know that a bent piece of glass is some- what expensive. Anything you have not under- stood of the construction I suggest, will, I think, be sufficiently intelligible from Fig. 2.—D. A.

Boring Holes in Glass. — H. M. (*Slevoye*).— Holes may be bored in glass with a steel drill lubricated with turpentine and camphor. I cer- tainly should not advise you to attempt to mend your own spectacles, for you will probably break the glass.—D. D.

Small Portable Electric Lamp.—Ammeter (*Woking*).—A small lamp to go in a kind of lantern surmounting a small box battery would just suit your purpose. I do not know the "Miner's Lamp made by the Mining and General Electric Lamp Company, Limited, Crown Works, Guildford Street, Lambeth," but shall be glad to see one, and will report upon it for the benefit of readers if the com- pany will send a sample to me to be tested. Until I have seen it I cannot recommend it to you. In answer to your second query, I may say that Mr. S. R. Bottone, Carshalton, will make you a small box battery (of the kind supplied to myself), and this, together with lamp and fittings, will cost about £1. The salt to charge it with can be supplied by the same gentleman, and the charge will cost about 1s. 6d. This will give a 5 c.p. light for three consecu- tive hours, or the light can be used at intervals as you suggest, as the battery is easily thrown in and out of action by a simple mechanical device. I shall hope to illustrate and describe this battery in my articles on "Model Electric Lights."—G. E. B.

Recharging Leclanché Battery.—G. H. W. (*Barnsley*).—You are right in thinking that a piece of gas retort scurf, sawn to the shape of a carbon plate, will do to form the negative element in a Leclanché cell. But I think you have gone wrong from this point. This carbon plate must not be packed in the porous cell with the little bits of carbon sawn off from the plate. This is not the stuff it was charged with, however much it may appear like it. The cell was charged with lumps of manganese peroxide mixed with little bits of carbon in equal quantity, and you must pack the carbon plate in the porous cell with this mixture, or your battery will not work. The manganese looks very much like carbon to the unpractised eye, hence you and your friend were deceived by ap- pearances. Again, it will be useless to recharge the old porous cell, for its pores are, most likely, clogged with zinc salts. You must get a new porous cell. The old carbon plate might be used again. Read what I have said about the Leclanché battery on page 419, No. 27, Vol. I. of Work, and this will help you.—G. E. B.

Fountain.—H. G. H. (*Lower Tooting*).—A paper on this subject was given in No. 31.

Wrought Iron Columns. — A Constant Reader (*Wolverhampton*). — For angle, tee, and channel iron columns, and for columns built up of these sections by themselves or in connection with plates, you may use the following rule:—Divide the square of the length by the square of the least width; divide the quotient by 900. Add the fraction so found to 1, and by the sum divide 19; the result will be the breaking weight per square inch of hori- zontal sectional area. Example—Require the strength of a tee iron strut, 5 feet long, 6 inches wide, and 4 inches deep; the least width is the 4 inches, $4^2=16$, 5 feet $=60$, and $60^2=3{,}600$, $3{,}600\div16=225$, $225\div900=\frac{1}{4}$, $19\div1\frac{1}{4}=15\frac{1}{5}$ tons per sectional square inches. The sectional area of the tee iron, if $\frac{1}{2}$ in. thick, will be $(6+3\frac{1}{2})\times\frac{1}{2}=4\frac{3}{4}$ square inches, and, therefore, its breaking strength $15\frac{1}{5}\times4\frac{3}{4}=72\frac{1}{5}$ tons. The strut should not be loaded with more than one-fourth or one-fifth the breaking weight. The same rule will apply to English rolled joists, but those of Belgian make are so unreliable we should not care to give a rule for them.—F. C.

Polishing Table Top. — Nil Desperandum (*Tamworth*).—Perhaps it would be more correct to say that your table top shows the inequalities of surface than that it acquires an uneven surface while being "bodied up." Are you sure that you have made it quite level before beginning to polish? It must not be forgotten that inequalities which might be passed over while the wood is in the white may show up when it is polished. If this is not the cause of the defect you notice, it must be owing to the polish being unevenly applied. The result of this is that the shellac, or body of the polish, is thicker in some places than others. If this be so, you have probably used your rubber too wet. In any case whatever be the cause, you must clean all the polish off again. You can easily do so either with a scraper or glasspaper used in the ordinary way with a cork block. I do not think you need trouble your head about the stuff you saw used. From what you say I imagine it was pumice powder, which might do well enough in experienced hands, though I certainly should prefer glasspaper. I am afraid the polishers you saw troubled in the way you are could not have been very skilful, or they would not have worked up an uneven surface. Possibly they used the substance merely to dull down, but anyway you will find the remedy sug- gested is effectual.—D. A.

Electric Accumulator.—C. D. (*Hull*). — Long before this appears in print you will have read my reply to D. S. (*Holloway*) (see page 477) on this subject, and will therefore know how to prepare your accumulator plates. You have done quite right so far in cutting the plates to the proper size. As the 1 c.p. lamp may have a voltage of 3 or of 8, I cannot say how many cells you will need, but you will have enough in the 6 at your disposal. You may reckon on getting an E.M.F. of 2 volts from each pair of plates in each cell whatever their size. The larger cell will not in itself give sufficiently high E.M.F., however many plates you may have in it, as the whole plate surface would only represent one pair. You may employ the 2-quart Bunsen cells connected in series to charge the accumulators, one cell at a time. When the liquid in the accumulator cells gives off bubbles of gas and appears to boil, the charging is com- plete. Although I have thus replied to your ques- tions respecting the accumulator you wish to make, I do not advise its use in lighting a buttonhole lamp. See reply to Asca (*Newcastle*), page 718.—G. E. B.

Battery to Fire a Charge of Powder.—W. G. (*Weybridge*).—I cannot see how a charge of powder could be fired by current from such a small battery without using a coil. With a coil it could be easily made to fire an Abel or a Statham fuse. If you wish to fire the charge with the battery current only, make up four cells, charge them with a solution of chromic acid or bichromate of potash, connect the four cells in series, and use a fuse made in the following manner:—Twist the ends of two cotton-covered No. 18 or 20 copper wires together, separate the extreme ends and uncover them. Connect the two ends by a very short piece of extremely thin iron wire twisted around the copper and soldered thereto. Insert this into the powder in the tube of the fuse. The tube may be of any- thing capable of holding powder, such as a quill, a hollow elder, hemlock, parsley, or hogweed stem, or a bit of metal tube stoppered at both ends with a cork or a tube of paper. A tuft of gun cotton around the iron wire will increase the firing quality of the fuse. The battery must be made so that the zincs may be lifted out of the solution when not wanted, or they will be eaten away by the acid.—G. E. B.

Miniature Electric Lamp.—VENUS (*Norwich*).—Four Fuller cells, with an E.M.F. of 1·6 volts per cell, will, if arranged in series, furnish current enough to light up a 2½ c.p. 6 volt lamp for the short time needed to see the time by a watch in the early morning. Have the lamp suspended over and close to the watch-stand on a table by the side of the bed, rather than on the wall at the head of the bed. Connection may be made between battery and lamp through a flexible cord carrying two No. 18 wires, and the push may be attached to the lamp support if you have this heavy as it should be.—G. E. B.

Ornamental Rock Work.—G. G. (*Gateshead*).—I am pleased to learn that you find WORK interesting and helpful. With regard to the ornamentation of house front, you will see in a reply to ROCKERY in present number a plan which cannot fail to be successful. A friend of mine a few years ago had a blank wall in a conservatory which he desired (as you do) to make more pleasing to the eye. I suggested and had carried out the method suggested to ROCKERY, and the result was very much admired, and very easy of execution. You see you cannot go wrong. The very clumsiness of one who does the work really improves its rustic and rugged appearance. With regard to your centre beds, I would suggest the formation of raised beds formed by "rock-working," and border of galvanised iron netting, say, 6 in. deep, as described in No. 20, filling up with earth, and repeat in a lesser irregular circle, thus forming a terrace for the plants, and a bold piece for the centre, made hollow, so as to be used for growing. You might also at the bottom of your wall, say, 2 ft. from wall at its widest part, erect a wire border of about 20 in. high, as irregular and bold as you can, using very large pieces of coke for the purpose, leaving here and there crevices for plants. Fill up with mould, and you will have a substantial piece of work.—C. M. W.

Rockery.—(*Clapham Common*).—You can make use of your wall for growing ferns, etc., with excellent effect as follows:—Decide upon the number of pockets of various sizes you intend to have, and hang them to the wall in irregular positions on strong French nails, then at distances of about 6 in. over all the remaining surface of the wall insert some French nails (not less than 3 in. long) into the mortar of wall. Have ready some pieces of cemented coke, as described, and lay a piece on each nail, using a little cement on each. Now mix up a quantity of Portland cement and very coarse sand—about 4 parts sand to 1 of cement—with water sufficient to make it a creamy consistency; thoroughly wet the surface of the wall, and fill up by dashing on the cement, so as to cover every inch of the brickwork. Lay on a little thicker where the coke and pockets project, and see that these are well secured with cement. The result of the foregoing will be that your wall will present an irregular and, to my mind, a very pretty rustic appearance. With regard to the fountain, I cannot advise you without further particulars. Where and at what height is the water supply, height of wall, etc.? Let me know these, and I will do my best to help you.—C. M. W.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Boot Bottoms.—SILLAW (*Rochdale*) writes:—"Will any reader kindly say how to fasten boot bottoms on when making a new pair? This information will suit me any time this winter. I am a clerk, but can mend boots, bind papers, etc., through your good work, WORK."

Furniture Cream Bottles.—T. B. (*Rochdale*) asks for the name of a firm who will supply him with these.

Terra-Cotta Stove.—NAGA (*Margherita, Assam, India*) writes:—"Having the facility for burning one, could any reader let me have through 'Shop' a sketch with detailed instructions for making a terra-cotta stove for bungalow? Not to have any iron in construction."

Watertight Boots.—RUTHENPHARL (*Saltburn-by-the-Sea*) writes:—"Can any of your readers suggest any means by which ordinary boots can be made watertight?"

Gold to Gild and Bronze Iron.—J. G. G. (*Glasgow*) will be glad of any information as to where to buy and how to use this.

Re-waxing Meerschaum.—A. H. (*Sydenham*) writes:—"I shall be much obliged if any reader will inform me as to the best method for re-waxing a meerschaum pipe."

Mandoline.—J. N. (*Tooting*) writes:—"I want to know how the body of a mandoline is made. I should be grateful for any information on the subject."

Exhaust Fan or Ventilator.—D. B. S. (*Ferns*) writes:—"Would any reader be kind enough to describe a simple way of drawing off dust from a grinding shop, 50 ft. by 24 ft., with loft overhead 8 ft. high from ground. There are a number of grindstones and emery wheels at work, and the dust from them is very unwholesome."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Building Railway Carriages.—F. C. (*Leytonstone*) in reply to R. C. C. (*Plaistow*) writes:—"There is a book published by Spon called the 'Car Builder's Dictionary.' The price is 12s. 6d. It is an American work, and is a dictionary of the terms used by American and English railway carriage builders. It gives no information respecting the process of manufacture. The engravings in it are excellent, but are principally of American stock. I do not think there is another book published in England on the subject."

Banjo without Brackets.—D. K. (*Gateshead-on-Tyne*) writes:—"In No. 37 of WORK, page 589, ALPHA (*Birkenhead*) asks information about banjo without brackets. I take opportunity of sending a very rough sketch, which I hope you will be able to understand. It is composed of two wood rims with wood screws, cup head for screwdriver, and small washers under the heads

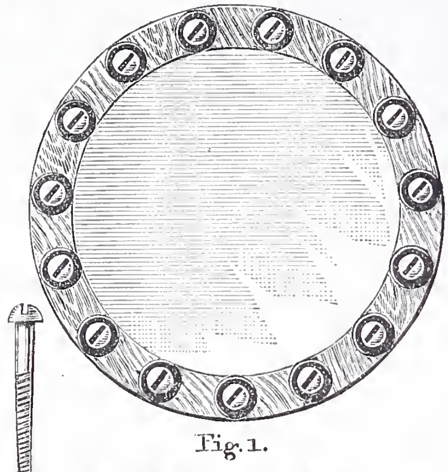

Fig. 1.

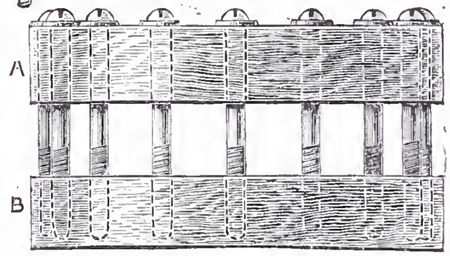

Fig. 2.

Banjo without Brackets.

of screws. Fig. 1 is the top rim over the top of the banjo skin showing the screw heads and washers. Fig 2 (A) is top rim showing screws, etc. Fig. 2 (B) is bottom rim into which the wood screws are screwed, and this rim is screwed on to the middle of the banjo drum from the inside, so that there are no screws seen outside. This is a very good and simple way, and I hope it will suit."

Pitch of Roofs.—W. D. (*Newcastle-on-Tyne*) writes in reply to C. M. (*Hornsey Park Road*) (see page 654):—"There is no definite rule for the pitch of roofs for greenhouse or shed, or in point of fact for any building at all, as a glance at the surrounding housetops will readily prove. However, a good roof for ordinary purposes would be to make the height one-third of the span."

Flux.—S. W. H. (*Aintree, near Liverpool*) writes to G. H. S. (see page 670):—"At a carriage factory in America with which I was connected they experienced a similar difficulty in finding a suitable flux for welding steel buggy axles. Ultimately marble dust (which may be obtained from any marble mason) was found more suitable than either borax or sand."

Dulcimer.—R. F. (*Norwich*) writes in reply to J. McF. (*Edinburgh*) (see page 636):—"I may say that I know of no reliable tutor for the dulcimer. There is one published by a London firm, but I hesitate to recommend it, as the scale shown is incorrect, being diatonic instead of chromatic—that is to say, there are no semitones corresponding to the black keys of the piano, so that it is impossible to play in more than one or two keys, and the tunes must be free from 'accidentals' sharp or flat, as no provision is made for them; and again, the method of beating there given is distinctly wrong. J. McF. will find a correct scale in No. 41 of WORK, page 645, and if he has access to a piano, and will tune his instrument to correspond with the notes, as shown in the diagram, he will find it fairly easy to master a few tunes in a short time. If he finds any further difficulty, I shall have pleasure in helping him in any way."

Trade Note.

OUT of the 380,000,000 of which the population of China is, according to the latest official statistics, composed, about one in ten is engaged in agriculture, one in 100 is a bricklayer or mason, one in 120 is a tailor, one in 140 is a blacksmith, and one in 9 is a washerman, while about one in 100 is a carpenter. All these classes are largely benefited by and increase and multiply with foreign trade. Emigration has caused an increase in the population to a remarkable degree. The places of those who leave are soon filled up, and when the emigrants return with their wealth, they react upon the general prosperity.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

J. H. SKINNER & CO., EAST DEREHAM, NORFOLK,

Manufacturers and Importers of Photographic Apparatus and Fretwork Materials.

J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.
The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price 3s. 6d., or securely packed by Parcel Post, 4s.

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price 7s. 6d. Securely packed, post free, 8s. 6d. If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.
Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

Catalogue of Machines, Designs, Wood, Tools, &c., with several Hundred Illustrations, and full Instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. Good Fret Saws, 1s. 6d. per gross; best ditto, 2s. per gross.

Eclipse Design, No. 102.

Wall Bracket.
Price 5d.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 48.] SATURDAY, FEBRUARY 15, 1890. [Price One Penny.

ENGRAVING ON METAL.

BY NORMAN MACLEAN.

Work on Silver and German Silver.

It is presumed that the workman on taking up this class of work will have been prepared, by previous practice on the commoner classes of work, to give due effect to the designs he may have to engrave on the better class of work known as hollow ware engraving. The methods of sharpening or whetting the gravers are modified according to the class of work on which the engraver is engaged, as for instance—a cake or card basket, round or oval, has usually a considerable depth, therefore an outlining graver must be "set off" very considerably, and the facility of cutting *towards the right hand* will, in this and other cases, enable an expert workman to engrave an article in about one-half the time that would be taken by another. Therefore, I strongly recommend the workman to practise the cutting from left to right, whether it is absolutely required or otherwise. (See Fig. 1, page 520.) Letters A and B represent a line cut towards the left hand, and which is the natural tendency. The line represented by the letters C and D is to be cut—not as a continuation of the circle, but from the left towards the right hand, commencing at C and finishing at D. There is little to say to the workman as to the way in which he should cut his work, as by this time his work will have developed an individuality quite his own, which may be a good style or a bad one. If it is the latter, he must take every opportunity of comparing his work with that of other engravers, and noting his own shortcomings. I will, however, give the workman a few hints. Remember that you will get a better price and more credit on best work, and, therefore, you can afford to spend more time in proportion than you would if engaged on common work. If the design is a repetition in sections, take great pains in dividing the sections, using the dividers freely. Get your prints on truly, and the shields exactly upright, for nothing looks worse than a shield all awry. Point in the pattern exactly as it is intended to be cut. I am speaking of the outline, and where parallel lines occur rule the second line by the first after outlining. In veining a scroll or leaf, study your pattern, and see that all radiating lines glide imperceptibly into the main vein. In cross shading and blacking out ground, see that no "whites" are left in either, and that the

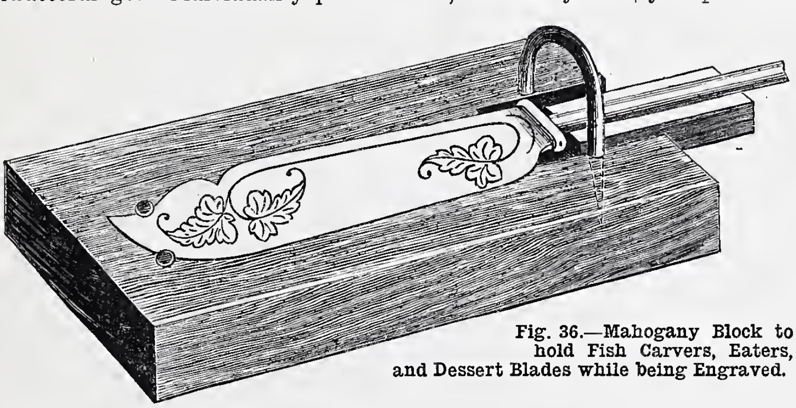

Fig. 36.—Mahogany Block to hold Fish Carvers, Eaters, and Dessert Blades while being Engraved.

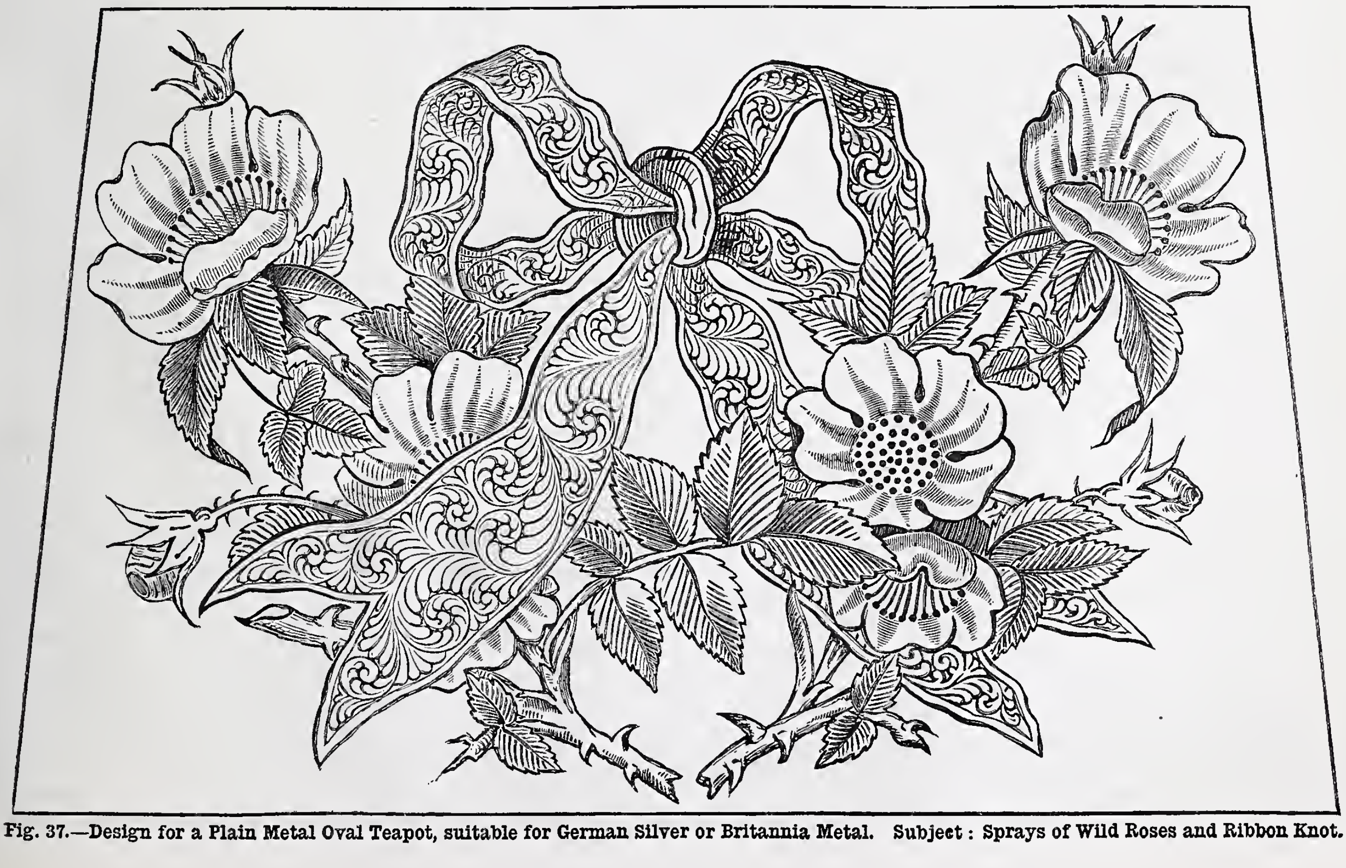

Fig. 37.—Design for a Plain Metal Oval Teapot, suitable for German Silver or Britannia Metal. Subject: Sprays of Wild Roses and Ribbon Knot.

shading is graduated artistically. I may here explain that "whites" appear when the surface of the metal is *not* entirely cut away by the consecutive strokes of the graver. When you have finished your work, give it a nice appearance by dusting it over with the pounce bag and polishing the surface, and removing the dirt from the cuts with a piece of bottle indiarubber. Do not use the vulcanised rubber, as the sulphur used in its manufacture will cause the article cleaned with it to turn black. I have said nothing about the prices of work, because so much difference in price prevails on account of the keen competition for work when there was little work to be done. Now that trade is improving all round, I have no doubt better prices will be paid.

The engraving of fish carvers, fish eaters, and general small work of an ornamental character, is practised by the engraver of small work, and who seldom or never attempts any other description of work. On this account he is much quicker than an engraver who is most used to larger work, who cannot as readily change his hand. But it must not be supposed that there are no engravers who cannot acquit themselves creditably as "all round hands." I admit they are few and far between. In engraving small work, much of it is done without the extra work of pointing in or tracing the pattern from the print. The work is cut from the print, which may be a black one or a white dry one, according as the engraver has been used to either. I prefer the white print for its cleanliness, and also for its lasting properties. A white print only requires renewing occasionally, whereas a black one will only lay down from a dozen to eighteen impressions. A block (Fig. 36) is sometimes used to hold fish carvers, eaters, and dessert blades, which facilitates the engraving of these knives. Other articles are held as best they may be in the left hand, and a few awkward articles are mounted on a cement block.

The workman in this line of business is generally assisted by an apprentice who prepares the work for his master, such as "laying down" the patterns, tracing such parts as are deemed necessary, and, as he advances in the art, cutting such parts as he is capable, leaving the whole to be finished by the workman, who will correct any little error as he finishes the work. The apprentice also runs the errands, thus giving him a little rest from his work, and enabling the master to work the whole of the working hours.

I give in Fig. 37, as promised in a previous paper, a design in the floral style for a plain oval teapot, a rather popular shape on account of its showing off all work to advantage; the lid is flat and "let in," and thus forms a smooth surface to work upon. This pattern is all line work, and as the sketch is for a five-gill teapot it can be traced and waxed down on a teapot of that size, but for any smaller size will require to be redrawn. I propose to leave this design to be dealt with according to the taste of the engraver, only remarking that the ornament on the lid should correspond with that of the body of the teapot.

ENGRAVING ON JEWELLERY.

The operation of engraving jewellery is altogether different to any that I have before described, and since the silver jewellery has had its day, I am at a loss to know to what branch of the profession the immense numbers of engravers of jewellery have turned their attention. But to those workmen who wish to learn something of the way in which it is done, I will attempt a description of the process, commencing with the bench, which is known by the name of "a three-holed bench," and which is also used by the makers of jewellery.

This bench is generally made of stout wood, such as elm; has three semicircular pieces cut out, with arm-rests in between, the object of which is to enable three workmen to work at one window. In the centre of the bench is an upright gas-bracket, an equal distance from each workman, who also has a small gas burner at his right hand, for the purpose of warming the cement on the chucks on which he mounts the articles to be engraved.

Each engraver has suspended just beneath where his work rests a leather apron, to catch all the gold and silver chips from the graver, which become a valuable perquisite. Instead of the ordinary sandbag of the ornamental engraver, the jewellery engraver uses one with a round hole left in the centre of sufficient size to receive a "bullet." This bullet is really a small round cannon ball with a screwed nose fixed firmly in, and on which the little boxwood chucks are quickly screwed. These chucks are round, about 2 in. by 1 in., and carry a female screw of $\frac{5}{8}$ diameter and eight threads to the inch. By means of the hollow pad and bullet, the engraver is enabled to quickly turn the work in any direction and at any angle which may be required during the progress of the work. This class of engraver generally works in sets of three, to facilitate the execution of the work. One engraver will outline, another will "fill in," while a third will shade and finish. A boy is usually kept to run errands and "stick on" and "take off" work from the small chucks. The tools used are the ordinary graver, the shading tool, a small spotting or round-nosed tool, narrow wrigglers and double wrigglers, with a tracing point, burnisher, and hare's foot for sweeping up chips.

A fine oilstone is necessary for this work, as it is nothing if not bright; and in addition to the ordinary oilstone, a stone known as a "black stone" amongst the engravers and engine-turners of Clerkenwell is used for finally polishing the graver before cutting the work. The use of this stone produces a cut on gold and silver of great brilliancy.

I am not geologist enough to tell the nature of this stone; its colour is black, very hard, and very scarce. I have often used it myself, but never had a piece to call my own, and the many inquiries as to its scientific name have left me as wise as before. I have ventured to think that it is iron in some form or other. If I am right, perhaps some of our geological readers will give us the proper name of the stone or metal. The use of the black stone, as I shall continue to call it, is very simple. The graver is sharpened in the usual way, and the black stone is drawn lightly along the cutting edges, which has the effect of removing the slight burr left by the action of the graver on the stone, and thus brightening the cut without taking away any of the sharpness of the graver.

HERALDIC ENGRAVING.

The successful practice of this fine art branch of engraving depends not only on the ability of the engraver to outline and shade well, but also upon the facility with which he can enlarge or reduce the coat of arms, crest, monogram, or cypher to the size suitable to the work in hand. In addition, a study of heraldry is advised. If an old crest book can be purchased in which the arms and crests have been printed by the copper-plate process, such a work will give a capital idea of the shading of crest work, etc. A book of monograms will assist the engraver; there are two or three published, all equally good, which can be seen and compared before purchase at almost any free library.

A book of plain and ornamental capital letters, and an occasional glance at Field and Tuers' "Specimens of Printing," will keep the engraver up to the most modern style of letterings. In addition to his work on metal, the heraldic engraver must be prepared to work on ivory and pearl. The practice of a crest engraver involves more work than that which appears upon the engraved article. We will suppose that the engraver has been invited by a manufacturer to compete for the engraving of the outfit of an ocean-going liner, which consists of many thousands of articles, and of all sizes, from a mustard spoon to a hot-water meat dish of thirty inches at its transverse axis. These all have to be engraved with the name of the vessel and the arms and name of the company who own the liner. In the first place, the engraver has to prepare a finished sketch of the work, which is submitted to the company for approval. This is returned, with the usual alterations and final directions as to how the work is to be done, through the manufacturer who has the work in hand. The engraver having secured the order, will now proceed to draw on a piece of German silver, similar to a practice plate, a series of twelve or more sizes, side by side, each size of the subject to be engraved being an exact counterpart of the other. The object of cutting the sizes on a plate is two-fold; in the first place, the sizes for the different articles can be better calculated, and more easily drawn; and secondly, the plate itself furnishes the black prints required for the work on the various articles. In course of time part of the original order is repeated, in order to meet the inevitable losses; the plate again is made use of, thus securing a perfect match with the original work. Crest work is done with a lozenge graver, whose angles are more acute than a square graver. Lozenge gravers are also used for making the flat tools for block letters, the main shanks of Old English, and other letters.

These flat tools are whetted at the usual angles, and flattened on the sharp angle by rubbing on the stone to the required width. A few narrow shading gravers are kept on hand, for blacking out the cheaper forms of lettering, etc. For these I recommend C and D fineness of threads, and Nos. 1, 2, 3, 4, 5, and 6 widths of both C and D.

In sketching in inscriptions due prominence should be given to "Presented," the name of the "recipient," "date," etc. But as these particulars—in fact, as the inscriptions—are generally "set out" for the engraver, he has nothing to do but copy it letter for letter, supplying ornamental capitals and lettering such as his own good taste will suggest. If the article is large, such as a tray, give prominence to the crest or coat of arms, so that it may be seen and recognised at a glance, balancing the whole in an harmonious style. If, on the other hand, the article is a small one, legibility is the first consideration. Engraving crests on pearl and ivory will require considerable determination and practice on the part of the engraver to overcome the natural difficulty of cutting against the grain of the ivory, and also the peculiar nature of pearl as opposed to that of metal. Otherwise, the work is finished exactly in the same manner as the same subject would be in metal, supposing the subject to be a crest. But with lettering the work has to be cut sufficiently deep to receive the necessary "blacking" to make the engraving prominent on the white substances. This black mixture is made of the very best black sealing wax dissolved in spirits of wine, which must be kept in a tightly stoppered bottle. The mixture when ready for use must "run" freely. To "black" the pearl and ivory already engraved, take a fine camel-hair or sable pencil and carefully fill all cuts with the black mixture, taking care that the ink, as I may call it, is confined to the part engraved. The articles are left for a time—say a whole night—for the ink to thoroughly dry, when the superabundance of ink on the surface of the ivory or pearl is removed by means of a "dolly" in a small lathe. The "dolly" is composed of a number of pieces of linen secured by clamps to the mandrel. This is revolved at great speed in the lathe, which causes the limp linen to take an upright position in the lathe, and the friction is increased by the application of finely powdered whiting, which soon removes the ink from the surface.

In conclusion, there are many articles which might have been engraved which it would have been impossible to describe in this paper. At some future time, however, I shall be glad to direct attention to a few articles which I myself have made and engraved for home use.

A STRAIN CHECK AND EXCESS LOAD ALARM INDICATOR.

BY JOHN CHARLES KING.

THERE is a correlation between moral and physical science in the warnings of one and the index limits of the other to prevent evil. For one, the simple word "Don't" has its counterpart in the other in a check-stop. The intelligent heedfulness of man to either would spare a world of suffering, not only for ourselves and others, but for the animals that serve us so faithfully with their willing toil.

Any invention that, by its simplicity of action, serves as a check-stop to undue strain on machinery or animal draught, and indicates excess, seems to articulate the word "Don't" to our understanding.

"A Stress Alarm and Excess Load Indicator," applicable to hauling machinery, running-gear, and harness of draught-horses, has been patented by the inventor, a Mr. Snellgrove, and is made by W. & T. Avery, of Birmingham and London. Being, for harness, as small as a trace buckle, it is not unsightly; and, for machinery up to fifty tons' pull, only slightly larger in proportion, and in no way interfering with the action of the chains, ropes, or traces. It seems to be the one thing so long sought for by mechanicians and horsemen to aid their judgment, and aid them also in the most important part of their undertakings, where strains from excess loads, sudden jamming, or hitches would strain the machinery or hauling gear unnoticed, and weaken it so that it might afterwards yield to moderate strain unexpectedly from a previous unrecorded strain.

This simple invention has not the word "Don't" on its front, but a dial with indicating hands, showing what maximum strain has been applied; and, for excess beyond the fixed limit, an alarm is sounded, and a red danger-disc covers the dial face till the load is taken quite off. So simple an invention hardly needs illustration. Perhaps its application to harness and carriage draught will be best explained by a diagram showing the defective attempts to arrive at the same result in one point only.

Horsemen who drive seek to avert the sudden strain on the shoulders of horses by putting a swivel-bar to the draught of a gig and dogcart, which means a central pull to the vehicle, whereas the retarding action of the wheels by the road is two and a half feet each side of this centre, forming a corresponding leverage against the horse's draught, which, in ruts, or in turning,

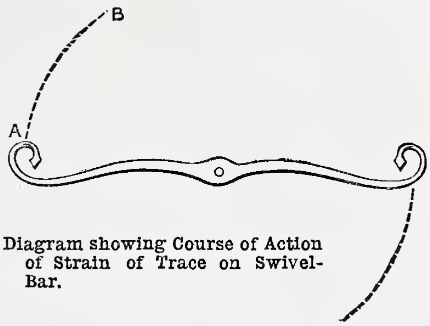

Diagram showing Course of Action of Strain of Trace on Swivel-Bar.

throws the strain on the shafts by the side pressure of the horse against them, which means straining the legs of the horse needlessly by side-pack action. The swivel-bar is a danger also. Should a trace come off or break, the other trace snatches the swivel-bar hook round into the leg of the horse, wounding it, and perhaps causing it to bolt, often with serious or fatal results to the riders in the vehicle. The dotted line A to B shows this action.

This invention serves at once to relieve the shoulders of the horse from concussion by wheel-jerking, and to tell of any wrong by the alarm indicating it, as a "fired" axle or strained wheel-fixing, which would be marked at once by the dial showing excess strain, or the little boss on the trace sounding the alarm; or, for teams, the pull of the free or lagging horses is indicated.

For heavy weights, the fifty ton indicator is tested up to a hundred tons, to allow for sudden enormous strains, and the alarm by fulminating charges of intense loudness of report automatically fed for the fall of the striker.

This invention does not appear to have been forward enough to be exhibited at the Berlin Exhibition of May last for the Prevention of Accidents; but it was shown at the French Universal Exposition, and attracted well-merited notice.

GESSO WORK APPLIED TO THE DECORATION OF ROOMS AND FURNITURE.

BY E. C.

IN the present paper I propose to consider gesso work as a means for the decoration of rooms and furniture.

In selecting the design for a frieze, and also in arranging the scheme of colour, much must necessarily depend upon the interior—upon its size, height, and aspect, and upon its present decorations if they are to remain unaltered. According to the height of a room the frieze may be two or three feet in depth; in low-ceiled rooms one foot will be sufficient. For myself, I prefer, whenever possible, a rather deep frieze of bold design. For the purpose a soft, shadowy grey-blue background is charming; on this the flowers may be done in terra-cotta tints and the leaves and stems gilded; the stamens of the flowers also gilded. In this case the background and blossoms would be done in oils and the leaves in the gold which is sold with the metallic colours. A chaste effect could be obtained by tinting the design in cream and shades of brown only, then laying in a background of bronzy gold. This would make an artistic frieze with blue and cream brocade wall hangings, or with oak panellings. A rich scheme of colour may be desired to suit surrounding decorations. Under such circumstances I should suggest that the lilies should be of tawny orange tints shaded with coppery red; the foliage in greeny-blue tints, with the under part of the leaves of a silvery-blue shade, and the background gilded. The lilies should be outlined with copper red. Many other schemes of colour could be suggested for Fig. 1 of our illustrations, but I have said enough to show that it is easy to paint a frieze to suit any and every room decoration imaginable.

The design I give for the ornamentation of an occasional table top will be sure to prove effective if well executed. It would be charming if carried out in varied tints on a metallic green ground: gold and silver foliage, and flowers and buds of terra-cotta tints with brownish stems. Or the background might be of walnut wood, untouched; the chrysanthemums and buds painted pale yellow, and the foliage in shades of green and silvery grey green. If the table is square, run two circular lines round the design, and add four separate corner decorations. The gesso is laid flat, and is here merely as a foundation for the painting; it would be contrary to the canons of true art that a table top should be decorated with a design in high relief. If liked, the decoration could be carried out entirely in silver and gold on the green lacquer ground. An accomplished worker will find he can secure beautiful effects by laying on a coat of silver, say on a rose, and then tinting the petals with oil colours used very thinly. Pale yellow or blush roses are lovely when treated in this manner. It requires some practice to do it well, but no art work can be successfully learnt without perseverance. A quiet but pleasing harmony might be arranged by painting the chrysanthemums white and the foliage in cream and fawn tints just thrown up with deeper brown in the veining of the leaves: the background to be the wood—walnut or rosewood—left plain. I am fond of these sober decorations myself.

Now we come to Fig. 3, a pretty little cabinet door with two gesso work panels. This design may be modelled slightly. To my mind it does not allow of high relief, although such would be perfectly legitimate on cabinet doors. Here a rich Oriental colouring would be admirable; such as a deep metallic blue ground, copper red and gold for the design with touches of green here and there. This would look well for the door of a black enamelled wood cabinet; the handles should be of silver and the hinges of silver of openwork pattern, such as are general on the lac cabinets sent to us in such quantities from the East.

A second plan is to lay the gesso on, and,

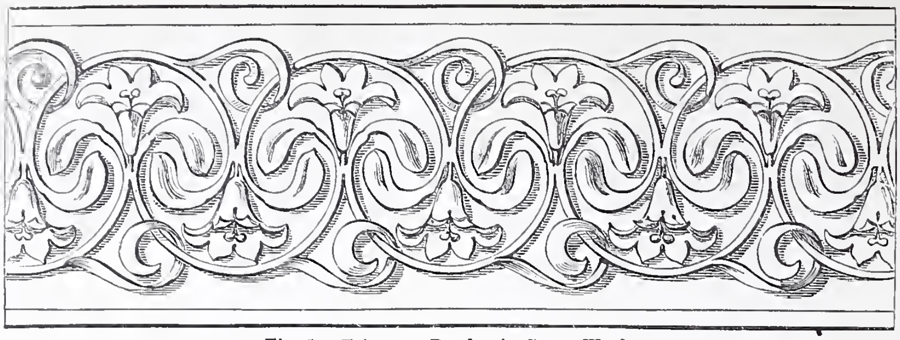

Fig. 1.—Frieze or Border in Gesso Work.

after modelling it, to tint it the same colour as the wood, when it resembles wood carving; I do not greatly recommend this style, because it is a mere imitation of carving, still it is, of course, far easier, not half or a quarter so much practice being required to accomplish a good piece of gesso work as to execute a carved wood panel. A turquoise-blue enamelled cabinet, the design carried out in ivory tints on a gold background, would be very attractive. It might well be accompanied by a settee decorated with gesso work. I give (in Fig. 4) a sketch of the back of such a settee ornamented with foliage in gesso and upholstered with self-coloured *frise* velvet or brocade. Pale gold coloured material (or chestnut shade) would accord well with the ivory and gold gesso work. It would not be at all difficult to enrich a whole suite of furniture in this way and so double its value. Furniture ornamented with garlands of roses and bows after the French style is extremely fashionable at present; this is merely painted, but I cannot doubt that any one who could execute gesso decorations well would have a fine chance of doing a good business with some of the larger furnishing and decorating firms. But they would need to be done in a masterly style, because rival workers soon appear wherever money is to be made; and to keep up with, or distance, such successfully, needs continuous attention and care. New and suitable designs would have to be constantly produced, and the work would have to be rapidly executed, for orders taken must be sent in up to time. Those who are only working for their own pleasure and can set about their self-imposed tasks leisurely will find it a pleasant occupation to decorate a room entirely with gesso work. If they do not wish to go to much expense, they could have a *stained* walnut or oak dado, and ornament the panels with gesso designs done in ivory tint with shading of leaves and flowers in warm brown. The background could be of stained wood; panels of door and shutters of the same; a self-coloured grey blue or terra-cotta wall-paper (or painted wall) with frieze in gesso carried out in soft terra cotta and gold and blue of a greyish tone. An effective interior could be arranged in the same way, but the panels should be grounded with gold; and copper red and silvery blue—toning to greeny blue—might be introduced in the design. Each panel would be decorated on a table or easel, and when all are finished would be inserted in the dado and door, so there is no fatigue in stooping down or sitting on steps to do the work. No end of lovely possibilities present themselves to my mind's eye as I write. I should like to see a dainty boudoir decorated somewhat in this manner. White enamelled wood dado with gesso panels bearing conventional designs in turquoise and ivory tints on an incised gold background. Turquoise satin panelled walls with flat white enamelled wood pilasters (decorated with designs corresponding with those in the dado); these forming the framework of the satin panels. In the centre of each of the satin panels, a figure after the style of Mrs. Wylie's "Dawn" exhibited in the Arts and Crafts Exhibition last autumn—a figure floating in mid air with the sun rising beneath her feet from behind golden-tipped clouds, her soft fleecy draperies fluttering in the gentle breezes. The figure executed in white with reflected sunrise tints, which also fleck the snowy cloudlets. A rich frieze of gold, turquoise and rosy tints, and a white panelled ceiling. I should enjoy describing the furniture and draperies of this ideal lady's sanctum, but I fear being called to account for running miles away from my subject.

Fig. 2.—Table Top in Gesso Work. Chrysanthemum conventionally treated: Design produced in very Low Relief.

There are many other modes and means of rendering gesso work subservient to the decorations of rooms and furniture with good effect, but I have said enough here to show its capabilities for this purpose.

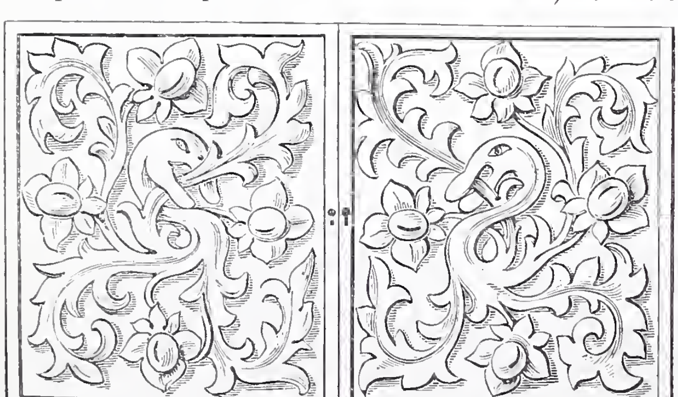

Fig. 3.—Design in Gesso Work for a Pair of Doors for Cabinet.

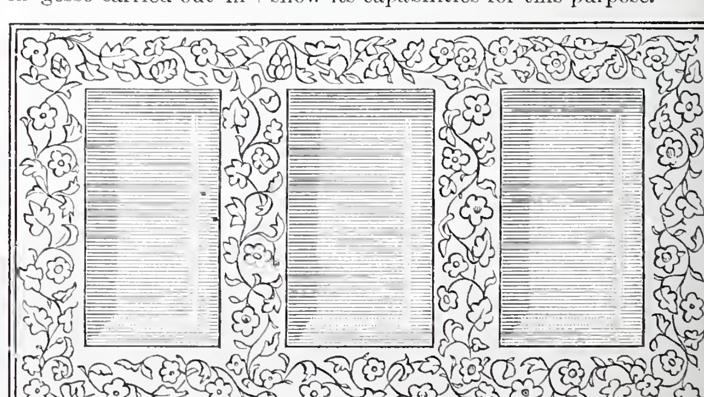

Fig. 4.—Design for Back of Settee, decorated with Gesso Work.

HOME-MADE SQUARES AND CALLIPERS.

BY J. H.

SQUARES.

THE square has much in common with the straight-edge and the surface plate. Like these, a square is made accurately without any reference to an original standard, and to a certain extent the same methods of construction apply to each. Squares are of two forms—the try square (Fig. 3) and the set square (Fig. 2). Each form is made both in wood and in metal, and in almost all possible dimensions.

A square is essentially two straight-edges set at right angles with each other. To test these relations, it is necessary to set the stock or base against an edge known to be straight, and to mark a line along the edge of the blade, or perpendicular. Then, if on reversing the direction in which the stock or base lies, the edge of the blade or perpendicular still coincides with the scribed line, the square is true. If there is any departure from absolute coincidence, half the amount of that departure is the extent to which the square is inaccurate.

To make a square in wood or metal, the first thing is to rough out and straighten the material of the stock and of the blade, and afterwards to work both edges of each perfectly straight, according to the directions given in reference to the making of straight-edges (see p. 500), and then to secure these together firmly and permanently. In the case of wooden squares, thin broad tenons are cut on the blade and fitted neatly into corresponding mortises cut in the stock. Half an inch or more of timber should be left at the end of the end mortise, to be dressed off after the blade or tongue is glued in place. This precaution prevents the splitting out of the end grain by the cutting of the mortise and gluing in of the tenons. While the glue is yet moist the square should be tested, and the blade adjusted thus :—

Select an edge of a drawing or joint board known to be true, and having a clean smooth surface. Lay the stock of the square against that edge, allowing the blade to lie flat upon the surface, and scribe a fine line upon the board exactly along each edge of the blade. Now reverse the direction of the stock (Fig. 1) to the position shown by the dotted lines, and note the coincidence, or otherwise, of the edge of the blade with the lines just scribed. While the glue is yet moist, some very slight adjustment of the blade can be made, so that no subsequent adjustments with the plane need be necessary. Each edge will be thus tried in turn.

A steel square is differently made. There are no tenons, but the blade is fitted into a saw kerf cut down into the end of the stock, and when fitted is secured with rivets. The slit is cut with a hack saw, and the blade must therefore be selected, or filed down, to the same thickness as the hack saw, to make a tight fit in the stock. If it is a slack fit it is not likely to remain true for any length of time, as the rivets, though holding the blade in place, are not sufficient to prevent slight disturbance or dislocation of the parts by accidental shocks or falls.

Some slight adjustment of the blade in the stock is possible at the time of making, by following the same method as that employed for a wooden square. The stock should, however, be laid against the edge of a metal marking-off table, or surface plate. First one rivet hole should be drilled, and one rivet inserted to hold the blade pretty firmly; then the blade may be tested and adjusted, and the second rivet hole drilled and the rivet inserted. If the square is small two rivets will be sufficient; if large, three, or even four, will be used. But after two rivets are inserted, no further adjustment of the blade is possible, except that of filing it in a tentative fashion, a necessary practice always when a square, by long service, has become worn more in one locality than another. When filing thus, or in the case of a wooden square, planing, the stock is held against a true edge as already described, and lines marked along the edge of the blade. The linear accuracy will be tested by means of a straight-edge, or by the turning over of the edge of the blade against a line just marked from that edge.

Set squares made in wood or in metal are tested either with a try square, known to be true, or by laying them against the edge of a plate to which a straight-edge is held for the base of the square to lie against. They are then reversed, still being held against the true edge.

Instead of cutting the hypotenuse of a square into some fanciful curve, it is always preferable to give it a definite angle in frequent use, as 45°, or 30° and 60°. A set square may also be utilised as a protractor, by marking out the quadrant into degrees.

Set squares made in wood are apt to warp when of large size. When over 5 in. or 6 in. in length, therefore, they should be grooved and tongued together (Fig. 2). They will then remain true for an indefinite time. The

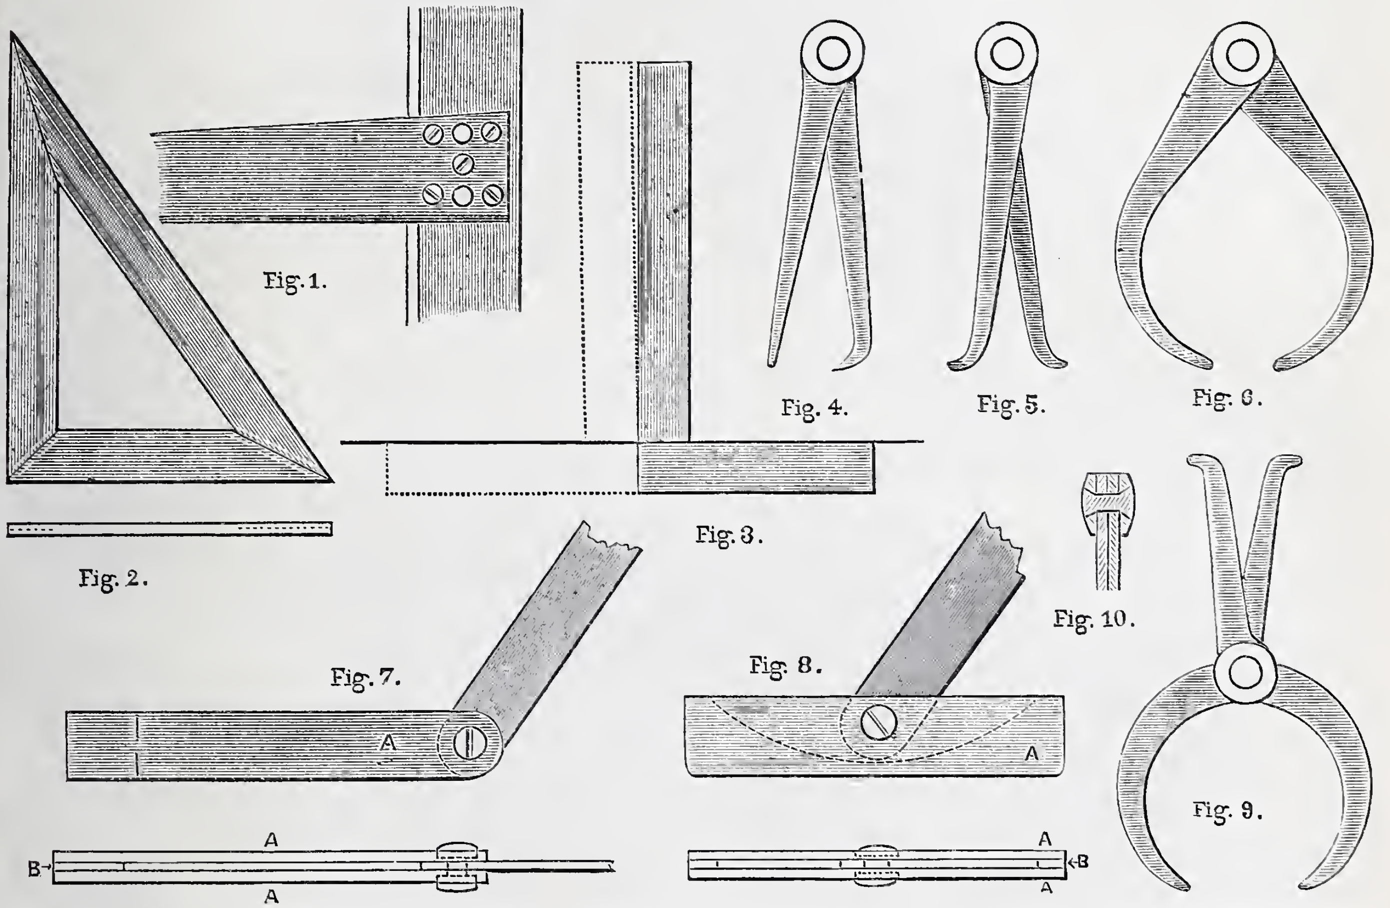

Fig. 1.—T Square. Fig. 2.—Set Square. Fig. 3.—Try Square. Fig. 4.—Compass Callipers. Fig. 5.—Internal Callipers. Fig. 6.—External Callipers. Figs. 7 and 8.—Bevels. Fig. 9.—Combination Callipers. Fig. 10.—Section through Rivet.

central portion may be left quite open, or a thin panelling fitted in by tongueing.

Large T squares and bevels are used in workshops for marking out work upon the drawing boards. They are usually made either of mahogany or oak. As the long thin blades are liable to spring, they should be cut out and roughly planed over several months before being finished. Sometimes ebony edges are used. If so, these should be glued on in the rough. The blades of long squares, say those of over 2 ft. in length, are made tapered for purposes of rigidity. One edge only then can be used. The blades are screwed upon the face of the stocks and prevented from dislocation by the insertion of a couple of dowels (Fig. 1). Squares such as these are expensive, yet they can be made very well by a careful workman.

Two useful shop bevels are shown in Figs. 7 and 8. In the case shown in Fig. 8, the stock is formed of two pieces, A A, between which is glued a thickness piece, B, a mere trifle thicker than the blade, and cut to allow the end of the blade to clear when in any position. The three pieces are well glued together and the end of the blade inserted between. The bit hole bored for the screw must be of the exact diameter; if larger, the end of the bevel will slop on the screw.

The other bevel (Fig. 7) is of a rougher type but very servicable in the shop. It consists of two sides, A A, united at one end by the distance piece, B, and receiving the end of the blade at the other, which is pivoted on its screw. If the stock is wide, its side well secured to the distance piece, B, and the screw fitted well into the sides of the stock and the blade, the bevel will be strong and firm.

Callipers.

These tools appear simple enough, and easy to construct and use, yet there are nevertheless some points about them which a workman learns by experience, but which have to be explained to an apprentice. These points are, that the legs should be tolerably free from elasticity, and therefore broad near the joints in proportion to size, thence tapering down towards the ends, that the pins should be large and close-fitting to prevent slop, that the points be slightly spreading, and that callipers should never be forced over the work whose diameter they have to measure, but be simply brought into bare and just perceptible contact therewith.

Is it worth one's while to make callipers? Yes, for more than one reason. A careful apprentice can make better callipers than he can buy, because stiffer and better fitted; and as he wants several pairs, and the material costs a mere trifle, or nothing, there is a saving in doing so. As a matter of fact, all apprentices do make squares, callipers, and scribing blocks, because they like to do so, and are proud of them ever afterwards, and because they afford good practice in their particular handicraft.

Four pairs of callipers are shown: Fig. 6 external, Fig. 5 internal, Fig. 4 compass, and Fig. 9 combination callipers. Only, or chiefly, in the matter of outline do these differ, and therefore a description of the method of making the first will suffice for all.

The blades of callipers can be drawn down from any bit of steel and bent, or they may be cut from steel sheet, the outlines being marked thereon, and centre popped, the severance being effected either by means of a cold chisel, or by the drilling of contiguous holes. This will have the effect of curving and twisting the legs out of shape, and they will accordingly have then to be levelled by means of a hammer upon a plate of metal. After this will follow the filing of the flat faces smooth, the legs being steadied with nails driven at intervals along their edges into a piece of board, as in the filing of the flat faces of straight-edges. Afterwards the outlines will be finished with files and emery cloth, and the legs are ready to be pivoted.

The holes will be drilled, and the rivets and the washers turned and drilled in the lathe. The rivets must fit closely into the holes in both legs and washers (Fig. 10), as there must be no slop in the mutual fitting of these. The rivetting over will be done with the cross pane of a small hammer. Then the semicircular ends of the legs will be filed round flush with the edge of the washer, and the battered ends of the rivets smoothed over with the file and emery cloth.

Observe with regard to the slight spreading of the points that they are thereby less liable to get diagonally across the work than if they are not thus spread. This very slight spreading out becomes to the delicate touch of a careful workman a sufficient indication of the square embracing of the work by the calliper legs. For some special purposes the points are spread to the extent of ¼ in. or more, but not so for common use.

A CHAT WITH FRENCH POLISHERS.

BY "LIFE-BOAT."

French polishing and spirit varnishing, or both in combination, is an art whereby our household furniture and thousands of other things are covered with a lac solution, the object being to give them a polished mirror-like surface By it the beauty and figure of the various woods are brought out and shown to the best advantage. If we paint them, the figure and beauty of the wood are hid, the article is given a lifeless look, and to a great extent the cabinet-maker's skill has been so much labour in vain. If we leave it alone, we have the appearance of an unfinished, unsaleable article, on which dust and finger-marks will soon accumulate, giving to the same a dirty, loathsome appearance, unless we, like Hollanders, content ourselves with making our household goods strong, massive, and plain, on which the good housewife might use the scrubbing-brush with impunity.

A good polisher who knows his business can stain and match the various pieces of sappy or common woods which, unfortunately, sometimes find a place in our furniture to match its surroundings. The amateur carpenter of to-day, who is having such capital lessons in our pages from the able pens and designs of David Adamson, Alexander Martin, J. W. Gleeson-White, and other able writers, may not be possessed of the needful cash wherewith to buy solid mahogany or walnut, nor yet be an expert at laying on veneers; he may find it to his advantage to do as others have done before him—use the mahogany or walnut at the front, deal or pine for the sides, back, or inside fittings of his cupboard, cabinet, or other article he may be making. To him, a knowledge of how to stain his inferior wood in such a way as to match his best woods may be useful.

True, there are some persons who lay claim to good taste who strongly object to staining, on the ground that things are not what they seem; but as these pages are printed for the British workman—amateur or professional—and they have been educated up to the use of finished articles, stained or not stained, I repeat, a knowledge of how to stain and match various woods cannot but be useful. It is not for me now to tell you how best this can be done—the Editor has kindly promised that this shall be done by other and, I trust, more able pens than mine; suffice for the time that I chat with you on other interesting phrases. To return: The gold incisions to be seen on much of the furniture of to-day gives to the articles thus treated a richer and more artistic appearance. Even these I have seen improved upon by staining inside of two gold lines—say, ½ in. apart—in imitation of some darker or black wood, thus giving an appearance of inlay; and by suitable stencils, designs, and colours, many articles can be made to look more artistic. Note the chests of drawers, wardrobes, etc., of pitch-pine and light bedroom furniture generally. Most of the decoration of these is done by the aid of stencils.

The polisher of to-day is called upon to do many ticklish jobs. It is not enough for him to be able to put a clear bright polish on anything that may be brought to him. He must, if he would hold his own, be able to match the various coloured woods, giving to the whole an appearance of carefully-selected and joined veneers. Here a knowledge of how to use chemicals, stains, and dyed polishes must be brought into play. Some parts must be made darker, dark parts may have to be made lighter, oak may have to be treated so as to present an appearance of age.

Here I cannot refrain from quoting portions of a lecture given in Dublin, some time ago, by Mr. T. R. Scott, whose able pen puts the subject so well before us:—"It requires some considerable skill and manipulation to turn out a genuine antique 120 years old inside six weeks. To get real good polishing is simply impossible. Of course, others as well as myself have to content ourselves with the best we can get for the want of better; but there is no reason why a better state of things should not be achieved. In my experience, I have come across very few polishers who know anything of chemistry. When I have spoken to them of this, I have seen a bland smile stealing over their countenances at the bare thought of their being chemists. But a knowledge of chemistry, as applied to the preparation of polishing materials, is a desirable advantage to the possessor. They ought to know all about the raw materials, where they come from, whether they are mineral or vegetable substances, how the colours are prepared and extracted for the market, and how these stains, dyes, or polishes are made. In this particular branch our French neighbours are ahead of us; indeed it is, and has been, the admiration of us Britishers to see the beautiful ebonistic work of Paris; and why our polishers should not be able to produce as good work as our Continental neighbours I cannot tell."

The unvarnished and unpainted oak fittings of stables have been noticed to change from their light colour to a rich brown. Observant minds have traced this result to ammoniacal fumes. Acting on this principle, many oak articles are given an appearance of age, or enriched in colour, by shutting them up for a time in a cupboard or air-tight box, on the bottom of which has been placed an open dish of liquid ammonia. Failing the acquisition of a suitable cupboard in which to do this, chemistry again comes to our aid, and tells us we can get a like result by wiping over with a solution of bichromate of potash, common soda, or even lime-water. Not alone is this useful for oak, but, by careful management, common bay wood or plain mahogany can, by the aid of these and dyed polishes, be made to look equal in colour, etc., to Spanish mahogany.

The coloured stringings, or inlays, found round ladies' work-boxes or on writing-desks, with their many-coloured woods, are not all real. No: the polisher and chemistry have been called upon to play their respective parts; and I have seen musical-boxes, etc., with imitation pearl inlays and stringing, which has been simply bird's-eye maple dyed green, verdigris and vinegar being mostly used for this. And yet, again, it is possible some of you may be able (as is now often done) to paint flowers, birds, etc., on the panels of doors; or, failing one's ability to do this, it is possible to get transfers that look exceedingly well when polished over or one may even cut out birds, flowers, and such-like from thin paper, and fasten them to the work with thin polish or varnish, giving them, when dry, a coat of white hard varnish, which can be polished, first taking the precaution of sizing the pictures with isinglass.

And here let me advise the embryo polisher, when getting his polishes, gums, etc., to get the best. They are far more satisfactory in the end. There is less waste, they work easier, and give far the best results.

One could but wish most heartily for a return of the good old times of polishing, when the work was done with small rubbers and small circular motion; when "patent fillers" and piece-work at low prices were almost unknown. I ofttimes meet with work now that was done at least twenty years, and some over fifty years, ago, which will put much to shame that has been done by my fellow-countrymen and women and Continental brethren only six months. Especially is this the case of some German goods, which, even in this short time, is covered all over with a greasy, sticky substance and cracked fretful surface, which, in nine cases out of ten, has been brought about by the use of patent filling and adulterated spirits and gums, or a too lavish use of oil. I do not mean to say our Continental friends are alone in this—far from it. I have seen work which has left the polisher's hands only a few weeks running with oil—or, as a master polisher remarked to me, "It's running after the fellows as put it on as fast as it can go." I have seen other work all blister up directly the sun shone on it, from the simple reason that resin had played a too conspicuous part in the preparation of the polish and varnish used.

Do not, for one moment, think that I mean to suggest that good polishing cannot be got for love or money. Give a good polisher a reasonable price for his labour, and then, if he is honest and true to himself, he will give a resultant polish that will bear future inspection.

On the point of brilliancy and transparent polish, *some* of our Continental brethren gain the day. They dispense with the use of fillers, using their polish very thin, and fine pumice pounced on in lieu of these; and, as they work longer—or, more correctly, more hours for a day's work—and receive less wages, they give us a polish we can but admire and envy.

This, then, in conclusion, is the cardinal point I wish to impress on your minds: If you wish to turn out work that shall bear future inspection, use the best of materials, have a clean, warm work-room, be sparing in the use of oil, and unsparing with your patience and labour.

WHY MY GAS-ENGINE WON'T GO.

BY F. A. M.

IGNITION OF GAS-ENGINES—IGNITION VALVE—FLAP VALVE—AIR INLET VALVE—SLIDE VALVE—ACTION OF SLIDE VALVE—CASTINGS: WHERE TO GET THEM—PRESSURE OF GAS ON GAS-ENGINES—HOW TO TEST PRESSURE—OTTO GAS-ENGINE.

It is usually through failure of the ignition that small gas-engines will not go. At Fig. 1 is a drawing of the arrangement for the ignition of the model gas-engine, which has succeeded very well. C is the section of the side of the cylinder, and P is the piston. On the side of the cylinder is cast a round boss, through which is bored a ½-in. hole, so placed that the piston, as it rises, will uncover the hole before reaching the middle of its stroke (see Fig. 1). Into this hole is fitted a kind of gland of brass, the shoulder of which is ground to fit against the boss, and held in close contact by two screws. The gland piece, G, contains the ignition orifice $\frac{3}{16}$ to ¼ in. in diameter, and over the inside of the hole hangs a light steel disc as thick as a threepenny piece; this is the ignition valve, V. The inner surface of G is cut slanting, because the object is to make it easy for the flame to get in, and also because there is no doubt of the closing of so light a door by the force of the explosion; the valve then is hung loosely upon a tiny screw, in such a way that it can open a passage underneath it at least ⅛ in. wide, but not so wide as to touch the piston. In working, it slams to with some force, enough to slightly bruise the surface of G. These two surfaces must, of course, be carefully filed flat, and slightly ground, to make a good fit. Although the valve shuts so quickly, it is not quick enough to prevent a sudden puff getting out, and meeting the igniting flame, I, which is instantly extinguished. To provide for this, the relighting jet, R, is placed underneath, out of reach of the explosion; it strikes across the path of the horizontal igniting jet, and relights it before the eye can see it has been put out. It is possible that if the flame, R, were brought close to the face of G, the flame, I, might not be required; but the ignition is a ticklish thing, and requires every advantage. The flame, I, requires to play pretty strongly against the outside of G, in such a way that no air, but only flame, can be drawn in; if air were drawn in, it would dilute the explosive mixture round the valve inside, and prevent any explosion. Finding that the shutting of the room door would often produce a draught sufficient to deflect the flame, I, and prevent explosion, the sheath, S, was added; this is simply a bit of sheet brass, doubled round to form a cylinder, and sprung on to G; this cylinder has a hole cut through it for the jet, R. The drawing sent with the castings of the model gas-engine showed the ignition orifice ⅛ in. in diameter, but, suspecting this was too small, I held a plate, having in it holes of different sizes, over a gas flame, when I found the flame would not pass through a hole ⅛ in. in diameter. It is no wonder gas-engines will not work if the ignition orifice is too small. The flame would pass easily through a ¼-in. hole, and less easily through a hole $\frac{3}{16}$ in. in diameter. However small then a gas-engine may be, the ignition orifice must not be less than $\frac{3}{16}$ in. in diameter, and it need never be larger than ¼ in., however large the engine may be. The little tap at B is obtainable at the gas-fitters', and is called a "pipe light." The piece, X, is a kind of "cross" made of a bit of brass rod; it screws into the foundation of the cylinder.

This engine is so small I did not find any gas-bag was needed on the pipe which supplies the cylinder, but as the lights, I and R, were supplied from the same source, and close to the intake valve, they used to bob up and down at every stroke when the lights in the room were quite steady. I found a small gas-bag 3 in. in diameter, on the pipe supplying X, sufficient to stop that mischief.

One other caution is needed with regard to the ignition valve. The slightest amount of oil, paraffin, or even of moisture, which may get under the ignition valve, is sufficient to stick it down, and, of course, stop the engine. In first lighting up, the engine being cold and the flame playing upon G, some drops of moisture may appear, and the valve, V, may be bedewed; that would be quite sufficient to overcome the very small suction in the cylinder; the valve, V, being open to begin with, the engine will give one stroke, the valve will slam to, and the moisture will prevent its lifting again. Insert a bit of wire into the hole of G, and feel the valve whether it is slightly adhering to the face; if it be only moisture, the ignition flame will dry it up before long; if the paste with which the cylinder was lubricated was applied too abundantly, some of that may have got under the valve; in that case it would be better to unfix the screws and take out G, with the valve attached, to wipe it clean.

These particulars will show why it is some fail to get their gas-engines to work, and why they are considered uncertain in action.

The flap valve over the gas inlet needs no further remark than that it is like the ignition valve: it prevents the force of the explosion from driving the burnt gas up the gas inlet; this valve is sometimes made of indiarubber, but as it is almost constantly surrounded by gas, this is not a good plan, since gas perishes the rubber. It does not so much injure the gas-bag, still it is well, on stopping work, to press out any remaining gas from it with the hand.

The air inlet valve may be simply a circle of holes covered with a disc of indiarubber: sheet indiarubber for making it can be got from the ironmonger.

The slide valve is different from that of a steam-engine in two respects; and, as my object is chiefly to describe those points of which those who understand the steam-engine may be supposed to be ignorant, I give in Fig. 2 a sketch of a slide valve suitable for a gas-engine. It is, as will be seen, a piston valve; it has the advantage of being balanced, that is, it is not affected by the pressure of the gases which it guides and distributes; they cannot, by their pressure, however great, force it up to the face on which it works; neither does the pressure of the gases tend to move it endways, or to retard its movement. In Fig. 2, C is the cylinder of the gas-engine; D D is a casting containing the piston valve, S; P is the port or opening to the cylinder; A is the air inlet; and *g*, where the dotted circle appears, is the gas inlet; *e* is the exhaust port in the valve leading to the exhaust orifice, E, into which the exhaust pipe is screwed. The second point of difference with the engine slide valve is that the gas-engine piston valve is arranged for a single-acting engine. It appears in Fig. 2 as in the middle of its stroke. If the dotted circle represents the path of the eccentric, then *a* will be the position of the eccentric, corresponding to the position of the valve: the piston being at the bottom of the cylinder ready to begin the "up" stroke; turning the wheel raises the piston and moves the valve to the right, the eccentric going towards *b*; as soon as the valve moves, the small part, *p*, comes opposite A, *g*, and P, and makes a clear passage for the air and gas to be drawn into the cylinder; just before the eccentric reaches *b*, the explosion should take place, the piston valve being fully open; the flap valve in the gas inlet, and the indiarubber valve in the air inlet, immediately close, as also does the ignition valve, and confine the pressure within the cylinder. While the piston is being driven up to the top of its stroke, the piston valve is closing, and is not shut until the eccentric reaches the point *c*, half round the circle. The valve is now again in its first position, but, as the piston begins to descend, the eccentric moves on towards *d*, and the edge of port *e* opens P to the exhaust, to allow the cylinderful of burnt gas to escape; port *e* remains open during the down stroke, as port *p* does during the up stroke. Placing the piston valve under the cylinder is convenient, though it involves mitre gear and a side shaft; the plan is, I believe, part of the patent of Mr. J. F. Barker (late Dorrington), from whom I obtained the castings of my model gas-engine; it is not at all necessary to have the piston valve in that position; it may be placed parallel with the cylinder, and then the eccentric can drive it direct as in the steam-engine.

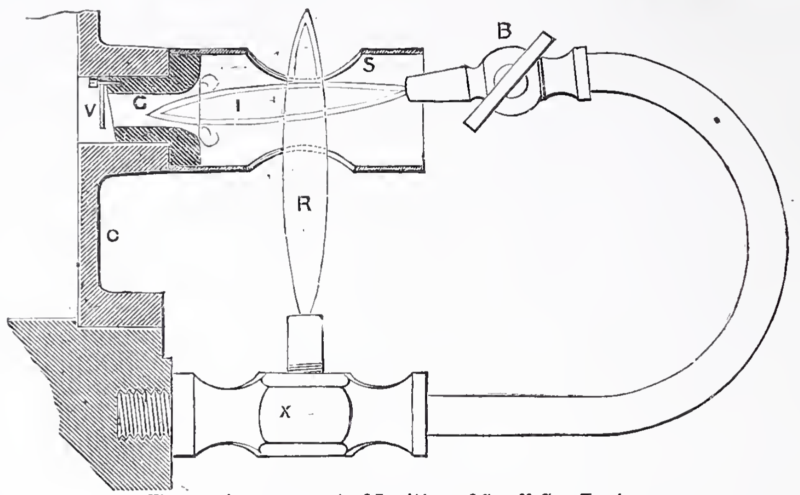

Fig. 1.—Arrangement of Ignition of Small Gas-Engine.

I found Mr. Barker's castings were very soft and easy to work, being perfectly free from hard scale; his address is 15, Dryden Street, Plymouth Grove, Manchester. He supplies castings of a half-man, one-man, two-men power, and other sizes of gas-engines. Were I going to make a one-man power engine, I should get the castings from F. Knoeferl, 100, Bolsover Street, Portland Place, W.; he offers them planed, and cylinder, fly-wheel, and crank, turned, for £5.

The model gas-engine, with cylinder 1½ in. in diameter and 4-in. stroke, can hardly be said to have any power; it might be strong enough to drive a light-running sewing-machine, but the least irregularity in working would cause it to stop; it would drive a fan or a tiny pump. The half-man engine has a 3-in. cylinder. I have not seen it at work; it should drive a sewing-machine, fret saw, overhead motion, etc. The one-man engine will drive a lathe as well as a man at least. These little engines are certainly unpleasant companions in a room or workshop; they smell and they thump. Still, a good stone foundation will lessen the noise, and a chimney over the ignition flame, or, better still, over the whole engine, will carry off the smell. I have not yet tried a governor, but I believe it improves the working of a small gas-engine very much.

I must now mention another possible cause of failure: it has nothing to do with the engine this time, but it caused me more perplexity than anything else. There were times when the engine seemed all right, yet it would not go. I have left it "till to-morrow," but, on the morrow, it would go off perfectly. At last, I discovered that when the gas was lighted in the house the engine would cease to work; this gave the clue: our gas main is rather too small, and when we light up, the pressure falls, and the ignition jet does not impinge with sufficient force upon the ignition orifice.

The pressure of gas can very easily be tested with a bit of bent glass pipe. Get a piece from the chemist, of a size that you can fit on to it your rubber tube; it may be bent like a U, with legs five inches long or more; pour a little water into the bend so as to fill half way up the legs, and fix the pipe upright on a board with wire or against the wall; the water will now stand level in the two legs, and you can mark its position on the board; now fit the indiarubber tube from the gas on to the top of one of the legs, leaving the other open to the air; when the gas is turned on, it will press down the water in one leg and force it up in the other; the difference of height measured vertically, in tenths of an inch, shows the pressure of the gas in height of water. In my own case, the gas is supplied at the works at a pressure of $\frac{15}{10}$ths, or 1½ in. of water, and this pressure is increased by its ascent from the works to this house to $\frac{24}{10}$ths.; but, in the evening, when the gas lights are turned on, the pressure falls to $\frac{17}{10}$ths.

The disagreeables connected with gas-engines, as mentioned above, do not refer to "compression" engines. The little "Otto" is a most beautiful little thing, working merrily away without more noise than a steam-engine, and practically free from smell; it is, naturally, more expensive than the simpler engines, and covered by several patents, besides being far more difficult of construction.

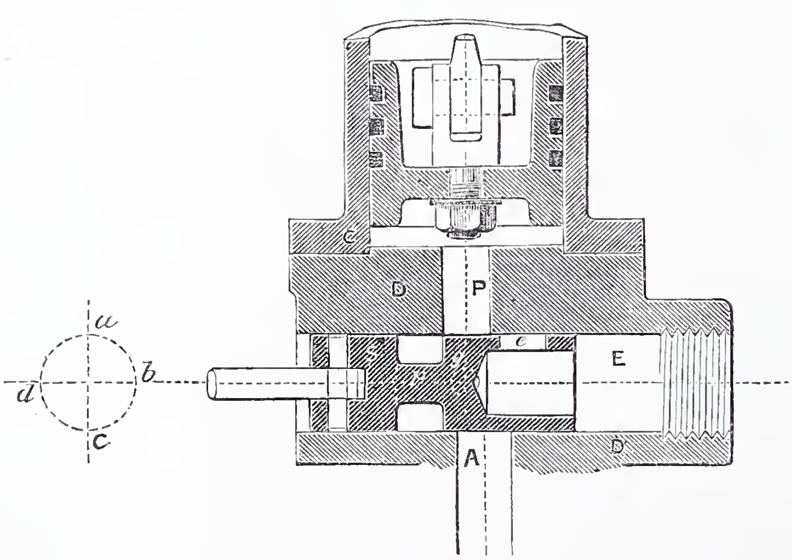

Fig. 2.—Sectional Diagram showing Action of Gas-Engine Slide Valve.

OUR PRIZE BOOKCASES.

II.—A Revolving Bookcase.

For which the Second Prize was awarded.

In a leading article which appeared a short while since in the *Times*, it was remarked "that the multiplication of good and cheap books, such as the masterpieces collected in 'Cassell's National Library,' has had a most powerful effect on the reading of multitudes of workmen, who now show an even greater interest in the problems of literature than in the problems of science." That such an effect has been produced by the publication of this library is a matter for general satisfaction.

It is, perhaps, well known that, at the end of last year, the number of the volumes of this particular series reached two hundred and eight. For those who are ignorant of the sizes, etc., of the books, I may refer them to the announcement of the prize competition in most numbers of WORK from No. 16 to No. 23 inclusive.

The bookcase here shown is designed especially to form a repository for the two hundred and eight volumes, and will form both a handy and appropriate article. It will stand with equal effect in the middle of a room, against a wall, in a corner, or, what is better still, in a bay window. In either case, the whole of the books can be turned round, so that a person sitting at it has no need to rise from his seat to obtain a volume

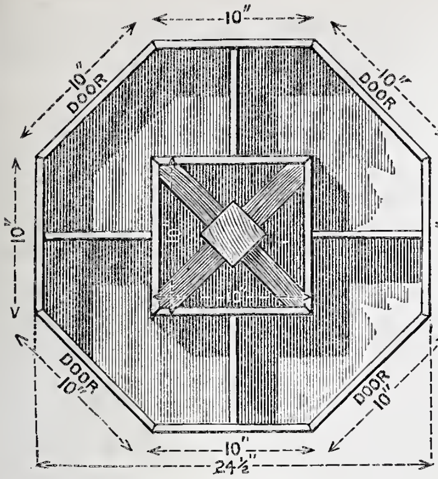

Fig. 3.

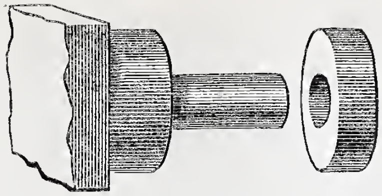

Fig. 6.

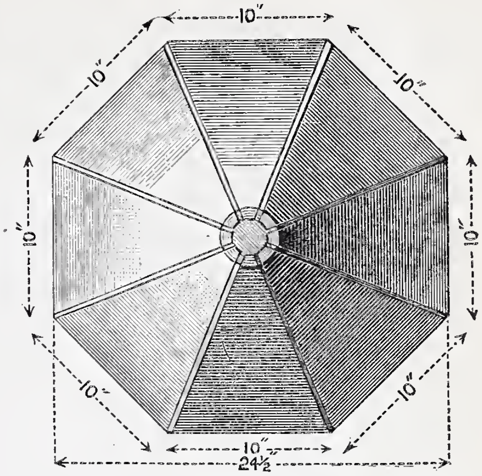

Fig. 4.

which may then be on the other side of the case. I have shown it with castors as well, for moving the whole article from place to place; but, personally, I should not fit it with them, as, when the top part is being moved round, the bottom part will thus become unsteady.

A few hints as to wood, etc., may be acceptable, although it is really a matter of individual choice. In considering the material with which it is preferable to build up any particular article of furniture, the effect to be produced by light and shade should always be studied. Where there is much shaping, and the article is of an open character, dark wood is the best; but, where there are flat sides—as in the present design—and the job has a square appearance, light wood produces the best lights and shadows. Now, I think that if the present design were built up in oak, satin-wood, or some other

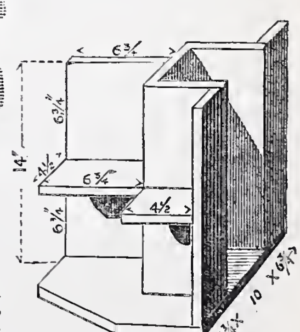

Fig. 7.

Fig. 1.—Perspective View of Prize Revolving Bookshelves. Fig. 2.—Front Elevation (half). Fig. 3.—Plan of Bottom at B. Fig. 4.—Plan of Canopy Top without Brackets. Fig. 5.—Sections of A and B, Fig. 2. Fig. 6.—Mode of cutting Centre Column to allow of A and B revolving on C. Fig. 7.—Perspective View of Inside without Doors or Panels. Figs. 2, 3, 4, 5, 7, 1-in. scale; Fig. 6, 3-in. scale.

good and light wood, with rosewood or mahogany top brackets, pillars, and door and other mouldings, a very effective artiele should result from the combination; for it must be remembered that, if the doors are glazed with clear glass, the deep shadows inside them will contrast with the lighter shadows on the outside, and the colour of the books will add a warmth to the cooling effects of the light wood. I trust I shall be forgiven if these few remarks are similar to any I have said or shall say; but, in a design of this kind, although strength and accommodation must be considered first, the appearance of the finished article must not be forgotten. Of course, the inside could be made of stained deal.

There are nine pillars supporting the top part, and, as the job is comparatively small, they will come rather close together; but this will add to the effect, and although not entirely necessary for the purpose of strength, I should not advise a less number to be used.

The sizes of this bookcase are: Extreme height, 5 ft. 1$\frac{1}{2}$ in.; extreme width, a little more than 2 ft. Taking the top, bottom, and middle boards first, it will be necessary to cut each as an octagon, each side of which shall be about 10$\frac{1}{4}$ in. long. These boards might be $\frac{3}{4}$ in. thick, but, if they are not quite so thick, they will answer the purpose just as well. As good a method as any to obtain the octagon will be to have a board 25 in. square, and draw two lines upon it so that they cross one another in the middle of the boaid, and the ends of them are in the middle of each side; then measure off 5$\frac{1}{8}$ in. each side of the point where the lines meet the edges of the board, and draw a line across each corner, so that it meets the points indicated after the above measurements are marked out.

The inside carcass should next be fitted up. Four boards, each 14 in. long and 10 in. wide, are fixed as shown in Fig. 7. To these, one on each side, and connected perpendicularly, are four other boards, each 14 in. long and 6$\frac{3}{4}$ in. wide. In each angle formed by these boards, and at an equal distance from top and bottom, are small shelves, four in number, each 6$\frac{3}{4}$ in. long and 4$\frac{1}{2}$ in. wide. All the inside boards might be $\frac{1}{2}$ in. thick.

Through the centre of the top, bottom, and middle boards must be a hole 2 in. or 3 in. in diameter, according to the stoutness the centre column is desired to be. The eentre turned column enters a square column which runs up the inside of the space formed by the four middle carcass boards (see Fig. 5), and which has another pillar joined to it at the top, which pillar is the one that can be seen in Fig. 1, to which the top brackets are joined. The square centre column is kept firm by means of eight pieces, of which one end of each is joined to the angles formed by the four middle boards. Four of these last-named pieces are fitted a few inches from the top of the space, the other four being fitted at a similar distance from the bottom. The turned centre column is cut right through just above where it penetrates the bottom and middle boards, an iron or wooden pin being driven into the top part of it, and fitting loosely into the bottom part, which has been prepared to receive it (Fig. 5) This is the means by which it revolves, and, if all parts are properly fitted and strongly joined together, it should be sufficient for the purpose; but I will give particulars of a method to facilitate a freer movement: Four or six thin long rollers of either wood or metal might be fitted under the middle board by means of a pivot passing through each of them, the ends of it being turned up and fastened to the middle board. The pivots through these rollers must fit neither too tightly nor too loosely, as, in case of their doing so, they will be an impediment rather than an assistance. If these rollers cause much of an opening between the bottom and middle boards, add a deeper moulding round one of them, or else fasten some fine fretwork to one of them.

It will be found that the canopy top will necessitate much labour, and, if it is desired that less labour should be spent upon it, have the top quite flat, with the brackets coming right in contact with the centre column. This will give room for any ornaments to be stood upon it, but I should say, *have the canopy*, as its appearance will compensate for the extra labour, and also the loss of the display of any ornaments. For this canopy eight boards are required; each should be 15 in. long and 9$\frac{1}{2}$ in. wide at one end, tapering down to a point at the other end. Eight brackets, each 15 in. long, are also required. The eanopy boards and these brackets can be connected by numerous methods. If, after the boards are joined, the outside sloping edges are planed down a little, the under parts of the brackets can be glued to these edges. Another method is to eut the bottoms of the brackets, so that in section they come to a point, and then to cant the edges of the boards inwards, thus forming, when the boards are put together, a triangular groove, into which the bottoms of the brackets fit.

The top centre column will be about 20 in. extreme length, and, of course, the backs of the brackets can fit it in a similar manner to that adopted in fitting them to the canopy boards.

The pillars now claim our attention. I should certainly advise having them not too stout. I think that, if they are turned from 1$\frac{1}{4}$ in. or 1$\frac{1}{2}$ in. wood, they will be quite strong enough. The length of them will be 27 in. In fitting them to the bottom board, do not have any side of the blocks come full with the edges of the bottom board, but have a corner of each block pointing to a corner of the board, while each side of the block runs at an equal distance from the corresponding sides of the octagon. Shaped pieces fitted between these pillars will look much better than spindles. The outside pillars are joined to the middle column by means of eight rails, each about 1 in. deep and $\frac{3}{4}$ in. thiek.

The doors and fixed sides come next. There is no need to have any pilasters to run the doors on. The fixed sides and the doors are all the same size, so that it is only necessary to describe one door. This will be 14 in. long and 10 in. wide. The stiles should not be more than 1$\frac{1}{4}$ in. wide. All the side edges of the doors and fixed parts will have to be canted a little to allow one to fit properly against another to obtain the form of the octagon. Clear glass might adorn all doors, ete., or only the doors, while the fixed sides are fitted with inlaid or carved panels. I should eertainly say, do not have the doors fitted with either silvered glass or wooden panels, as a lot of the effects of light and shadow will, in that case, be lost, in addition to the heavy appearance it would thus present.

In the above I have given only the bare measurements, and allowance must be made according to the various methods adopted in putting the parts together.

A moulding should either be worked round the edges of the top, bottom, and middle boards, or else one should be glued round them. Along the front of each shelf place some embossed or painted leather.

It will, without doubt, be noticed that, when each of the four doors is opened, four shelves of books, with thirteen volumes in each row, will be exposed; and that the corner space between these answers the purpose of a shelf where one volume can be placed while reference is being made to another.

Fig. 1 is not drawn to scale. All other diagrams, excepting Fig. 6 (which is to 3 in. scale) are drawn to 1 in. scale — that is, 1 in. represents 1 ft.

I trust that enough has now been said concerning this case for the volumes resulting from—as the *Athenæum* says—"*the greatest publishing feat of the last quarter of a century.*"

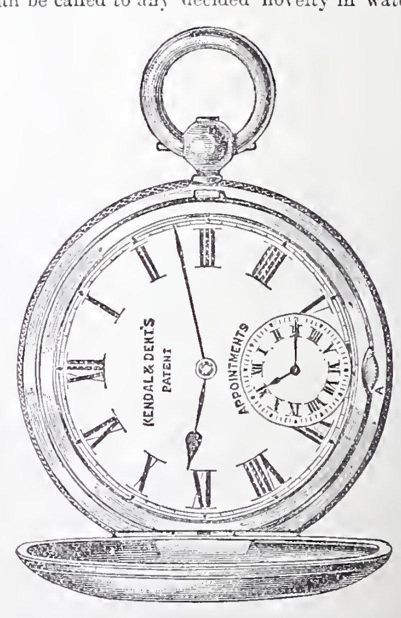
It is one of the most gratifying signs of the times to find that a firm with such a deservedly high reputation as that of Cassell & Company have brought our great authors within reach of all classes of the people by issuing these threepenny volumes. Every well-wisher to the spread of education will hope to see the NATIONAL LIBRARY receive a welcome far in excess of the utmost anticipations of the enterprising publishers. What a boon would be the perusal of these volumes alone to any working man! Here we have two hundred books which constitute in themselves a liberal education in English literature.

OUR GUIDE TO GOOD THINGS.

. *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

124. — KENDAL AND DENT'S "APPOINTMENT REMINDER" WATCH.

IT is not often that the attention of the public can be called to any decided novelty in watches



Kendal and Dent's "Appointment Reminder" Watch.

which can be readily understood and appreciated by any one who may happen to see it. By this I mean any addition to, or alteration or improvement in, the external parts of a watch, such as the case, glass, dial-plate, etc., for it is manifest that any change in the parts of the internal mechanism can only commend itself, or otherwise as the case may be, to experts in the art of watchmaking, or those who thoroughly comprehend the construction of a watch. Thus the improvement in the dial-plate of a watch, recently patented and introduced by Messrs. Kendal and Dent, Watchmakers and Jewellers, 106, Cheapside, London, E.C., is a novel feature, the utility of which every one can recognise, and whose practical value may be determined at a glance by any one who has been accustomed to carry a watch. It is shown in the accompanying illustration, and consists in the substitution for the old seconds dial another miniature dial corresponding to the larger dial of the watch itself, and furnished in a similar manner with hour hand and minute hand. Its purpose is indicated by the word "Appointments" above, from which it may be gathered at once that the small dial is to be used to fix the time of any important appointment that the wearer of the watch may have made, and is anxious to keep with the utmost punctuality, by putting the hands to the dial to the time in question in the manner that time is usually indicated by the hands of a watch or clock. It will be naturally asked, how is this effected? If the reader will look at the rim of the watch in the illustration, he will see just below the small dial the projecting segment of a small milled wheel, A. By turning this wheel, the hour and minute hands will be set in motion at the relative speed common to each, and may be kept moving in proper progression until the time fixed for the appointment be denoted. Messrs. Kendal and Dent shall speak for themselves with regard to the utility of their invention. They say, truly enough, that the new dial "occupies the position of the old and useless seconds dial." It is scarcely right, I think, to set down our old friend, the seconds dial, as useless. I can only say myself that I have found it of use at times in measuring speeds, etc., but I am bound to add that I am inclined to believe I should have found the new "appointment reminder" dial of greater use, because it would have been more frequently called into requisition. They continue: "How many of us, after referring to a time-table in the morning, and mentally repeating the exact time a train starts which we have to catch later in the day, have had a feeling of uncertainty as to whether it was, say, five minutes to one or five minutes past one? But possessed of this 'reminder,' we can now calmly set it to the time of departure, and there it will remain for instant reference, and every time the watch is looked at it acts as a reminder. As a train catcher it is really more valuable than the timekeeper itself. Again, to record the duration of a speech, or of a race, a railway journey, or of any process of distillation, cooking, or the like, when the interval of time is pre-arranged, the 'reminder' is at the commencement set so far in advance of the time as the operation should occupy, it will at once denote where the hands of the watch should be when it is concluded. Or, if at the beginning of any similar event of unknown duration the 'reminder' is set to true time, the period that has elapsed is denoted by the difference between the 'reminder' and the hands of the timekeeper."

Messrs. Kendal and Dent, as a matter of course, wish every one to buy a "reminder" watch, but although they may be had in silver from 42s., and in gold cases from £6, many, including myself, would like to be able to buy a "reminder" to be worn as a pendant to the watches we have. Could not Messrs. Kendal and Dent do something in this way, and thus extend their base of operation against the pockets of the purchasing public? The "reminder" pendant could be worked in the same way as the manufacturers have adopted in the case of the watch, and would have the merit of being far more useful and appropriate than the majority of pendants or "charms," as they are sometimes called, or even the spade guinea often worn as such. The Editor.

SHOP:

A Corner for Those who Want to Talk It.

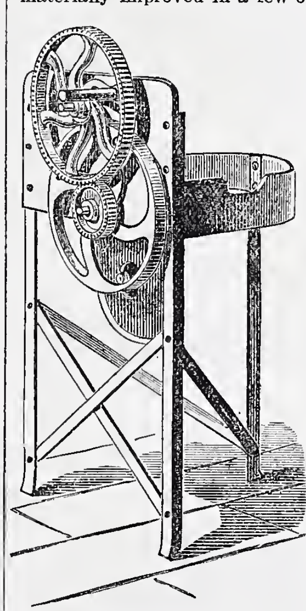
NOTICE TO CORRESPONDENTS.

*** *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

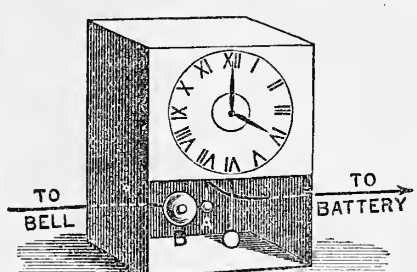
I.—Letters from Correspondents.

Cheap Hearth for Smithing.—J. M. (*Manchester*) writes:—"Your correspondent A. H. (see page 556) gives a fairly good description of a portable forge, which, however, I think can be materially improved in a few of its details:—The plates should be ⅛ in. thick, but anything thinner than 16 B.W.G. would be flimsy. The legs would be sufficiently firm and strong if made ½ in. or even ⅝ in. diameter; but for a fan the discharge pipe is far too small, as shown in sketch. For the further information of A. S. (*Liverpool*), I have seen portable fan forges made by Messrs. R. Clarke & Co., Moira Iron Works, Rochdale Road, Manchester (of which I enclose a sketch), at a cost of £3 5s. complete, and at which I have seen 1¼ in. square bar iron welded in a few minutes; the fans are of the Sebiele type, and can be easily turned by a very small boy. No doubt this firm would supply the fans, gearing, or other parts separately to any of your readers who might desire to build their own."



Cheap Hearth for Smithing.

Electric Time Alarum.—N. H. B. (*Ardwick*) writes:—"As a reader of your valuable paper from its start, I wish to congratulate you on the success of the paper hitherto, and the admirable way in which it has been managed. Having a slight knowledge of electricity, I thought I would venture, with the assistance of a friend, to fit up an



Electric Time Alarum.

electric time alarum. The clock was an ordinary alarum one with metal dial. We made the connections as shown in figure. One wire was attached to the bell and the other to the hammer. The alarum was 'set' in the usual manner, but not wound up. When the hour to which the alarum was put is reached, the hammer hits the bell and keeps in contact for about an hour, when it flies back. I send you this slight description, hoping it will help some fellow amateur. The bell must not be connected with the works or hammer."

Canoe Planks.—W. E. H. (*Bognor*) writes:—"I noticed in Work advice given about the planks of a canoe, and steaming them where the bends are. Now to have strips of mahogany 4 in. wide and straight would be absurd for either a canoe or boat planks, as every plank from garboard strake to gunwale strake is a different shape, and must be cut to shape or they will not work in, and no amount of steaming will induce them to either. I have built fishing and pleasure boats, and rarely want to steam the planks after the first one, and not always that, unless it be a boat with a long floor. I shall be pleased to answer questions that I may see on boat work. Do your readers know anything about the North Sea coble? There is no such boat here on this coast, and I want to introduce it, as I feel it will be a boon to the fishermen here on account of their light draught of water. Our boats here draw so much water, and the water is so shallow, that the boats ground so soon."—[Please send a paper describing the coble on approval.—Ed.]

Zinc Photo Etching.—O. G. B. J. (*Dover*) writes:—"Seeing some answers in 'Shop' from persons who understand zinc etching, I thought they might help me in a little trouble I have in that kind of work. Some time ago I purchased some photographic bitumen rendered sensitive from a maker who can be relied upon. I followed the directions sent in dissolving it in benzole, but when the plate had been coated and exposed to sunlight for a time, far exceeding the directions given, on placing it in turps the bitumen all washed away except a very little, but I could not get anything like a perfect image. If you could help me by any hints I should be very much pleased."

Combined Music Stand.—J. S. (*London, N.*) writes:—"I would like to make a remark or two about the scale mentioned in my article on Combined Music Stand (see page 552). Some readers may probably get confused, unless I explain. In dealing with feet, when we say a thing is drawn to ¼ in. scale, that means a ¼ in. represents a foot. When our measurements are small and we speak of inches, and say ¼ in. scale, that means ¼ in. to every inch. So that ¼ in. scale, seeing that I speak of inches, is quite correct; so also is 3 in. scale, and ¼ in. scale, although it might probably have been better had I kept to one proportionate scale."

Fret Machine.—Fair Play (*London, E.C.*) writes:—"There is not the slightest doubt that A. A. (*Coventry*) (see page 636) does not understand W. R. S.'s design for fret machine, so he must say that it will not work. Having made one according to W. R. S.'s design, and which I find to work well, I must say that it is rather good of him to condemn it, and then to give an illustration of one which he considers superior. I would like to know how he gets his motion to the crank, E, as he has no fly wheel, so when the treadle is at its lowest there it must remain, as there is nothing to counteract its weight, or, as I said before, to give the motion. I should now like to thank W. R. S. for the design of his machine, and would like to see A. A.'s answer to the above."

Work's Museum of Models.—J. Brox writes:—"I would suggest that all who have ideas and are capable of carrying them out should present you with a model, if possible, so that in time Work would be possessed of a small and growing museum of models, to be seen on some small payment at the gate, the proceeds to be used for Work and its museum. I shall be happy to start it by sending a model of the chair described in the paper enclosed, should you deem it worth a place in Work."—[I have much pleasure in accepting both your paper and your proposal as above. I trust that all inventors, makers, patentees, etc., who are readers of Work will follow in your footsteps, now that you have set them a good and praiseworthy example in going over the hedge first.—Ed.]

Levelling Oilstones.—C. A. B. (*London, E.*) gives many thanks to W. H. D. (*Birmingham*) for the way he has adopted in levelling oilstones (see page 636). It is far better than the old-fashioned way, rough flat stone and silver sand. My stone, which I have got nice and flat with emery cloth tacked on a piece of board, was ½ in. deep in the middle, and in fact in a very bad state, and in a very short time I could see a difference in the stone."

Etching.—C. A. B. (*London, E.*) writes:—"I shall feel very much obliged to W. J. P. (*Tunbridge Wells*) if he will furnish me with a little idea how to do etching, and the tools that may be required. Thin brass is the material I should require to etch. I am not in a good position at present, and it would be very useful in my business."—[Some papers on etching will appear shortly.—Ed.]

II.—Questions Answered by Editor and Staff.

Evening Classes for Electrotyping.—W. T. (*Hackney*).—Write to the Hon. Secretaries, City and Guilds of London Institute, Gresham College, London, E.C., and enclose stamped envelope for reply. They will probably direct you to an evening class on the subject you name.—G. E. B.

Electric Bell.—V. J. W. (*Ireland*).—From the fact that your bell has been working satisfactorily for two years with the current from a 2-cell battery, you may infer that the cause of the present failure is due to some fault in the battery itself. As the black japan on the heads of the carbon blocks is chipped off, and the lead heads have the appearance of plaster, it is evident that the ammonia fumes have undermined the lead caps, and destroyed their connection with the carbon. In a word or two, they are worn out, and must be replaced. It will pay you better to get newly charged porous cells than to recharge the old ones, or attempt to reeap the carbons. A little dust or corrosion on the contact parts of bell or pushes might cause fitful working, but the probable cause is in the battery. I do not suspect adulteration in the sal-ammoniac. Thirty feet is not too far from bell to push. This is proved by the past record of your bell, for it would not have worked satisfactorily for two years if the distance had been too great.—G. E. B.

Nickel Plating. — SIMPLEX (*Stamford*). — A small dynamo worked by foot power might be used by a working jeweller to furnish current for gilding and silvering small trinkets, but would be a cause of drudgery if employed to deposit nickel upon parts of bicycles, or to silver-plate large articles. Nickel is deposited from its solutions at the rate of about 16¾ grains per hour for each ampère of current, and it will take from 1 to 1½ hours to get a fairly good coat of metal. It will not be necessary to leave the articles in the bath for a long time if you have power at hand to force the nickel on fast, and only want to put on a flimsy coat of this metal, but such coats would be useless on bicycles, which, of all things, should have a tough, durable coating, put on slowly. You will gain nothing by making up a train of wheels to lift a heavy weight for the purpose of working machinery in its descent. You would require a weight of 5,555 lbs., falling at the rate of 1 foot in 1 minute, to develop the power of one man, estimating this to be ⅛ of a horse-power. If this power has to be applied through a train of wheels to get up speed in the machine, you will have to calculate the friction of the wheels together with that of the machine, and, after estimating the power needed to overcome this friction, deduct the sum from the power obtainable from the falling weight. Then please understand that it will take more power to raise the weight than you will get out of it whilst falling. A dynamo for plating purposes cannot be made to run light, since it must have a large output of current, and this absorbs energy. A series wound machine would be almost useless; it should be either compound or shunt wound. I do not know of a book that will instruct you how to make a plating dynamo. Goods to be nickel-plated must be well polished before being plated, and the coat must be polished afterwards. This may be done by hand, but it is best done with a machine. I should advise you to get Mr. Watt's book on "Electro-deposition," and study what he says about the deposition of nickel, as I have not time or space at my command to give you the necessary instructions here.—G. E. B.

Re-enamelling Clock Dials.—PENDULE.—Try the "Chez-lui" white bath enamel. I am afraid you will not be able to undertake this work in the usual way, as it requires a rather costly outfit, and the work requires to be stoved. You can get all you require from some of the Clerkenwell houses if you make a little inquiry. I can also give you directions for resilvering and regilding dials—easier operations. Do you know that Messrs. Willing, 12 and 13, Clerkenwell Green, E.C., the advertising agents, now sell patent enamelled figures for cementing on watch and clock dials? They are very good; write them for sample and prices.—H. L. B.

Modelling in Clay.—H. T. N. (*Malmesbury*).—Papers on this subject will shortly appear in WORK. The staining and shading of the inlaid portions in marquetry are two distinct operations. The former is done before the pieces are cut, the latter afterwards, whether the veneer is in the natural colour or stained. Shading is done either by engraving lines or by darkening with hot sand. This is the usual plan in such inlays as you describe, and the process may be thus briefly described. A pan or dish containing sand is heated over a fire or by other convenient means, till the sand is sufficiently hot to darken the veneer. The piece to be shaded is then pushed edge downwards into the sand, the gradations being arrived at by judicious manipulation. The process is a tedious one, but a certain amount of success is not difficult to attain even by a novice. Great care must be taken that the sand is not hot enough to burn or char the wood, and the best results are got on light veneers such as box.—D. A.

Camber in Girders.—H. H. W.—The camber is obtained by making the top flange longer than the bottom; in the lattice girder the distance from joint to joint is made longer in the top than the bottom flange, and in plate webbed girders each web plate is wider at the top than the bottom, and the rivet-pitch should be less in the bottom flange than the top, so as to suit the joints. The amount of difference of length depends upon the camber, the length of the top flange being to that of the bottom flange as the radius of the bottom flange plus the depth of girder is to the radius of the bottom flange simply. The rule for determining the radius of the bottom flange in feet: Divide three times the square of the length in feet, by twice the rise in the centre in inches, and add one twenty-fourth of the rise. This matter is thoroughly explained in an article on "Wrought Iron and Steel Girder Work," No. 12, page 186, which we advise our correspondent to read.—F. C.

Steel Colour on Brasswork. — BRONZE — To produce a bluish or steel-grey bronze on brass fittings for fishing rods, pour about half a pint of water into a gallipot; to this add 1 drachm of hyposulphate of soda, and 3 drachms of sulphate of copper. Place the gallipot with its contents in an old saucepan, and surround it with about 3 inches of water; apply heat until the ingredients are dissolved, when (as you do not specify the desired tint, whether blue or grey) it will be well to introduce a slip of brass as a test. Should it prove too dark, add more sulphate of copper, or if the opposite is the case, then more hyposulphate of soda will produce a deeper tint. When satisfied on this score, and still keeping the mixture heated, immerse the articles to be stained, which, of course, must have been thoroughly cleansed by dipping in dilute nitric acid, from this into clean water, and then dried in sawdust. After staining, heat the articles as hot as the hand can bear, and lacquer with pale clear lacquer. A steel-grey colour may also be produced on brass by immersion in a weak boiling solution of arsenic chloride, but this requires cautious handling as arsenious acid gas is evolved, which is a very powerful poison; it is therefore not advisable to attempt the experiment except in a stink closet, where all probability of inhaling the fumes could be avoided. The first mentioned method I have tried and proved.—T. R.

Magnetising Telephone Bars. — T. A. L. (*Reading*).—You ask for the simplest way of magnetising bars of steel for telephone purposes. Well, if you can get access to a dynamo, the simplest plan will be to draw the bars carefully across the pole piece, taking care to draw the bar always in the same direction. By doing so ten or twelve times the bars should be sufficiently magnetised for your purpose. Failing the dynamo, if you have a horseshoe magnet (the larger the better), you can use it for magnetising your bars. Proceed in this manner:—Lay one of your bars upon the table, and bring the horse-shoe magnet over it with the north or marked end nearest the bar, and draw the magnet slowly from left to right. Do this patiently

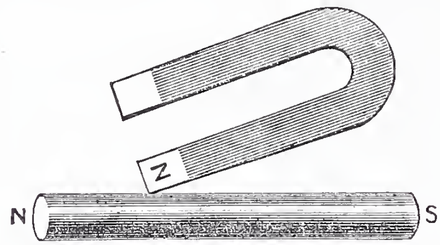


Fig. 1.

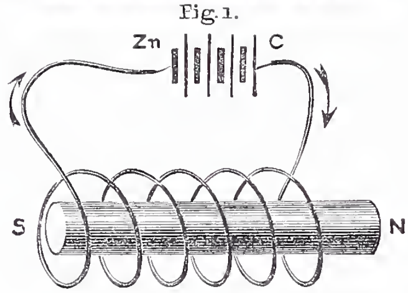

Fig. 2.

Magnetising Telephone Bars. Fig. 1.—Magnetising a Bar of Steel with a Horse-shoe Magnet. Fig. 2.—Magnetising by Means of the Electric Current.

for about twenty times, always commencing and leaving at the same ends. Turn the bar longitudinally during the process, and when bringing back the magnet for the next stroke raise the hand well above the table. The other bar is magnetised in the same manner. Fig. 1 shows the process, and gives also the names of the poles. You may turn your magnet and draw the south end across the bar, but you will require to turn the bar also. This will, however, be of no advantage, so rather than get mixed up keep to the method described. It may seem strange that by rubbing a piece of steel with one pole of a magnet you convert it into a magnet with two poles. Such is indeed the case. We cannot get a magnet with one pole; if there is south magnetism at one end of the bar there will be north magnetism at the other end. You will notice in Fig. 1 that the end of the bar where the rubbing stops is marked S or south. I cannot take up space in giving the reason of this. I merely draw your attention to the fact. In magnetism the law stands, "Like poles repel, unlike poles attract" —*i.e.*, a north pole repels a north but attracts a south, and a south pole repels a south but attracts a north. This by the way. Here is another method of magnetising your bars. Make a coil of No. 24 wire, using several hundred yards about the length of your bar, and pass a current from a battery or dynamo, giving about 2 ampères through it while your bar lies inside the coil. If you can arrange a make and brake like a Morse key in the circuit, and keep tapping now and again, it will be an improvement. If you look at Fig. 2 you will see the way to wind your coil and the method of joining up the battery so as to get the poles where you want them. I might give you other methods, but I hope you will succeed in getting your magnets the required strength by one or other of these methods. If you were not so far away from me I would do them for you with pleasure. As for the cost of magnetising such bars, I do not think any one could make a charge for it with the apparatus already at hand. A few minutes is all that is required for the process. Messrs. King, Mendham & Co., Western Electrical Works, Bristol, sell round bar magnets 5 in. by ⅜ in. (which is your size) at 10d. each. Write again and let me know how you succeed.—W. D.

Cycle Work: How to Braze.—CYCLE BRAZER. —You require, first of all, a small forge, or a blowpipe. The materials used in brazing are spelter and borax. The joints to be brazed must be well fitted and filed clean. Mix some of the borax with water into a thick paste, heat the joint to be brazed over a clear charcoal fire, sufficiently to make the wet borax fizzle when it is put on, and it will penetrate into all parts of the joint. If the part to be brazed is a solid fitted into a tube, put some borax inside the tube, allowing it to saturate the joint. Now put in some spelter, allowing it to rest on the solid in the tube; bend a piece of soft brass wire round the joint on the outside, and place on the fire if a fire is used. The fire should be clear and without smoke, and the blast kept up with a fan blower. Place a piece of wood over the joint on the fire; the heat from the burning wood will fall on the upper side of the joint. When the metal begins to get a good yellow heat the wire will disappear. Throw on a little dry borax over the joint and remove carefully from the fire. With a piece of iron clean off any cinder or scale on the still red hot metal, and lay aside to cool. If it is cooled in water the steel tube will become hard and brittle. Many joints may be made with spelter only, but in the case of tubes it does not lie well on the outside, hence the use of wire. All joints are brazed by running liquid brass into them, and the borax acts as a flux or penetrator.

Tempering Taps.—CYCLE BRAZER.—Heat the tap in a fire or gas flame to a dull red, and plunge into cold water. This will make it too hard. To bring it back, brighten one side on a bit of sandstone, and heat it in the middle through a gas flame. If you watch the brightened side you will see a yellow tinge travel slowly to the point, then cool in oil. It requires some experience to do it always with success.

Three-Inch Screw-Cutting Lathe.—F. W. (*Hitchin*).—To give you all the dimensions you ask it would be necessary to make complete working drawings, as it would not be easy to find details of a complete lathe on such a small scale. I most strongly advise you to make your lathe 3½ in. centres, because that is a size these lathes are often made, and for this you can easily buy a set of castings—say, from the Britannia Company, who will supply them with all machine work done. You can, of course, sit to work at it, if you use a high stool, and that is better than having the standards lowered, because then you can stand where you wish. If you follow my advice you will get all the main dimensions from the castings; you may, however, get the proportions and much useful information from the numbers of the *English Mechanic* mentioned in my reply to J. A. (*Preston*). —F. A. M.

Removing Varnish from Painting on Zinc.—J. M. G. (*Leeds*).—Your picture could be cleaned by any process which can be successfully applied to an oil painting on canvas, but more care will be necessary in handling and manipulation, since the colour would be more liable to peel and cake off from zinc than from the former. As you have, apparently, a picture of some value, it would be the wisest plan to hand it over to an experienced cleaner and restorer of paintings. If you are, however, determined to try the task yourself, the following may help you. The varnish which you wish to remove is a preparation of oil and resin, and can be removed, with more or less success according to the care and experience of the manipulator, by two methods—friction, or by dissolving the varnish with oil (mis-named spirits) of turpentine. In No. 26, p. 414, H. G. (*Liverpool*) gives a very reliable and commendable treatment for cleaning an oil painting, which will repay your turning up. This, however, may not be so suitable for your purpose of removing old oil varnish, which is of a much tougher nature than mastic (spirit) varnish. Try this:—Procure raw potatoes, and grate into some cold water until of the consistency of cream, then purchase at the chemist, if no large colourman's store is convenient, a little finely levigated pumice-stone. Mix well together, and then with a penny piece of sponge rub carefully and patiently. If the painting itself is carefully laid, or rather lays, evenly upon the zinc, this friction should safely remove the bulk of the old varnish. You might then try an equal mixture of methylated spirit and raw linseed oil; use with cotton wool, and carefully watch for the least sign of colour. Turpentine alone applied with cotton wool would dissolve the old varnish, but would require a very careful hand to use it. Friction of the hand alone will sometimes remove mastic varnish, but I am afraid it would only polish the face of your picture. In using the pumice mixture, this would require well rinsing off with sponge and cold water; then dry with a soft cloth. Messrs. Brodie & Middleton, Long Acre, are sole agents for a mixture called "Anadeiktine," by means of which they claim that any intelligent person can clean any valuable painting. You can get a sample bottle for a shilling, and it would pay you to try it, I think.—H. P.

Design for Safety Bicycle.—W. G. (*Bolton, N.B.*)—Yes, the probability is that your contrivance would be practicable, for so far as can be gathered from your rough sketch, it is on much the same principle as that of the "Facile" and "Xtra-ordinary," which were introduced some years ago. If, however, you know that yours embodies improvements on these, in my opinion the best thing you can do is to submit the design to some good manufacturer, and see whether he will take it up. If patentable—which you will understand I do not think it is—you should, of course, protect it before submitting it to any one whom you cannot thoroughly rely on. I am sorry to have to throw cold water on your plan, especially as you are an invalid, and no one would be more pleased than I to learn that through the indistinctness of your sketch I am mistaken in supposing it to be a revival of an old form.—D. A.

Circular Saw Bench.—C. W. T. (*Leicester*).—I am sorry to say I have read your letter over several times without being able to get your meaning as clearly as would be necessary before I could help you, but from what I can make out I have no hesitation in saying that you could not cut anything like the thickness you name. Without more knowledge than you have of the fitting up of such a machine you will do better to leave it alone; or, if you are determined to make a circular saw table, try one according to the directions already given in Work. I think your intention is to use hand power only, in which case I do not see the object of the two large wooden wheels. It is possible you contemplate availing yourself of steam power, but in this case you would hardly have asked the questions you do. Without going into calculations, for which there is no reliable basis to start from, the probable cost cannot be estimated. With regard to sharpening saws, your inquiry will be sufficiently answered by saying that the practice varies, some sharpening from one, others from both sides. Each method has its advocates.—D. A.

Lathe: Fitting Fast Headstock.—J. A. (*Preston*).—The proportions shown in your tracing are good, except the inside cone in the mandrel nose, which looks too steep. Set your slide rest over 2¾ degrees, to turn out that hole; and if the hole be ⅝ in. at the mouth, it will be about ⅜ in. diameter, at 1½ in. deep, not ¼ in. as you have it. You will find all the details you require, given for a 4-in. lathe, in Nos. 1,117, 1,121, 1,123, 1,125, and 1,128, of the *English Mechanic*. You can easily reduce in proportion.—F. A. M.

Index to Work.—F. R. (*Sutton Coldfield*).—When Volume I. is complete, an index to its contents will be issued.

Dovetailing.—F. R. (*Sutton Coldfield*).—Papers on this subject are in preparation, as I have said more than once already. Articles cannot be written and printed directly they are asked for.

Safety Bicycle Making.—J. T. H. (*Neath*).—As far as I am aware, no book has yet appeared on the subject of safety bicycle making.

Bicycle Wheels, Where to Buy.—J. T. H. (*Neath*).—You can buy bicycle wheels 30 inches high of any maker of bicycles. If the precise size is not in stock, a pair will be made for you.

Coloured Glass Windows.—Jay Bee.—Papers on this subject will appear in Work, but when I cannot say. All particulars relative to tools and materials and their cost will be given in them.

Fret Machine and Lathe to Sewing Machine Stand.—An Amateur.—It is quite impossible in the limited space of "Shop" to give directions which would occupy several pages, and then only be useful to readers who might happen to want to use up a stand exactly the same as the one you have. As you reside in Clerkenwell, why not keep your eyes open and hunt about the iron shops which abound in that neighbourhood? You would, probably, be able to pick up a second-hand lathe, etc., or such parts as would enable you to complete one at far less cost than you could make. The stand might do for a fairly serviceable fret saw, but the lathe would only be capable of doing very small work, and I cannot recommend you to waste your energy over it. You will, no doubt, agree with me that when cost is the main consideration in inducing one to make anything, that it is foolish policy to go to as much or even more expense for materials, not to mention labour, than would be involved in the purchase of an appliance of a more reliable and satisfactory kind.—D. A.

Re-magnetising Bar Magnets.—V. R. (*Liverpool*).—(1) If a steel magnet is made red hot, it becomes demagnetised, however it may be afterwards cooled. (2) Steel bars for magnets should be made as hard as fire and water can make them—viz., by beating the steel and cooling in water in the usual way for hardening steel. (3) Any number of Bunsen cells from 1 to 6 may be used in the process of magnetisation. (4) The cells must be arranged in series if you use a long coil of fine wire, or in parallel if you employ a short coil of thick wire. (5) Any gauge of wire may be used, but it must be of copper, and insulated with silk or with cotton. If for use with a large battery, with the cells coupled in parallel, use from 3 to 5 or 7 layers of No. 16 or 18 wire. (6) It will take nearly 24 yards of No. 16 cotton-covered copper wire to envelop one of your bar magnets with 3 layers of wire, and this will weigh 1 lb. It will take over 45 yards of No. 18 cotton-covered copper wire to envelop one of your bar magnets with 5 layers of wire, and this will weigh over 1 lb. You will only need to magnetise one bar at a time. (7) Begin winding at the end marked N, and wind from right to left. This will give the required polarity to the magnet if the current is made to traverse the coil in this direction. (8) The wires should go to within half an inch of each end. (9) The end of the coil should be at the opposite end from the starting point. (10) The position of the bar need not coincide with the magnetic meridian of the earth whilst being magnetised. (11) When coupling up the coil to the battery, connect the carbon element with the commencing end of the coil. (12) It should only take a few minutes to fully saturate the bars, but the process can be hastened and the effect intensified by lightly tapping the bars, or interrupting the current by drawing the connecting wires over a file during the time. (13) Bar magnets may be made of any size and length you may desire. (14) Old files may be used, but they should be first forged to proper shape, smoothed, and hardened. (15) Very large magnets will require more layers of wire or a stronger current to properly magnetise them. Are you satisfied with the replies to your fifteen questions?—G. E. B.

Bicycle Cone.—G. S. (*Liverpool Road, N.*).—It would be hard to say what is the matter and how to cure it without having seen the bicycle head. Your correspondent speaks of a cone. Does he mean the cone pin that screws down from top of head, and on which the backbone swivels? This pin usually has a jam nut to screw down hard on the head after the pin is adjusted. If his has no jam nut, let him have one put on by a repairer, or blacksmith, or mechanic. As to a bent or buckled wheel, it would be better and cheaper to put it into the hands of a repairer.—A. S.

Watch and Clock Tools.—Would-be Watch Cleaner (*Slaugham*).—The broken jewel hole is quite sufficient to stop it. Take the watch to pieces, and send plate, scape wheel bar, and scape wheel to Grimshaw & Co., 35, Goswell Road, Clerkenwell, or J. Hunt, 21, Ironmonger Street, St. Luke's. They will put a new jewel for a shilling or two, and from either you can get any and every watch and clock tools you may require.—A. B. C.

Something To Do.—Pleasure and Profit (*London, W.*)—Your question is a puzzler to answer. You might take up any of the subjects which are treated of in Work, and having now told you of something to be done I want to give you a bit of "straight" talk. Does it not strike you that you are the best judge of what you can do in your spare time? Though your letter shows you to have proper ambition and a desire not to waste time, I cannot know your capacity, amount of spare time, and fifty other matters which it would be necessary for any one to be acquainted with before he could advise you in such a manner as to be helpful to you. Your question about work that will be pleasant must also be dismissed in the same way, for "pleasant" work depends altogether on a man's taste. For example, mine leads me to prefer working in wood to working in iron, but plenty of our readers like the latter, and do not care for the former. As for profit, it may almost be said that any work is profitable, though perhaps not from a monetary point of view. Whether you can make it so must depend entirely on your own energy. As you are still a youngster, if you have mechanical abilities, why not learn some handicraft as a means of livelihood? Anyway, if you will write and let me know what you have done in the way of work, possibly I might be able to suggest something to your taste. Remember, however, that unless you show skill which, for one so young, will be quite exceptional, you are hardly likely to be able to earn money yet awhile by making things on your own account, as you will have to compete against older and more experienced workers.—D. D.

Finishing Fretwork.—F. S. B. (*Guernsey*).—The best method of finishing fretwork is to French polish the wood before cutting, and afterwards just to touch up with the rubber. Another way, and almost as good, perhaps giving better results with an amateur, is simply to body up before cutting—*i.e.*, do all the polishing except spiriting off. When the fret is cut, instead of spiriting finish with glaze. This is made with equal quantities (more or less) of gum benzoin and methylated spirits. Allow the mixture to stand till the gum is dissolved, then strain to remove impurities. It is applied by rubbing or wiping on with a soft rubber. You are quite correct in supposing glaze gives a finish superior in appearance to varnish. Varnishing, however, is easier and quicker in application. Perhaps your fretwork is dull because the varnish has sunk, and if so, give the work another coating. You don't say what kind of varnish you have used, but you may easily make a good spirit varnish by dissolving resin in French polish or methylated spirits. French polish, you know, is nothing but a thin varnish of spirits and shellac. Resin, or more shellac, added makes the mixture thicker, and you have what is commonly known as "varnish." Au revoir, m'sieur.—D. D.

Drawing-Room Chair Repairs.—Phosphor (*Plaistow*).—The chairs have not gone wrong "through being very straight-backed," but through being badly made. You will seldom find the joints at back work loose in a really good chair. Without seeing them or knowing more about yours than I do, it is impossible to tell you the best way to repair them. You might manage to fix in angle blocks between the back feet and side rails of seat, but this would be a very unworkmanlike way of doing. The only really effective way is to rejoint, but if your chairs are stuffed, I can hardly advise you to attempt the job yourself. It is not one for an amateur, as the upholstery must be partly undone if not altogether ripped off, and you will find it a difficult matter to replace it. The screws you mention might have answered. If you bored holes for them I cannot understand how they broke before you could get them in. If you like to run the risk of spoiling the back feet of the chairs altogether you might bore through them into the framing, and insert a glued peg which must fit tightly.—D. A.

Patent in Boxes.—H. H. T. (*Barnsley*).—Pray do not regard any question coming within our scope as a liberty, for it is not regarded as such. The services of both Editor and staff are freely at the disposal of readers of Work in helping to remove the little difficulties which crop up or, as in your case, by giving advice to the best of their ability and judgment. You and other intending patentees may also rest assured that you may with perfect safety, using your own words, trust to our good faith in not divulging schemes which are naturally communicated in confidence. As a general principle it is not wise to communicate particulars of anything which is intended to be patented before provisional protection, at least, is secured, and they are not invited; but when they are sent the trust is not violated, and it is a gratifying proof of the esteem in which Work is held that so many inventors apply to it. As for your own idea I may say that it seems feasible, though there are one or two points in the construction which I do not see can very well be managed. It is, of course, impossible for me to write so openly as I would wish about these, for fear of giving any one else a clue to the construction you suggest, but if you will "read between the lines" I think you will understand. First the "boring." How are you going to manage that? or, as I don't want to be inquisitive, let me rather say that this appears as if it would be sometimes impracticable. I don't think you need go to the trouble of clenching. If you do not see how this is to be avoided, I may be able to give you a wrinkle. Before spending any money on patenting your idea, you will, of course, see that it has not been forestalled, and you should also consider whether it is likely to be commercially a success. For instance, if the cost of making a box by your method is more than by the one you allude to, without preponderating advantages you could not reasonably expect to profit by your invention. Yours may be a novelty, but unless it is also an improvement on existing methods of construction in someway, novelty alone is not sufficient to make it pay. It is from a disregard of these plain business considerations that so many abortive patents are taken out. I don't want to throw cold water on your hopes, and it would undoubtedly seem more pleasant, and possibly more in accordance with your own views, to tell you that your plan is everything that could be desired, sure to be a success, and all that kind of thing, but it is only right as you ask for "opinion and advice" to put the business aspect before you as fairly as I can. I sincerely wish you success, and shall be pleased to hear of your progress.—D. D.

Clock Design in Keen's Cement.—C. R. H. (*Kilburn*).—It will be impossible to promise a paper on this subject at any very early date.

Varnishing Picture Frames.—A. L. D. S. (*Leicester*).—Before revarnishing your maple frames you must be sure they are quite clean and free from grease. I should advise cleaning them with a piece of flannel or sponge, and warm water with dry soap dissolved in it, afterwards rinsing with cold; don't let them get too wet, however. If they are very dirty try Brooke's Monkey Brand Soap, which combines the effects of soap and friction. The best varnish, I think, would be brown hard spirit varnish, applied with a camel-hair brush, such as polishers use. Copal varnish, applied with an ordinary hog's-hair brush, would do, but the former is preferable by reason of quick drying and hardening qualities, and looks more like polish. As to staining, unless all the old varnish were removed, this must be done in oil or varnish stain. A spirit and shellac mixture is sold in 6d. bottles called "Varnish Stain," or some fancy name. It is merely spirit varnish stained to match walnut, rosewood, oak, etc. This would probably suit as well as anything for you. The *Furniture Gazette* is the only one of two mentioned that I can get knowledge of. It is 4d. monthly. Order through newsagent or W. H. Smith's bookstall.—F. P.

Books on Graining and Coach Painting.—R. C. (*Chertsey*).—Coach painting is quite a distinct trade, and although I have known coach painters to turn house painters with some success, it is not often that a house painter changes over. It requires a thorough practical knowledge of the particular preparation and materials used to get up the body of a carriage, or so forth, in first-class style, and the time so necessarily expended wouldn't do in house painting, or at least on anything but the finest "hand-polishing" work. Otherwise, any painter who understands his business could paint a cart or cab in a serviceable and passable manner. I am not acquainted with any "manual" teaching purely coach painting, and do not think such exists. Respecting your second paragraph, you will find all you want in the articles now running on painting, graining, marbling, and general decorating. Cultivate patience and persistent application, or in your general desire—which is otherwise a very commendable one—to master every branch you may get but a smattering of them all. There are several works on such matters published, but no single one, I believe, treats the plain, the imitative, and also the advanced decorative branches of house painting. This the articles in WORK will make a point of doing, therefore work on at writing, and take the others as they come, and save your cash.—F. P.

Ink Drying. — LITHO (*Burnley*).—At first, in reply to our correspondent, we were about to reply very curtly that we had never had any such experience similar to his, for we always used good inks and paid a fair price for them, instead of purchasing low-priced inks, deluding ourselves into the belief that they were cheaper. As if an ink manufacturer could afford to supply an under-priced article of the same value as the best-priced article, or in other words give something away. Without seeing a sample of the bronze blue ink our correspondent refers to, we can only conjecture that it is made of inferior materials, such as varnish adulterated with resin, instead of consisting solely of boiled linseed oil, or acid added in excess to throw up the bronziness, or perhaps only half ground, and too much driers added to conceal it. Our correspondent does not say what rollers he used, whether varnished rollers or black rollers—viz., rollers baving the "nap" properly "up." We have, however, taken counsel with several of the best litho printers we know, and our opinion as above is confirmed. One recommends adding a little Russian tallow to the ink, another says a little palm oil is a good thing to "feed the job," and prevent its being pulled off the stone. We think, therefore, that our correspondent should well wash his rollers with "turps" or "terebine," and then, if "nap" rollers, well scrape them so as to bring them up, and then with clean linen rag wipe them with "methylated spirits of wine." The stone should be put on to a band press, be washed out, rubbed up well to feed it, rolled up with the hand roller in black, pounced and well etched, and again washed out, and put into full ink with the press roller by hand in bronze blue. Add to each pound of ink in the duct, a piece of palm oil the size of a haricot bean, and a piece of tallow of the size of a hazel nut. Rub well in on a slab with a muller, and add enough really good "middle" litho varnish to suit the fineness or boldness of the job. There is yet another possible cause of the trouble—namely, the paper. Paper is now so much adulterated with china clay or kaolin (silicate of alumina), especially cheap foreign kinds, that it actually falls out on to the stone in going round the cylinder, and there mixes with the water, which weakens the job on the stone, soaks into the rollers, and forms into a nasty paste, utterly subversive of good printing. In conclusion, our correspondent should learn that a just retribution will surely fall on all who are illogical enough to suppose that, by buying rubbishy materials because they are low-priced, they can take work in to do below the market value.—J. W. H.

Fretwork Designs. — H. B. (*Leeds*). — The American designs you name would most probably be obtainable of Messrs. Harger Bros., Settle. Or if they had not got them they would be able, no doubt, to indicate their whereabouts to you.—E. B. S.

Bronzing Goods. — MAC (*Wandsworth*).—Glad to hear that you were successful with the silvering solution. With respect to the urn that you wish to make look like new, I fear that will be beyond your power. If it is simply dirty, procure at an ironmonger's some urn powder, a speciality for cleaning urns; this will clean it and make it look well if the bronze has not worn off, but if it has I should not meddle farther with it, but send it to be done properly.—R. A.

Blowpipe for Soldering.—W. H. (*Birmingham*).—The blowpipe you mention can be had from Rhodes & Sons, Wakefield. It is slightly different in form to the sketch, Fig. 11 (see page 501), as it has no wood handle, and the price, I believe, is 4s. 6d. or 5s. It is just the thing for the work you specify, and for smaller pipes, but not larger.—R. A.

Brass Labels.—J. N. (*Sunderland*). — Messrs. Rhodes & Son, Grove Iron Works, Wakefield, supply the labels you ask about, and also dies for making them. Prices as under:—

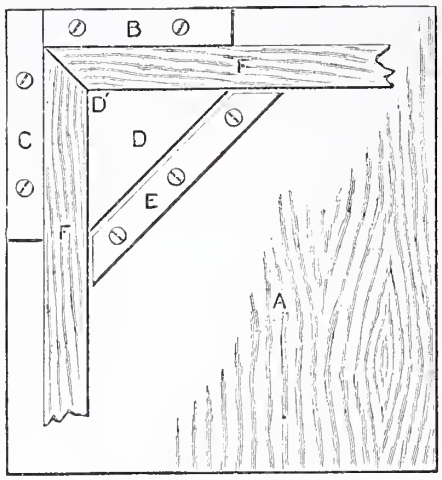
No.	Size.	Die.	Labels per 1,000.	Labels per Gross.
	in.	s. d.	s.	s. d.
1	$1 \times \frac{3}{4}$	13 6	20	3 9
2	$1\frac{1}{4} \times \frac{7}{8}$	14 0	23	4 0
3	$1\frac{1}{2} \times 1$	16 0	26	4 3

Larger sizes at proportionate prices.—R. A.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Patent. —LOCO (*Finsbury Park*) writes in sequence to PATENTEE (see page 574):—"I should like to show that the remarks made by MINERVA (see page 446) were quite right. In the 'Patentee's Manual,' by Johnson, published by Longmans, Green & Co., which is one of the best authorities on Patent Law, the author, in speaking of provisional protection, on page 109, says:—'This protection, however, gives the applicant no right against the public. He is only protected against the consequences of his own publication in case of his employing workmen, making experiments, or exercising the invention—that is to say, he will not thereby prejudice the patent afterwards granted to him. He must not forget, however, that as he cannot take any legal proceedings for infringements committed before the publication of the complete specification (Sect. 13), his proceedings even under protection should be conducted with due caution.'"

Wood Mitre Cramp.—H. J. L. J. M. (*Ealing*) writes:—"Perhaps this may suit J. H. (*Blackburn*) (see page 605). A very good way to join up mitres is to take a stout board, A, and after planing it quite true screw on two pieces, B, C, of hard wood (such as solid oak moulding), lined on one surface and one edge, in such a way that they form a perfectly true right angle. Then prepare a triangular piece (with one angle a right angle) of similarly hard wood, and a slip similar in size to B or C, with two or three holes bored through it. When the pieces are cut and ready for gluing up, glue them and place them (F, F) in position on the board A. Next put D in its place, so that the right-angled corner, D, may press well into the mitre joint.



Wood Mitre Cramp.

Then screw down the strip E, leaving room to insert a few thin wedges, with which D may be forced more tightly into F, F if required. In the case of larger mouldings E might be fitted with two large sash screws, the points of which could unhinge on the hypotenuse of the triangle-shaped piece, D; a small stud of metal, such as a screw, being first fixed into D where the sash screw points would exert their pressure. This idea of mine answers very well for gluing up frames, and was thought out long before a somewhat similar but more expensive one in iron was introduced into use. As the apparatus can be made of any size as required and so very inexpensively, I have not given any measurements or dimensions. For the making of small picture frames a board might be made with all the four corners similarly fitted, and thus the four mitres of the frame could be glued at the same time."

Cab Drawings. — G. W. writes in reply to W. M. C. (see page 631):—"Working drawings of Forder, Showful, or four-wheel cabs, regulation sizes (London), and all details, may be had on application to me, Spring Road, Bournemouth."

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—A. C. (*Leeds*); J. KENNEDY; H. D. (*Blairgowrie*); J. C. (*Cork*); WINDMILL; J. D. N. (*Glasgow*); TIM BOBBIN; SALE MOOR; J. M. (*Nottingham*); J. S. A. (*Manchester*); E. B. (*South Shields*); Dr. H. (*Ireland*); J. P. (*Byker-on-Tyne*); J. R. J. H. SKINNER & CO., EAST DEREHAM, NORFOLK,

Manufacturers and Importers of Photographic Apparatus and Fretwork Materials.

J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.
The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price 3s. 6d., or securely packed by Parcel Post, 4s.

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price 7s. 6d. Securely packed, post free, 8s. 6d. If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.
Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

Catalogue of Machines, Designs, Wood, Tools, &c., with several Hundred Illustrations, and full Instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. Good Fret Saws, 1s. 6d. per gross; best ditto, 2s. per gross.

ARE universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, Frightful Dreams, and all Nervous and Trembling Sensations, &c. The first dose will give relief in twenty minutes. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

WORTH A GUINEA A BOX.

For Females of all ages these Pills are invaluable, as a few doses of them carry off all humours, and bring about all that is required. No female should be without them. There is no medicine to be found equal to Beecham's Pills for removing any obstruction or irregularity of the system. If taken according to the directions given with each box, they will soon restore females of all ages to sound and robust health. This has been proved by thousands who have tried them, and found the benefits which are ensured by their use.

For a Weak Stomach, Impaired Digestion, and all Disorders of the Liver, they act like magic, and a few doses will be found to work wonders on the most important organs in the human machine. They strengthen the whole muscular system, restore the long-lost complexion, bring back the keen edge of appetite, and arouse into action with the rosebud of health the whole physical energy of the human frame. These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the Nervous and Debilitated is, BEECHAM'S PILLS *have the largest Sale of any Patent Medicine in the World.*

Beecham's Magic Cough Pills.

As a Remedy for Coughs in general, Asthma, Bronchial Affections, Hoarseness, Shortness of Breath, Tightness and Oppression of the Chest, Wheezing, &c., these Pills stand unrivalled. They are the best ever offered to the public, and will speedily remove that sense of oppression and difficulty of breathing which nightly deprive the patient of rest. Let any person give BEECHAM'S COUGH PILLS a trial, and the most violent Cough will in a short time be removed.

Prepared only, and sold Wholesale and Retail, by the Proprietor, THOMAS BEECHAM, ST. HELENS, LANCASHIRE, in Boxes, 1s. 1½d. and 2s. 9d. each.

Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

THE DARK ROOM AND ITS EQUIPMENT.

BY AN OLD HAND.

The Arrangement of the Dark Room or Laboratory—Print-washing—Accessories.

The "dark room," as it is generally called, is somewhat of a misnomer, the word "laboratory" being much preferable, for the amount of light admitted to this so-called dark room may be sufficient to enable the operator to see comfortably over the whole place and yet be perfectly safe; that is, not affecting the sensitive surfaces with which he has to deal, unless they are very unnecessarily exposed to its influence. It may be borne in mind that *no light* is absolutely safe for an unlimited period. Sensitive plates and papers should never be exposed to it more than is absolutely necessary; this matter has been already referred to in treating of lanterns. The conditions required for constructing a "dark" room are, first of all: convenience in size and design, good ventilation, and thorough protection from any white or actinic light when desired. The photographic dark room bears the same relation to the studio and the rest of the premises as the kitchen does to the ordinary dwelling house; or rather the dark room is to the photographer as kitchen to the cook. It is true all sorts of holes and corners have been used as "dark rooms," but are makeshifts at best; good work may be done in them, and frequently is, on the same principle that a good workman will make good work under almost any disadvantages, but this is no argument in favour of the makeshift. Where opportunity offers, no trouble should be spared to make this portion of the photographer's premises as perfect and convenient as possible.

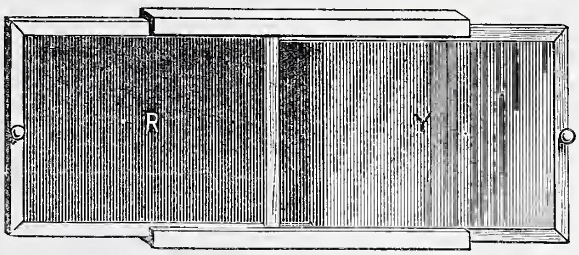

Fig. 3.

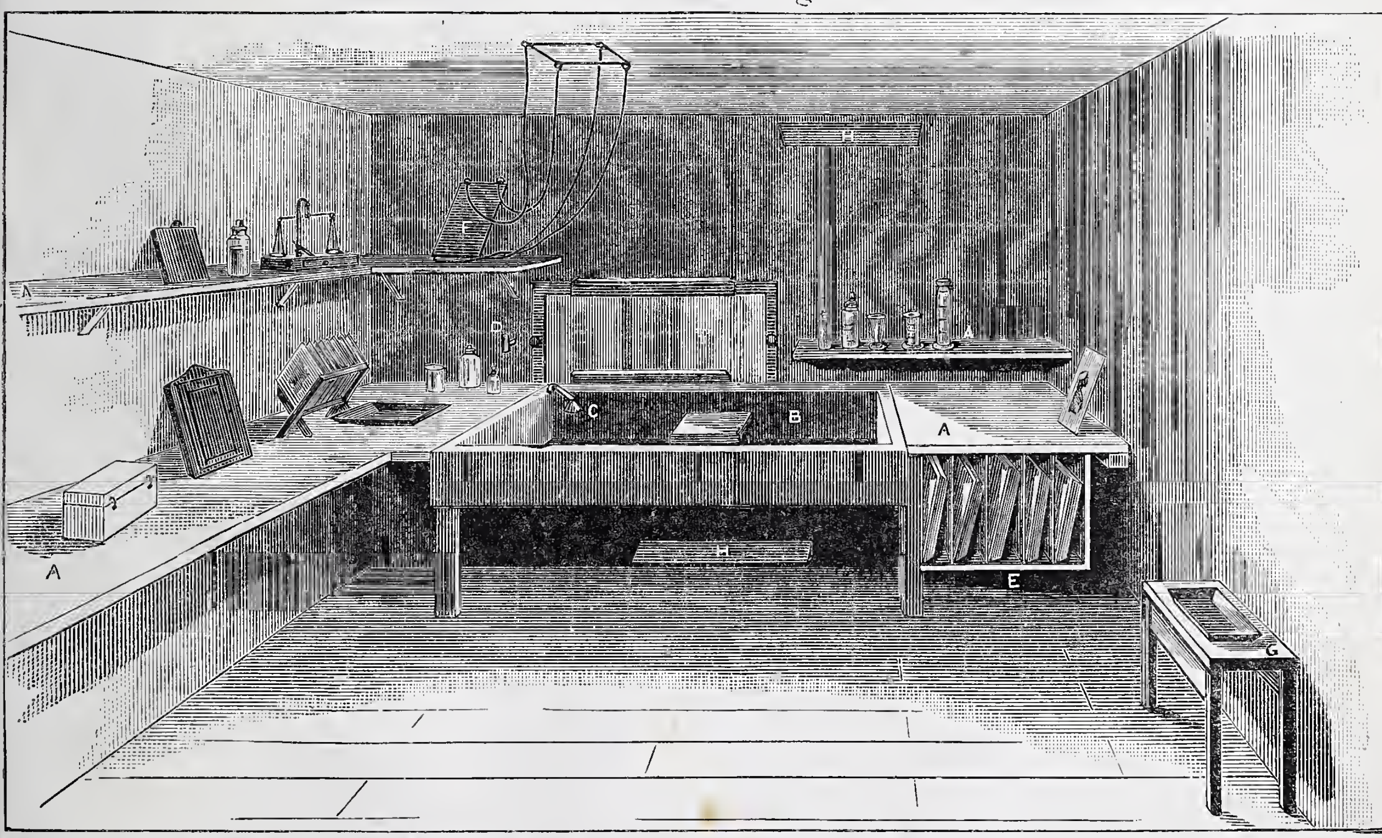

Fig. 1.—Plan of Dark Room—A, A′, Shelves; B, Sink; C, Water Tap; D, D′, Doors; E, Lobby; F, Window; G, Small Table. Fig. 2.—Curtains over Doors. Fig. 3.—Sliding Sashes in Coloured Glass. Fig. 4.—Interior of Dark Room—A, A, A, A, Shelves; B, Sink; C, Water Tap; D, Gas Tap; E, Shelf with Partitions for Dishes; F, Oscillating Table; G, Small Table for Hypo. Dish; H, H, Trapped Ventilators.

The area of such a workroom should be sufficiently large to contain two persons at the same time, with plenty of elbow room. This I consider the smallest space that can be fairly designated as convenient; but if the size is that of an ordinary sitting-room, so much the better. The larger the place the more healthful and pleasant it is to work in.

Let us suppose we have a space at command of about 8 ft. by 6 ft., which we will now proceed to fit up. The ground plan (Fig. 1) shows the disposition of the window, door, sink, and shelves. The door must either be doubled, or covered with double curtains, impervious to light. The doors, D and D′, being double, should have a short lobby, E, between them, that may either project into the dark room, or, if there is sufficient space, extend outwardly, a hinged rod connecting the two, preventing both doors being opened at the same time. The edges of the door should be made to fit into a deep felt-lined rebate, so that when closed they are absolutely light tight. If a single door is used, one opaque curtain is fastened securely along the top and down the side, the other being also fastened along the top and down the opposite side, taking care they are sufficiently voluminous to permit easy passage between them (as in Fig. 2); these curtains take the place of the outer door. B is a lead-lined wooden sink, 4 ft. long, and 2 ft. wide, and 9 in. deep; A, A′ are shelves, A being 3 ft. wide and the whole width of the room, A′ being the width of the sink, grooved and sloping gradually to it, so that any fluid may drain into the sink, filling in the space between the sink and wall. F is the window, consisting of a grooved frame that is glazed with white glass, and in which other frames filled with orange or ruby glass, or other non-actinic material, can be slipped at will (Fig. 3). The light is preferably a gas jet *outside* the room, regulated by a tap on the inside. Of course daylight *may* be used; but, owing to its fluctuating character, is not to be recommended; C is the water tap with rose, from which the water flows on its being pulled forward. A narrow shelf is fixed against the wall over the sink, for any measures, bottles, etc., that may be required. Another shelf at a distance of 2 ft. above the lower one is convenient, and a roller towel hung behind the door. Brown or yellow varnished paper should cover the walls and ceiling, as less likely to retain dust and dirt, and can be readily cleaned with a damp cloth. In Fig. 4, the general appearance of such a room is given. Placed in the sink are one or more small movable platforms, on which to place dishes and bring them under the tap at will; to the right, below the sink, is a shelf divided into cells for the purpose of storing developing dishes and trays. In front of the window and screwed to the ceiling are four eyes, from which an oscillating table is suspended, such as described in a previous chapter, and which in the diagram is represented placed out of the way on a shelf. The door should be provided with the means of securing it on the inside. The fewer the bottles, jars, or other articles (than those required for daily use) stored in the dark room the better. There should be a place for everything required, and everything in its place, so that even in total darkness they can be found at once. This methodical arrangement is of much more importance now, in these days of plates and papers of such exalted sensitiveness, than when only wet collodion was used; in fact, when working orthochromatic plates only the merest glimmer of deep ruby light is permissible, and very little of that, if we expect to produce bright, clear negatives. With regard to temperature of the room, it should never be below 60° Fahr., or above 70° Fahr. The hyposulphite fixing bath is best placed on a stand separate (Fig. 4) from any of the shelves or sink, and let the dish or dipping bath be used for nothing else, when it has once been devoted to this purpose. Contamination with hyposulphite of soda is a fruitful source of stains and trouble; after touching it, the hands should always be rinsed and wiped before proceeding with any other operation. It is convenient if the bottles containing the accelerators or restrainers are of different shapes, for labels soon get partially or wholly obliterated. Once get accustomed to a particular shaped bottle for a solution, and there is very little probability of using the wrong one. This may be an apparently trifling matter, but the advantage of adopting it will be soon appreciated.

Fig. 9.—Waste Plug. Fig. 9 A.—Diagram showing how Plugs are Soldered together. Fig. 10.—Water Wheel and Crank. Fig. 11.—Iron Frame to support Axle of Wheel.

Print-washing.—One of the most important processes in the preparation of silver prints is that by which they are freed from the hyposulphite compounds formed during the fixing; very many kinds of washing tanks have been devised for this purpose. We will select two: one of which is suitable for small quantities of prints, and the other for larger numbers. Fig. 5 represents one of the smaller kind, and consists of a circular vessel with a false bottom and syphon attached, in order that the contaminated water may be periodically drawn off, the supply coming from a series of small jets near the top of the pan. The force of the supply and the angle at which the jets are set cause a continuous circular movement in the water, that prevents the prints sticking together, and thoroughly cleanses them from those hyposulphite compounds that, suffered to remain in the prints, would destroy their permanency. Usually this washing pan is made of zinc, but glazed earthenware is frequently substituted, and answers the purpose thoroughly well. The pan being provided, proceed to drill a hole about an inch from the bottom, into which fasten a bent syphon tube A, the bend being about 2 in. from the top of the pan; compo gas-piping answers every purpose. If the pan is made of zinc, soldering is the method used to make the attachment; but if earthenware, a cork ring is most easily adapted; various methods will suggest themselves; the idea is to have a syphon outside the pan, to draw off the water from below the false bottom (Fig. 6). This drainer is made of a perforated zinc disc supported on three short legs, just above the outflow of the syphon; the reason for having the syphon outside is, that any roughness or projection inside interferes with the movement of the prints, and is apt to make them clot together and escape that thorough cleansing so essential to permanency. The supply pipe (Fig. 7) is the next consideration. This is best made of $\frac{1}{2}$-in. brass tubing, bent to follow the curvature of the pan for about a third of the circumference; one end is stopped up, the other connected by indiarubber tubing to the water supply. At a distance of about $\frac{1}{2}$ an inch apart, fine holes are drilled in a line along the lower inner side of the tube. When the water is turned on, it issues through these small holes with considerable force, striking the water in the pan at a sharp angle, so that it and the prints are driven round and round during the time the water is allowed to flow; as soon as it rises above the bend in the syphon, the pan begins to empty, and continues to do so until the discharge is completed, when it again fills. This is automatically repeated during the time the water is flowing into it. The rapidity of the process depends on the size of the syphon and force of the water supply. It does not require to be very rapid; a syphon of ⅜ tube is quite large enough, the supply of water being regulated accordingly.

An arrangement for large numbers, or large prints, is shown in Fig. 8; it consists of a slate trough, 8 ft. long by 3 ft. wide, and 8 in. deep, with a false bottom of perforated zinc, made in sections for convenience of removal for cleansing. A syphon plug (Fig. 9) is adjusted in one corner. This plug is made of a short tube, one end of which fits into an aperture in the bottom of the trough, the upper end being about an inch and a half below the upper edge. This is surrounded by a case open at both ends, the upper end being an inch or so above the plug, and the lower half an inch above the bottom of the trough; when in position they are fastened together by solder. It will be seen by this contrivance that the impure water from the bottom of the tank is carried off, whilst the supply of fresh comes in at the top, thus setting up a continuous and thorough circulation. The method of keeping the prints from sticking together is by gently agitating the water by means of a paddle attached to a small water wheel (Fig. 10); a brass wire cage prevents the prints getting torn by contact with the paddle. In this arrangement no syphon is used, the quantity of water being considerable, and being steadily renewed the whole of the time is considered equivalent. If it is thought desirable to heat the water, hot-water pipes can be arranged below the false bottom. I may here mention that in all apparatus in which zinc is likely to come in contact with the silver print, the prints should be washed face upwards, for however well the zinc may be varnished or protected at first, the coating very soon partially wears off; but by keeping the *face* of the prints from lying in contact with the unprotected metal, no harm will happen.

Accessories.—Under this head is comprised almost everything that is used for pictorial effect in conjunction with the figure; it will be therefore out of the question to enumerate them. We will therefore in a great measure limit our remarks to a few of those things it is better to avoid. We will at once say, that anything that has an unreal appearance in the picture is bad, and that a theatrically made-up look is the bane of portraiture; both faults are so easily avoided, that it only proclaims the uncultivated taste of the photographer if he indulges in them. The inconsistent mixture of wild mountainous or other landscape scenery with fashionable upholstering and carpeted foreground is most absurd. The bizarre and extraordinary designs of studio furniture, such as are never seen in an ordinary household, are other objectionable points in the matter of accessories. The only deviation from the usual every-day style of furniture is, that it should not be polished; let it be chosen for chaste, elegant, or solid design, and the seats of the chairs not provided with springs, but merely firmly stuffed. The rest may be left to the good taste of the user; baskets, fans, and good artificial flowers will be found useful. Ferns and palms in vases are very effective. Curtains of rich material and Japanese screens are frequently admirable aids to composition. Having thus given a passing mention of a few of the most generally useful accessories, it may be left to the individual to select such things as will be most in accordance with his or her taste, and in harmony with the subject that has to be photographed.

THE BROOCH: HOW TO MAKE IT.

BY H. S. GOLDSMITH.

Catches of Brooches.

I think I said that a brooch tongue was but a piece of wire soldered on to a piece of tube, and with very few exceptions this is the case. Now that we are dealing with catches, they can be just as easily defined as some kind of hook, so shaped that it will retain the tongue in its position, and yet allow of its withdrawal easily.

You will see by glancing at the diagrams that the forms vary considerably; but throughout the lot the principle that is defined above is there. They are all hooks of one kind or another.

Now, undoubtedly, the main thing is that we obtain some piece of metal bent round in the form of a hook; and if our business did not (and rightly) lay claim to being an artistic one, I should be the last to desire anything more than mere utility. Neither should I bother about giving a good shape to this or anything else; but the whole *raison d'être* of our productions is that they shall give pleasure as ornaments, and to do that all the details should be carried out in the best way we know of, artistic as well as mechanical, even down to the catch, which is seen by nobody but the wearer.

To begin, as usual, with the simplest and most general forms, such as Fig. 1, A and B, we notice that the shape is a nice C scroll, or rather should be, of the shape of diagrams. But if you will take notice of the next dozen brooches you see, I feel pretty sure that four or five out of the dozen will be rather like the carelessly made ugly thing sketched in Fig. 1, D.

Perhaps it will not be wasted time if we consider the way to make them properly. It is but the same old story of beginning at the beginning: thus it is the *ends* of the wire or whatever you are using that have to be turned first—and it is the very end I mean that has to be bent; ⅛ of an inch from the end will not do unless you are going to be content with a wretched article like Fig. 1, D. When the ends are properly curved it is easy enough to get the other part into shape.

This ordinary catch is really so simple that I feel almost inclined to apologise for the foregoing; but it is these details that help so much in the style or character of the work—hence all this writing.

There is just a word more: and that is, don't get it too high. There is no actual need for the curls to be wider apart than just to let the tongue pass easily in and out. You will see what I mean by Fig. 1, C, where I have drawn the tongue in section in several places.

Also note that both ends are thinned down, both to improve the shape, and at the top end to facilitate the tongue's entry and exit.

The next sort I have sketched are examples of spring catches. They really ought to be called safety catches; but the custom of the trade decrees that "safety" is the word to be used when "protecting" catches are what is actually meant.

In Fig. 2, A and B, you see there is a spring acting against the lower part of the top curl of the catch, which is prolonged as much as possible, in order not to let the tongue drop down below it, and also to give an unmistakable lead when it is desired to unfasten the brooch.

Of these two, the first one (Fig. 2, A) is most decidedly the better, for this reason, viz., that the spring is a separate piece of gold, therefore you can make it of any quality you think best, and you can hammer it as much as ever you like; while if it is soldered like Fig. 2, B, there is the chance of breaking it off, besides the greater difficulty of getting it hard enough to act as a spring.

This separate spring in Fig. 2, A, is fixed in its place by a pin or screw passing through it; or you might pewter-solder it in its place.

Just a word or two about pewter-solder. Now I daresay in the course of these papers that I shall occasionally speak of its employment; but you must understand that it is not to be used as a rule for ordinary work—not even for repairs if it is possible to avoid it. It is a bad sign when it is always, or even often, used.

In this case, if sparingly, neatly, and cleanly employed, it is all right. But if not, then it but proves the rule against its use; and the fellow that slobbers his work all over with "soft tommy" as a regular thing, had better go and be a tinker at once, then perhaps he will have enough of pewter-soldering.

I think that I may say without exaggeration that, as a rule, double the quantity of pewter-solder is used more than is actually required to do the work it is wanted to do. But enough for the present on that matter. I daresay that I shall have to return to it later on.

Safety catches—that is, catches that protect the point of the tongue—are made as you see from the diagrams, Fig. 3, A, B, C, D, E, F, G, and Fig. 4, A, B, C, from both flat metal and from wire.

Every one is a means of guarding the point of the tongue, and so are Fig. 5, A, B, C, D. In Fig. 3, F′, is given the shape plate out of which Fig. 3, F, is made.

Fig. 3, E, F, and Fig. 4, B, are used for narrow bar brooches, and to show their width you will please refer to the next illustration for each, namely, Fig. 3, E′, F′, and Fig. 4, B′. Fig. 6 is shown as a type of ancient Etruscan work. There are a few in the British Museum of these fibulæ; and in my outline drawing, you may perhaps notice that the protective catch is very much there. As a rule these are beautifully ornamented with fine wire and small grains of gold; but sufficient for our present purpose is shown in the diagram.

Safety-pin brooches, as they are called, are now, and have been for some time, very fashionable. You will find but one in its entirety (Fig. 5, A), for it is of no use taking up space by drawing the joint ends to each when they are all alike—except that some make them with three instead of the usual two turns.

Fig. 5, A′, is the side view of the catch of Fig. 5, A. It is the neatest of all, and is mostly used in the best houses here in London—at least, I think it is.

Fig. 5, B, C, D, are simply different ways of forming them.

The last one (Fig. 5, E) is put in as a horrible example of how not to do it; and I should not have thought of introducing such a scarecrow but that I came across it as I was drafting this paper; and it had on its front a diamond beetle worth, I should say, about £15. Why, the one with the five turns (Fig. 5, c) is infinitely better, and that is one of the same pattern as they use in hospitals, etc., for it is the safety-pin (*i.e.* the non-scratching pin) of surgical practice that gives the name to this class of ornament, and may account for the double-barrel name—pin and brooch—that it bears.

Fig. 7, A and B, is the most usual way of arranging a fall-down catch. The catch is simply soldered on to a joint in such a manner that it can move about the quarter of a circle—that is, from its proper upright position to one where it lays down close to the back of the brooch. To prevent the catch falling *outwards* a stop is formed, either by the catch itself (Fig. 7, A) or by soldering a grain of gold to the side of the joint, which does quite as well. The method shown, however, keeps the work more compact, for the grain of gold would only be used when the catch is soldered on top of the joint. This is the catch I should use with any of the removable tongues I spoke about in my paper on Joints.

Fig. 8 is a slide arrangement, to catch the end of the tongue. It is shown open, with the tongue in position, while the dotted lines indicate its position when closed.

This is but one of the different forms that have been introduced from time to time, and the only one I have seen with a date, which is registered June 19th, 1848, and has the initial punch of G. U. as well. My Birmingham readers, and I daresay many in London as well, will recognise it as that of George Unite & Sons, a well-known firm of silversmiths.

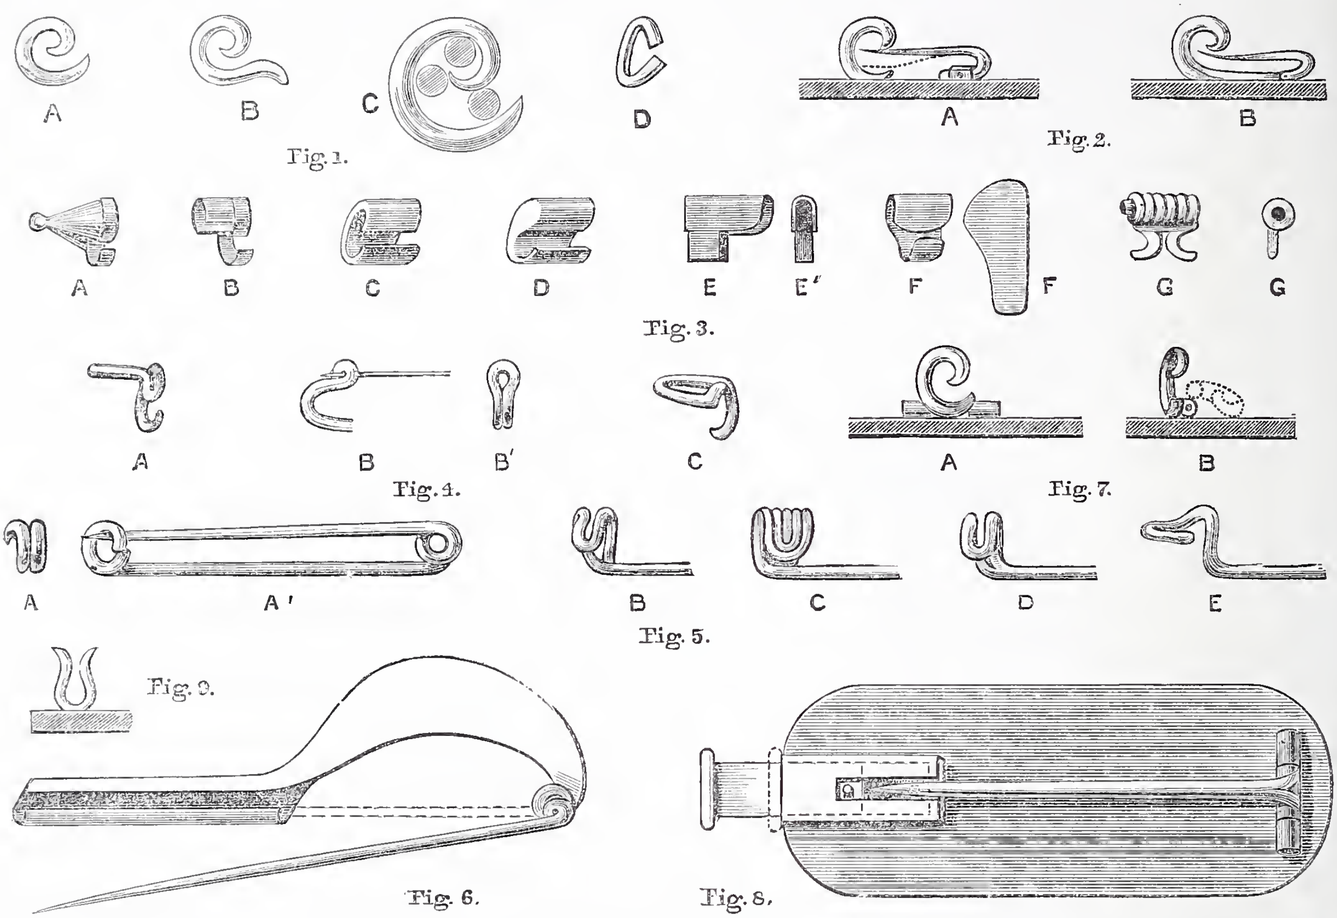
Several others have been made, some with a spring attached to the movable piece, but none seem to have obtained much favour; at least, one meets them but rarely, and then it is to find that they have been patented or registered. What is the reason of this scarcity? Is it the excessive royalty demanded, or the difficulty of finding the maker? or the fact that the simple scroll catch does not get out of order? Be the reason what it may, the fact remains that none of these strange arrangements have "caught on," as the Americans say.

Fig. 9, the lyre shape, is a clip catch that one can occasionally use to fasten scarf-brooches and ear-ring hooks. I know scarf-brooches are old-fashioned, but some customers will have their work done that way. And to steady the brooch, this shape catch is easier to adjust than the C shape, but does not hold so well, of course.

You see how it works. The two horns or ends act as springs to some slight degree, and retain the wire—clipped in between them—steady, but hardly secure.

The next paper to this will be on the positions that joints, tongues, and catches are to be placed, and in other papers which I trust will appear at some future time, I hope to take up some other of the numerous details of our business.

But with the article next to come, which will be a paper on brooch mounts, my instructions on brooch making will be complete. It will be noticed that my papers on this subject have been arranged in a systematic manner, so as to embrace the various details, and to touch on each and all in the order in which the workman would naturally have his attention drawn to them when engaged in the manufacture of this article. Thus the method employed in making the tongues of brooches was first dealt with, then the joints of brooches, and thirdly, in the present paper, the catches, a piece of curled metal on the under part of the brooch, used as a means of holding and retaining the tongue after it has been passed through the material to be fastened together by the brooch.



BROOCH CATCHES. Fig. 1.—A and B, Correct Shapes of Catches; C, Tongue in Section in several places; D, Bad Shape of Catch too often made. Fig. 2.—A and B, Forms of Catches with Spring to keep Tongue in place. Fig. 3.—A, B, C, D, E, F, Shapes of Safety Catches or Catches that protect Point of Tongue. Fig. 4.—A, B, C, Other Forms of Safety Catches made from Wire; B′, End View of B. Fig. 5.—A, B, C, D, Forms of Catches used in Safety-Pin Brooches; E, Ugly and Bad Shape of same. A CARVED BUREAU.

BY D. ADAMSON.

Chippendale's Frets and Ornaments.

Although Chippendale furniture is often spoken a good deal of, confusion exists as to what it really is, so perhaps it will be well to devote a short space to a few remarks about it. First and foremost, Chippendale was a prominent cabinet maker who flourished about the middle of last century. His business lay among the aristocracy, hence, along with his appointment as Court cabinet maker, it may be assumed that he was able to command good prices, which is sufficient to account for the careful finish which characterises all his work. As, however, he only followed—or, perhaps, to a certain extent led—the then prevailing fashions, much, indeed most, of the furniture which is said to be "Chippendale" is, undoubtedly, not of his construction—*i.e.*, it did not emanate from his shop. It may be quite correct to say that a piece of furniture is Chippendale *style*, but quite the reverse to say that it is "genuine Chippendale." The latter can only be truly said of furniture made under his superintendence; the former may be said of all that bears the character of his designs, whether by himself or not. As he published various editions of a well-known book of furniture designs, it is not surprising that we find many of them reproduced by cabinet makers contemporary with him, but there were also others who issued books of designs about the same time, some of them anterior to his. These being the same in their leading features, it cannot be claimed that Chippendale originated the style which goes by his name, but it may fairly be conceded that he produced many new designs in what, as a business man, he knew would meet the taste of the times. That his work was good is not to be gainsaid, so good, indeed, that we are apt to lose sight of the fact that his style—or the style of the times in which he lived — was not altogether commendable. He hardly descended to the fantastic vagaries of some of his contemporaries, and there is a certain refinement about his lines which almost disarms criticism of the style. Let any one compare the designs in his book with those published by Johnson, another artist of the same period, and the restraint of Chippendale will at once be apparent, however florid his work may appear when contrasted with other styles. It should be said that Chippendale's later work is not so meritorious as his earlier productions, which are free from many of the extravagances found in these. It almost seems as if, after having, no doubt, personally prepared his earlier designs, he left this part of the work to others not possessed of the same skill. Be this as it may, few will be found to dispute the fact that his style deteriorated as it advanced, and that few, except his simplest—and best—are desirable as models for reproduction, especially by amateur craftsmen.

As these remarks may not be in accordance with the notions of those who—generally without much, not to say without any, knowledge of the subject—"swear by" Chippendale, let me point out the singular mixture of styles, "Gothic," Chinese, rococo, etc., which he combined often in the same article of furniture. At the very least, it cannot be said that this conglomeration is in accordance with present taste; so that to make a bureau which shall be "Chippendale," and at the same time such as could be regarded with pleasure, we must confine ourselves to a simple mode of treatment. We find this ready to hand in the fretwork of which Chippendale made such free use. Much of it was avowedly derived from Chinese sources, but in addition we find that other ideas were engrafted along with them, so that there is no reason for confining the frets to those which are distinctively Chinese. To ornament a bureau in the manner indicated the frets should be cut out of thin wood—veneers will do very well—and glued on to the fronts of the drawers, etc. It must be understood that the veneers should be saw cut, not knife cut, as these are altogether too thin. If the three lower drawers are made of the same size, the frets for them may be cut together, as, the material being thin, it will be almost as easy to saw through the three thicknesses as through one; in fact, the risk of breakage while sawing will be considerably reduced. If, however, only one thickness is to be sawn at a time it will be necessary to protect it by cutting along with it a thicker piece of wood. As this is merely required to prevent the veneer being broken by the saw catching, a piece of pine will do very well. The fretwork may either cover the whole of the drawer fronts, or be limited to strips glued on round the edges, if a simple decoration is all that is required. In the latter case the labour is considerably diminished, as all the strips being of the same width, as many as convenient may be cut at a time. To hold them together while being sawn they should be fastened by small wire nails driven through the waste wood. The pattern, of course, must be on the top veneer before nailing together, in order that the nails may be only in the waste wood, *i.e.*, in the pieces to be cut out. Needle points may be used instead of small nails, but they are open to the objection that there is a risk of the veneers springing apart. This is not the case if nails are used, as these can be driven right through, and the projecting points hammered over to form a kind of rivet. This method is far preferable to the one sometimes adopted by amateurs of fastening the wood together by dabs of glue here and there. This may be done, but there is the difficulty of getting the glue only between the waste and preventing any of it getting between the parts which form the finished fret. It will be found to promote easy working of the saw if a piece of greased paper is fastened in between the veneers, as the grease forms a continual lubricant as the saw proceeds. Tallow is about the best medium, as being tolerably hard it is not absorbed by the wood. The paper used should be soft and not too thin — an old newspaper answers very well. As the paper is cut at the same time as the wood, on separating the layers of this it will be found that the papers are identical, so that they may be used as patterns for any repetitions of the fret which may be required. This may frequently save the trouble of drawing a pattern a second time, and the outlines are clearer than those reproduced by heelball rubbings. Owing to the difficulty that may be experienced in gluing the greased paper, template, or pattern on to the wood, it will be advisable, when duplicates for this purpose are wanted, to let one of the pieces of paper between the frets be ungreased and fairly thick. After the frets are completed, it is only necessary to glue them to the drawer fronts; but some care will be required to do this neatly and prevent glue exuding beyond them. It will be almost impossible to avoid this entirely, but any which makes its appearance should be carefully scraped away while it is still soft, for if allowed to get hard the difficulty of removing it and the risk of injuring the wood will be much increased. The glue should be applied thinly and evenly. If of the ordinary kind it should be freshly made, but for work of this sort Le Page's carriage glue, now obtainable at most dealers in tools, possesses many advantages. The fret must be well pressed down to ensure perfect contact and adhesion to the wood under it, any tendency to rise being overcome by weights left on till the glue is set. Should it be found on removing the pressure after the glue has hardened that any parts have failed to adhere properly, they may be laid

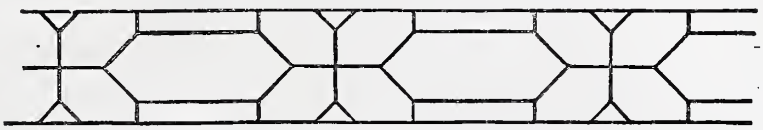

Fig. 8.

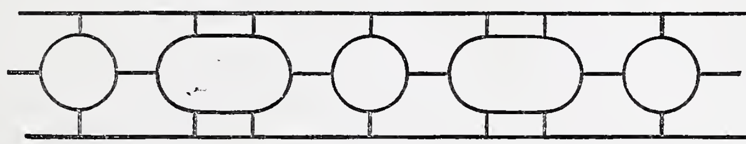

Fig. 10.

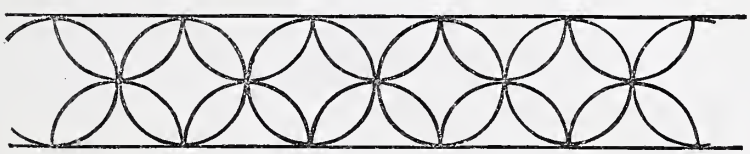

Fig. 11.

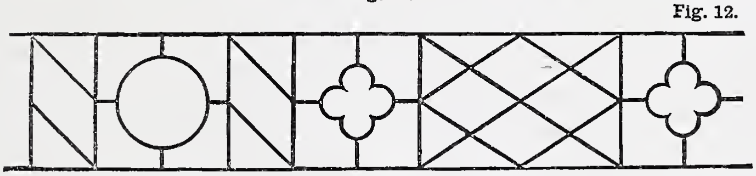
Fig. 12.



Figs. 8-12.—Examples of Chippendale Frets.

by the application of a warmed flat iron. This should be previously made hot enough to melt but not to burn the glue. Any defects of this kind ought to be rectified before the polishing is done, as the heat would damage the polish. It should also be said that there must be sufficient moisture remaining in the glue to permit the heat to soften it; therefore, blisters should be laid as soon as possible.

Now a word about the polishing of such applied fret and the ground on which it is fixed. It will be found that this requires much care to prevent the polish spoiling instead of improving the effect, the difficulties consisting in the almost impossibility of getting uniform brightness on the sunk portions, and the liability of any excess of polish in the rubber to congeal in the open corners of the fret. The best way to overcome these difficulties is to let the ground be dull, merely finishing it by oiling, and then giving the subsequent polish with a firm hard rubber to the surface only of the fret. This will then appear bright on a dull ground. A still better method, though involving more labour, is to polish the veneers before fretting them—when, after they are laid, it will only be necessary to oil over the groundwork, and to touch up the surface of the frets. Any oil getting on while finishing the groundwork will not hurt the polish, though it will be necessary to wash off any "sweating" which may, and probably will, appear in course of time. If the fret is only applied as bordering, it is hardly necessary to say that the remainder of the work should be polished thoroughly, either dull or bright, and not merely oiled. To those who are at all conversant with Chippendale's style, mahogany will at once suggest itself as being the most appropriate wood, though there is no practical reason why the work should not be executed in any other; for example, much furniture ostensibly reproduced, wholly or in part, from his designs, has of late years been finished black or ebonised. With the faces of the frets polished bright, and the remainder either dull or dead, the effect is rich, and there is the further advantage that choice, finely-figured wood is not required. However, if the work is to be of mahogany finished in its own colour, this should be darkened if the deep tint of old mahogany is wanted. It may be effected either by fuming with ammonia or washing a liquid stain in, but as the former does not raise the grain it is to be preferred.

The accompanying illustrations (Figs. 8 to 12) of frets are all suitable for Chippendale furniture, and as they are purposely selected for the facility with which they can be drawn enlarged to suit the work, it is to be hoped even those unskilled in drawing will be able to make use of them, for being of a geometrical construction they can easily be set out by means of ruler and compasses. It must be understood that these frets by no means exhaust the Chippendale style, but they are such as any amateur can easily cut, and they are, therefore, more suitable than those of more complicated arrangement. They may easily be cut in sections and neatly joined together when laying them, but it may be useful to know that any length can be cut with the ordinary fret-saw frame if this has adjustable clamps, so that the saw can be adjusted to work in different directions. The same may be managed, irrespective of the length under the arm, with many of the fret machines which have a perpendicular action, as, for example, the newer machines of the Britannia Company. The Chippendale style, which, as here exemplified, is given in its least objectionable features, seems soon to have outrun its popularity, and before closing the remarks anent it, an extract from a writer may be quoted, showing that even when it was all the rage it did not meet with universal approval by those who were unbiassed by fashion. Thus wrote an architect contemporary with Chippendale, mentioning his style:—"An unmeaning scrawl of C's inverted and hooped together. . . . . . It is called the French, and let them have all the praise of it. The Gothic shafts and Chinese bells are not beyond it nor below it in poorness of imagination." It will, of course, be understood that as we are not giving a full analysis of Chippendale, the features so strongly condemned are not included in the directions how to make a Chippendale bureau.

After the vagaries of the Chippendale style had exhausted themselves, it is not surprising that a strong reaction set in against the absurdly devised ornamentation which he affected, and it is with almost a feeling of relief that one turns to the simpler designs of Heppelwhite, the next in order of the trio of cabinet makers whose names are landmarks in the history of English furniture. As in the formation of the Chippendale style we may easily discover the influence of an architect (Chambers), so in the Heppelwhite may we trace the inspiration to the classical feeling which pervaded the works of later architects, among whom the brothers R. & J. Adam stand prominently forward. There is a refinement about Heppelwhite's lines, with a simplicity for which we look in vain among the productions of those cabinet makers immediately preceding him, but as applied to our bureau there is little that is sufficiently distinctive to warrant any lengthened description, without, indeed, so far complicating the work that it would be practically useless for the amateur artisan to attempt it. It may, however, be said that mahogany still remained the characteristic wood for good domestic furniture, and that the ornamental details of carving and inlay show a strong classical tendency, with great neatness of execution. The keynote of Heppelwhite's style may perhaps best be explained by an extract from his book, which we may well imagine was written just one hundred years ago, as it was published in 1789. His words run thus: "To unite elegance with utility, and blend the useful with the agreeable." As Heppelwhite worked in the style of the Bros. Adam, who, in addition to their purely architectural work, have left us some specimens of their smaller work in the shape of furniture, it is not incorrect to regard them as being identical. True, there are distinguishing features between the two, but it would be almost beside our purpose to consider them, and, as in the case of Chippendale, though for different reasons, an exemplification of Heppelwhite's style in an easy form is all that is required. As already stated, it does not in the case of plain carcase work offer any very marked characteristic, a certain severe simplicity being all that is required. In fact, if we make the bureau as originally described, but in fine dark mahogany with a little inlaid stringing, taking, let us say, the form of the Grecian key pattern, it may be said that the style is "Heppelwhite."

With this we may take leave of this great cabinet maker, whose works, though not perhaps like Chippendale's, "familiar in our mouths like household words," are yet deserving of consideration as marking very emphatically the return to a purer style. We may deny ourselves the further examination of Heppelwhite's style with less regret when we remember that the last and, perhaps, the greatest cabinet maker, as an artist of the eighteenth century, designed on much the same principles, developing the style of Heppelwhite (or Adams) with a grace and purity of line peculiarly his own. The maker referred to—Sheraton—published his first book of designs in 1793-4, and though ostensibly an educational work on drawing for cabinet makers, it contains representations of furniture in his best styles, for in his later works, published in 1803 and 1804, we find that there is an extraordinary deterioration, a fact of which Sheraton seems himself to have been conscious. Those who wish to reproduce his work will therefore do well to note this, as all is not gold that glitters, neither is all good that's Sheraton's. We find that he made free use of choice veneers and inlays. Many, I am aware, object to veneering, but when conscientiously employed there can surely be sound reason for regarding it as a legitimate means of decoration. Sheraton certainly did not think its use incompatible with either beauty of design or sound work, but exception must be taken to some of his arrangements, and the modern designer will do well to avoid copying them. I refer particularly to grain of the veneer running across instead of along the piece on which it is stuck. For example: in a drawer front the grain should run from end to end, horizontally, not from top to bottom, perpendicularly. Much more is this the natural way of arranging veneers on the frames of doors, yet it is often seen—happily not now so much as formerly—just reversed. Now, though Sheraton erred in this respect, it must not be supposed that he was the only one who adopted this construction; but, whenever found, it can only be regarded as faulty, unless, indeed, in the case of stringings or bandings introduced for purely decorative purposes, and should not be copied. If we wish to see how Sheraton's style may be adapted to modern requirements in the light of increased attention and knowledge to the principles of design, we cannot do better than study the modern inlaid furniture which is to be seen in every good cabinet maker's. This, popularly but erroneously regarded as Chippendale, is, in fact, the modern rendering of the principles which guided Sheraton, without, it is to be hoped, his faulty work, such as has been alluded to above. We find that Sheraton's furniture depends for its effectiveness not so much on carving, at least, where flat surfaces are concerned, as on coloured inlays, bandings of various woods, such as tulip wood, and contrasts between different kinds of woods. Rosewood and satinwood seem to have been a fashionable combination, the surface of the latter being often ornamented by decorative paintings of a delicate character, in the form of festoons, wreaths, garlands, ribbons, etc. Inlaid panels of a very similar character to those so often seen nowadays in rosewood furniture were also largely employed, so that the artificer who desires to work in Sheraton style will find plenty of scope for his talents and mechanical skill.

SMITHS' WORK.

BY J. H.

ARMOUR.

THERE was plenty of work for the armourer smiths in the Middle Ages. It would be interesting to trace the development of the arms and armour of that long period. Though few authentic specimens of ancient armour remain, we have history in tapestry, stone, and brass, by which we are able to rehabilitate the old knights. There was, first, the mailed shirt or hauberk, a woven fabric covered with chain mail, consisting of numerous rings in close contiguity. By-and-by the custom arose of covering the more vulnerable parts of the body more effectually with plates of iron, and this finally developed into the massive panoply of armour of the ages of chivalry—armour so weighty that a knight unhorsed was helpless and at the mercy of the meanest foot-soldier. The helm also protected the head itself against the battle-axe and mace, but afforded little or no security against the stunning effect of the blows dealt by those weapons.

The hauberk, or coat of mail, underwent various modifications. At one time it had a coif or hood, which might be drawn over the head, and over this the helm was worn. Below it was lengthened, and divided to cover the lower limbs. The sleeves were lengthened to cover the wrists. Gauntlets or gloves of leather, and leggings (*chausses*) and coverings for the feet, also covered with mail formed of small plates or rings, came into use. Then, when these were found insufficient for protection, arose the practice of protecting the more vulnerable portions of the body with plates of iron fixed by straps and buckles over the mail. These were at first fitted to the elbows, knees, and shoulders, and afterwards to the arms, thighs, and legs, first on the outer parts only, but afterwards clasped completely round the limbs.

The advantages and disadvantages of light and heavy armour were apparent in the Crusades. In the first Crusade the heavily-armed knights of the West coming into collision with the light-armed Saracen cavalry clothed only in chain or ring mail, bore down all before their solid phalanx. But, afterwards, the Saracens gained the advantages due to their lighter equipment under a Syrian sun. Lightly clad, they swept round the comparatively inert masses of their opponents, and attacked them on all flanks, watching their opportunities to beat down the long serried lances, and so bring their light swords into play. And thus they more than made up, by their swiftness and bravery, for the advantages gained by the heavy panoply of armour worn by the knights of the West.

By the close of the fifteenth century armour had about reached its highest stage of completeness, as far as multiplication of parts is concerned; though, in the matter of elaboration and ornament, a great deal yet remained to be done. At the close of this century a knightly suit of armour covered the whole body *cap-à-pie*—breast, back, shoulders, arms, legs, feet and hands, head and neck; and each separate piece had its distinctive name.

With the invention of guns and cannon the disuse of armour commenced. But, in the period of its decadence, there prevailed the utmost elaboration of detail and beauty of art workmanship. As its value in actual combat declined, so the richness of its ornamentation increased, and the work of the smith merged into that of the jeweller. To this period belong most of the suits of armour still in existence, and they are well worthy of careful study as specimens of handicraft of the highest kind.

Then the armour gradually fell into disuse before the spread of firearms. First the protection of the lower limbs was abandoned, the cuirass remaining to protect the vital parts of the body. Even this was presently felt to be a useless and intolerable burden, so that it was only with the utmost difficulty that kings and princes could enforce its use.

The armourers of Milan supplied the nobles of Europe with the choicest productions of their art. Suits of plate armour of steel were covered all over with elegant arabesques beaten up and then chased. Sometimes damascene work in gold and silver was added to the beaten arabesque work. Sometimes, again, the work was fluted, and polished like a mirror.

A study of the examples in the Tower, and in numerous other collections at home and abroad, will inspire us with regard for those who, with rude tools, could execute such intricate and difficult tasks as are involved in the formation of armour.

Our surviving specimens of armour are not so old as was formerly supposed. It is doubtful if any authentic specimens of the Norman period remain unaltered. Very little of the Plantagenet period remains. Nearly, if not quite, all of the armour in existence dates from a period subsequent to the introduction of firearms, when armour had become less valued for purposes of defence than for ornament, when it was used for jousting or military show rather than for actual warfare. The armour, therefore, which we can actually study affords, though of comparatively recent date, excellent examples of periods in which the art had reached its highest stages of development, in which perfection of workmanship was combined with the highest ornamentation.

In our great national collection of armour in the Tower, the development of the later period can be profitably studied. Beginning at the left hand as we enter the armoury room in the White Tower, we have the earlier specimens, consisting of mixed chain and plate armours. The making of this chain armour must have been a very tedious process, particularly when we remember that the wire itself had to be beaten out by hand. The rings are, in most instances, welded together. Some are of round wire, and others of flat section, with the appearance of having been stamped out of sheet iron. The dimensions of the rings of which the armour is composed vary considerably. For the most part they average from $\frac{3}{8}$ in. to $\frac{1}{2}$ in. diameter. In exceptional cases they are as large as $\frac{5}{8}$ in., or as small as $\frac{1}{4}$ in. They are, in some cases, lapped and thinned out, and apparently welded; others appear as though lapped and riveted, each with a minute rivet. In some examples rings punched from flat iron, and rings made of round wire with abutting joints, alternate in rows. Gradually the use of plate armour began to supplement the chain mail, and this transition period is well illustrated. At last we have the warriors armed *cap-à-pie* with plate.

The earlier plate armour was plain, that of later date is variously ornamented. At the first the pieces were ribbed or fluted with a succession of contiguous flutes, the effect being very pretty. Then engraving and damascening were resorted to, and finally attained a very high pitch of perfection. A suit of armour belonging to Henry VIII. in the Tower, presented to that monarch by Maximilian, is foliated and engraved all over with human figures illustrative of passages in the lives and martyrdom of St. George and St. Barbara, with the badges of roses and pomegranates, and the letters "H" and "K," for Henry and Katharine of Arragon. This suit was formerly covered with silver. The horse is also in complete armour. There is another suit of Henry VIII. beautifully damascened—that is, wire of brass, gold, or other material, is beaten into narrow grooves punched in the plate, and so worked all over into patterns more or less elaborate. The appearance of these suits of armour in joust and tournament must have been truly magnificent. But the minute details of workmanship are no less noteworthy.

Some of these suits of armour were very heavy. There is one of Henry VIII. weighing ninety-two pounds; another of Charles Brandon, Duke of Suffolk, bearing date 1520, of one hundred pounds weight. And these are built up of thin plates and minute rivets. The plates are bent to the difficult forms required to permit of the free play of the joints and various parts of the body, and then, besides, they are frequently fluted and covered with inworked or inlaid ornament. There is never a bruise to be seen—never any flat, or angular, or waved portions; but the curves are as perfect as though stamped between dies. Probably the hammering of the broad surfaces was done with wooden mallets, the work being laid on a bed of pitch or similar yielding substance.

The accoutrements are as elaborately finished as the armour itself. Spurs and bits are engraved similarly to the armour. Helmets, gorgets, casques, and morions are artistically finished. Pikes, maces, and roundels are also excellently made, and covered with engravings.

SIGN-WRITING AND LETTERING.

BY HENRY L. BENWELL.

EXPANDED LETTERS—ELONGATED, CONDENSED, AND COMPRESSED LETTERS—HAIR-LINE ITALIC—HOW TO SET OUT, LETTER, AND FINISH A SIGN—SPACING, ETC.—PAINTING ROYAL ARMS, ETC.

HAVING digested as thoroughly as space will permit the subjects of ornamental and church lettering and other matter appertaining thereto, I have now only to draw attention to one or two other much-used forms of letters before finally quitting the subject.

I refer here principally to letters that have to be somewhat distorted in shape to suit the exigences of space, which in some cases is too much, and in others too little. Let us first take the case of having to write a rather short name over a shop-front or on a long narrow board or surface. In this example the ordinary-shaped letter could not be made to fit or look well, and we therefore have to expand it, so that it may not only fill out the long space better, but also be sufficiently decreased in height to come within the compass of the width of the board and allow for shading, etc.

We do not in reality decrease the height of the letter, but use a letter small enough for the purpose, and widen this to such an extent as not to look positively ugly, and which would be the proper width of a much higher letter in its normal form. When, therefore, it is desired to fill out an extra long line with expanded letters, the expansion must be proportionate throughout, so that the work may have a symmetrical appearance.

This expansion can be executed with mathematical precision according to the following method:—

We will suppose that we have to put some letters on a signboard 6 ft. long by 1 ft. 6 in. wide, but that the ordinary letter, properly spaced, would only extend to 3 ft. 3 in., and that we therefore require to expand the letters so as to make them up to 5 ft. We must now refer to the diagram which is given in Fig. 81, and drawn to a scale of one inch to the foot, roughly. The length of the normal letters, 3 ft. 3 in., is from A to B, and we have to spread them out 1 ft. 9 in. without increasing the height. We first rule two parallel lines at any convenient distance below, and 1 ft. apart and 6 ft. long, *i.e.*, from C to D. We now draw a diagonal line, A to D. Then draw slanting lines parallel with each other from the bottoms of the top row of letters to the diagonal line, and from there vertical lines to the line C D. If we now proceed to draw in the bottom letters according to these lines, the result will be as shown in the diagram. Letters can be extended as much as possible by this method by simply increasing the slant of the diagonal line, and they may also be condensed

Fig. 75.—Alphabet of Expanded Letters.

by drawing the diagonal line within a shorter compass—as, for example, from A to E. To use this problem in actual practice, the student may either work it out, as I have done here, in a scale drawing, or draw the letters full size on two lengths of lining paper tacked to a wall or floor, and the outline of the extended letters prepared for pouncing the design upon the signboard. An alphabet of expanded letters will be seen in Fig. 75, and some Expanded Ionic in Fig. 80.

Elongated letters are just the reverse to the former series, and are principally used in circumstances where the surface to be lettered is very short in length, but of an unusual height. I do not know that I can give any practical advice concerning them, but a reference to Fig. 79 will illustrate form and probable usefulness.

There are also condensed letters, such as the letters H, E, R (Fig. 78), and compressed letters, as T (Fig. 82), which all come in useful on certain occasions. Other useful alphabets are the italic and hair-line italic, a full complement of the last-named being shown in Figs. 76, 77.

Having now finished my remarks respecting the various styles of letters and the method of forming them with truth and graceful outline, I will now describe how to put them to practical use in "setting out" and lettering a sign. Taking it for granted, therefore, that the signboard is quite ready to work upon, we make a start by damping the whole surface with a wet chamois leather. This simple process must always be gone through, otherwise the colours will "ciss," and no end of trouble will be the result. This "cissing," as it is called, refers to the colours running off the ground colour and leaving a ragged edge instead of a sharp clear outline. This can only be rectified by the workman going over the same outline repeatedly, with the natural result of deteriorating the quality of the work when complete. Even this, however, will not always cure the evil. If the student finds his colours "ciss" after damping his board, he should give it another rub over with the leather, and should that fail to improve matters he must conclude that he has too much oil in his colour, and may be it is also too thick. He should, therefore, thin it with a little turpentine. I have always found that the addition of a little turpentine will at once prevent the colour from "cissing," and it, of course, makes the colour flow easier from the brush.

The size and character of the letters being determined upon, we strike the necessary lines to contain them, and proceed to set out the writing with the prepared pipeclay mentioned in a previous chapter.

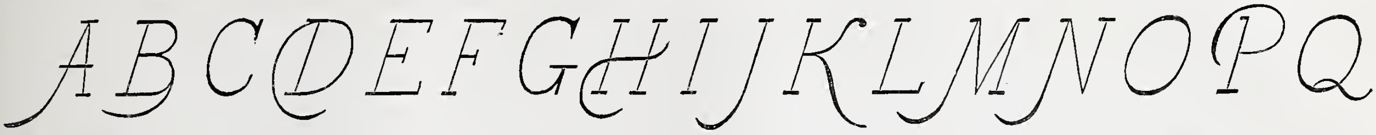
Much depends upon this setting out and spacing of the letters, as it may mar or make the success of the young workman's effort; for no matter how well shaped the letters may be, if they are badly set out the whole work will look clumsy and inartistic.

In the first place, we must mark the whole of the letters out in a very light and sketchy manner, taking pains to make them fill up the board as evenly as possible. If when finished they do not "come in" properly, we must wipe out the chalk marks with the damp leather and try again. Great care must be taken not to press the pipeclay upon the ground surface, otherwise it will leave unremovable markings. With practice the young writer will soon be able to set out his letters with the utmost exactitude. But there is another matter to be considered, and that is the spacing of the letters themselves, one from another, as it were. In printed matter the letters are all spaced the same distance apart; not so, however, in sign-writing. The letters A, J, K, O, Q, P, V, and W, Y, if not some others, require to be placed closer to their neighbours on either side than the rest of the letters, for the simple reason that they are not of the same width throughout, and therefore leave a much greater space between letter and letter. A reference to any large printed matter, or to the alphabets given with these chapters, which are, no doubt, evenly spaced by the compositors, will prove the force of these remarks, and point out to the novice how to avoid the appearance of uneven spacing, which, strange to say, truthfully-spaced letters always give. The name, or whatever the matter may be, must be exactly in the centre of the board, with an equal space or margin at each end.

Nothing displays the want of skill in a workman quicker than the careless arrangement of a name in large letters, and which leaves a wider margin at one end of the board than the other, yet it is frequently seen, through indifferent spacing.

We will, however, take it that at last the letters are properly spaced and marked out, so we must next turn to our colours and pencil, and prepare for outlining them in colour. Having got the pencil into working order by dipping it in a little "turps" and wiping out any excess with a piece of rag, we spread sufficient colour upon the palette with the palette knife, and thin it out to a proper working consistency. I cannot give any exact guide as to the best working consistency of any colour. It should, however, be somewhat thicker than good rich cream. If too thick, it will not flow freely from the brush, and will probably "ciss;" if too thin, it will not only not cover sufficiently, but will very likely run and spoil the work. It must be absolutely perfection; a little variation either way will put everything out of order, and the workman out of temper.

The letters should be outlined boldly with a pencil well charged with colour, and which should not leave the surface till the outline is complete from top to bottom.



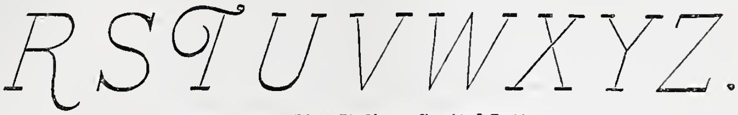


Fig. 76.—Hair-Line Italics: Capital Letters.

Fig. 77.—Hair-Line Italics: Small Letters.

Most amateurs and beginners make their outlines in a series of short strokes, and frequently stop in the middle of a line to recharge the pencil with colour, which renders the letters of a shaky aspect, and betrays the nervous, unpractised hand. Of course, in very large letters, the pencil will not hold sufficient colour to enable the operator to work from top to bottom without a break; but, as such letters are generally at a good height, distance softens off any imperfect or ragged outlines. If the student takes care to refill his brush with colour before starting on every fresh line he will generally find it hold out to the end. He must remember that the larger the letter, the larger the brush and its holding capacities, and so there need be no excuse for short, uneven strokes in any moderately-sized work. It is, I admit, more difficult at first to make a line in one continuous stroke than in two or three, but if the beginner once gives way to the latter method, faulty and unworkmanlike as it is, he will have great difficulty in shaking himself free from it in after life. The hand must not rest on the sign; if it be an unsteady one, the wrist may rest on the mahl stick, or upon the wrist of the left hand; but never touch the sign, or it will be cramped and hindered in its free movement. In curved letters this is especially so, as nothing is so necessary for their correct formation as a bold, free, and pliable hand. For the sake of practice, the student should make all his outlines of the same thickness throughout, as he will find this somewhat hard to accomplish at the onset. When the outlining is complete, the letters are filled in with a short thick brush (Figs. 44 and 44a, page 357), and then leave all to dry. On the succeeding day, the thicknesses (if any) are added and the shadows "put in," and, after undergoing any little extra touching up, we may consider our job finished and ready for varnishing. If the work is surrounded with a plain or fancy border, corners, and other ornaments, they are naturally proceeded with along with the letters, and the whole completed together.

One last word as a caution: Always use the point of the pencil in outlining, and you will get a straight even line; but, use it on its side, and it bulges or shrinks in with the varying pressure of the hand, and a waved, or "in and out," line is the natural consequence.

In italic and script lettering, the greatest care must be taken to keep the letters all of the same slope or slant, and, for this purpose, the workman had better make himself a few set squares, which may be used as guides. The slant in italic letters should not be so great as that used in ordinary script or writing characters, hence at least two set squares would be necessary. In script writing the capitals should be just double the height of the ordinary or lower-case letters. It seems now to be fashionable to use script writing for indicating milliners' and such-like businesses, for which it seems very appropriate, especially gold letters on a black ground. It should always be the endeavour of the sign-writer to make the style of his letters appropriate to the trade they indicate as far as he finds it practicable to do so. Some businesses allow of much more showy colouring than others, as I have already pointed out in a previous chapter.

In varnishing the completed work, it is best to give it three thin coats, well worked, than two thick ones, allowing each to dry thoroughly hard before applying the next. By doing this, the workman may do much to prevent the sun from cracking the varnish and blistering the paint.

Messrs. Wilkinson, Heywood & Clark make a splendid varnish specially for the use of sign-writers, and the name of this firm is, I think, a sufficient guarantee of good quality combined with a moderate price.

I will now describe the method of painting a few of those common objects, or ornaments as some prefer to call them, which the writer is so often called upon to execute as a part of a tradesman's sign or of an inscription on a trade cart. We also frequently

see the best work surrounded with a plain or an ornamental border which cannot very well be dispensed with, even if the writer is accustomed only to the simplest of work. Starting, then, with Royalty and the Royal tradesman—happy and favoured beings—I will first take in hand Her Majesty's Coat of Arms, which, I need hardly say, is always executed in gold and certain regulation heraldic colours. Now, I am honest enough to say that I know very little about heraldry, and also that I have never painted the Royal Arms in my life, for the simple reason that I have never had occasion to do so; nevertheless, if I had, I am one of those sort of fellows who "would be bound to do it." I am, however, going to rely on the undisputed authority of Mr. Wm. Sutherland in regard to the Royal Arms, and in doing this I know my readers and I are in safe hands.

The Royal Arms of England, with which are combined those of Scotland and Ireland, consist of a shield surrounded by the ribbon of the Most Noble Order of the Garter. The shield is surmounted by a royal crown, upon which is a lion, also crowned. The shield is divided into four equal parts—the first and third quarters are blazoned with the arms of England proper, viz.: three golden lions on a red or vermilion ground. The second (Scottish) quarter of the shield is a red lion rampant, that is, standing on its hind legs, pawing the air with its fore legs, surrounded by a tressure, that is two lines a little way apart, having small *fleur de lis* at each corner, and on the sides. This tressure is red also, the ground being gold. The fourth quarter of the shield is occupied by a gold harp on a blue ground, being the Irish national emblem. Round the shield is placed a blue ribbon with gold edges, upon which is displayed the motto of the Order of the Garter, *Honi soit qui mal y pense*. Each side of the shield is supported by a lion and a unicorn; the lion to the left, as we look at the shield, and the unicorn to the right. The unicorn has a gilt horn springing from out of his forehead; round his neck is a collar of gold, to which a gold chain is fastened, overlapping his body, and secured below. The lion is painted proper, that is in natural colours; the unicorn is white with gold hoofs, and the tip or tuft of hair at the end of his tail is also gilt. Underneath the shield are scroll ornaments upon which the feet or claws of the animals rest, and upon which also a ribbon is hung. Upon the ribbon is the motto, *Dieu et mon droit*. This ribbon is blue, but generally of a lighter colour than the blue of the garter round the shield. The letters on both should be in gold, outlined with black. Underneath the shield and springing from the scroll ornament are conventional representations of the rose, the thistle, and the shamrock, national emblems of the three kingdoms. In painting this, or in fact any heraldic emblem, every part of the work is outlined with black, and shaded more or less. The gold is best shaded with burnt sienna, with a little burnt umber added; and the white parts, with Vandyke brown and ultramarine blue, or with blue black alone; the reds and blues with purple lake, or burnt umber and crimson lake. It must be understood that the colours of coats of arms are fixed, and therefore there can be no departure from them or we create false heraldry.

I will now describe the arms of the Prince and Princess of Wales. As Prince of Wales His Royal Highness bears the shield of his mother (as Queen of England), differenced with a silver label of three points, as the Princes of Wales, his predecessors from the time of the Black Prince (who was the first English Prince of Wales by creation), have borne the Royal Arms with the same difference. Accordingly the arms of the Prince of Wales are quarterly, first and fourth England; second, Scotland; and third, Ireland; the label being in chief (*i.e.*, on top part of shield), and extending across the entire width of the shield. Upon this shield that of Saxony is now charged in pretence. The arms of Saxony are *barry of ten, or, and sable, a crown of rue in bend, vert.*

His Royal Highness also bears the feather badge, the well-known cognisance of the Prince of Wales. The three ostrich feathers of the famous badge were first ensigned with a princely coronet by Edward Tudor, Prince of Wales, son of Henry VIII.; and Henry Stuart, eldest son of James I., established the arrangement of the feathers within the coronet as they have since been blazoned. A single ostrich feather having a scroll with the motto *Ich dien* (I serve), may probably have been borne, after an early usage, by the Princes of Wales.

A coloured sheet of the Royal Arms of England appears in Part CVIII. of "The Journal of Decorative Art" for December, 1889. It should prove very valuable to the sign-writer, who so frequently has to paint it on signs and trade vans.

MEANS, MODES, AND METHODS.

A Lost Colour Material Discovered.

The brilliant blue of the Egyptians and Greeks in use more than twenty centuries ago was regarded as lost to modern science and industries, as it had been out of use for many centuries. The traces of it were manifest in the ever-brilliant colours in the Pyramids, Greek tombs, Pompeii and Roman tombs, and in the frescoes from walls preserved in the Vatican.

It was sometimes called the "Egyptian Blue," and by the Romans—who never scrupled at appropriation—the "Vestorian Blue." Several chemists of note tried by analysis to ascertain its constituents—Sir Humphry Davy, amongst others—but without result.

Vitruvius, a Roman writer of about the calibre for science of our daily journalist writers, gives a description of its composition of about their stamp of writing, and worthless to workmen or scientists. In the many attempts to reproduce this colour, the experimentalists showed sad lack of comprehension by using alkalies, acids, and compounds not at all likely to have been in the laboratory of ancient pigment-makers. Had they gone to Egypt to do as the Egyptians of old had to do, they would not have found these materials within handy reach. A French chemist, M. Fouqué, took a common-sense view of the matter, and for his colour used oxide of copper; for his bases, lime and silica; and the pigment material only needed a bright red heat and patient mixing, and the long-lost blue of the ancients was revived, and will form a new commercial article of surprising cheapness, and no money wasted in patenting it.

The proportions of the ingredients are:—

Silica	63·7
Lime	14·3
Oxide of copper	21·9

The variation of the quantity of copper, of course, affecting the intensity of the colour, or its tint and shade, may be modified by oxides of other metals.

As a dye-stuff, it is as good as it is as a pigment. J. C. K.

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

125.—A New and Good Self-Clipping Buckle.

I have received from Central India a specimen, with drawings, of a new—as far as I know, remembering that there is nothing new under the sun—and good—which I think nobody who sees it will deny—self-clipping buckle, with which, I must confess, I am very much taken. The sender of the article in question writes:—"I am taking the liberty of sending you a patented invention of mine in the shape of a 'self-clipping' buckle, if you would be good enough to notice it in 'Our Guide to Good Things.' I am desirous of selling the thing, and would be glad if you would mention this in your notice. You state in Work that you are willing to bring forward anything new like this, so I hope that a request such as I am making will not be thought impertinent, especially when it is considered how greatly handicapped one is in being so far from England in trying to dispose of such a thing, it being so difficult to find out from this outlandish place who exactly are the people who would invest in an article like this, besides a great amount of time being lost in carrying on correspondence. From the specimen I send you by this mail and the enclosed drawing, you will see that pulling the strap tight makes the buckle grip it, and, theoretically, the harder the pull the greater the grip. No holes are required in the strap, and a special feature is that the thinning of the strap through wear can be compensated, for which purpose the upper clipping limb is made curved. When the strap wears this limb has merely to be flattened, thus bringing the two gripping bars closer together. To loosen the buckle and free the strap the central bar has merely to be lifted with one hand, instead of having to employ both, as in the ordinary buckle. It could be made as cheaply as an ordinary buckle, and if desired wholly of wire it could be made as shown in Fig. 2 of the drawing. The buckle is well adapted for bedding straps, Gladstone-bag straps, tourniquets, leggings, ladies' and gentlemen's belts, etc."

I have now done what I have been asked to do by my correspondent, whose letter shows me that Work has made its way into Central India, and is read there by Englishmen and appreciated. "But where is Fig. 2?" some reader may say. "I don't see it here, nor do I find Fig. 1, and as Fig. 2 is mentioned, I suppose there must of necessity be a Fig. 1." True, oh, reader, but the giving of the drawings would have revealed the whole secret of the buckle, respecting which I must, for the writer's sake, preserve a fitting reticence until the invention is safe in port, if it be really a new thing. It is declared to be a patented article, but I do not know that it is patented in this country. When the time comes that the drawings may be safely published, they shall find a place in Work. Meanwhile I shall be happy to show the article itself to any well-known manufacturer of goods of this kind who might wish to enter into communication with the writer with a view to purchase his rights. Men who live at home can have help rendered to them more directly in other ways. I am in sympathy with every inventor who has a good thing to place on the market, and is seeking to make his invention profitable to himself, but much more so with those who are heavily handicapped by distance from the place where buyers and sellers most do congregate, and it is this sympathy which has prompted me in this case to step somewhat out of the beaten course, and to set up a fingerpost to what I believe to be undeniably a "good thing." The Editor.

A Corner for Those who Want to Talk It.

NOTICE TO CORRESPONDENTS.

*** *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Steel Distorting.—Worker Bee writes:—"In 'Shop,' page 476, I observe A. B. C., in reply to a query on this subject from G. H. (*St. Helens*), gives it as his opinion that the steel became distorted in tempering by being heated 'too hot or not dropped perpendicularly into the oil or water to cool it.' May I point out to G. H. that there are many other reasons why his steel became distorted in tempering besides the one given by A. B. C.? The chief and most difficult to avoid is the treatment the steel has been subjected to in forging. If it has received a greater number of blows on one side than the other, or the blows have been given with greater force on one side than the other, although the steel may be straight when dipped into the cooling bath, it is certain to become distorted during cooling in proportion to the inequality in number and force of blows given during the forging process. Not knowing the article G. H. has been making, I will suppose it is a taper steel bar. It has been forged, and now he wishes to turn it in a lathe and afterwards temper it without risk of distortion in the latter process. Let him proceed thus. Having centred it, take a rough cut from end to end in the lathe; now make it a dull red heat throughout, and plunge it into dry slaked lime or charcoal dust, and allow it to cool. When cold take another cut down it in the lathe, and repeat the heating and cooling process. Unless the bar has had extra rough usage during forging, this will usually be sufficient. It may then be finished in the lathe and tempered, and be found free from distortion, but if doubtful, I have seen it heated and cooled the third time before finishing. If the article is flat instead of round, and fitted by grinding or filing, the same process must be observed if you wish to be very accurate. The cause of distortion, you will gather from the above, is the outer surface has become of a closer texture in some places than others, and unless that surface is removed it is certain to contract greater there than elsewhere, when 'cooled' during the tempering process. Without wishing to be hypercritical to A. B. C., I venture to write this, on the principle of 'help one another' that prevails in 'Shop.'"

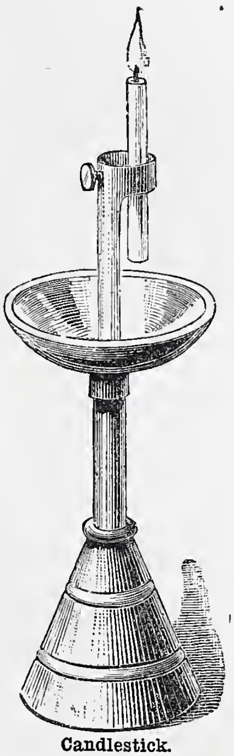
Incubator.—J. O. K. (*Aylesbury*) writes:—"Will W. L. (*Kingsland*) kindly enlighten me on a few points as to his mode of making incubator? I will put the questions. (1) What size garden pots would he allow for, say, fifty eggs? How does he regulate his heat? He must have a thermometer, considering the thickness of sand the heat must penetrate before it reaches the eggs. (2) Does he close the top of the upper pot to keep the heat in? (3) As the eggs require damping at times, how does he manage that part? (4) Would not two pails answer the same purpose, as one bottom would fit close into the other, and only one piece of tin would be required to fit, or the bottom pail might have a large hole cut so as for the heat to reach the bottom of the upper pail? I have seen the water tank used to heat by steam, but never the arrangement named by W. L."

Home-made Articles.—B. G. S. (*Dover*) writes:—"You seem to have discovered a clever mechanic at last. Have you seen these productions of H. G.'s (*Bishopsgate*) (see page 636), because I can't quite believe in them, though they are said to be made with the aid of a keyhole saw, an iron chisel, and a shoemaker's knife. Not a large tool chest required for those. Why, the dresser rails would have to be turned. What about the rails being decently round. I don't wonder he refused 20s. for it. It must have taken a month to make. And these are all his first attempts! He must indeed be a genius. Is it true? Have you seen the articles, or only his sketches? I can do them that way out of books with a little tracing paper."

Bell Metronome.—R. F. (*Norwich*) writes to Fiddler (*Glasgow*) (see page 654):—"I would say 'Go it, Fiddler, there's nothing like asking for enough when you are about it.' His very modest request is something like asking for instructions how to make a clock, and is quite outside the limits of 'Shop.' If I thought it would be of sufficient interest, I would, with the consent of the Editor, get up a paper on the subject, but as the articles in question are very little used except by music teachers, and can moreover be purchased very cheaply, I think it would be using valuable space that might be devoted to subjects more interesting to a larger class of readers."

Purchasing Timber.—A. J. H. (*Brixton, S.W.*) writes:—"I have read with surprise the remarks by A. R. (*Scorrier*) (see page 635). How long has he been in the trade not to have learnt yet that a 2-cut is always understood to be 3—1-in. boards, and a 3-cut 4—⅝-in. boards? I am quite aware that they do not measure the exact thickness, but few expect this. In fact, speaking from twenty years' experience, I do not remember more than two or three persons who required a 2-cut deal to cut 3 full 1 in. board. A. R. must be aware that every thickness in the trade is calculated to run the size less the saw cut, and that the only boards that do hold the full thickness are those cut on the 'other side'—*i.e.*, at the mills when the timber is first cut. Of course, if a customer requires a full 1-in. board, a deal can be cut for him, and leave a ⅝-in. board off. I presume A. R. must have left his thinking cap at home—that is, if, etc., when he wrote his letter. In writing the article I gave only the trade sizes and expression, so that the amateur could be on a level with the professional in asking for his timber. I may add that I have had the article quoted to me in the yard, thus showing that it has been of some use to the many readers of Work."

Candlestick.—W. W. C. (*Peterboro'*) writes:—"The enclosed drawing of the raised cup candlestick I send to the editor of Work to illustrate it in a place in any part of the paper."



Candlestick.

Misuse of Terms—Bookbinding, etc.—H. B. (*Jarrow-on-Tyne*) writes:—"I have repeatedly noticed correspondents use the word bore in relation to metal. Now I always understood that wood was bored, but that metal was drilled. Again, as a practical joiner, I must take exception to the way in which Mr. B. A. Baxter is teaching young joiners how to use the mortise chisel. In the number for December 28, page 647, Fig. 4, I think most practical joiners will bear me out that the chisel is turned the wrong way, and for this reason the chisel as there shown has a tendency to jam the core in the mortise, whereas if used the reverse way the tendency is rather to free the core than to jam it. To refer once more to the misuse of terms, in the part of the country where I served my time (Norfolk) the outer uprights in the framing of a door were always called 'mullions.' Now I find almost invariably in Work correspondents use the word 'munting'—Mr. Baxter, to wit, in the above mentioned article. Now in the only dictionary I happen to have by me at present (it's only a small one, 'tis true) I don't find the word munting, but I find mullion—a bar in a window frame. Now even that, I think, is scarcely correct. Strictly speaking, a mullion in relation to window frames is the stone or brick upright or column that divides a window opening into two. I would like to correspond with some subscriber who is interested in bookbinding with a view to mutual help. I have carved a piece of mahogany with the word 'Work.' If any subscriber who has facilities for casting small articles in brass would like to have one, I would lend him the pattern if he will cast me one. They are for lettering the back of Work when bound."

Copies of Fretwork.—F. C. (*Leytonstone*) writes:—"Perhaps the following method of making copies of fretwork designs may be useful to some of your readers. Instead of cutting one piece of wood at a time, clamp two together, and put three or four pieces of paper between them, then cut. The saw will cut the wood, and the paper as well, and as many pieces of paper as are used there will be copies of the design. A piece of thin copper or tin-foil may be used instead of the paper, and thus make a stencil plate."

Fret Machine.—Sceptic (*Brixton*) writes:—"I notice on page 636 of Work that A. A. (*Coventry*) has been kind enough to give particulars of a fret machine which he says works well. I should esteem it a favour if he would answer the following questions:—(1) When the frame is down how does he get it up again—he has no flywheel in the illustration? (2) Does it require two people to work it, because the saw frame is parallel with the treadle? (3) If you want to cut the inside of any piece of work, how is it done?"

Blowpipe and Fan.—W. G. (*Cheltenham*) writes:—"As a reader of Work, and rather an impatient one for every weekly number, I should like to ask A. S. P. what he means by a curve to a radius of twelve inches for a fan. I should esteem it a favour if he would explain it fully for me to understand, as I am making a double fan, and should like to see section of curved fan blower. I understand fully everything else."

Organ Materials.—B. F. (*Birkenhead*) writes:—"There are many inquiries by amateurs for organ pipes and parts. I once started to make one, but it cost too much. I saw one with, I think, four stops and room and holes for more not put together, the case all complete for £7. It stood about 7 ft. high, and was to be seen at Mr. Hall's, 4, Moor Place, Liverpool. He might sell the parts. My advice is, take the lot and fit it up yourself."

Belts Slipping.—B. F. (*Birkenhead*) writes in reply to J. P. A. (*Walthamstow*) (see page 524):—"I use this every day on the boiler or steam chest: Place an old tin with tallow and resin mixed together like glue; not too much tallow. Stir it up, apply hot while in motion, pour on. Put it back when done; it will always be hot and ready. You will find it stick."

Brazing Machine.—A. X. E. (*Nottingham*) writes "that the maker's name of the brazing machine referred to on page 635 is Thomas Duncan, machine maker, 305, Manchester Street, Oldham, and not Duncan and Mills, who are the patentees only."

Cigarette Maker.—C. W. B. (*Plymouth*) writes:—"I have had a cigarette tube made out of a piece of brass tubing in accordance with the sketch shown on page 670, but find it a complete failure for the purpose intended. The ends were left open to allow the stick to pass into the tube. There is evidently a defect by the open space where the tubing is hinged causing the tobacco to jam instead of passing freely through it. My idea is that a thin slip inside would obviate this defect."

A Simple Incubator.—B. F. (*Birkenhead*) writes:—"I have been busy or would have written earlier. Thanks to those who replied to my question *re* a simple incubator (see page 302). Mr. W. L. (*Kingsland*) (see page 557) says cut a piece of tin to connect the two pots together, but he does not show how far up to keep the sand from going below. Won't it burn the flannel? I thought the heat should be above the eggs, not below. The tin could go through, and a bollow tin box on top to throw down the heat. B. A. B. (*Hampstead*) (see page 573)—thanks for your reply. I had seen on dissecting an old Bourdon pressure gauge a hollow horseshoe shape which expanded, telling the steam pressure. I have a plan which I am working on that will turn the lamp off and on for the gas as required, similar to the governors of an engine. This idea I am going to sell, or get a partner and patent it. The whole affair could be made for 2s. 6d. It can be used for anything requiring steady heat, stoves, etc. Did any reader hear of such being patented? It is self-acting on the burner of lamp damper or gas. No chemicals or hollow vessels; cannot get out of order, being so simple."

II.—Questions Answered by Editor and Staff.

Colouring Brass Work.—Plumber (*Glasgow*).—I find that a beautiful violet colour is imparted to brass work by the application of chloride of antimony. Get the work perfectly bright and clean by the usual methods, either in lathe, or by dipping, etc.; heat it over gas flame or spirit lamp, so that water will steam off it but not fizz, and then apply the chloride of antimony liquor with a piece of rag or pad attached to a piece of wood; when the metal has assumed an even colour polish by rubbing with a soft cloth, perfectly clean and dry, and protect with a coat of clear lacquer. Should you prefer a darker colour use either of the following recipes:—(1) To 1 part oxide of iron, or iron filings, add 1 part arsenic, and 12 parts hydrochloric acid. Dissolve the oxide of iron or filings in the acid, then add the arsenic; strain, and bottle for use. (2) One pint of strong vinegar, 1 oz. of sal ammoniac, ¼ oz. arsenic, ½ oz. alum; dissolve in the vinegar, and bottle. These mixtures are to be applied in the same way as chloride of antimony, and, as you are doubtless aware, the ultimate shade may be varied by treating with various lacquers. In all cases the work should be polished with a dry cloth immediately the desired colour is obtained, and in the case of the two latter recipes the work should be lacquered at once, but with the chloride of antimony this is not essential. With regard to Florentine bronze, I should be glad to hear some other contributor's views upon the subject, as I am not aware of any recipe for a mixture, etc., which will impart the desired red shade, and also a metallic appearance. The only recipe I know of is the following:—The work having been finished bright and clean, is covered with a thin coating of copper. Now make a paste with Spanish brown, 12 parts, and blacklead 1 part, in hot water. Dissolve a small quantity of oxalic acid—say as much as will fit on a sixpence—to ½ lb. of other ingredients, also in hot water, and thoroughly mix the whole; thin with hot water to a workable consistence, and apply with a soft brush. When dry, polish with a medium brush. This done, the work is ready for lacquering, a pale lacquer being employed. I give you this recipe for what it is worth; to my mind it seems like directions for a coat of paint, and hope some one practically acquainted with "Flor" may give us the benefit of his experience.—Opifex.

Spence's Casting Metal.—D. O. (*Blackhill*).—The firm you refer to is not now in existence. Upon hearing from you I inquired of one of the leading London firms in this line, and they reply that they have not heard of the casting metal you ask about for years. There are various alloys which might suit you. Write again and state exactly what your requirements are, and I am sure we shall be able to obtain the information you need.—OPIFEX.

Small Castings.—E. W. (*Petersfield*).—There are several foundries in Southampton where you could get your castings made. If, however, there is anything specially difficult about them, which heavy founders do not care to tackle, and the Editor cares to furnish you with my address, I will, on the receipt of the pattern, get them cast, or advise you if there is any difficulty in the work, and how to remedy it.—J.

Browning Rifle Barrel.—PADDY BROWN (*Belfast*).—To prepare your rifle barrel for browning, all the old colouring, rust, etc., must be removed. To accomplish this rub it down well with emery cloth, and then polish with finest emery and oil until quite bright. Remove all trace of grease by rubbing with quicklime and water, rinse in warm water, and let dry. Plug the muzzle and vent with wood, and avoid handling the barrel. A good plan is to leave the piece of wood with which you plug the muzzle long enough to hold the barrel by during subsequent operations. There are various recipes for browning composition. The simplest is chloride of antimony and olive oil. Add the oil to the chloride of antimony until the mixture is of a creamy consistence; heat the barrel slightly, and apply an even coating of the mixture, and allow it to stand for twenty-four hours, when it will be covered with a fine coat of rust. This is removed with a perfectly clean and very stiff brush. Repeat these operations until the desired depth of colour is obtained. Should you wish to hasten the operation, add a little nitric acid to the browning mixture, when about ten hours will be sufficient for each application. When satisfied with the colour the barrel is washed in hot water, dried, and polished by rubbing with a very smooth piece of hard wood, when it should be varnished with pale lacquer. I need hardly add that every process of this nature requires practice, and that all operations in which chemicals are employed are liable to disappoint the worker, but if the foregoing directions are followed carefully I think I may promise you success.—OPIFEX.

Camera Fittings.—WM. McM. (*Cupar*).—A lens tube and cap can be procured from almost any lens maker. Lancaster, of Birmingham, or Taylor, of Leicester, would, I have no doubt, supply the want. The price would of course depend on the amount of finish, or if made for single or compound arrangement of lenses with or without diaphragms. If WM. McM. can work in metal, by the exercise of a little ingenuity he could construct one himself from a piece of brass tube of the right dimensions. The cap is easily made of a disk of thin wood of a suitable size, around which is glued several folds of stout paper. Cover with leather on the outside, and line the inside with black velvet. The cap should fit smoothly and evenly, but not too tight. He might possibly find something to suit him at some dealers in second-hand apparatus. The price of a whole plate lens complete (new) varies according to the maker's reputation from 30s. to £7, and for a portrait combination considerably more.—E. D.

Screen Materials.—BOB (*Sunderland*).—Paper, as you suggest, will do very well for lining the reverse side of your screen, but it should be laid on a calico, or some similar support, or it will be very liable to get torn. You may use almost any fabric instead of paper. If you want a glossy surface you might use oil baize or leather cloth. This you can also get with a dull surface more closely resembling morocco leather. Then there are cretonnes and chintzes in an almost endless variety. Cretonne lining is very good if you want a plain cover. Any of these materials are suitable, but prices vary so much that I cannot give them here. Your best plan will be to go to some good upholsterer or furnishing draper, and tell him what you want. He will quote price, when you can easily calculate the entire cost.—D. A.

Advice as to Trade.—B. R. G. (*Dorking*).—The subject on which you ask advice is, indeed, a serious one, for, as you say, it may affect your whole path in life, and I should strongly recommend you to take counsel with friends who know more of your circumstances and capabilities than I do. At the same time, as a friend who only knows as much of you as your letter tells, I may give you my own views. The most serious hindrance to your learning a trade in the ordinary way is your age, for I do not think any one would take you as an apprentice at twenty-two. You might get some employer who would be willing to take you on for a time with a premium till you had acquired sufficient knowledge to continue with him, or with another as an improver. Your taste for the carpenter's bench, and your familiarity with amateur woodwork, I am afraid, will not be of much use to you in a practical shop. Ability to work well as an amateur is a very different matter from being of the slightest use in a workshop, where a sharp lad, who had worked at the bench for a few months, would probably be of more value than the most skilful amateur. This may seem rough on amateurs, who, as a rule, have great ideas of their own skill; but I do not want to mislead you by giving you the idea that your present knowledge of joinery is likely to be of material aid to you. It may indicate that you have a natural bent for mechanical work, but otherwise it has little or no value. Amateurs are rather too apt to air their skill to the disparagement of others who have practical knowledge, so that on the whole if you want to become a joiner, I think you will do well not to lay much stress on what you can do now. Your employer will soon see what you can do. Many in similar circumstances to yourself have applied to me to be taught practically, most of them because they "have a taste for the business," or "are clever with tools," but such people, I have generally found, know too much to be taught anything. You will take these remarks in good part, I am sure, and not consider them personal further than indicating an error you should try to avoid. The terms for teaching you would have to be entirely a matter of arrangement, and probably before anything could be definitely decided you would have to go on trial for a month or so. If you are sharp and capable, you might be able to secure a small wage from the beginning almost, and if I were in your place I would regard with suspicion, or, if this is too strong an expression, examine with great care, any offer made to teach you if the premium required be a large one. Probably your services would be an equivalent for premium. I do not know what you have been brought up to, but could you not, presuming that you know something of any business, manage to get into some trade in which your knowledge might be of use? Very few men can get into precisely the trade they like, and after all, you know, a man is not always the best judge of the course of life for which he is most suited. Circumstances have to decide for most of us, and you must, to a great extent, be guided by these. I do not know that I can answer your inquiry as to wheelwright or joinery more definitely. They are both good, reliable trades, but if the choice be open to you, I am inclined to think that joinery offers the best prospects, especially if you turn your attention to the finer branches, such as cabinet making. The only way I can suggest for you to put yourself in communication with an employer is to write, or call on him. If you do not know any you might advertise, but the most reasonable way seems to try the local people first. If there is anything more I can tell you, write us again.—D. A.

Postage Stamp Gum.—E. M. (*Ashton*).—I believe dextrine is used for postage stamps, but even if not you will find it an excellent material for similar purposes. It can be obtained from chemists in the form of a powder, which readily dissolves in water. It is very strong as an adhesive, and cheaper than gum arabic, which may be used instead, if you cannot get dextrine.—D. A.

Polishing Fretwork.—A. J. M. (*Gravesend*).—You want "directions how to polish or varnish fretwork that cannot be done with a rubber," and I am sorry to say I cannot tell you, for I do not know of any fretwork which cannot be done with a rubber. Of course, if you varnish fretwork no rubber is required, as the varnish is laid on with a brush. Let us know what the peculiar kind of fretwork is which cannot be finished with a rubber, and then I may be able to help you, and tell you "what material is required to do it with."—D. A.

Varnishing Violins.—T. P. (*Birmingham*).—Violins should not be stained and subsequently varnished, but should be covered with a varnish charged with colour; a camel-hair brush is used for the purpose. Every fiddlemaker has some special "fad" for varnishing, and mine will be explained after the instructions in violin making.—B.

Small Camera.—W. J. A. (*Morley*).—A quarter-plate lens may vary in price from a few shillings to a few pounds, according to the kind and reputation of the maker; excellent lenses may often be procured at very low prices. If W. J. A. does not understand them, it would be as well to get some one experienced in the matter to select one for him. Landscape or single lenses are less expensive than double combination or portrait ones. As to the kind, the work to which they will be put must determine that. The portrait lens works more quickly than the landscape form, but does not possess so flat a field or so much depth of definition; that is to say, objects at different distances are not simultaneously depicted on the focussing screen so distinctly as with the single lens: the principal advantage of the portrait lens is rapidity. With regard to stops, a strip of blackened brass, in which an aperture has been made, and fitting into a slot cut in the lens mount between the lenses, is the most simple form of diaphragm existing. With regard to a camera, a full description of one was given in WORK about two months ago. A camera to be of any use at all must be as good for an amateur as for a professional, or *vice versâ*. One box sliding in another, telescope fashion, in order to adjust the focus, with a lens fitted at one end and a plate at the other, can be made, by one who understands what he is about, to produce good photograph negatives. The principles of negative making are complied with in this simple arrangement.—E. D.

Castings for Rivetting.—CASTING (*Camberwell*).—I could answer your question better if I knew the nature of the articles you require. The cheapest metal of course is cast iron. But unless the castings are tolerably stout and solid, they will not stand rivetting. Malleable cast iron is next best, and will stand rivetting very well, and can be recommended. Send for these to Harrison & Co., Malleable Iron Works, Lincoln. Gun metal will also stand rivetting, but is probably too costly.—J.

Knife Repairs.—H. W. H. (*Anerley*).—Knife blades may be fixed in their handles by putting some powdered resin or shellac in the holes, heating the tangs of the blades sufficiently to melt the lac, and inserting them. When cold they can be as firmly fixed as ever. Brackets and tables for painting will be described, but there is very little fancy furniture which may not be made of pine, and painted. You will find several designs suitable for your purpose in our back numbers. For instance, the two tables described in No. 1 would look well if painted.—D. A.

Photographic Changing Boxes.—TRIPOD.—The matter will receive attention. Changing boxes of the usual type are seldom used now by practical men, the double dark slides being infinitely better from all points of view, as it has been found that much more nicety in cutting the glass for the dry plates and grinding the edges is a necessity with these boxes, as the least inequality in size or roughness on the edges or corners of the plates is apt to disarrange the whole affair, and necessitate a careful examination in the dark room before the apparatus can be made to work. These, with the liability of getting the films imperfect from dust and fragments of glass detached from the plates by the friction of carriage, are such serious drawbacks, that double dark slides of light modern make are better in every respect, and weigh no more, a matter of considerable importance to the tourist, who is jealous of any extra weight unless coupled with corresponding advantages.—E. D.

Connections for Carbons.—A HUMBLE ADMIRER (*Bradford*).—My experience with bichromate batteries goes to show that lead caps cast on the ends of carbon plates make a more lasting connection than copper-electro deposited on them. Paraffin wax is worse than useless as an insulator in the presence of chromic acid. Bore a hole in each of the carbons to make a holdfast for the lead, and cast a lead head to each, in which embed a binding screw of the pattern shown at Fig. 5, page 474. As this is sketched full size, perhaps you can make it yourself. I hope shortly to show exactly by diagrams how to cast lead heads on carbons. Warm the lead caps when finished, and paint them with Brunswick black, allowing this to go well on the carbon below the head for half an inch. Connect to the copper rings above the board, if you choose, by means of copper wires attached to the binding screws.—G. E. B.

Chloride of Lime Battery.—D. D. (*Glasgow*). Why bother your head and myself with scheming out such a hodge-podge battery, when there are so many good and cheap ones already invented and proved? I cannot say how you would succeed with a battery charged with dry chloride of lime in the porous cell with the carbon, for I have never tried it, nor am I likely to do so. Neither should I cement glass plates together to form a battery cell, whilst such cells can be improvised out of any old crocks, providing they are not cracked. Try this as a cheap battery for your bell. Get three small porous pots and three meat tins. Solder a copper wire to each of the tins to form connections. Put in the porous cells, and pack them in with iron turnings from the lathe. Fit an air-tight bung to each cell, and soak it in paraffin wax if possible. Through this bore a hole to closely fit a zinc rod for the positive element. This must not touch the bottom of the cell. Charge both cells with a strong solution of caustic alkali; black potash will do for the purpose. This is not so good as the Leclanché, but it will ring a bell, and is a cheap battery.—G. E. B.

White Lead.—J. G. (*Cottingham*).—Strictly, chemically speaking, white lead is a mixture of carbonate of lead and hydrate of lead. The true oxides of lead, I am well aware, are of a considerably different appearance—for instance, litharge and minium, or, as the latter is most familiarly known, red lead. How far I am chemically justified or incorrect in terming the commodity not oxide merely—as you will notice on reference—but white oxide of lead, it may scarcely be worth while to consider here; but the late noted writer on pigments and colours, George Field, author of "Chromatics," etc., so designates the whites of lead, and I preferred to retain the support of so generally acknowledged an authority (whose works upon the subject formed my earliest lessons on pigments), when briefly explaining the nature of the substance in question, than to repeat the nomenclature of the ordinary cyclopædia. Whether Field was justified by analysis, logic, or usage of his time, I cannot answer, since we know that many oxides have no acidity, and are, therefore, to some extent, misnamed. Space will not allow me to go further into this and other apparently similar instances, but I trust my answer will satisfy you, and be some return for your courteous sentence on the matter.—LONDON DECORATOR.

Green Paint for Venetian Blinds.—G. S. (*Greenock*).—I am not directly acquainted with the methods practised by those who make and paint laths in large quantities, but I have confidence in recommending the subjoined to you. To paint laths two or three coats, and then to varnish afterwards, is a method that scarcely pays where there is competition to be considered. Most large lead and paint manufacturers now prepare enamel paints ready for use for the purposes of coating cheaply ironmongery, machines, implements, etc., and the ordinary mineral-green colour of Venetian blinds is one of the most used articles.

If you do any quantity it would best pay you to buy some of this, which is usually most satisfactory, and dries in about one hour. Give the new laths first a coat of patent knotting composition, and then finish with two coats of green enamel paint; or if a fine cut and the colour will cover in one good coat, give two of knotting and one of enamel. If you cannot get enamel conveniently, or do not require much, make it yourself, with mineral green ready ground to paste in oil, beat up with cheap, hard-drying varnish, and strain before use. Don't use size instead of knottings! For enamel paint write Pontifex & Wood, Shoe Lane, London, E.C.—F. P.

Safe Locks.—J. A. (*Hull*).—In attempting to open a safe it is always as well to try the bolt with a pick. If the bolt step of the key is worn it will not throw the bolt home, the stump will remain in the gate of the levers, and the bolt can be thrown back with a pick. But if the bolt is fully shot home it is useless trying to open it in this manner. All good safes have lever locks fitted with improvements, which absolutely prevent the possibility of their being picked, so that there is no alternative but to open them in the manner you describe. Should the lock, however, be an ordinary lever one, it could be picked with an instrument similar to that described on page 404. To show that safes nowadays cannot be opened easily, I may mention that early last year a gang of burglars spent the entire night at the Agricultural Hall, Islington, endeavouring to open one, but were obliged to take their departure early in the morning, leaving the unopened safe, and the whole of their tools—to the value of several pounds—behind them. T. W.

Repairing Locks.—W. M. (*Dover*).—Your query is rather a difficult one to answer, as there are such an enormous number of patents in door furniture. Is there no patentee's name on it? If the rose is fixed with wood screws which are visible, take them out, and possibly the knob will come off with it; this is called Pitt's patent, and is in very general use. If there appears to be no fixing for the rose, try to unscrew it, and if you succeed in doing so, you will probably see how the knob is fixed to an inner rose, some by means of a fork that secures the knob to the rose that is fixed on the door, while others revolve in a collar. If you are still unable to remove them write again, and try to give more particulars.—T. W.

Glaze for Porcelain.—W. B. (*Holloway*).—It is difficult to give a definite receipt for this purpose without knowing what kind of porcelain is to be glazed, and what special result is desired. There are many glazes—transparent, opaque, and coloured. For hard or true porcelain we believe the only glaze employed is ground felspar or Cornish stone, with sometimes gypsum added. For soft or tender porcelain the common glaze is of much the same materials as those which form crystal glass—viz., flint, alkali, and about ⅔ oxide of lead. The glaze for what is styled English porcelain (that in which there is a considerable admixture of calcined bone) is an intermediate one, felspar with about ⅙ of lead. Oxide of tin, etc., render the glaze opaque, and other metallic oxides will give it various colours. Indeed, the variations which may be made in glazes for various purposes are almost endless. The method of using them is by reducing the material to a fine powder, mixing this with water to a thinnish paste, and dipping the article to be glazed into it, which to give a uniform coating of glaze needs to be done skilfully. The parts by which the article is held need to be glazed over with a camel-hair pencil. The articles have, of course, to be fixed afterwards. —M. M.

Watch Wheels. — C. C. (*Chippenham*).—You can get any clock wheels to order or pattern from Grimshaw & Co., 35, Goswell Road, Clerkenwell, or J. Hunt, 21, Ironmonger Street, St. Luke's, or better still from J. Mayes, 55, Red Lion Street, Clerkenwell.—A. B. C.

Transfer of Lithographs. — In answer to Young Cabinet Maker, several so-called "secret" methods of transferring lithographs, drawings, woodcuts, etc., to wood are practised. Our correspondent, like most of those who ask us questions, does not give us full enough details as to the kind of process he wants to try. The word lithograph embraces so many sorts of printing that we scarcely know how to reply to the query. We can thus only deal in generalities. If the paper upon which the lithograph is printed be steeped in strong isinglass, care being taken to sponge it off the ink all over its surface with methylated spirits, it should be then dried. The surface of the wood should be then glass-papered with No. 1, and finished with No. 0, and sponged over with hot (not boiling) water, and left to dry. This will swell up the grain. Then paper first across, then with the grain, with No. 0. Repeat this, and finish by applying with a soft rag methylated spirits, which let alone till it is evaporated, and paper off again with No. 0 with the grain. Then with japan gold size let down with "turps" so that it may be laid on rapidly and flat so as to show no brush marks with a flat camel-hair brush, similar to those used for damping letter-copying books. Leave it until it is "tacky" enough for gilding, then lay the lithograph face downwards upon it, and rub it till it sticks all over, and let it stand several hours. When thoroughly set, moisten the back of the paper with very hot water (not boiling) and rub away all the paper. The ink alone, being greasy and therefore insoluble in water, will be found adhering to the gold size after all the paper is rubbed away. Give the wood either a coat of mastic varnish or French polish; with white (colourless) lac polish spirit off, and the work is finished. White of egg may be substituted for isinglass, and for light-coloured woods, such as pine or satinwood, Venice turpentine and Canada balsam, two parts of former to one of the latter, should be used instead of gold size. If "transfer lithographs," such as are sold for decorative purposes, are used, a very thin coating of gold size will suffice, and the paper when moistened through with cold water will peel off, and the transfer remain on the wood ready for a coat of varnish or French polish as before.—J. W. H.

A Complaint. — C. H. (*Bloomsbury*).— I know fully what I am talking about when I describe plane patterns. A sensible man would have pointed out the errors into which he supposed I had fallen, but my haughty critic only sneers and snarls, and does not condescend to particular facts. Therefore all I can do is to challenge him to point out my errors. If he will name particularly any example or examples whose description he deems unpractical, or inaccurate, or misleading, I will send patterns, core boxes, and castings of such particular examples to the editor of Work for his inspection and verdict. Beyond this I will not waste words.—J. H.

Steatite Burners.—H. W. L. (*Ealing*).—I am not aware of any manufactory of these in England, the English market being mainly supplied from the Continent—notably Nuremberg in Germany. The principal factory there has a representative house in London—Messrs. Falk and Stadleman, Farringdon Road, E.C.—who would undertake the making of any experimental work, however small; but, as I gather from your letter that you can use a lathe, why not make them yourself? Steatite is identical with soapstone used by tailors to mark lines for cutting out cloth, and is easily worked, and may be bored, turned, planed, and polished like a piece of wood. When in the form of a powder it is termed French chalk. There are not two sorts, as you suppose—hard and soft; in the raw state it is soft; when baked it is hard and brittle. You would require to get some of the material in the lump, and proceed exactly as though you were making a burner out of a piece of wood. When made submit it to a gradual heat (the kitchen oven will do) until it becomes a whity-brown colour, and perfectly hard. Of course in that state you can no longer manipulate its shape.—C. M. W.

Books for Laundry Men.—Fitter (*Walsall*). —In the October 5th number of Work, page 459, the names of a few books likely to be of use to laundry men are given, among which are "Stationary Engine Driving" (by Reynolds, 4s. 6d.), "The Safe Use of Steam" (6d.), and "A Treatise on Steam Boilers" (by Wilson, 6s.). I should feel very gratified if you would (through the medium of 'Shop') kindly give the price of each and where to be obtained.--[Prices have been added as requested, and all are published by Crosby Lockwood & Co., Stationers' Hall Court, London.—Ed.]

Conducting Wire.—F. S. (*Bermondsey*).—The meaning of the wire, which is shown in Fig. 1 in the article on the "Construction of the Telephone Running to Earth," is sufficiently explained in the text. But as it is sometimes difficult to understand little things I will endeavour to give you a little more explanation. To get work done of any kind by electricity we must have what is called a "circuit." Now a circuit is a conducting wire going to the work from the source of production, and returning from the work after that has been accomplished to the original source. Shortly after the invention of the telegraph it was discovered by Steinheil that the earth could be used as the return. So for convenience sake, and also to effect an economy in wire, instead of running two long wires—viz., from the battery to the work and back again—one long wire only is run connecting the battery and the work called the "line," while from each end a short wire is run to the nearest gas or water pipe, thus connecting them to the earth. Telephones made as described in the article do not require a battery in the circuit unless a microphone is also used, so the two wires either run directly to the pair of instruments, or to the earth, as shown in Fig. 2, not to a battery. You might profit by reading the article again.—W. D.

Pedestal Sideboard.—J. H. B. (*Manchester*).—The firm you refer to is Messrs. C. Gibbons & Co., 2, Avenell Road, Highbury, London, N. Their "bead router" was described in No. 17 of Work, page 267. All the back numbers of Work are in print, and can be obtained through any bookseller or newsagent. Regarding quantity of timber for the sideboard you contemplate making, I can only give you these approximately for your small sketch, though an assistance is not sufficiently defined to enable me to tell exactly. The only way you can ascertain exact quantities is to take the measurements from working drawing, but no doubt the following will be of assistance to you:—

52 feet	1 in.	stuff for	top, lining, door frames, ends, back frame, etc.
8 "	¾ "	" "	pediments, mouldings, etc.
15 "	½ "	" "	door panels, etc.
12 "	¼ "	" "	drawer bottoms, etc.
32 "	1 "	" "	pine, for shelving, bearers, etc.
46 "	½ "	" "	back.

From this quantity, allowing for a fair amount of waste, you ought to be able to make the sideboard, but, of course, a good deal will depend on the way you cut your stuff up. The quantities might also be considerably altered, and in fact everything may be summed up by saying that till the working drawing is made out you can't arrive at an exact specification. As one example of how you might considerably alter the above I may remind you that the first item, 52 feet, might principally be of ½-in. stuff. You would also save a good deal by facing the front of the back frame and veneering the sides—*i.e.*, of the back. To go into all the details which you might alter would require a few pages of Work, but I dare say enough has been said to assist you. Your sketch does not show any rail or glass framing just above the top—*verb. sap.*—D. A.

Staining and Varnishing Cabinet. — E. J. (*Leith*).—I am glad to hear you have succeeded so well in your first attempt, but it is a pity you have used such a mixture of woods if you wish to stain your cabinet walnut or mahogany colour. Owing to the different colours of the woods, you would, as a novice, experience a great difficulty in securing anything like uniformity, for you will readily understand that to get the teak and butter-nut woods to the same tint would require careful and experienced manipulation. A really expert polisher might manage, but I fear you would be disappointed with the result were you to attempt to stain as you suggest. However, if you wish to try I should advise you to stain walnut colour rather than mahogany. Go over the wood with the walnut stain of Vandyke brown ammonia and water, then when dry either polish or varnish. A far better way will be to ebonise your cabinet, as the different woods used will not be apparent, and you will have little difficulty in getting a uniform appearance. You had better buy the black stain, as it will cost you no more than to make, and there will be no difficulty in procuring it in your neighbourhood. Go over the wood with it once or twice, allowing each wash to dry before repeating. You may then varnish, using a hard varnish, which may be improved by adding some gas black. Strain through muslin. It will save varnish if you size over the surface before applying it, but whether you use size or not, if the varnish, when dry, seems to have sunk, leaving a patchy surface, give another coat of varnish. Possibly the wet stain may have caused the wood to become rougher looking than you like. If so, rub down with fine glass-paper before varnishing. When the varnish is dry you ought to have a glossy surface, not so smooth and fine as if it had been well French polished, but sufficiently good for a first attempt at cabinet making, and probably better than it would look if you had tried your first attempt at French polishing it. If you want to get the dull black surface so often seen on ebonised furniture, all you have to do is to brush it lightly, or even rub it down with a little fine emery powder. Brush in the direction of the grain. You will see the brilliancy is quickly removed. Of course the varnish must be quite dry and hard before you attempt to "dull down."—D. A.

Electric Light for Photo Dark Room.—G. E. S. (*Berkeley*). —No other apparatus beside that described on page 445 will be needed. The cost per hour will be 1½d. per cell of pint size. No. 18 wire will do to connect the lamp with the battery if the distance is not over 12 feet. If over this No. 16 will be better. Lead caps, holding binding screws, must be cast on the carbons, and binding screws fixed to the zincs for convenience in connecting up. I hope to fully illustrate and describe this battery in my articles on "Model Electric Lights."—G. E. B.

Glass for Overmantel.—J. G. W. (*Stratford*).—As you are not "connected with the trade" you cannot do better than get what glass you want from any cabinet maker of good repute. If you are ever in the neighbourhood of Shoreditch you might see what Mr. Vincent, Rivington Street, can do for you. You must make your own arrangements about price, which, as you do not give sizes of plates, I cannot even form an idea of. The rate per foot varies considerably, increasing according to superficial measurement. Read the answer to Pedagogue, who also inquires about looking glass. —D. A.

Looking Glass for Bookcase. — Pedagogue (*Aldershot*).—As you want the name of a London house supplying looking glass, I give you one, Andrew Gibson, Garden Walk, Great Eastern Street, E. C. I do not know, as he is a wholesale man, whether he will care to supply you with such a small piece as you want, and if he does you must not expect to get it at a wholesale price. So far as my own experience goes *bonâ-fide* wholesale houses do not care to be bothered with small retail orders. Your best plan is to get what you want from one of the leading cabinet makers in Aldershot. I do not think any of them do their own silvering, but they are constantly getting glass down from the wholesale houses who supply them. Of course, they get a profit, but you would not buy at the same rate that they do, so that by the time you had paid carriage on single plate, including case, and cost of this or return carriage, you would probably find that by ordering direct the expense to yourself would be much greater than if you went to a good local tradesman. The cost of mirrors varies considerably according to quality of glass and silvering, but you may reckon on yours costing 6s. or 7s. If it costs more it does not necessarily follow that you have been overcharged.—D. A.

Camera Fittings.—P. A. C. (*Hornsey*) will be able to procure camera fittings of all kinds from Henry Park, 1, Orchard Buildings, Acton Street, Kingsland Road.—E. D.

House for Watches. — SCOTY (*Leith*). — The most reliable people who are makers, not mere dealers, are Messrs. T. Russell & Sons, Church Street, Liverpool. They do an immense trade, and turn out a well-finished article, be it a silver lever or a gold chronometer.—J. S.

Repairing Verge Watch.—W. K. (*Leeds*).—You misunderstand my words. I say "for repair, see last chapter;" I ought to add at end of watch, and how to clean it. I did not say "previous chapter." You must learn to take to pieces, and clean before repairing, or it will be like trying to learn to read before mastering the alphabet. You must not clean watch plates with oil; do as I say, or when bright touch the brush in rouge, and give a few sweeps in a circular motion; by using oil you cannot expect but to have a dull appearance.—J. S.

Stain.—FRETWORK (*Oldham*). — I suppose you refer to the common fret cut and carved brackets, etc., which are made on the Continent. I do not know the particular stain used, if indeed there is a general one. Probably there, as here, different preparations are found. The colour, as you know, is walnut, and you cannot do better than use any of the ordinary walnut stains. One of the simplest and best has already been several times referred to in these columns. It consists of Vandyke brown, ammonia, and water.—D. A.

Re-staining Bookcase.—G. B. (*Leeds*).—I am not acquainted with the "Castle Brand walnut stain," but having used it on a piece of pine furniture which you now wish to stain and polish in imitation of mahogany, I should think you must clean it off before you can do so satisfactorily. A good deal, however, depends on the darkness of your present stain, for if this is only of a light walnut colour, you will probably get the effect of a dark mahogany by using a red polish over it. To get a good mahogany colour on pine furniture you cannot do better than adopt the method above given, being careful not to make the wood too dark with the walnut stain.—D. A.

Address and Moulding.—J. H.—Secretary of London Association of Foremen Engineers and Draughtsmen, W. Smith, 101, Thomas Street, South Hackney. Meetings held in Cannon Street Hotel. There is a similar society in the Yorkshire district, but I cannot give particulars. Articles such as you mention are in course of preparation.—J.

Burnisher. — W. H.—No book specially on the subject, but consult Holtzapffel's "Turning and Mechanical Manipulation," Vol. 3, page 1042.—J.

To Mount Tracings. — J. E. J. (*Middlesborough*).—Prepare a flat straining frame the size you desire your mounted tracing to occupy. Then cut some calico just large enough to cover it and to fold over the back to the extent of one inch. Damp this slightly, paste edges, and fix on strainer. When dry it will strain quite tight. The next operation requires the most care. Damp your tracing either with a sponge or by steaming it, but be careful the colours do not run. Then paste round one inch of the edges (of course at the back), then fix on the calico. The best way I find to do this is to put your damped drawing face downwards on your bench, paste edges as directed, then lay your covered strainer down on the drawing. Taking it up press round the pasted margin carefully with clean hands or linen cloth, but beware of finger marks, and in damping do not deluge, and take care that colours do not run.—F. B.

Book on Painting.—E. M. J. (*Ipswich*).—You had better advertise for a second-hand copy of the book in question.—ED.

Telephone Fittings.—CURIOUS (*Belfast*). — I am very pleased to have your letter. It shows considerable acquaintance with the subject, and I am quite delighted to be able to set you right. I hope you will succeed in getting your telephones to work properly. As you have numbered your questions, I will answer them in rotation. (1) In Fig. 4 you will observe two little articles lettered respectively A and B. A is a binding screw, which is shown at B in Fig. 1. and has no connection with Fig. 8. B is an adjusting screw, which has a neck wrongly shown screwed in the figure. This neck fits into the brass collar, Fig. 8, which is itself screwed to the top of the body of telephone. The screw fits into the S end of the magnet, and the whole is for the purpose of adjustment. The arrangement which you have described and are going to adopt will do just as well. (2) The bobbins can be made of boxwood, and the spindle part must be very thin—in fact, it is no thicker than paper. I was showing one to a friend the other evening, and I could easily squeeze it out of shape between my fingers and thumb. (3) It is not necessary to insulate each layer of wire on the bobbin with paraffin paper. The depth of the bobbins may be seen from Fig. 1. It is not necessary to have them any particular size. Make them to fit the end of the magnets, and to hold a ½ oz. of wire No. 36. (4) You can have a bell in the circuit with the telephones, but you must have a battery or a generator of some kind to work the bells. In a circuit arranged with bells you would also require a transmitter. (5) Certainly rig up your telephones with a battery, and dispense with the earth wire. This wire is the return wire, and is only connected to the earth through the means of a water or gas pipe for the sake of economy. (6) You understand the microphone perfectly. It is as you say two pieces of wood joined at right angles, and three pieces of carbon. The two end pieces are just fastened to the upright in the most convenient manner, so as to get a connection. I think Fig. 6 explains it fully. Fig. 11 shows the connections.—W. D.

Painting Magic Lantern Slides.—P. M. C. (*Finsbury Park*).—In answer to your question "Can you tell me how to paint lantern slides with water colours?" I can here only give you a few hints. The glass must be perfectly clean, and of special quality. Give the glass a very thin even coating of finest sheet gelatine dissolved in warm water. This may be done with a flat camel's-hair brush, or let gelatine form jelly, heat the glass, and rub with jelly. The colours to be used are the ordinary moist water-colour paints in pans or tubes, but in slide painting you are restricted to the use of the transparent pigments—viz., Prussian blue, indigo, gamboge, carmine, crimson lake, Italian pink, sap green, ivory black; the semi-transparent colours are sepia, burnt sienna, Vandyke brown, and burnt umber. This is not a full list, but will serve as a guide as to the choice of pigments. Lump sugar dissolved in water to form a syrup is about the best vehicle for mixing and thinning the colours. Oxgall may be used to make a refractory colour take upon the glass. Use camel's-hair brushes, except for the very finest work, when a sable pencil will suit best. Do not try to give a second wash or put in shades without giving the slide a thin even coating of collodion, applied by pouring upon the centre of the glass, letting it run all over, and then draining off at one corner into bottle. The compound colours, such as purple, violet, greens, browns, greys, etc., may, of course, be produced by combining the colours mentioned above. When the picture is finished it should receive a thin coat of best mastic varnish.—OPIFEX.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Gilding on Satin.—S. H. (*South Norwood*) (see page 637) writes:—"On white satin, etc., size spoils the look, and gold size, oils, varnishes, etc., all spread. But if you could explain how it could be done, and some people know the way, it would oblige some of your readers."

Glue.—A SUBSCRIBER asks:—"Can any reader give me the name of the maker of glue with the trade mark on—a dragon standing up against a shield?"

Book on Sheet Metal Work.—L. P. (*Deal*) wishes to know the publisher of a book on the above subject written by H. Warne.

Furniture Cream Bottles.—T. B. (*Rochdale*) repeats his question:—"Will any of our kind readers of WORK give me the name and address of any firm of glass bottle makers where I can obtain furniture cream bottles from, such as are retailed at shops when filled at one penny each?"

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Fairy Bells.—R. F. (*Norwich*) writes in reply to SUBSCRIBER (*Bristol*) (see page 654):—"I will send particulars of the interior of fairy bells in a short time."

Spence's Metal.—H. J. L. J. M. (*Ealing*) writes:—"In answer to J. S. B.'s (see page 541) query as to Spence's Metal, I think I am right in saying that it is a combination of sulphur and iron in the shape of fine dust or filings. The metal is used for fixing railings in their sockets (just like sulphur pure and simple) and for fitting grindstones on to their axles. The compound is much cheaper than lead, and melts at a very low temperature. I have a small grindstone that was mounted for me in this way by the friend from whom I learned the nature of the metal. Like most sulphur compounds it has a very evil smell, and it is better to melt it out of doors. At the present time I have some small pieces by me, and if J. S. B. cared to write to me through the Editor, I should be glad to send him a piece. By the way, the addition of iron to the sulphur seems merely to change the colour of the sulphur to a dark slate-coloured black, as the compound, when it cools, seems to have the same shaped crystals on its surface as pure sulphur has."

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—P. E. (*Ebbw Vale*); REGULAR READER; G. H. (*Congleton*); R. H. (*Birmingham*); YOUNG ENGINEER; G. P. (*Elgin*); GAMMA; ONE INTERESTED; LANE (*Nottingham*); C. H. L. B. (*South Shields*); PAINTER; T. H. D. (*York*); R. L. (*Liverpool*); CREST; J. H. (*Crewe*); PEEPING TOM; J. B. (*Tiverton*); V. A. H. (*Hackney*); J. A. C. (*Plaistow*); H. J. A. (*Dover*); M. S. G. (*Oldham*); W. R. (*Oswestry*); SLIGHTED; A. H. F. P. (*Stockport*); M. R. (*Glasgow*); LIGHT OAK; I. H. N. (*Worcestershire*); PATIENCE; BRITANNIA COMPANY.

Trade Note.

THE highest chimney in the world is now being erected at the Royal Smelting Works near Freiberg in Saxony. The horizontal flue from the works to the chimney is, the *Builder* says, 1,093 yards long; it crosses the river Mulde, and then takes an upward course of 197 feet to the top of the hill, upon which the chimney is being built. The base of the structure is 39 feet square by 30 feet in height, on which is placed a short octagonal transition, from which the round shaft starts. This is 430 feet high, or, together with the base, 460 feet high, with an inside diameter of 23 feet at the bottom, and 16 feet 6 inches at the top. It will take a million and a half of bricks, and the cost is £6,000. Mr. H. R. Heinicke, of Chemnitz, in Saxony, is the architect.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

A WONDERFUL MEDICINE.

BEECHAM'S PILLS

Are universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, and all Nervous and Trembling Sensations, &c. &c. The first dose will give relief in twenty minutes. This is no fiction, for they have done it in countless cases. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

Worth a Guinea a Box.

FOR FEMALES THESE PILLS ARE

"A priceless boon, a treasure more than wealth; the banisher of pain, the key to health."

These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the nervous and debilitated is,

BEECHAM'S PILLS have the Largest Sale of any Patent Medicine in the World.

Prepared only by the Proprietor, T. BEECHAM, St. Helens, Lancashire, in Boxes 1s. 1½d. and 2s. 9d. each. Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

SANDOW'S famous Trainer, Attila, writes:—"Pumiline Liniment is the finest thing in the world to relieve the muscles and to impart strength. I strongly urge its use to all athletes."

STERN'S PUMILINE LINIMENT

NEVER FAILS to give immediate Relief and finally to Cure all cases of **Muscular** and **Chronic Rheumatism, Gout, Stiffness of Joints, Sprains, Bruises,** etc. Also most efficacious in **Bronchitis** and **Throat** and **Chest Affections.**

OVER 700 TESTIMONIALS FROM MEDICAL MEN.

One of the Physicians to H.R.H. The Prince of Wales writes:—"Nothing gave my patient so much relief as Stern's Pumiline." Sir Morell Mackenzie writes:—"Admirable in Throat Affections." Dr. Stevens writes:—"Pumiline cured me in a severe bronchial attack." *The Medical Press* says:—"Stern's Pumiline is reliable and curative."

Price 1s. 1½d. and 2s. 9d. per Bottle.

From all Chemists, or 3d. extra for postage, from

G. & G. STERN, 62, GRAY'S INN ROAD, LONDON, W.C.

A work on the "Home Use of Pumiline" sent free on application.

Stephens Stains

FOR WOOD.

Specimens and Prospectus giving full details as to use free by post.

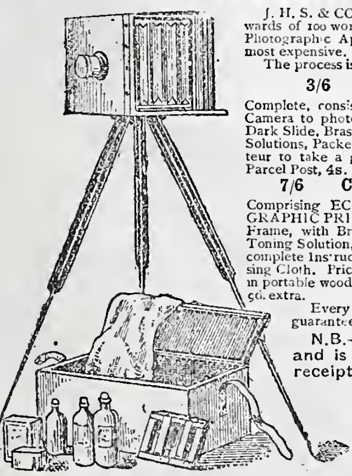
MANUFACTURERS AND IMPORTERS OF

PHOTOGRAPHIC APPARATUS AND FRETWORK MATERIALS.



J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.

The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.,** or securely packed by Parcel Post, **4s.**

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price 7s. 6d. Securely packed, post free, 8s. 6d. If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. **J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.**

Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

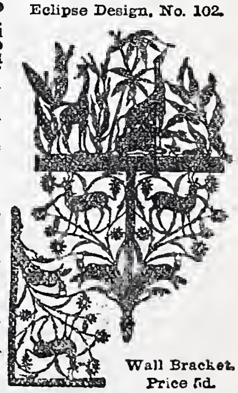
Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

JUST PUBLISHED, NEW CATALOGUE of Machines, Saws, Designs, Wood, &c., 56 pages, 600 Illustrations, with Instructions, 4d., post free. Good Fret Saws, 1s. 4d. per gross; best ditto, 1s. 9d. per gross.

Eclipse Design, No. 102.



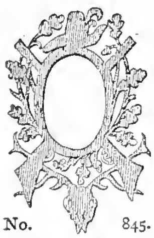
Wall Bracket. Price 6d.

MURIEL A. TURNOUR.
Age 1 year and 6 Months.

HASLEMERE LODGE,
KEW GARDENS,
SURREY.
19*th February*, 1889.

The Honorable Mrs. Turnour writes:—

"She was a most delicate child, and I quite despaired of rearing her; she could not digest any Milk Food. I consulted a Physician, when she was four months old, and he told me to give her 'Mellin's Food.' From that time until she was eighteen months old she was fed entirely on it, and became perfectly healthy and strong."



No. 845.

PROPER HEIGHT FOR MECHANIC'S VICE.

BY H. B. PILKINGTON.

If men were all of the same height there would be no difficulty in regulating and determining the right height of the carpenter's bench and the mechanic's vice, for it would be easy enough in each case to arrive at a standard which would serve equally well for all. There is, however, a considerable difference in the stature of men, some being above and some below the average height, and as work at the bench and vice has to be done by the workman when standing, it is manifest that a tall man would be compelled to stoop too much when working at a bench or vice of suitable height for a short man; and a short man obliged to stand upright and raise his arms to an inconvenient height if put to work at either appliance at which a tall man could work with ease and comfort. Without doubt a great many amateurs, and, possibly, not a few intelligent and skilful professional workmen, would be puzzled to give with promptness a direct and satisfactory answer to the question: At what height from the ground should the jaws of the ordinary mechanic's vice be placed? To such as are ignorant, or perhaps in doubt, on the point, the accompanying sketches will be helpful in fixing on both mind and memory the right solution of the problem. For the sake of comparison, four have been given. In Fig. 1 the vice is too low, and the workman has to bend his knees and stoop too much over his work, and thereby loses power. In Fig. 2 the vice is too high, and this compels the workman to assume too erect a position and raise his arms too high, and in this case also power is lost. In Fig. 3 the vice is just at its right height, midway between the too low position in Fig. 1 and the too high position in Fig. 2; and the position assumed by the workman is such as enables him to bring the whole weight of the body, or nearly so, to bear on the stroke, and thereby the power exerted is at its maximum. How is the proper and most convenient height for each workman to be obtained? This is answered by Fig. 4, which shows that, to suit the workman, the top of the anvil should be just high enough to touch his elbow when he stands erect and bends his arm as drawn.

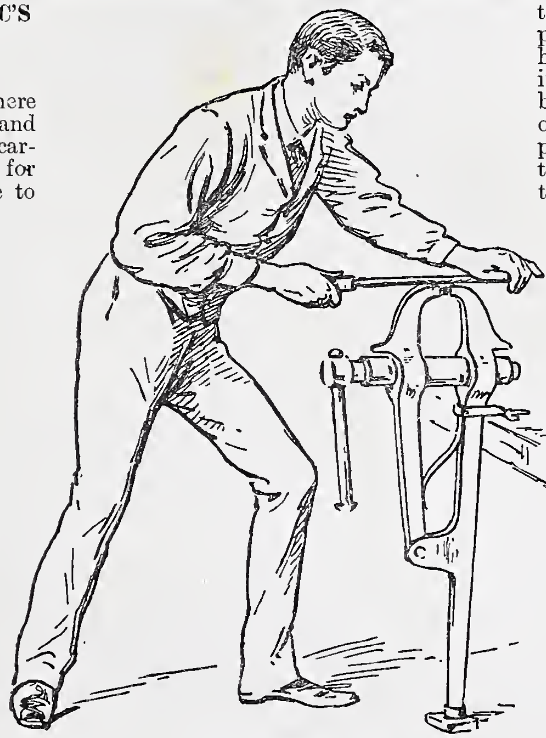

Fig. 1.—Vice too Low.

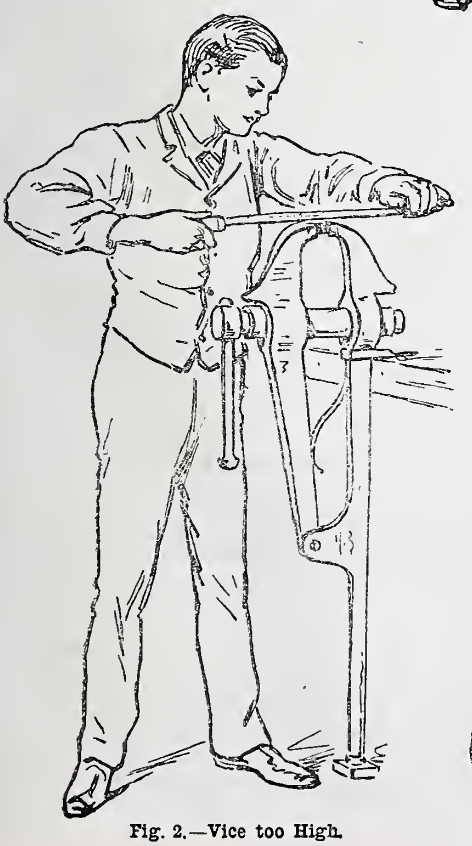

Fig. 2.—Vice too High.

Fig. 3.—Vice at Right Height.

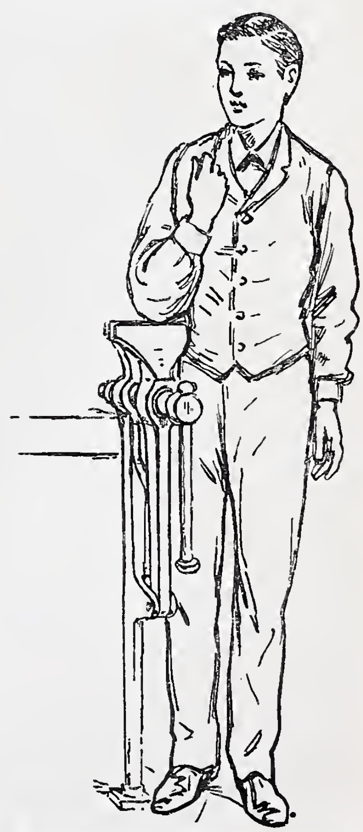

Fig. 4.—How to Determine Right Height of Vice.

PLAIN AND DECORATIVE HOUSE PAINTING.

BY A LONDON DECORATOR.

DISTEMPER OR TEMPERA PAINTING.

In writing technical papers upon house painting, and indeed upon most trades and callings, there are many words and expressions used in connection therewith that the writer always feels require but little explanation other than the words themselves convey. "Oil paint" and "varnish" for instance are examples of such. Upon the other hand it is very desirable that words of a more complex nature—notwithstanding their meaning may be very patent to most of my readers—should be accompanied, if only for the benefit of a small minority, by a practical knowledge of their proper sphere and use. "*Distemper*" is, certainly, a word of this latter kind; for although the process of *distempering* is familiar to all of us, I suppose, in its most elementary form of "whitewashing," the word has a distinct interpretation in its connection with the brightening and embellishing of our buildings.

Briefly, its Italian derivation, of *tempera*, gives at once a key to its meaning, when compared with the word "tempering," *to temper*, *to work up*, or *to mix*. Notwithstanding this mixing, or tempering, is a process common to all painting, oil and otherwise, *tempera* is the recognised name for *water painting*, that is to say, the compounding and spreading of *opaque* solids and pigments with water for the solvent, and some suitable *vehicle* introduced to bind the particles together.

At the present time, in which it is our privilege to be workers, the qualities and cheapness of distemper make it as invaluable a servant of the decorator as are oil and flatting paint. For preservative purposes, and as a covering for surfaces exposed to our humid atmosphere and weather, distemper is, however, practically useless; and although under fair conditions it will stand much "wear and tear" on walls, it is principally for situations out of reach and beyond abrasion that it is used with more advantage than oil paint. The most satisfactory purpose to which we can apply either oil paint or distemper will readily be apparent if we consider their totally distinct qualifications and nature. In the former mixture we know that whilst the linseed oil is the *solvent* it is also the *binding* factor, driers being added merely to hasten and accentuate the hardening. On the other hand, in distemper colour, the solvent, namely, water, has no such permanent action as has the oil in the former, but is entirely dispersed and carried away by evaporation.

Distemper, it therefore follows, besides being prepared from dry pigment and with water added to enable us to manipulate the former, requires a third and highly important factor which shall of itself bind the particles together and maintain this action when evaporation is complete.

Having, satisfactorily I hope, now explained the term, and also the nature of, *distemper*, we will consider separately the solids and the binding factors which are necessary to preparing it; concluding my paper with instructions for mixing and using it for general purposes.

In both oil and distemper painting there is one item, or rather substance, which ranks pre-eminently for its purpose above all other pigments. In the former process this position we know is held by the ordinary *white lead*, and other similar *carbonates* known as "Flake," "Nottingham," and "London" whites, etc., but which latter are seldom required for ordinary house painting. Mother Earth favours us even still more for *tempera* painting, providing us with an unlimited store of limestone and chalk, from which we derive the ordinary lime, *oxide of calcium*, of building processes, and a further preparation known as *carbonate of lime*.

Whiting, or *whitening* as it is sometimes termed, is the most ordinary and also the most useful form of carbonate of lime. *Paris white* and *gilders' whiting* are the best qualities of the same article, and differ from the cheap kind in fineness of substance and purity of white. *Paris white* is in far greater demand in the United States of America than in this country, where, under the term of "*Kalsomining*," the practice of whitewashing is carried to perfection. Repeated grinding and washing are resorted to in order to convert the chalk into the condition of whiting, the processes being worked to extremes when the finer qualities of the above-mentioned are required. For the practical benefit of the young learners amongst my readers, I may mention that Paris white is usually sold in a loose or powdered form, whilst gilders' whiting is commonly dried in the form of large knobs, each weighing three and four pounds, and being therefore about twice the size of the cheap knobs of "oil-shop whiting."

Whiting that has been properly washed and prepared, will easily break in the hands by pressure of the fingers, and there should also be a total absence of grit and sand. If it does not crumble up and dissolve easily, we have evidence that insufficient washing has left objectionable traces of a binding nature, common to lime.

I have gone somewhat minutely into *whiting*, and its desired condition and qualities, with good reason, however, for upon its purity much of the permanency and beauty of our *tints* of distemper will depend. Whiting which contains grit is entirely useless for gilders' work, namely, the preparation of surfaces for *water-gilding*; whilst if present to any extent in our distemper, grit will settle to the bottom of the vessel and, what is more troublesome, often carry with it the bulk of any powdered pigment used for tinting or staining purposes.

It is not my purpose herein to consider exhaustively every description of *vehicle*, ancient and modern, that has been, or can be, used for binding or cementing the particles of whiting or pigment to each other and, collectively, to the surface our distemper is applied on, but to notice the best and most convenient preparations of "to-day."

Until recent years, the ordinary glue of commerce was the only serviceable "binder," or water-vehicle, that house painters could conveniently use and obtain for making distemper. To the present day glue is still largely used in the provinces and places remote from the larger trade circles. The usual mode of preparation is to soak it in cold water over night, and then by breaking it up with the hand, or the application of heat, to convert it into a liquid or jelly form, when it is ready for adding to our whiting. The chief and only advantage of thus using and preparing glue lies in being able to stock it without detriment to its service ability. In London, Manchester, and, in fact, all large towns, glue for distemper purposes is now entirely superseded by a jelly substance of similar source and nature, termed "size."

The nature and preparation of *size* is almost identical with that of glue. The hoofs, hide-clippings, and other refuse of the tanyards is the source from which they are prepared, both being a gross kind of gelatine. The substances mentioned are purified with lime, and then the gelatinous matter extracted by gradual boiling, and the clarified condition of this extraction is the *size*. When required to be converted into glue, this liquid, after the greater portion of the water has been evaporated, cools into a very strong jelly. It is then divided into blocks which are ultimately converted into cakes of hard glue by a double process of drying by natural and artificial methods.

Clear, or *gilders'*, *size* is a simple decoction made by simmering "parchment cuttings" in a vessel—preferably with an enamelled inside—until the gelatinous "virtue" is all extracted therefrom. It is then poured off in its liquid state and strained through fine muslin, and when cool is almost colourless. Gilders—I mean those who are masters of every branch of this craft and follow it entirely as their trade—always prepare their own clear size; and as this article is one of the most important used in all water-gilding processes, knowledge of and practice in preparing it are very essential to such work. *Clear size* is also used for finishing decorative "oil gilding" in buildings, etc., hence this knowledge should be common to the decorator also.

Painters' size is usually sold by the pound weight, or in firkins containing about 28 lbs. The finest and whitest variety, used in London and district, is known as "Young's patent size," which for purity and strength is equal to anything that can be produced. *Double size* and *extra double* are the two varieties most used for distemper, the latter being the strongest; neither of these are, however, to be compared with the first-named for purity and translucency, their colour being similar to size prepared from a good quality of ordinary glue.

When required for use these jelly sizes are put into a vessel and dissolved by heat, a little water being first introduced to prevent them from burning. Size should never be made very hot, but dissolved sufficiently only to allow of its being thoroughly incorporated with the whiting or other pigment. The only disadvantage the jelly form has is its liability to putrefy and decompose during the hot weather. It is for this reason that glue is often substituted in the provinces and districts where there is no factory at hand, and where the comparatively small demand for it does not warrant the trader or house painter keeping it.

Still more recently, and in order to cope with the disadvantage above-mentioned, glue and size in a powdered form have been placed upon the market, and can usually be obtained in any district. "Cannon's Concentrated Size" was, I believe, the first in the field, but at the present time every glue and size factory makes a glue powder, size powder, or concentrated size, which is usually retailed in penny, quarter, half, and pound packets. By dissolving this powder in boiling water, according to the directions sold with it, we get a good binder for distemper work without any of the risks or trouble attending the use of glue, or the storing of size.

The best method of mixing distemper is to first put some cold water into the vessel we purpose making it in, and then put the whiting into it, breaking up the lumps at the same time, so that, without unnecessary delay, the whiting may be thoroughly dissolved. Care should be taken not to use too much water, sufficient only to cover the whiting being required. When properly "slacked" and settled down, the surplus water must be gently poured off. A careful worker will then thoroughly stir the whiting to ensure its all being properly dissolved, this being best done by the bare hand and arm, and, gently pouring in his warm size, will continue to stir and mix until the two constituents, size and whiting, become thoroughly worked together. This should now be set aside in a cool place, when it will gradually assume a white jelly form. The amount of melted size used would be about half the bulk of the soaked whiting, but should there be an excess of water in the latter, it often so dilutes the size that there is not sufficient strength contained in the whole mixture to gelatinise or set it. Some of my readers may feel that this simple pail of whitewash requires more care than was anticipated, but good work cannot be done without properly prepared material. For the very common kinds of whitewashing, on country cottage ceilings, etc., it is very often the case that the housewife brushes the surface over with whiting and water only, just as lime is used for "white liming." No solid appearance is possible with such, however, and although for ceiling work in general less proportion of size than that given above can be used, jelly distemper works far easier, presents a more solid appearance, and is manipulated with far less splashing and mess than is usual with the watery wash we often find used by others than country housewives.

Those of my readers who have studied the previous papers on oil painting, will have in their mind how far the condition of the surface to be covered affects our proportions of material in that process. The same principle underlies both oil and distemper work; and the success of the latter will greatly depend upon the preparation of the plaster work. In describing the nature and necessary manipulation of flatting paint, I have also shown that no "break" must be made in a piece of continuous work, or flank of wall, but that every surface complete in itself, like a ceiling-flat or side of a room, must be commenced and expeditiously completed without join or "miss." We must therefore ensure a uniformity of absorption, or rather non-absorption, by previously coating the plaster with a mixture, which, like the first thin coats of paint in oil painting, shall stop the unequal suction common to all such plaster-work.

For this purpose the most convenient preparation is strong jelly size diluted with about one-third of water and just sufficient whiting to colour, without practically thickening, the size. This clear-coat, or "clearcole" as it is termed, should be prepared in precisely the same manner as the finishing distemper, and when convenient the addition of a little alum is desirable. The hardening action of alum on substances of a gelatinous nature is well known, especially among those of my readers who know what a photographic dry-plate is—not a few, I am sure! The introduction of the alum is not obligatory; the strong size and whiting alone will suffice, and this should be applied warm, as soon as mixed, for when cold it would be too stiff to spread with the brush. No such precautions concerning joins and streaks are required for using clearcole, since there is not sufficient body in it to form an appreciable incrustation on the wall. The size soaks into the face of the wall, and when dry is ready for finishing upon.

When distempering or tinting, that is, with tinted distemper, a ceiling of any dimensions, it is advisable to have a scaffold to work from, consisting of a plank resting upon two pairs of steps or, preferably, trestles made for that purpose. All cracks in the plaster should, if at all bad, be first "cut out," the face of the plaster each side cut away for half an inch, and then finished to a level surface with plaster and a small trowel. A broad, thin piece of wood with a square, bevelled edge is very useful for stopping plaster walls, for many operative painters even, in trying to stop a crack or hole with a sharp steel "stopping knife," will badly scratch the surrounding face of the plaster, the evil result of which is only seen when the job is finished. Repairing should be done on new ceilings before the clearcole is applied, and with old ceilings, at the time they are "washed off"—that is, when the old, dirty distemper is removed with water and brushes.

Ceilings should always be distempered by working away *from* the light towards the door or entrance to apartment. Two men are required to do a good-sized ceiling-flat; they should start at the window end, and, keeping their work in one general line, spread the distemper from the end as far towards the centre as they can both conveniently reach. The scaffold is then brought forward and another "shift" covered, and so on until the whole is finished. The solvent we use for distemper work being water, it will readily be seen that extreme heat or draught of air, such as will evaporate the water, is to be avoided during manipulation; but so soon as a piece of work is completed, our object must be to *dry* it off as *quickly* as possible, and hence open door and window to create the draught we previously had to avoid. A properly executed piece of distempering should have a level, but not perfectly smooth, surface; should show no joins or coarse brush-markings; should have a perfectly "dead" appearance, be solid and uniform throughout, and should, finally, *not* rub off by ordinary wear, or leaning against.

In distempering walls where a good job is required—and this I aim to direct all workers to—the stopping and clearcoling must be carefully performed, and thoroughly dry before the finishing coat, in a nicely jellied condition, is spread. In covering a wall of ordinary height, two workers are necessary, one standing on the scaffold and taking from the top, half-way down, the other working beneath him. It is a good plan for the bottom man to start spreading and keep slightly ahead of his fellow, who then, in his "laying off" strokes, will nicely cover all traces of the join. Distemper neither requires nor allows one-half the manipulation that oil paint does; and, as before mentioned, its nature rather corresponds with "flatting."

The brushes made for distempering, and the proper method of using them, I shall describe in the following paper, and which will cover also, as far as possible, all the tools and brushes used by the house painter.

By far the greater proportion of plaster ceilings are finished with distemper paint. Besides the advantages of cheapness and of covering in one coat where, with oil paint, four would be required, distemper shows superiority in other respects.

In large halls, dining-rooms, and similar places where people congregate, the moisture in the atmosphere—unless the ventilation of the apartment is exceptionally perfect—will condense upon a painted surface and run down the walls. This can be easily noticed by any of us. When distemper is substituted for it in such situations, no unpleasant effect is seen, since the distemper will absorb the moisture for the time being, and ultimately give it forth again without any detriment to its colour.

This property of distemper also points out the necessity of removing all old colouring and whitewash from ceiling and walls, but which are, in some cases, coated over with size, instead of the dirty, unhealthy coating being removed with brushes and water. The size binds the dirt down, and the opacity of distemper paint allows us to do this without its showing the dirt through; nevertheless, it is a practice to be condemned by all who think of sanitation. Doubtless this labour-saving plan would be used to a more general extent but for the fact that continuous coats of distemper and size soon discover the bad worker by the surface cracking and peeling off, owing to excess of size thereon.

In all preparations of paint the purity of our tints of colours is very much dependent upon that of the body pigment used. As good whiting is far more white and brilliant than white lead, it follows that we can obtain much purer and more delicate tints in distemper work than is possible with substances more affected by the atmosphere, as are the carbonates of lead, and oils which contain yellowness. If *gilders'* or *Paris* whiting be used with *clear* or *Young's patent* size, the purity of distemper tints is so very much in advance of those of white lead paint that it is impossible to match them in colour. In desiring our paint to suit the colour of the paper of a room this fact must be borne in mind, and allowance made for it. In such cases, *exact matching* is neither necessary nor possible. Our colours should always be judged by the general or dominant effect, and not by any infinitesimal portion thereof.

Notwithstanding the natural characteristics of distemper are absence of gloss, and suitability solely for interior and unexposed situations, many attempts have been made to combine its cheapness with the permanent qualities of oil paint.

When distemper work was scarcely so ordinary a process as size and size powders and improved pigments have of late years made it, the walls of apartments were sometimes painted in *tempera*, and finished, at some expense, by polishing or "satining" with French chalk and flat brushes. Nowadays, however, it is very seldom done directly on wall surfaces, although a similar process is still used on paperhangings, termed "satin goods." As before mentioned, excess of *vehicle* in distemper, whether gum, glue, or size, causes it to crack and peel off; so that, notwithstanding an "egg-shell gloss" could be obtained were sufficient used, it would only be at the sacrifice of permanence.

Pure beeswax can be added to distemper with occasional advantage for decorating ceilings in tempera. It forms a far harder surface for painting or stencilling ornament upon, without any risk of peeling off. It can scarcely be termed washable, but may be made to stand a considerable amount of wear and cleaning. The mode of preparation is to dissolve the yellow beeswax—not the paraffin-adulterated article—in oil of turpentine by heat, to have one's whiting ready for mixing, then add strong and very hot size, and well mix together before stirring in the melted wax. I do not commend this to the novices amongst my readers; it requires the professional hand to work it successfully.

Mixtures of distemper—that is, size and

whiting—with "turps," hot linseed oil, Russian tallow, etc., are occasionally made to spread on outside work, and are successful so far as they contain the oil or grease which repels the water. For inside work a washable tempera is impossible from ordinary ingredients and without mechanical processes. There are, however, a few so-termed washable distempers in the market. The best known are J. B. Orr & Co.'s "Duresco" and Griffiths' "Acquol." The former has been much used on such large buildings as colleges and hospitals, but only for interiors. As *washable* paints they are fairly successful, but, since they are prepared from a basis other than whiting, they lack considerably the opacity we can obtain with one coat of good plain distemper.

In tinting, or colouring, distemper, the pigment used for staining, whether ground in water or in powder form, should be mixed with the whiting before the size is added. It cannot otherwise be properly worked into the whiting, and, after the size is added, the distemper should be run through a thin gauze or hair sieve. If it is strained after getting set, this will give it in a very agreeable condition for spreading—"to work like butter," it is termed.

The nature of distemper is such that, when dry, its tints are very much lighter than when mixed. This is due to the action of light upon the solvent—water—used for mixing, and the evaporation of which allows the pigment to convey an equally bright sensation as it did before being so saturated.

The pigments most suitable for staining whiting will be gathered from the opening papers of my subject, but I append a few of the most useful and ordinary:—For *warm*—that is, red—tints, Venetian and Indian reds and burnt sienna. For *buffs*, *cinnamons*, etc., the natural *ochres*, *umbers*, and *siennas* with the above reds. Lime blue and ultramarine, so-called, make blue and grey, with red added for French grey, and *blue-black* or *Paris* black where the neutral is required. Greens are seldom required bright, and mixtures of raw sienna or ochre with lime blue, indigo, or ultramarine are most reliable. All dark-colour distemper paints like purple-brown, for instance, seldom require whiting, only the pigment prepared in similar manner. All mixtures should be tested and dried on paper to allow us to judge the colour, and when this is correct, add the size.

THE BROOCH: HOW TO MAKE IT.

BY H. S. GOLDSMITH.

Brooch Mounts:

The Principles that Govern their Position, both on the Brooch and with Reference to One Another.

We have made the different mounts, and now we have to attach them to a brooch. So, if you please, we will consider if there is a proper place for them, and what relation they bear to each other.

I can simplify these considerations, inasmuch as custom decrees that all ladies must be right-handed—at least, we make brooches for them alone.

The poor ladies who are left-handed must be content with insecure fastenings, for, as far as my knowledge goes, they are never considered by us at all in this matter.

A circular brooch (Fig. 1, A) will be the type from which we can point our moral, even if it does not help to adorn a tale.

As the perpendicular lines on the front of the brooch (be they what they may, either ornament or stones) depend on the *position of the tongue*, this must be so placed that it is parallel with the true horizontal line, or, as we say, straight across the brooch, as in Figs. 1, A, and 1, B, but a little above the middle line, else the brooch will topple forward.

To get the tongue right, the joint and

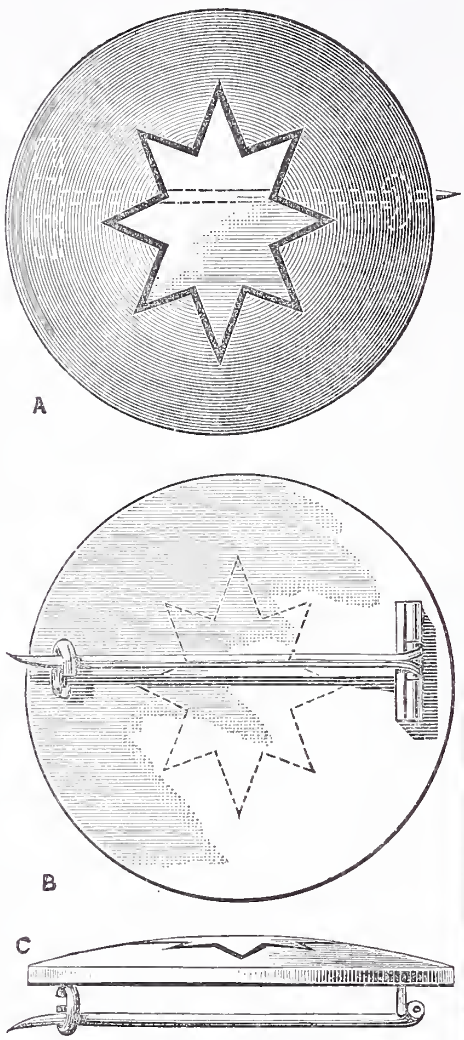

Fig. 1.—Circular Brooch.

The Star in front is to show the horizontal and perpendicular lines; correct position of tongue is shown in A, B, and C, that is, straight across and above the middle line. A, Front view, showing by dotted lines the position of the various mounts as they would appear if seen through the brooch. B, Back view, giving the positions of the mounts; note that the opening of the catch is downward. C, Top view, to show parallel position of tongue when fastened.

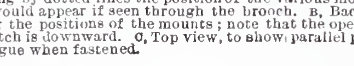

Fig. 2.—Form of Double-Pointed Tongue, to prevent tilting forward of Narrow Brooch.

catch have to be properly placed. It is not difficult to see where the centre of the joint should be—as that is in the same line as the tongue—and with the catch there is no difficulty here either, if you remember that the natural spring of the tongue will force it to rest against the highest part of the inside of top curl.

This point being fixed, you have but to solder such highest point in line with the centre of joint.

You will, I feel sure, without being told, solder the joints and catch parallel | thus | and not / thus |.

Besides obtaining the horizontal position of the tongue in reference to the front, we have to get a proper distance between it and the back of the brooch (Fig. 1, C). This distance will vary according to the size of the brooch, and to the material that it will have to fasten; for example, but little space is wanted between them when silk ties or lace is to be secured, while something like $\frac{1}{4}$ in. may be wanted for a heavy shawl brooch. You will have to judge that for yourselves, as it will probably vary with every brooch you make.

The side view of the brooch (Fig. 1, C) indicates the position that should be tried for: it is, as you see, quite parallel with the back all along.

What should the length of the tongue be? For the ordinary tongue we have it projecting a little beyond the catch, say $\frac{1}{8}$ to $\frac{1}{4}$ in., and, at the same time, bear this in mind, it *must adjust easily*, therefore don't cut it *too short*, and it should not give opportunities for the wearer to *get scratches*, therefore, *not too long*. You must find the medium; I cannot fix one for you.

You should also turn up the point a little away from the brooch, in order that it (the point) may rest against the dress, and so obtain a little protection.

The length of the tongue in a protecting or safety catch decides itself, for we should never be mad enough to let a tongue project when the catch is made expressly for its protection—should we? Of course, never! Well, perhaps, we had better say hardly ever!

The catch, you will notice, is placed with its opening *downwards*, for a very simple mechanical reason that I leave you to guess for yourselves. If you do not know what it is, just observe the way left-handed ladies put their brooches on, then you will see the insecurity of turning the catch the other way about. I expect a good proportion of us have put a catch on head over heels when we were but young at the trade, and the same thing still happens even now with apprentices, so, kind reader, you are warned: be ready to do this properly when first asked to solder a catch on.

Fig. 2 indicates a suitable way of using the double tongue, for if a narrow bar brooch has a heavy or high front, then it will look towards the ground, and show us its edge instead of its front, unless we take some such means as this to keep it up.

The artistic part of our work I am purposely refraining from making but little allusion to, at any rate, for the present; but this I should like to say, with all the authority that others' opinion and advice and my own experience give: *Learn to draw*, and, if possible, to model in wax as well. For without a knowledge of drawing it is *simply impossible* for you to do your work properly. You have not educated your eyes, and cannot appreciate, and, consequently, cannot reproduce the drawings given to you to carry out.

I could write for hours and give examples without number of the advantages this confers, but I will content myself with asking those who mean to be good workmen to study freehand drawing and geometry during their leisure hours. Go to some art school. There are evening classes held nearly everywhere now, and, at first, keep to simple outline scrolls and leaves: it will give the best results for your business.

I am so convinced of its necessity that I advise the giving up of some hobby or other for this purpose, if you can find no other time, for if you do not, then in the race to the front you will be left behind.

Drawing is of paramount necessity as a means to convey your ideas or methods, and in this I have our worthy editor's experience to go on as well as my own. And he has had the greatest opportunities of knowing the value that illustrations have as a means of making others understand.

Therefore, endeavour to obtain the power to convey your thoughts by means of the pencil—it is a pleasant task, and one that foreigners have mastered. Why cannot our countrymen do the same, and not be beaten on their own ground, as they sometimes are, through being unable to indicate their method even by the roughest of sketches, to say nothing of their more artistic way of work?

This lack of becoming acquainted with everything connected with our business or craft as far as opportunities allow us seems to be a usual thing now, for I noticed the other day that William Morris, poet and socialist as he is, said "that there were no craftsmen now except surgeons." Such a statement as that from one who, I fear, knows only too well what he is talking about, hits, and hurts too, as Mark Twain says, "until we get level again." I hope some of my readers will help us to get level by removing some of the truth of that accusation, for it is an awful condemnation as it stands, be the fault whose it may.

HOW TO MAKE A PIANO.

BY "NIL DESPERANDUM."

POLISHING THE PIANO—THE PROCESS—FLY FINISHING.

IT is now necessary to beautify the exterior in some way. As I pointed out in the paper on "Fitting-up" that the ornamentation was decidedly a matter of taste, I think the same remark applies equally to this part. It is usual in the pianoforte trade to polish with shellac polish: this is made from shellac held in solution with methylated spirits; the lac is manufactured in several parts of India, and is produced on the branches of trees, in the form of a cellular incrustation, by an insect—the *Coccus lacca.* This incrustation is scraped off the branches by the natives, and after being washed is put into linen bags; the bags are then held before a large fire, while a native at each end twists the bag in opposite directions, and the lac exudes through the bag and drops in a trough; it is then formed into thin sheets, and afterwards broken into fragments. Polish ready made can be procured at most oil or paint shops. You begin the work by rubbing a piece of fine glass-paper over the part you intend polishing, to remove any spots of glue or foreign substance that may have adhered to it since it was cleaned up; now take some plaster of Paris, and mix into a paste with methylated spirits and a little brown umber, to make it the colour of your walnut. Rub this well over the work so that it fills up the grain of the wood, employing plenty of friction, then wipe off clean with a piece of rag; next put some raw linseed oil on a piece of wadding, and rub over the surface; do not flood it with the oil. Although the oil is necessary in the working of the polish, if too much is used it has a tendency to sweat or ooze out on the surface. Make a rubber in the following manner: take a piece of wadding and form it in the shape of a ball, with one flat side; make this in size according to the size of the work you have in hand; now put about a teaspoonful of polish on your rubber; see that it penetrates the wadding well; by pressing with the thumb it will enter the wadding better. Now put over the wadding a nice piece of soft linen rag free from holes, and twist it round, the twist occupying the hollow of the hand when using; now rub your fine glass-paper over again, and commence by going over the surface with your rubber, in all directions, up and down, then across, then forming the letter O, then the figure 8, and every way, so that you do not work your rubber too much in one direction, as this tends to make minute spots on the work, instead of being level; work on until your rubber is dry, then replenish with more polish; you will probably have to put a drop of oil on the face of your rubber—with your finger this time—so that it works free; repeat supplying your rubber with polish until the grain of the wood is quite filled up, and a smooth surface is on the work. Up to this point of the work it is called bodying up; before finishing or spiriting off, it is best to leave the work to stand a day or two; you can then proceed to finish. Instead of using polish only in your rubber, you use half polish and half spirits, and work with this until you remove some of the smears left from the bodying: this has the appearance of steam on the work; your object is to remove this. After using half and half, you make a rubber of methylated spirits only, using very lightly until you find it getting dry, then you can use more pressure, until the smear is finally removed. The fly finisher now receives the parts of the case from the polisher to put together; he has to see that all the different parts of the case are complete. I will now describe what the reader has to do at this stage: a very important and necessary work is to take a pair of bellows and blow out all small particles of dust or shavings which may have lodged behind the strings or in any other part of the piano; it is better to stand the case on its top on a clean board, and tap the bottom gently with a hammer: this makes the dust fall from under the bottom plate. Now put the trusses or brackets in their place between the key bottom and truss toes: these are secured with screws through the bottom of truss toes and top of key bottom; you then put on four castors with screws, two being on the truss toes and two on the bottom of the back. At each end of the key-board you will find there is a vacant space: this you fill with blocks 7 in. long and the width of the spaces, to stand $\frac{1}{8}$th of an inch above the key: these are called key-blocks. Now you can hinge the fall and back flap together; see that it fits in its place nicely, and try whether it locks; if it does to your satisfaction, then put the name-board on: this is screwed to the back flap from its bottom edge. Now that the name-board is in position, you will find that it will not go down into its place by reason of the sharps or black keys being too long; you cut the ends off these after marking, so that they are $\frac{1}{8}$th of an inch clear of the front of the name-board. You may have to plane a little off the bottom edge of the name-board so that it rests on the top of the key-blocks and the back flap on the cheeks; also glue a strip of red cloth or flannel along the bottom, allowing it to stand over so that it shows behind the keys; now hinge your top together, fit panels, and fasten them in. On the pedals you put bosses: these are round pieces of brass to prevent the wood being

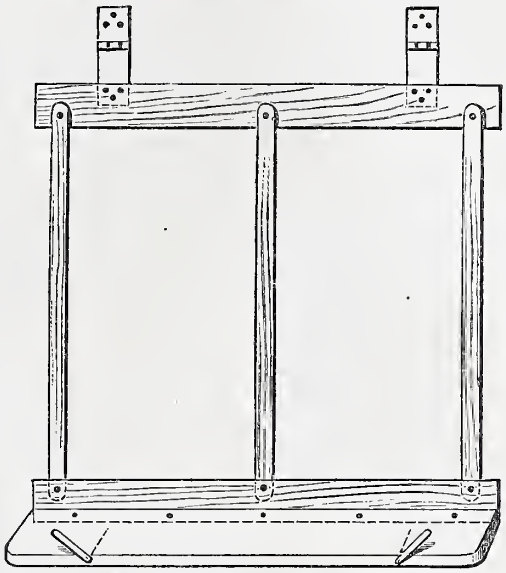

Fig. 1.—Desk to support Music. (Scale, 2 in. to 1 ft.)

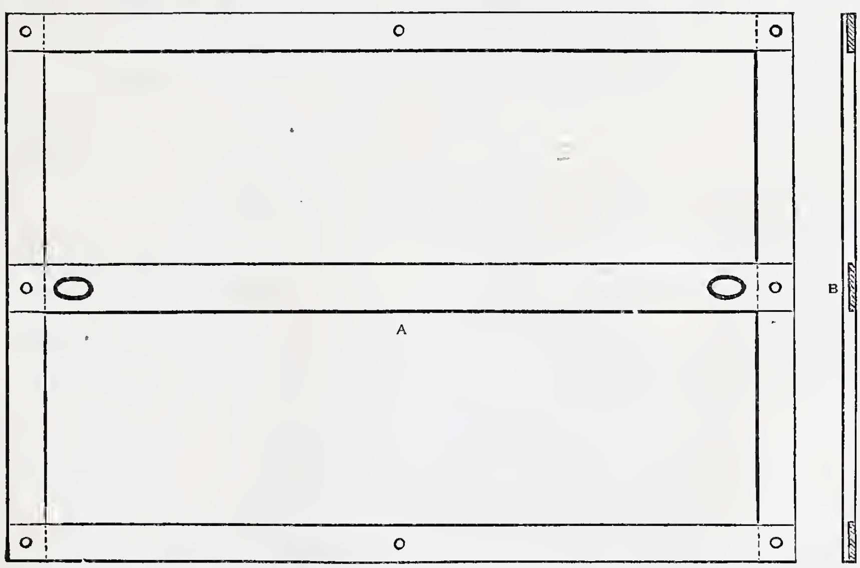

Fig. 2.—Back Frames in Plan (A) and Section (B). (Scale, 1 in. to 1 ft.)

worn by the feet; you will now require a back frame to fit in the back of the piano to be covered with lining, or any material the reader may choose: this is merely a square frame made of $\frac{3}{4}$ in. pine, with a rail crossing its centre: this is used in lifting the piano about; you level the ends down to the frame, and clean up with glass paper and colour it with brown umber and polish. Now screw your back frame in, and put in two round knobs just under the top at the back, to prevent it touching the wall. You will now require a music desk for your piano; the kind that will suit this piano is what is known as an overhanging desk; this is comprised of six pieces of walnut, $\frac{3}{8}$ths of an inch in thickness, two pieces $\frac{1}{4}$ in. wide, one piece $1\frac{1}{2}$ in. wide, and three pieces $\frac{1}{2}$ an inch wide; when complete, it closes up, and turns over the top door out of sight; you will want six desk rivets and washers, a pair of overhanging hinges, and a pair of book-holders; the two $1\frac{1}{2}$ in. pieces have three holes bored in each for the rivets to go through, and are $14\frac{1}{2}$ in. long; the $1\frac{1}{2}$ in. piece is the same length, and is screwed by its edge to one of the $1\frac{1}{4}$ in. pieces, while in the other edge is placed the book-holders; the three $\frac{1}{2}$ in. pieces are 12 in. long, and have a hole for a rivet at each end: these three are riveted, one end to the top of the desk and the other to the bottom; the overhanging hinges are screwed on the top edge of the top door (and are let in the thickness of the hinges) at one end, and the other end to the back of the top piece of the desk. Sconces or candle holders are not always used, but if you require them, these can be screwed on the panels on the door.

MEANS, MODES, AND METHODS.

How some Broken Roman Pottery was Mended.

A few months ago, some seven or eight small Etruscan vessels and vases were put into my hands for repair. They were mostly in fragments, as their discovery was due to the partial disappearance of a ploughshare in a tomb near Soriano, over which the unsuspecting ploughman was driving his team.

I have seen similar and larger specimens in museums repaired with narrow tape cemented on the outside; this, no doubt, is strong, but it certainly is unsightly. It might do on large vessels such as amphoræ, but on small ornamental vases would be quite out of place.

To rivet Roman remains would in most cases be impossible; the outlay of time and extra care would be enormous, and the risk of further increasing the number of fractures too great.

Ordinary cement and liquid glues seemed to be absorbed into the crumbling and very porous clays too readily to make a good joint, and I was rather at a loss how to go on. Then it occurred to me to try ordinary carpenters' glue. I had some by me (it is needless to repeat here how to prepare and mix it, and how the best quality is cheapest in the end), and making it rather thin, I tried the effect. First, I moistened the edges to be joined with clean warm water, and then put on the glue rather freely with a long flexible chip of bamboo (this, by the way, is my invariable substitute for a glue brush), put the broken edges in their places, and held them there with stout indiarubber rings, crossing and recrossing them wherever required. The glue, when dry, made an excellent joint; and a little trimming up of excess glue finished the job.

To further strengthen the vases, and to make good several pieces that were missing, I mixed some fresh plaster of Paris about the consistency of thick cream, and after slightly wetting the inside of one of the vases, poured the mixture inside, and turned and twisted the vase in all directions till the plaster was quite set. In this way I had built up a new vase inside the old, and the result was and is successful to this day, as the vases so repaired stand the dusting of the ordinarily careless housemaid.

One little vase of the saucer kind had a triangular piece missing from its circumference; this I was able to build up by chucking the saucer by the foot in a Whitton chuck, moulding moist plaster into the gap, and then removing the superfluous plaster with a chisel as the saucer revolved in the lathe; in this instance, the lathe reverted for once to its original form, viz., the potter's wheel.

The friends who had entrusted their pieces and fragments to my care were so delighted, that I became the proud possessor of two vases dating from B.C. 29, and this year some more vases were brought specially from Italy for me to mend.

Prevention of Air-Bubbles in Graph Composition.

Those who, like myself, prefer the hektograph or chromograph, or, in fact, any of the simple graphs or gelatine processes for reproducing letters and designs, may have often been worried by the air-bubbles which will keep rising while the liquefied composition is beginning to solidify. These bubbles can easily be removed in the early stage of the solidifying process (in fact, they only rise then) by holding a heated piece of metal such as a poker or a soldering-bit near enough to the bubble till the air therein expands and bursts the bubble. I always use a gas-blowpipe flame myself, and find it very simple, and more effective than the heated metal; care, of course, must be taken in either case to avoid scorching the composition.

H. J. L. J. M.

Two Misfortunes and their Lesson.

The other day, in mending some broken articles, I had two curious experiences. An old Sèvres cup (which I had picked up for a mere trifle at a curiosity shop in the country) got cracked. After cleaning and warming the edges, I cemented them with Le Page's Liquid Glue, wiping off the superfluous glue, as I usually do, with a damp rag. However, I had inadvertently left some on the gold with which the cup is plentifully adorned, and after some hours, in cleaning off the little hard ridge of superfluous glue which had formed under pressure, I was surprised and disgusted to find the gold come away with it in a thick flake.

At the same sitting I had mended, with the same useful cement, one of those little views which are apparently phototyped permanently on some white unglazed material. I glued it carefully, wiped off the glue that oozed through the joint, and placed the view, face downwards, on a thick piece of plate-glass to keep everything level, and to enable me to see if any additional pressure were required in any particular place. All seemed well; but next day, in removing the view from its resting-place, I found that a little glue had oozed out under pressure, and had spread about one-eighth of an inch on either side of the joint; the photo, which I had fondly fancied indelibly reproduced on the porcelain or glass, was firmly stuck on the plate-glass.

In both of these cases the acid in the cement may have caused the mishap by acting on the gold in the one case and the photographic film in the other; but the moral to be learned is certainly this: In cementing any surfaces that are not perfectly plain, remove very carefully all superfluous cement with a damp rag or sponge, so that the joint will not require cleaning off when dry.—H. J. L. J. M.

A Cheap Graph.

Take 8 oz. of glycerine, 2 oz. best glue; to the glue add 8 oz. of water, and when dissolved, stir in the glycerine, pour the mixture into a zinc dish, and as soon as it sets it is ready for use. If too much glycerine is used, the paper will stick to it; if too much glue, it will not take a good impression. The remedy for this is remelting, and adding either glue or glycerine till it is right.—E. A. P.

The first volume of Work is now fast drawing to a close, and the hints and suggestions given here are the last that can be given in the numbers of which it is composed. I trust in time to come that much more will appear in "Means, Modes, and Methods" than heretofore, and that readers, who know a thing or two that they have found to be of use and benefit to themselves, will send a brief account of their experiences in makir or mending, and recipes which have fairly stood the test of trial, for insertion in this part of our Magazine. There should be no holding back under the notion that the idea or process or wrinkle to be sent is lacking in importance or is too simple to be of value. Whatever it may be, without doubt it will be useful, some day or other, to one or another of those who read Work. The only thing I stipulate for is that the information sent shall be the result of experience and not copied from a book.—Ed.

WHEEL CUTTING AND DEPTHENING.

BY FRANCIS CAMPIN, C.E.

Having in a former article ("Toothed Gearing," page 581) shown how to draw correctly the forms of the teeth of wheels and how to proportion their dimensions, I now purpose to describe how the teeth are made, and the distances of the wheel centres properly adjusted.

Wheels of moderate and large diameters are cast to form, and subsequently have the teeth cleared out; but those of small size must be cut or stamped from blanks prepared for the purpose. Stamped wheels are chiefly made in America, for the cheap clocks supplied by that country. They are necessarily far inferior to wheels formed properly by suitable machinery, and will not here receive any further consideration. The largest spur wheels have the teeth finished in a kind of planing machine, the cutting tool having its edge accommodated to the form of tooth required, but smaller ones are finished by rotary cutters and other milling appliances. Very great advances have been made during the past ten or twelve years in the improvement of milling machines and the tools used in them, and the introduction of emery wheels in some cases in which steel rotary cutters were formerly employed has been attended by advantageous results.

For clearing out the teeth of cast wheels of moderate sizes, the emery wheel has been found very effective, as the occurrence of a hard spot will not be so destructive as it would prove to a cutting edge. Rotary cutters were formerly made of the best wrought iron, and after being reduced to the required shape were "case-hardened" by being buried in powdered carbonaceous material, such as charred leather, and kept at a red heat for some hours, and then hardened by cooling in water; by this process the exterior parts—to a depth of about one eighth of an inch—were converted into steel, thus giving a hard cutting edge, supported by a tough interior body of metal. The improvements in the manufacture of steel, however, have enabled us to make these tools entirely of that metal, without having any fear of their failure through want of toughness. The cutters used in the finishing of wheels must, of course, have their peripheries made in the form of an exact counterpart to that of the teeth to be produced, and of a thickness or breadth of face equal to the distance between two teeth.

A simple form of wheel-cutting machine is shown in Figs. 1 to 4; Fig. 1 is a side elevation; Fig. 2, a plan; Fig. 3, a cross section, taken vertically through the bed of the machine along the line, X X. It shows the cutter in position to act upon the blank. Fig. 4 is an enlarged front elevation of the dividing plate. Like letters indicate the same parts in all the diagrams.

The machine is supported upon two end frames or feet, A A, upon which is securely bolted the bed, B B, which is somewhat similar to that of a lathe, but made wider in the middle to carry the cutting gear. At the left-hand end of the bed is the headstock, C, securely fixed there, with the centre line of its mandrel truly in line with that of the poppet head, D, at the right-hand end of the bed, B B. On the mandrel of the headstock, C, are carried the speed pulleys, E, and the dividing plate, Q, and on its extremity is screwed a chuck, by which one end of the bar, P P, may be securely held, the other end being supported by the poppet head centre as shown.

Upon the bed, B B, is fitted a saddle, F, which is made so that it may slide truly, and without shake, upon the front part of the bed, a lip, Y, running against the inside of the bed, and a strip, W, which fits under the front V shaped edge of the bed, holding it in position and guiding it. The surfaces of the bed upon which the saddle works must be made exceedingly true, both in respect to being true planes and to lying with their edges exactly parallel to the line of centres of the machine, so that when the saddle, F, travels along the bed, B B, its motion shall be truly parallel to the centre line of the bar, P P. The strip, W, is secured to the underside of the saddle, F, by set screws, which pass through holes which will allow of a slight adjustment, so that the strip may press evenly throughout its length upon the front of the bed.

Within the projecting part of the bed (see plan, Fig. 2) there is fitted a longitudinal screw, G, which may be turned by means of the handle, G′, made to fit on to a square on the end of the screw, G. This screw, of which the longitudinal position in relation to the bed is secured by collars at each end, works in a nut attached to the underside of the saddle, F, so that by turning the handle, G′, the saddle is caused to move along the bed of the machine in either direction, as may be desired.

Upon the saddle, F, is fitted a slide, H, so as to slide upon it in a direction at right angles to the length of the bed of the machine, the rubbing surfaces in this case being as accurately prepared and adjusted as in the case of the saddle and bed. Within the saddle, F, and in the direction of its length, is fitted a screw, I, actuated by a handle, I′; this screw works in a nut attached to the underside of the slide, H, so that it can be moved along the saddle at pleasure by turning the handle, I′, which, like G′, is removable, being fitted on to a square at the end of the screw, I. Upon H is mounted a standard, K, to afford a bearing to the upper end of a vertical spindle, of which the lower is earried in a footstep on H; on this spindle are secured a rotary cutter, L, and some grooved pulleys, M. For very light work the cutter spindle may be held entirely by the bottom end, and so the standard, K, dispensed with, thus allowing clearer access to the work. N is a blank centred upon the bar, P P, and firmly secured thereon by washers, O O, screwed tightly up. Q is a dividing plate, already referred to, as fixed upon the mandrel, and R is a stout spring, fastened to the bed of the machine, and having at its upper end a pin, Z, which fits into perforations in the dividing plate. S S is a gut band carried round one of the grooved pulleys, M, to drive rotary cutter, L, and being itself driven from some running pulley placed in such a position that the action of the band will not be affected by travel of the slide and spindle. T is a hand wheel, by turning which the centre in the poppet head is advanced or retired when placing the bar, P P, between the centres. The wheel is fixed on to the end of a screw, which works in the tube carrying the centre. When the proper adjustment is made, the tube is secured by screwing down the set screw, U. The nut, V, retains the poppet head in place upon the machine bed; this has to be loosened to set the poppet head approximately when the range of the poppet head screw is not sufficient for that purpose. The dividing plate, shown in enlarged elevation at Fig. 4, has several series of holes drilled in it to allow of wheels being cut with different numbers of teeth.

The method of operating this maehine must be described; and, in the first place, it is to be noticed that it can be used for turning the circumference and side of the blanks as well as cutting the teeth on the wheels. For this purpose, the slide, H, is removed and replaced by a tool holder, the same as that ordinarily employed on a lathe; this being adjusted, and the blank in position, the machine is driven like a lathe by a belt upon one of the pulleys at E; the blank being prepared, the slide, H, with its appurtenances, is replaced, the belt removed from E, and a gut band fitted to one of the pulleys, M. The circle of holes in the dividing plate suited to the number of teeth required in the proposed wheel is now selected, and into one of them is let fall the pin, Z, on the spring, R. This holds the blank in position, and by means of the screws, E and I, the rotary cutter is brought up to the work, and being set in motion a hollow between two teeth is cut, the cutter being travelled by the screw, G, completely across the edge of the blank, after being set by the screw, I, to cut to the proper depth. One space being thus cut, the cutter is withdrawn by working the screw, G, leaving the screw, I, alone, so that the cutter will be set right for depth for all the following spaces.

The pin, Z, is then pulled back, and the dividing plate—and with it the blank—turned until the hole corresponding to the next space comes under the pin, which is then allowed to fall into it, and another space is cut, the cutter being traversed through the blank by means of the screw, G, and this operation is repeated until all the teeth are formed.

In the adjustment of this machine, there are a few points which require especial attention, in addition to those already referred to. The spindle which carries the cutter must be exactly at right angles to the machine bed in all directions, and the centre of thickness of the cutter must be exactly the same height from the machine bed as are the centres upon which the bar, P P, turns; the cutter itself must, of course, run with absolute truth upon its spindle and entirely without shake; otherwise the teeth cannot be made of the proper form.

When it is only occasionally that wheels are required to be cut, as in amateur work, an attachment may be made to fit on to the slide rest of an ordinary lathe, being in form as shown at Fig. 5. Let A A be the top of the saddle across the lathe bed, which latter is shown in section, B being the handle of the cross-traversing screw; C and C′ represent the two parts of the slide upon the saddle arranged for angular movement, D being the handle of the screw for working the top slide, E. The tool clamps are supposed to be removed from the top slide, and the frame, F, secured to it in their place; this frame is made with bearings, G G, in front, in which is carried a vertical spindle, having at its lower extremity the rotary cutter, H, and at its upper the grooved pulley, I, over which runs a gut band, K, driven from some convenient running pulley.

When the wheels are very small, such as clock wheels, they will not be mounted between the centres on an arbor, as shown in Figs. 1 and 2; but put upon a short arbor fixed in the mandrel of the headstock, and secured thereon by a nut.

In cases where teeth are cleared out by a single cutting tool acting in a straight line, the tool as it descends must be guided by a template of the same form as the side of the tooth when finished.

Worm wheels may be cut in the lathe by first roughing out with a rotary cutter placed at the proper angle, and subsequently finishing the teeth off with a "hob," which is a fac-simile of the worm or tangent screw with which the wheel is intended to work, but which is made of steel, and hardened after having notches cut in its threads to form cutting edges by which the spaces between the teeth of the worm wheel are cleared out. The "hob" must be set to work at right angles to the axis of the worm wheel.

There are a few special wheel-cutting machines made by machine tool makers, and there are also some special machines of this class used by watch and clock makers; but for general use, the apparatus here described should be sufficient, with such modifications or additions as may make their desirability self-apparent for particular cases.

I now come to the adjustment of the wheels in gear, after the teeth have been properly formed, in regard to the distance apart of their centres. The importance of this depends upon the form of the teeth, for if they are involute, the distance of the

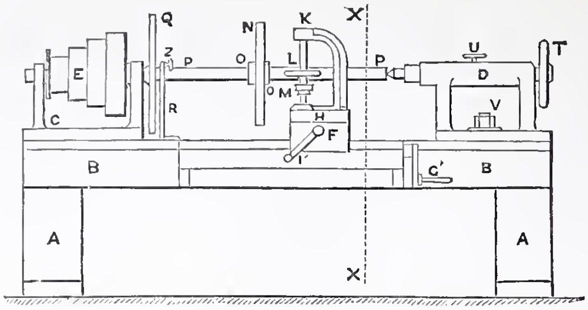

Fig. 1.—Side Elevation.

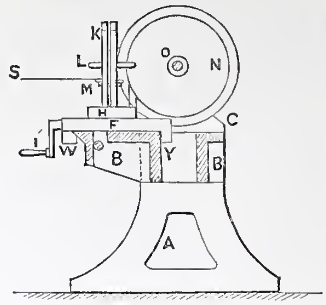

Fig. 3.—Section on X X (Fig. 1).

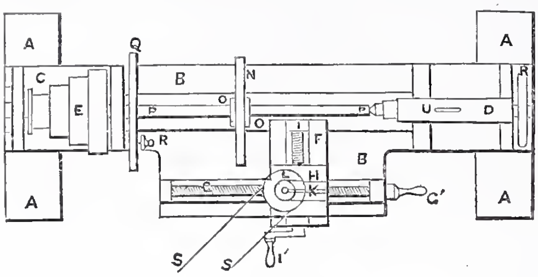

Fig. 2.—Plan.

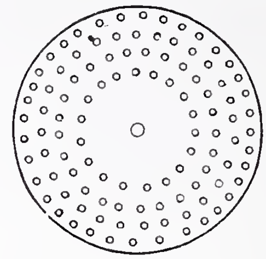

Fig. 4.—Dividing Plate.

centres need not be accurately defined; so long as they are close enough to prevent rattle, the teeth will work together accurately; but with epicycloidal teeth, the case is very different; here the face of one tooth works in contact with the flank of another—that is, the epicycloidal curve of one tooth is in contact with the hypocycloidal curve of another, and the curve of each tooth changes from epicycloidal to hypocycloidal at the pitch circle of the wheel; in order, then, that the teeth may work properly together, it is obviously imperative that their pitch circles should be just in contact; if not, the teeth will be set either too deep in gear or not deep enough.

In ordinary machinery, the sizes are such that the errors of measurement are insignificant in proportion, and the wheel centres can be marked out with practical exactitude, and the shafts upon which they are carried are also of such dimensions as to entail no necessarily perceptible error in their construction; but in the finer mechanical apparatus, such as clocks, watches, and certain mathematical and physical apparatus, the details themselves are so diminutive that a very slight actual error becomes proportionately a very serious one; therefore it is customary to determine the depth to which the teeth shall gear in such delicate machines by the sense of touch, and the centre distances are fixed by means of an instrument called a "depthening" tool. Its form is shown in Fig. 6. It consists essentially of two frames of the form shown by A A′; these frames are hinged together at the bottom, so that they can open out like a double vice. At the upper end each frame has two heads, C, C′, in which are secured centres, B B and B′ B′, by the set screws, D D′. These centres are so adjusted that they are exactly in line with each other, and the two sets parallel to each other. The inside ends are formed to support in a countersink the arbors of the wheels to be adjusted; and the outside ends are sharp points for marking off the centres, when their distance is determined, upon the plates of the machine for which the wheels are intended. The tool having been opened, the two wheels are adjusted between the centres, and the frames gradually brought together until, on turning the wheels with the fingers, they work perfectly smoothly and easily together; the sense of touch is sufficiently delicate, after some practice, to detect any roughness of action, and then the tool is adjusted until the working is satisfactory, or the operator is satisfied that the wheels do not fit, and must, therefore, be changed for others. A satisfactory result having been reached, the tool is clamped, and the centres for the wheel arbors marked off by the outer ends of the centres. The tool may be held in the table vice while in use, and the wheels are to be removed by releasing the back points before marking the centres—called pitching the wheels—on one of the parallel frames by which the wheel work is intended to be carried.

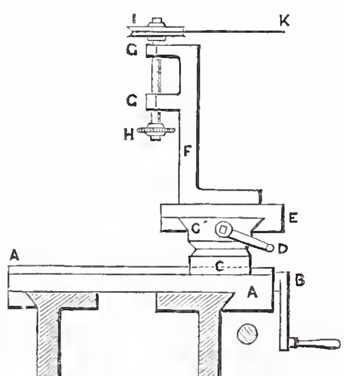

Fig. 5.—Lathe Attachment.

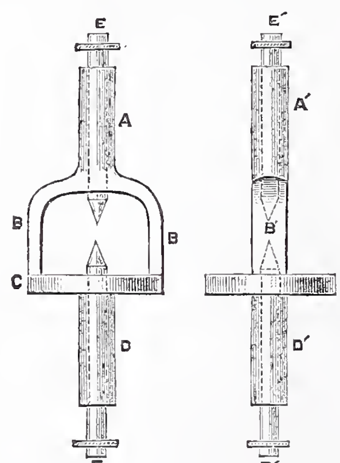

Fig. 7.—Uprighting Tool.

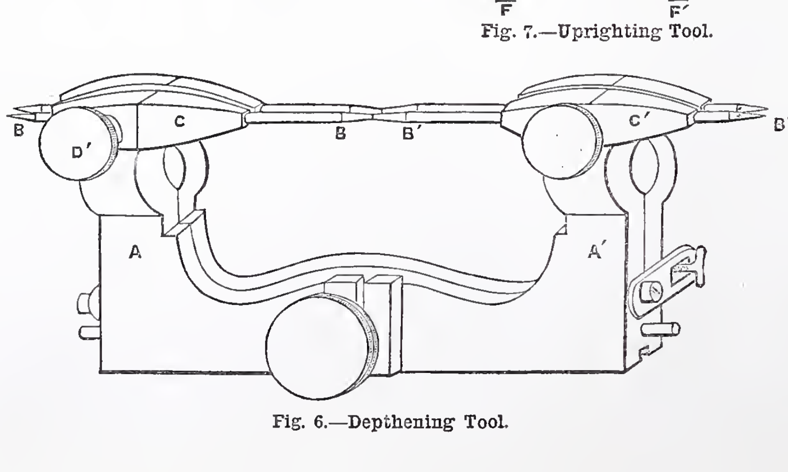

Fig. 6.—Depthening Tool.

The wheel centres having been marked upon one of the parallel plates, the holes are to be drilled to receive the ends of the arbors, and from these holes the centres are to be marked upon the companion parallel plate. It is obviously indispensable that the wheels should revolve in planes parallel to the plates, and to this end it is necessary that their axles be at right angles to the same. To ensure this, the second plate is pitched from the first by means of an "uprighting tool," shown in Fig. 7, held in the vice; E, A, etc., refer to a front, and E′, A′, etc., to a side elevation of the tool, the letters themselves indicating the same parts in both views.

The upper part, A, is an accurately bored tube, terminating in a stirrup, B B, to the bottom of which is attached a disc, C, having its upper surface perfectly true, and depending from its centre is another bored tube, D, similar to A, and in exact line with it; the centre line passing through the two tubes is at right angles to the upper surface of the disc, C. In the tubes, A and D, are fitted centres, E and F.

The pillars by which the parallel plates are held together, and which also determine their distance apart, having been truly turned, the frame is put together and laid upon the disc, C, with the pitched plate upwards, the centre, F, being, of course, drawn back into the tube, F, to commence with. The centres, E and F, are made to fit the tubes accurately, and their points are truly turned and exactly opposite each other. The frame is now moved until one of the holes is brought under the top centre, E, and there secured by pressing the point of the centre into it, while a corresponding hole is marked on the under plate by the lower centre, F, which is pushed up for that purpose; it must follow then that an arbor working in holes drilled to these marks will be exactly at right angles to the side plates of the frame. In a similar way a mark is made on the under plate corresponding to each hole in the upper one, and to these marks the holes are drilled at right angles to the plate.

Some time since a correspondent asked for instruction in wheel cutting, etc. The subject, which could not be conveniently treated in "Shop," has therefore been taken up and sufficiently explained in this paper.

A SMALL STAND-TABLE IN CARVED OAK.

BY HIRAM PRICE.

THIS small piece of furniture, of which a sketch in perspective is given in Fig. 3, will be found a handy as well as an ornamental article, and with the working drawings and practical directions about to be offered no one who can carve a little in wood will find any serious difficulty in making it. The only difficulty likely to present itself is with regard to the pillar. That shown is turned, and there are many who can handle carving tools who cannot turn ; but, to meet this difficulty, an alternative design will be given, by which the pillar can be worked without having recourse to the lathe.

The dimensions of this table are exceedingly modest ones, since it is intended for no heavier duty than that of standing beside an easy chair to hold a book occasionally, a coffee cup, or any similarly unimportant matter. It barely stands 25 in. high, and its top measures 12 in. by 10 in. only. The perspective drawing of it (Fig. 3) is not to scale ; all the remaining diagrams explaining it are on $\frac{1}{4}$ scale, except where otherwise specified.

Whether we use the turned shaft which appears in Fig. 3, or the alternative one shown in Fig. 8, the general dimensions of the pillar remain the same, excepting only that the turned work occupies more of the length by $2\frac{1}{2}$ in. than the twist.

The length of the pillar from top-piece to foot-piece is 22 in., to which is to be added the tenon, passing through foot-piece, $1\frac{3}{4}$ in., making $23\frac{3}{4}$ in. in all: its base and top are $1\frac{3}{4}$ in. square. The section of top (Fig. 6) shows at *a* how the two pieces of $\frac{1}{2}$ in. wood which serve to support the table-top are secured to the upper part of the pillar by screws.

At the base of the pillar the tenon *b* (see section of bottom, Fig. 9) passes through the foot-piece, and is secured by a peg; the hole through which this peg passes must be bored so high that, on tightening it, the shoulder of the tenon will be drawn thoroughly home. This, with glue, will make a joining as strong, solid, and immovable as it is possible to make: so that the four base-stays (*c*, *c*, Fig. 9) are rather added for effect than for the increased strength which they nevertheless give. Fig. 7 shows a side view of one of these base-stays, and Fig. 4 a front view as seen from above. The better to explain the carving upon them these stays are drawn to half size. They are cut from inch board, which will be better if somewhat gnarled in grain, as English oak often is, that there may be no danger of splitting. The various diagrams show how each is fixed by two round-headed brass screws, which are made to form a decorative feature.

The foot-piece, the upper side of which is shown in Fig. 5, and the under side in Fig. 10, is also of inch board, and will, like the last-named pieces, be best made of cross-grained stuff. It will be seen that though 12 in. across, this can be cut from a somewhat less than 10 in. board. In Fig. 5, *d* shows the square space on which the base of the pillar rests, whilst *e*, *e*, *e*, *e*, mark the positions of the four base-stays. The carved ornament running round the edge of this foot-piece is shown at full size in Fig. 1. The small hollows indicated as at *f*, *f*, in this figure, are each taken out with a single scoop of the gouge, and will give a crisper and better effect to the border if left sharp from the tool than if sand-papered down. In Fig. 10, *g*, *g*, *g*, *g*, indicate the places of the four balls on which the table stands: the same letter also marks these balls in the section, Fig. 9. They are an inch high, and two wide. If they cannot conveniently be turned, they can readily be worked, as octagons, by hand, from inch board. Each of these balls is, as shown, fixed in its place by a stout screw, the head of which will need to be well countersunk.

To give any separate diagram of the two pieces of board, screwed to the upper part of the pillar, and supporting the top, can scarcely be necessary. They are sufficiently explained at *a*, Fig. 6, and at *h*, *h*, Fig. 11. They are of $\frac{1}{2}$ in. oak, and their outer edges along their three lower sides are bevelled off: the screws which fasten them to the top are indicated.

The top is of $\frac{3}{4}$ in. stuff 12 in. by 10 in., and the corners are taken off as seen in Fig. 11, which shows its under side. At the edges it is planed down to $\frac{1}{2}$ an inch on its lower side, as appears in the section Fig. 6, which shows its narrower dimension. In Fig. 11, *h* and *h* indicate the places of the two supports mentioned above, which, it will be observed, cross the grain of the top. The screws which fix it to these supports are driven upwards, that they may not show on the upper surface. A little very simple ornament running round its edge is shown at full size in Fig. 2. This ornament, it will be found on trial, is by no means difficult to carve, and presents a highly effective appearance when finished.

Provided the person making this stand-table can turn, or can procure a turned pillar, he cannot perhaps have a shaft of form better suited to his purpose than that shown in Fig. 3. But if not, something will be needed in its place which can be made without the lathe, and as an alternative the twisted shaft, Fig. 8, is offered. A twist always looks well in oak work. In our old English (17th century) furniture it is a frequent feature, and is as artistic in effect as its successors, the screws in 19th century furniture, are the reverse. In the work of the earlier half of the 17th century we meet with single twists which frequently taper upwards, but in things made a little later than 1650 the double twist more abounds; that in the illustration is sketched from an example of (apparently) the time of Charles II.

A twist such as this may at the first glance appear a difficult thing to set about. Such, however, is not the case: it can in reality be laid out with the greatest ease and simplicity.

From a square it is no difficult matter to reduce the shaft to an octagon, and were the twist a large one, it might be well to reduce this still further, and bring it to a sixteen-sided figure; but for our present dimensions the octagon will suffice We may set out the twist upon this, and for so doing we shall need two strips of paper, each of the intended width of one fillet of the twist from hollow to hollow, and these we wind spirally round the octagonal shaft from bottom to top, giving them the desired inclination. And with regard to this inclination it should be observed that it is a mistake to attempt to get the appearance of a tight twist. The work to look well should look as if slackly twisted—that is to say, the spiral should incline to the vertical rather than to the horizontal. When we begin to wind the strips of paper they will seem to fall quite naturally, and without any trouble on our part, into their right places, and we can fix them in a temporary way with three or four drawing-pins or tacks.

One of the strips we can now remove, and having divided it in half lengthwise, we *paste* one half back where it was before, then we treat the other strip in the same manner. We now have two spirals in paper running up our shaft, and between them two bare spaces of the same width—the paper will represent the two fillets of the double twist and the bare spaces the hollows between them. This simple little operation takes some time in description, but in the actual work it is very easily and quickly done.

The twist being thus ready for working, we have to cut away the wood in the bare places, which are to be the hollows, with the gouge, to the necessary depth; making a slot with the saw up the middle of the hollow is a help to doing this, and when the hollows are worked out, we can trim off the edges of the fillets with the chisel. In finishing the hollows the half-round file is useful, and the fillets need file and sand-paper. Making a twist is a thing that any one can do if he only knows how to set about it.

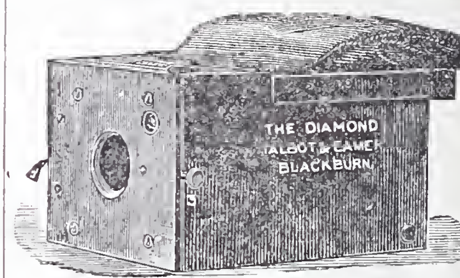
In the pillar before us, as given in Fig. 8, the square base and top are left somewhat longer than in the pillar with turned shaft. This is to prevent too great a length of twist tiring the eye by its monotony. One never sees long unbroken twists in old work.

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

126.—TALBOT AND EAMER'S "DIAMOND" DETECTIVE OR HAND CAMERA.

AMONG the many cameras of all kinds that are now offered to the notice of all photographers, professional and amateur, the "Diamond" Detective or Hand Camera, figured in the accompanying illustration, appears to be one that is in every way well suited for the purpose for which it is intended. It is claimed for this camera that it is "the smallest, lightest, and cheapest efficient hand camera yet introduced," and yet is capable of taking twelve pictures, $3\frac{1}{8}$ in. by $2\frac{3}{8}$ in., on ordinary dry plates without recharging. The size of the little instrument itself is 6 in. by $3\frac{1}{2}$ in. by 3 in. It is fitted with a rapid rectilinear lens always in focus, a finder, and a shutter for time or instantaneous pictures. It is said to be entirely new in principle, form, and construction, and is thus possessed of advantages and special features



Talbot and Eamer's "Diamond" Detective or Hand Camera.

which render it particularly desirable for all who are desirous of obtaining permanent records of subjects of all kinds at a minimum of cost and trouble. In taking a picture nothing else but the camera is required, all other appliances, such as tripod, focussing cloth, etc., being entirely dispensed with, which renders it, indeed, the least burdensome of cameras to those who use it, and this will be readily understood when it is said that the instrument, which is excellently well made and most convenient in form and arrangement, weighs very little over $1\frac{1}{2}$ lbs., and is supplied complete in case and with one dozen extra rapid dry plates for 30s., additional dry plates being bought at 1s. per dozen or 6s. per half gross, carriage paid. The pictures taken are of course smaller than the ordinary carte de visite, but mount nicely on the carte de visite card. They are both sharp and crisp, and will be found to be especially suitable for lantern slides, and lend themselves readily to enlargement. The camera is always ready for use until the dozen plates with which it is stored are used, and a fresh lot required. As will be seen from the illustration, the camera itself is in the form of a box, having the lens and instantaneous shutter in the front, and the dry plates, twelve in number, at the back. By an ingenious arrangement each plate when a picture has been taken is raised from its position in front into the leather pocket at top, and is then, by the finger and thumb, raised clear of the camera, and brought to the rear of the other plates. Thus each plate is brought in turn to the front for exposure, and then transferred behind the rest. The last plate cannot be lifted out of the camera, and thus shows that the entire number has been used. It is made and sold by Messrs. Talbot and Eamer, Photographic Apparatus Makers, Blackburn. THE EDITOR.

NOTICE TO CORRESPONDENTS.

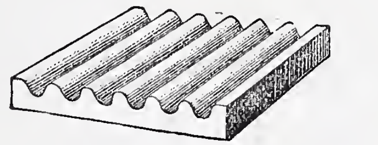
**** In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Electric Time Alarum.—C. H. M. (*Wylam-on-Tyne*) writes:—"I have recently received the December number of Work, and have read the article by G. E. Bonney on an electric time alarum. Some dozen years ago I constructed an alarum which, as it differed from the one described, and had some good points of its own, I daresay, if you think fit to publish it, may interest some of your readers. My object in designing the following arrangement was to make an alarum which did not require setting, or switching off, or setting on daily, because one is quite as liable to forget to attend to the alarum before going to bed as to go to sleep again after being called up. My alarum, therefore, I made so as to ring every weekday morning, but to be silent on the Sunday, and experience of years has shown that it always answers its purpose. The proper bell to use is the kind known as 'continuous ringing'—that is, when a momentary current is passed to the bell it starts ringing till stopped by pulling a cord. This current should only be sent to the bell for a very short time, say not more than for a quarter of a minute, as you cannot stop the bell till the current from the clock ceases. This makes it necessary to depend on the minute hand of the clock for completing the circuit, as the hour hand alone would remain too long in contact. This, however, is not an objection, as it makes the connections to the clock much simpler, and such as can be made without pulling the clock to pieces. The arrangement is this: a little wheel about $\frac{5}{8}$ in. diameter is placed in the path of the hour hand, and is made with 14 teeth, because in a week the hour hand passes any particular hour 14 times. This little wheel is a pin wheel with the 14 pins standing out on one face. The pins are alternately conductors and non-conductors of electricity except where the Sunday morning one comes in. It is also a non-conductor. The hour hand in passing this little wheel acts as a 'wiper,' and carries the wheel on one pin or tooth. If the tooth is a metal one the current can pass to the hour hand while the contact lasts, but when the tooth or pin is of ivory no current passes. The contact lasts about a quarter of an hour, but the circuit is not completed till the minute hand touches a fine wire placed so as to lightly touch the tip of the hand. One advantage of this mode of passing the current is that no sparking takes place at the hour hand, because the 'make' and break take place long before and after the current passes, and the only sparking is at the point of the minute hand, and this does no harm, because the minute hand passes over this connection 168 times a week, out of which only 6 times will be when the current is passing, so that the 162 times when there are no currents are devoted to rubbing the 'contacts' clean. The alteration to the clock is very simple. Pass two insulated wires in from the back, and bring one out just above twelve o'clock, and the other out just below six o'clock. The top wire should terminate in a bare end of very fine wire (36 B. W. G.) like a hair, which may be made to stand up in the way of the point of the minute hand. This wire being so fine offers an insignificant resistance to the path of the minute hand, which merely sweeps over it on each passage. The bottom wire must be connected to the little pin wheel, which is made as follows:—Take a piece of latten brass and cut out a piece the shape of the letter Q, making the circle about $\frac{5}{8}$ in. diameter. In the centre rivet a portion of a toilet pin, leaving it standing out about $\frac{1}{16}$ in. This forms the base plate and the centre pin on which the little wheel is to revolve. Next take a piece of ivory $\frac{1}{64}$ in. thick and $\frac{5}{8}$ in. diameter, and another piece of the latten brass. Lay these together, and drill 14 holes through them near the outside edge, and one hole at the centre. Put 6 points of toilet pins through the ivory, and rivet them over in the brass. This will hold the two well together, and being spaced in alternate holes they will go nearly round the wheel. Then file up 8 little ivory pins for the rest of the holes, and fasten them in with shellac. Level all off till they stand about $\frac{1}{32}$ in. out from the ivory face. The wheel being finished place it on its pin, which stands in the middle of the base plate made in the shape of the letter Q. Spin it round and see that it runs true and very freely. Now we want to introduce a little friction to make the wheel stay where it is placed, but to give little or no work to the hour hand to move it. This is best done by a small washer of felt, say, $\frac{1}{16}$ in. diameter, which place over the centre pin together with a similar one of the latten brass, and rivet the centre pin to keep all in place. The wheel being now complete, attach the bottom wire to the tail of the Q, and fix the Q base plate to the clock face with thick shellac varnish. Being so small it does not look unsightly, any more than does the addition of a seconds hand to a clock face. It will be seen now that when the hour hand touches lightly against one of the metal pins of the little wheel the current can pass through the wire which we attached to the tail of the Q because the metal back of the wheel is touching on to the Q base plate, but that the ivory front of the wheel and the ivory pins prevent any current from passing at any other time. This arrangement is of course only for passing the current at one particular time, namely, 6 o'clock, but in most cases it is all that is required. I don't mean that 6 o'clock will do for everybody, but that one fixed hour will do in nearly all cases, and the clock can be fitted accordingly for 5, 5.30, or any time that may be required. In the few cases that I found it necessary to get up extra early or late I put the clock on fast or back slow the night before. If any one wants the arrangement made so as to be able to vary it to any extent, the little pin wheel instead of being made a fixture could be made to attach to any hour or half hour position, and the wire which is to be touched by the minute hand could be brought out at each quarter hour, and being so small would never be noticed. However, I write more for cases like my own, where the getting-up time is the same all the year round, and hope that others may find the advantage of having a bell which will ring every workday morning at their usual time of rising, and will continue to ring till they get out and pull the string to stop it, but which will leave them to sweet sleep on the Sabbath, and all without having to arrange it overnight."

P. K. P. Glass.—E. P. (*Great Yarmouth*) writes:—"Please to explain what P. K. P. glass is, as the tradesmen in this town do not know what it



Fluted Glass.

is. A. G. (*Newcastle-on-Tyne*) speaks of it (see page 619) under the heading 'Rubbing down Oilstones.' Will A. G. say if he means fluted glass?"

Book Repairing.—W. J. C. (*Birmingham*) writes:—"I learnt bookbinding from papers in a periodical. I find it most useful in repairing. I always put on a strip of smooth brown paper over the muslin. It is almost necessary to have a handy press to keep the back tight while cleaning off glue, gluing up, etc. Mine is made thus:—Two pieces of ash 3 by 3 in., about 20 in. long, are bolted through near the ends by about 12 in. bedscrews; these will hold the book well compressed. This press is more convenient if mounted in a box—say, 20 in. long inside—resting on a piece of wood at each end, so that the top of bars is level with top of box; the bedscrews will come through the front edge of box with nuts outside working against washers or plates. The box and press should be big and deep enough to drop into it, say, a volume of Work or Quiver—20 in. long by 10 in. deep, any breadth. If the loose back of the book is broken through at the hinges, it may be repaired by some fabric of similar colour inside; or, still better, fasten the two lids on as directed (see page 588), and then put on a loose back as below, covering the back and 1 in. each side with dark buckram, a very strong material, gluing the old back outside, or cover with white ticket buckram, which is not so strong, but one can write a title on it. To make the ordinary loose back which falls away when the book is opened, screw the book (with lids) back upwards in the press. Cut a piece of thin card or cartridge paper or thick note paper just to cover the back between the lids, roll this round a round ruler, so as to give it the proper curvature, then place it on the back, securing it to the lids by a bit of thin paper pasted on overlapping the lids; then cover the back with buckram, or leather, etc. Lepage's Fish Glue is a very convenient thing for the book repairer. The following paste is always ready:—Best flour, 2 oz.; water, $\frac{3}{4}$ pint; salicylic acid, 16 grains; alum, 32 grains. Break down the flour with some of the water with a paste brush, and add the rest of the water; heat it till it no longer thickens, stirring constantly; lastly, add the alum and acid, and put it into small pots—say, $\frac{1}{4}$ lb.—and tie over. I am not in love with Mr. Bonney Steyne's plan of sewing through buckram (Work No 6), but I have tried a modification of it with success—viz., cover the back of the pamphlets or sheets with a piece of white buckram overlapping 1 in. on each side; screw up the back so covered in the press, and then make four or six sew holes through the buckram and sheets; then the sheets or pamphlets can be sewn quickly and easily, making a strong book which opens very flat. I thank Mr. Bonney Steyne for some happy suggestions. I have just bound Cassell's 'Cathedrals' in Japanese gold paper with old gold Roman satin for the back.—N.B. In using Roman satin, glue the boards, not the satin."

II.—Questions Answered by Editor and Staff.

Gilding Methods.—J. S. L. (*Long Eaton*).—Several answers have recently appeared in "Shop" concerning gilding, and these you have doubtless carefully perused, as bearing upon your query. To gild with gold-leaf oak mounts and fillets, such articles being of an absorbent nature, requires some preparation. By frames in the white, I take it that you mean wooden frames, and not compo-faced ones, in which case this description will suit for all three. Stop the suction of the wood surface to be gilded either by rubbing in French polish, or by two coats of white, or brown-hard, spirit varnish. The former gives the best surface, and the smoother this is the more burnish the gold will have. Finely glass-paper down, if necessary, then apply a very bare but regular and evenly distributed coat of gilders' oil gold size. This must now stand aside out of dust until the next day, when it is dry, yet not so hard but that the wondrously thin gold leaf will stick to it. The process and object of the gold-sizing is this: to spread as thin as possible a film over the object, so that its presence is only known and justified by its holding the gold leaf. You will thus see that neither the polish or gilding should in the least prevent the grain of the mount from appearing. The manipulation of the gold leaf, if you are not used to it, will give you the most trouble. Gold leaf is sold in books of twenty-five leaves, each about 3¼ in. square; the ordinary, known as extra deep, which chiefly refers to its tone or colour, lies between paper leaves, dusted with rouge of some sort. Transfer gold is the same, but upon each leaf of gold a piece of white tissue paper is superimposed, so that the latter—the book having been subjected to pressure—when drawn out, has the gold affixed thereto. To use the first kind you require much practice, and gilder's tip, cushion, and knife, etc. The transfer, however, costing about 1s. 6d. per book, you may manage. Draw out a leaf of the tissue, and lay upon the mount, press evenly but gently with cotton wool, and it will affix itself to the size. When all is gilded gently rub with the wadding, and remove gold dust. Finish with a weak coat, and spread quickly but evenly, of clear size or with isinglass, one pennyworth thoroughly dissolved in one gill of hot water, used when cool or just warm. Prominent portions of a frame, etc., can be easily, if previously carefully gold sized, gilded by transfer, but hollows, etc., you can see would be rather awkward to get at. If you have compo frames, prepare them with paint or enamel, anything to make the surface regular and non-absorbent, then gold size and gild. The process of gilding will, in the house-decorating papers, be fully dwelt on. Space will not permit of more here. Many thanks for your letter and your pithy remarks. Let me assure you that the Editor of Work and his staff are both enthusiastic and practically minded as to the position of this paper in contemporary literature, and that the former is determined to justify, by its lasting success, his address to all workers contained in the first number. Any new modes or methods showing merit and originality upon any trade or calling, will receive a hearty welcome and a most careful consideration by the Editor of Work.—F. P.

Mixing Paints.—E. L. (*Preston*).—To mix, say, one pound of ordinary oil paint, take about 8 oz. of the colour pigment you intend using: thus, white lead for white, light greys, pinks, cream, etc., Venetian red, or vermilion, for red, and so forth, according to price and colour desired (see "Plain and Decorative House Painting" papers, pp. 450–51, etc.). Add to this 8 oz., about two more of patent paste or liquid driers; then make up to one pound with either linseed oil, or oil and turpentine, in equal parts. Remember, the more oil the more driers is advisable, but never less than 1 part driers in 8 or 10 of entire bulk. If you only want casual pounds of paint, that sold ready mixed at prices from 3½d. to 5d., according to district and maker, per lb., would be cheapest, and should do for common inside work. You would not be able to make a single pound so cheap, and some of the colours sold—bright red, for instance—you couldn't make at twice the figure. If varnished they stand a lot of wear. For cork picture frames buy varnish stain, either oak, walnut, or rosewood, stain and varnish combined, and it dries quickly. Colour for bedroom suite would depend on personal inclination; study the painting articles, or write when you have decided as to style. Frame making is in hand.—F. P.

Repairs to Verge Watch.—H. (*Brighton*).—In reply to your query, read over again the part speaking of repairs. I say "see last chapter," not "previous chapter," one gone before, but last one at end of the chapters on watches. You must know first how to take to pieces and clean before repairs. For me to begin the papers with repairs would have been folly.—J. S.

Verge Watch Cleaning.—W. G. B. (*Handcross*).—The putting in of verge staff is above the amateur's capabilities; the tools and time would be more than the cost of a pullet staff to balance; place the broken part in a small box so as to have same size inserted, and send on to Morris Cohen, watch tool, etc., maker, 132, Kirkgate, Leeds. Attach a label with above address, so that the P.O. people will only stamp on it, and not injure your new balance staff. He charges most reasonably, and I have no doubt you will be satisfied. You see you could not make one, so you might as well have it put in, costing very little more.

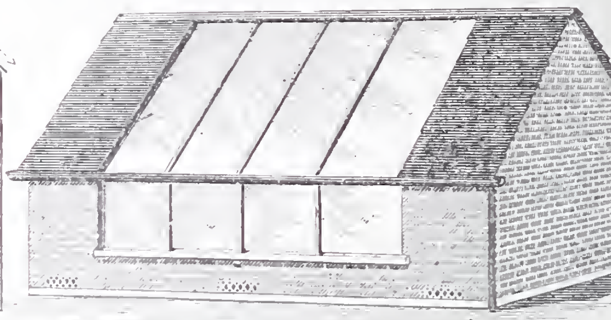
Stereotyping.—A. W. (*Paisley*) pours in a string of questions which space precludes our answering fully prefacing them with an interesting account of his experiments in stereotyping. We note, however, that A. W. either omitted a very important factor in his process, or else omitted to mention it in his account of it. We refer to what the French call "pate," or paste, consisting of flour paste, with a good proportion of plaster of Paris, and a little glue; layers of this paste harden in the drying, and render the matrix solid behind the flong and between the sheets of tissue and that of the wrapper paper. (1) As to curling, we advise A. W. to dry the matrix thoroughly whilst still on the forme and under pressure. We think this will prevent warping; and in putting the matrix into the casting box the side bars should lie on the beard, or margin, of the matrix, so that when screwed up the matrix should be held tight to the back plate, whilst the bottom bar should hold it tight transversely. The weight of metal as it is poured into the box should force the intermediate portions of the matrix back against the plate. (2) Any means of gradually drying matrixes cannot be objectionable. (3) Papers on photo-typography have been invited and received, and are under consideration. (4) To give in detail the process of producing a phototype would occupy too much space except in the article above referred to. In Wyman's Technical Series is a volume which A. W. should read, entitled "Zincography, or Process-block Making," by Josef Bock, 2s. 6d., 65, Chancery Lane. (5) We are quite unable to state whether you can claim to be the first to use blotting paper in stereotyping, but we should think not, as the papier-mâché has been thoroughly threshed out years ago. In conclusion we would point out that cuts, by which we presume wood engravings are meant, should never be stereotyped by this process, which, in the first place, is not nearly fine enough to reproduce their sharpness, and is unfitted by reason of the dampness necessary in the first stage and the subsequent heat of the second stage (which must split any wood up into numerous pieces) for the purpose. Electrotyping is now so cheap that stereotyping, either cuts or zincos, is quite out of date. Formerly they were done either by the polytype process, or with plaster matrixes. The former process consisted in first striking the block into type metal in the waxy state between fluidity and solidity which it, during cooling, attains, and as rapidly withdrawing the block before the heat has time to burn or crack it. The matrix thus made was used to strike any number, hence its name of stereotypes. It is now never resorted to, electros having quite beaten it out of the field, one valid reason being that in colour work the contraction in cooling that type metal exhibits utterly upsets all register.—J. W. H.

Ebonising Pine.—A. J. (*Glasgow*).—The greenish shade of which you complain may be owing to bad stain, or it may be (probably is) owing to a vegetable black having been used with brown polish. However, by adopting the following process you ought to be able to get a perfectly jet black surface either bright or dull. Of course, if the grain rises you must paper down. Mix some black with ordinary glue size, and apply to the wood. The mixture acts both as filling and stain. For the polishing medium use white polish and gas black mixed. Finish in the usual way with spiriting for a bright surface. To dull down use fine emery powder poured on. I am of course assuming that you are acquainted with the ordinary routine of polishers' work, so have not gone into minute particulars.—D. A.

Wooden Swing Cradle.—François (*Dulwich*).—I have the construction of a child's cot on my list of subjects, but I am afraid it cannot appear yet awhile. However, as the matter is urgent, the following hints on the construction of a swing cot may help you. The cot itself may measure about 3 ft. 3 in. by 1 ft. 8 in. by 1 ft. 3 in. deep. This is slung between two uprights by means of a couple of rods, of which one must be fastened to the foot, the other to the head end of the cot. In these days of cheap iron bedsteads you will find it much less costly to buy one ready made, and it does just occur to me that, however proud your wife might be of your swing cot, she, and perhaps you, would hardly care to trust your firstborn in it. I don't want to hint that you could not make the cot safe—safe enough, say, for the second—but the first is really such a precious little being, and in every other way superior to any previous youngster, that your wife might prefer a cot of somebody else's make. Instead of making a swing cot I think it would be safer to confine yourself to making a cradle on rockers. Some of this advice perhaps is not definitely asked for, but it is founded on experience. Somebody else for a time had an only baby, for whose use something was made by *pater*, who thought, like you, that *mater* would be pleased. She was, but baby used something else—very similar, but not *entre nous* home-made. Glad you like Work.—D. D.

Platform for Stage Purposes.—J. H. (*Liverpool*).—You cannot do better than make your platform of ordinary flooring boards. On account of the size make it either in two or in four parts. A drop scene will be much better than a screen to shut off the stage, but possibly the room may not admit of the necessary fitting. The entrances to the conservatory could easily be hidden by a judicious arrangement of curtains. If you cannot drive nails into the walls the difficulty would certainly be increased, but by a little contrivance you should be able to effect your purpose. For example, uprights could be fitted to the front corners of the stage, and a rod supported by them would do for a pair of curtains. These could be made to be drawn from the sides without trouble. Side curtains and a couple of screens would then hide the conservatory doors. I do not know if all the hints you want are now given, but I fancy from your letter that you have your "head screwed on," and will be able to see how to arrange details. Of course, it is always difficult to give precise directions for these unless one has seen the room, but if I am right in supposing the one you refer to is near Prince's Park, you will not need anything very complicated.—D. D.

Photographic Studio.—B. B. (*Holywell*).—Usually a photographic studio has to be constructed in accordance with conditions of light available, regulated by surrounding buildings, etc. The most usual form is the ridge roof studio, and this is one in which most excellent work may be made. We will presume that you have an open space with uninterrupted light. The following diagrams will give you an idea of its construction. The glazed side should face north, and the length of the room be about 30 feet, with about 20 feet to the highest point of the roof, and 15 feet wide. Six feet from each end should be brickwork, with a slated roof in which ventilators are placed, and ventilators at intervals near the ground. Access is gained by a doorway in the brick wall on the south side. Backgrounds at each end. Some photographers prefer to carry the glass roof in an uninterrupted slope to the solid low wall on the north side on account of greater facilities for fixing blinds. The lighting in both cases is identical. A series of working drawings for a studio would occupy too much space for these columns. The floor should be made as free from vibration as possible, and if erected on the ground should be on low brick pins about 6 inches above it for dryness' sake. A steep pitch to the roof tends to prevent leakage of rain and protection from hailstorms, and also improves the quality of the light. These are the principal points to be attended to in the construction.—E. D.



Photographic Studio.

Emery Wheel.—A. H. (*Manchester*).—Directions for making emery wheels at home were given in a paper in Work, August 31st, page 370, but if you require only one wheel it would hardly be worth while making it yourself, as wheels of all sizes are easily got and are not expensive. For most amateurs' work, a wooden wheel with leather rim covered with emery powder answers very well, and possesses one advantage over solid wheels, viz., that it may be renewed when worn, and also does not choke. The best wheels require to be faced up from time to time, as the pores of the material of which they are composed get stopped, and the cutting surface becomes glazed. Of course, if you require the wheels for grinding edge tools, the wooden, or buff, wheel will not suit, as it does not admit of the use of oil or water, and your only course is to purchase a wheel or make one as directed in the paper alluded to.—Opifex.

Chest of Drawers.—F. W. A. (*Forest Gate*).—To give detailed directions for making a chest of drawers would be little more than to recapitulate the instructions for making the lower part of the bureau. As you have the back numbers of Work, you will be able to refer to them. If you want to thicken up the top, read also the article on "Lining Up." I do not think you will find any difficulty, apart from that inseparable for a novice, in making a chest of drawers. In case you may not know how to fasten the top down, I may as well say that you must make what may be called an inner top which connects the ends, and screw the top down to it. As a rule, this inner top takes the form of two pieces of board, one at the front and the other at the back, widened out at each end. If this construction is not quite clear to you, it will be found more fully described in a paper which will appear shortly, giving directions for making a kitchen dresser. The tool you inquire about is a very comprehensive one, and no doubt will do all that is claimed for it, but I must say I am not altogether in favour of such things. For you as an amateur it may do well enough, but a practical workman would find the loss of time in altering from one arrangement to another too great to compensate for the undoubted saving in prime cost. I cannot speak from personal experience of the tool's durability and stability, but so far as I can form an opinion I do not think you need have any fear about them. I am glad to hear Work has been so helpful to you. I have no doubt you will find as you make progress that working in wood is not only an agreeable but very useful "hobby." You have evidently an aptitude for it, and your success ought to be an encouragement to other beginners. Apply to "Shop" for anything you want to know.—D. A.

Moulding.—Mitre (*Peckham*).—The man you saw cutting a mitre probably set it out, or, as you say, made certain lines with a pencil as follows: Down the back a line was run by the square, the wood block either on the top or bottom of the moulding. On the top another line would be marked with the aid of the bevel. This would give the direction or guide for the saw, and might be sufficient for an expert. I do not, however, wonder at your not having succeeded in making a good mitre by this means, for at best it is but an unreliable method. The man you saw do it must either have had great confidence in his skill, or not had a mitre box by him, or was not particular about getting a perfect mitre. Possibly he put the moulding in a mitre trap after he had sawn the ends in order to true them up. You will understand I do not say he was doing wrongly, for the probability is that as an expert he would know the best course to adopt in the particular instance named. It is not, however, a plan I could recommend you, nor indeed any one in a general way, to adopt. You will find it much better to use the mitre box mentioned in an early number of Work in connection with "Artistic Furniture" (overmantel), and if necessary trim up with the mitre trap. A separate paper was devoted to the construction of this. Yes, you are quite right. The great bulk of amateurs are workers in wood.—D. A.

Letter "B" in Sign Writing.—H. P. (*Plaistow, E.*).—I have not yet had an opportunity of seeing the letter "B" in No. 31 of this Journal, and even if I had, it would ill become me to speak of a fellow contributor's work in a disparaging sense. Nevertheless the specimen "B" you have submitted is correct in formation. I am glad the articles on "Sign Writing" have proved of some little use to you, and I thank you for the information *re* ticket-writer's ink, about which I have received a large number of inquiries.—H. L. B.

Books on Illuminating.—G. E. (*Liverpool*).—There are many works published on this subject. Some good ones are as follows:—(1) "A Primer of the Art of Illumination," by De La Motte (price 9s.), coloured plates; (2) "A Practical Treatise on the Art of Illumination," by Marcus Ward, Illuminator to the Queen (2s.), coloured plates; (3) "A Guide to Illuminating and Missal Painting," by W. and G. Audsley (2s. 6d.), coloured plates; (4) "A Practical Manual of Heraldry and of Heraldic Illumination," by G. J. Baigent and C. J. Russell (6s.), coloured plates; (5) "Art of Illuminating as Practised during the Middle Ages," etc., by Henry Shaw, F.S.A. A second-hand copy may be had for about 25s. from B. T. Batsford, 52, High Holborn, W.C., who has many other books second-hand on same subject; write for catalogue. John Calvert, 99, Great Jackson Street, Hulme, Manchester, will send you the first four post free at prices named above. He also issues a capital technical catalogue, price 6d. Get it by all means.—H. L. B.

Electric Lighting without Engine.—K. C. B. (*Darlington*).—Yes, electric lighting can be done without using an engine and dynamo machine. It may be done by means of batteries, but at what a cost and trouble! You do not give the height of your workshop—this must always be given in addition to the superficial dimensions—but, assuming that it is 12 ft. in height, then a room 20 ft. by 16 ft. by 12 ft. will take four 16 c.p. lamps, at a height of 8 ft. above the floor, to effectively light it. To supply current to these from a battery you will need at least 30 cells of a double fluid, chromic acid type, each having not less than 2-gallon capacity, and costing about 8s. per cell. The acids to charge each cell will cost nearly 1s., and the battery will need recharging every evening. The time taken up in charging the battery, and cleaning it, cannot be less than 4 minutes per cell, or about 2 hours each day. For further information await my article on "Model Electric Lights."—G. E. B.

Morse Telegraph Instruments. — T. E. (*London, S.E.*).—We have not yet published in Work instructions on making and working Morse telegraph instruments, but these shall receive attention when we are writing on the subject of telegraph instruments.—G. E. B.

Zinc Palettes for Sign-Writing. — J. L. (*Walworth, S.E.*).—No chemical action would take place between the colours and the zinc, but why not beg some thin pieces of mahogany from a cabinet maker, and make a palette or two with it, according to the designs shown in my articles or any colourman's catalogue? A wooden palette is much better than a zinc one, and the latter would cut the thumb and fingers I am afraid. I am glad you have made practical use of the elementary papers on "Sign-Writing," and made a blackboard and an easel from the designs; you are going the right way to work in commencing there. I will endeavour to give you some more advanced alphabets shortly. In the meantime keep repeating those already given.—H. L. B.

Wood for Cupboard. — Ambitious Height (*Cornhill*).—From what you say of the cupboard you intend making, I think you will find the following thicknesses appropriate. You must chiefly bear in mind that the stuff must not be too thin, and that anything more than is necessary is so much waste, unless indeed appearance is considered to be improved by extra thickness. If it be, you can get the same result, that is the appearance of a very massive job, by lining up the top, and putting a pilaster on the front edges of the ends. If you adopt the latter form, the doors must be hinged within the ends, and not as shown on your sketch. Taking this, however, as given 1 in. or 1¼ in. stuff for ends, top and door frames will do very well. Thickness of shelves must depend on the weight of the things to be placed on them, but 1¼ in. stuff ought to be ample. For door panels use ⅜ or ½ in. stuff, and the same for the back, muntins, if any, being proportionately thicker. The plinth may be of ⅝ in. stuff. If the cupboard is well made of good clean pine the figure you name is not excessive, but I think it is quite high enough. So much, however, depends on the quality of the workmanship, etc., that without seeing the job it is impossible for me to state its value. It might not be worth 15s., while, on the other hand, it might not be dear at 40s. Glad to hear you "are more than pleased" with Work.—D. A.

Preserving Books from Insects.—Bookworm (*Gloucestershire*).—To *destroy* insect pests, powdering the shelves, and, if necessary, the bindings and books themselves, with finely-powdered burnt alum and pepper has been recommended; the "Insect Destroying Powder," sold as such, would answer the same purpose. To *prevent* their ravages, it is held good to wipe the shelves, and even the books also (two or three times a year), with a cloth steeped in a solution of alum and afterwards dried; or with a flannel in which some white birch bark has been kept. Birch bark contains a powerful essential oil, the smell of which is highly obnoxious to insects, hence the above; hence, also, the recommendation to have some books on your shelves bound in "Russia" (Russian leather is tanned with birch bark), or to lay scraps of this leather on the shelves behind the books.—M. M.

Melting Rubber. — J. W. (*Bolton*). — Melted indiarubber — *i.e.*, indiarubber liquefied by heat alone—cannot be employed for the construction of articles, as it always remains soft and gummy. It may be used for certain purposes in solution, the solvent used being either bisulphide of carbon (which is probably the substance referred to by the querist), mineral naphtha, benzole, or caoutchoucine; but a solution of rubber is not adapted for use in any case where the sharp outline of the mould has to be preserved, owing to the enormous contraction brought about by the evaporation of the solvent. Sheet rubber (pure, not vulcanised) may, however, be greatly softened by prolonged exposure to the vapour of petroleum or benzoline in a close vessel, either with or without the aid of a moderate degree of heat, and in this state will readily conform to the form of moulds not too irregular in shape. If used in this state, pressure must be applied and maintained until the petroleum or benzoline absorbed by the rubber has been evaporated, the time needed being much lessened by using porous moulds if practicable, and placing them with the rubber inside in a current of warm dry air. But the most generally useful method is to use vulcanised rubber, the vulcanisation being effected under pressure in the mould. No precise instructions which will meet J. W.'s case can be given without a knowledge of the exact object in view, but if J. W. will supply this information, in strict confidence, through the Editor, I will endeavour to help him over his difficulty.—Qui Vive.

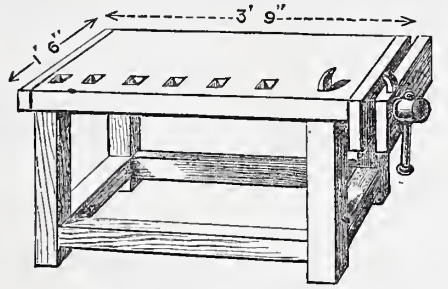
Learning Marbling, etc.—W. H. (*Newington Butts*).—The best answer to your query, "Where could I learn graining and marbling at a small cost?" I can make is to advise you to await the publication of the papers in Work upon this branch. For small cost of tuition, and with this recommendation, that also of practical usefulness, these papers will, I believe, distance any other letterpress lessons upon the subject now published. In any case you will have to devote a large amount of time and patience to it. There are, of course, various other ways open to you—for instance, a course of practical lessons from a clever marbler, costing from two to five pounds a term, or the purchase of a very good existing Dutch work on marbling, published, I think, at £2 18s. Only the litho specimens of this might be useful to you, unless you are a linguist and could interpret the Dutch articles. Hence my advice to you is to wait for lessons in Work.—F. P.

Electro and Nickel Plating.—J. S. (*Leicester*).—We have not room for the treatment of this subject in "Shop." In future numbers it will be fully dealt with. You may obtain a silver plating and nickel plating outfit for £20 from Messrs. J. E. Hartley & Co., 13, St. Paul's Square, Birmingham. Thanks for kindly words of appreciation.—G. E. B.

Italian Fret Designs.—W. J. (*Edinburgh*).—I know of no fret designs produced in Italy. If you mean those in the Italian style, Mr. Ziller would probably be able to send you those you require.—E. B. S.

Aquarium.—C. M. (*Gloucester*).—I can offer you nothing better for outdoors than the design in No. 31. Instead of ferns, however, I should use ivy in the pots; a slow-growing, non-clinging variety to be found in most hedgerows in England would answer admirably. I find the roots run into the water from central rockwork, and require no attention whatever.—C. M. W.

Slöjd Carpentry.—J. S. (*Hampstead*). — Slöjd, pronounced *Sloyd*, is the name given to a branch of carpentry coming to us from Sweden, sometimes called Swedish carpentry; it is intended to train the eye as to form, and the hand as to uses, of tools. It is being introduced in boys' schools as a beginning or introduction to the carpenter's workshop, and also in schools for young ladies. The work mostly consists of articles made from models (which models are generally very nicely made), so that the learner has to match an object by the use of his hands and eye. The tools usually employed are certainly not



Bench for Slöjd Carpentry.

of the very best quality, or, at least, those I have seen, and this is accounted for by the very low price at which they are sold. The bench is somewhat different from the ordinary one, and is something like above design, and the work is all done from the right-hand end of the bench, similar to the German pattern bench. It is made of deal, and its cost is about eighteen shillings only. Messrs. Syer & Co., of 45, Wilson Street, Finsbury, E.C., make this bench, and supply all the tools necessary, and I should recommend any one requiring these to apply or write as above, where I feel sure they will receive every attention to their wants. I may add the knife is the tool mostly employed in this work.—T. J. S.

Iron Oil Drums.—J. H. & Co. (*Liverpool*).—Oil mill machinery is made by Messrs. Greenwood & Batley, Leeds; Manlove, Alliott & Co., Nottingham; Rose, Downs & Thompson, Hull.—J.

Gesso Work Materials.—J. N. B. (*Halifax*).—Gesso materials are to be obtained at the depôt of the Society of Artists, 53, New Bond Street, and the metallic colours for tinting the gesso work also.—E. C.

Slide Rule.—Slide Rule.—Some information on the Slide Rule, to be of any value, would have to extend into several articles. "The best engineer's rule" is, of course, that which is most comprehensive. Of these there are many, and the choice in any particular case must be made according to special requirements. There are, at least, a dozen, and those which are most expensive are the most comprehensive, and therefore the best. For workshop use a rule costing 4s. 6d. is suitable; the best will cost a pound or more.—J.

Short Distance Telephone.—G. C. (*Morpeth*).—Surely G. C. has not been reading his numbers carefully, or he would not have sent this query. The telephone was fully described in No. 23 of Work. If you will turn up that number and follow the instructions there given, you will find the instruments suitable for your purpose. If, however, you find any difficulty in making these instruments, I will be pleased to help you through "Shop."—W. D.

Indelible Ink, Indian or Chinese. — J. N. (*Bowes Park*).—You have asked a question which is very difficult to answer for many reasons. In the first place, the manufacture of the indelible Indian inks sold by Rowney and other firms are trade secrets, and there can be no doubt their receipts are the best. Again, pure Indian ink, which is really Chinese, is a most expensive article, the best costing as much as 25s. per stick, so I do not see how you are going to make half a pint of indelible ink with the real article any cheaper than you can purchase it ready for use. Please note, the best Chinese ink will never rub up when washed over with water; it is only inferior sorts and imitations that do so. Here are some receipts; whether they are indelible or not I must leave you to prove: (1) Dissolve horn strip with caustic kali root till it is melted. This brown liquid is to be boiled in an iron kettle until it is thick. Then pour on it boiling water, double its weight, and precipitate it with dissolved alum. Dry, grind, and mix it with gum-water, and pour it into a mould. A few drops of essence of musk, or of ambergris, may be added as perfume. (2) Mix finest lampblack with a solution of 100 grains of lac, with 20 grains of borax and 4 oz. of water. (3) Pure lampblack, mixed with asses' skin, glue, and scented with musk. Regarding No. 3, it is a well-known fact amongst photographers that animal glue when treated with bichromate of potash, and exposed for some time to the sunlight, is insoluble in water. Impure Indian ink (by analysis) contains such animal glue, so if a small quantity of bichromate of potash be added to it, it should prove indelible after being exposed for one hour to sunlight. I advise you to try a 6d. bottle of Stephens's ebony stain. It is now largely used in place of Indian ink. It is cheap enough for the purpose—8s. per gallon, from Henry Stephens, 191, Aldersgate Street, E.C. It is very black, and works well with pen and brush alike.—H. L. B.

A Baker's Oven.—Baker (*Blairgowrie*).—I do not see clearly how I can help you, unless you give more particulars. Correspondents would save us an endless amount of trouble and thought if they would only give full explanations. You ask for advice concerning an oven that will bake a loaf or two at a time, and give as requirements that it shall be simple, easily erected and removed. An oven constructed as bakers' ovens usually are clearly would not answer this requirement. I cannot see that you can have anything better than an ordinary cottage range with a good-sized oven, or a powerful petroleum stove. Without further information as to your intentions as to price, kind of fuel available, whether to be made by yourself, etc., I cannot advise you farther.—R. A.

Brazing.—Paul Jones (*Kentish Town*).—From the wording of your letter I suppose it is bicycle fittings that you wish to braze. This to the ordinary workman presents no difficulty. The main thing is the fitting of the parts together; the joints must fit tightly, and not only tightly but accurately, for a joint might possibly be tight and yet only bear in two or three places owing to unequal filing. It is a very true saying that there is very little difference between a fit and a "wobble." Presuming that you are able to fit the parts together "well and truly," you will, I trust, after perusing the following, make a good job of the brazing part of the process. A Fletcher's injector pattern gas blowpipe and foot-blower would be the best thing you could use for the purpose. It gives a great heat, and can be used in any position, and is clean and manageable, but if you do not possess one, and are limited to a forge, proceed as follows:—Build your fire so that you have room to manipulate your work—that is, bring it well out into the centre of the hearth by means of a pipe, if necessary; blow up a fire of charcoal or coke—I prefer coke myself—let the fire be perfectly clear and free from smoke; this is very important, for if any smoke gets round your joint it is certain to prevent the spelter running in as it ought to do; pound up some borax very fine; in a tin or some convenient article mix about two tea-spoonfuls of spelter and one of borax to a paste with water, and have some of the powdered borax ready to hand; place the article to be brazed on the fire and blow gently; when it gets a bit hot dab on some of the mixed spelter and borax with an iron spatula. It will fizz and rise up off the work, and then sink and adhere closely to it. Now blow gently, and gradually increase in force; as it gets red-hot, sprinkle a little of the powdered borax on the joint; keep blowing till you see the spelter run, then rub it with the spatula; add more spelter if necessary, and when all seems well run, give a final sprinkle of borax, cease blowing, and after a minute gently remove from the fire, and allow to cool of itself. On no account cool it with water. I advise you as an experiment before doing your tubes to try brazing two pieces of iron pipe—say, a piece of ¾ in. gas barrel into a piece of 1 in. gas barrel; it will give you practice, and show you what to do and what to avoid.—R. A.

Violoncello Case. — S. E. T. (*Glasgow*).—With the Editor's permission, I will communicate with you per post. I think I shall be able to assist you — B. [Kindly send information through me—*pro bono publico*.—Ed.]

Bazaar Ideas.—Bazaar (*Skipton*).—We might, by way of novelty, suggest "An Automatic, Infallible, Moral, and Intellectual Balance." Its professed use would be to ascertain with exactness how much of any good or bad quality might be possessed by the visitor. For instance, a lady whose "constancy" is to be tested takes her place on the scale. The attendant (who might be dressed as a necromancer) would put such weights as he thought proper on the opposite scale, and it would go down; the scales, of course, being really controlled by a confederate, either placed behind a curtain or in a large pillar through which the beam works. The fun of the thing must largely depend on the humour of the attendant; and capital could be made in such cases as that of a lady well known to think herself good-looking, who might be shown to have, by the balance, not half an ounce of beauty; or that of a man reputed to think himself clever, and yet whose record might show no more than a few grains of wit. We imagine that a little thought will show how this idea may be worked out successfully.—M. M.

Materials for Painting.—W.C. (*London, N.W.*).—The queries shall be answered seriatim:—(1) The brushes used in oil painting are chiefly hog-hair and sables. The size used must depend on the work. A flat hog-hair, ½ in. wide by ¾ in. long, is one of the most useful; very useful also is a rather smaller size in sable. For painting skies on a fair-sized scale, a somewhat larger hog-hair becomes necessary. Flat brushes are more useful than round ones, as they give greater variety of touch. The "sweetener" is properly made of badgers' hair, but, if the cost of this be a consideration, a cheaper large, flat, camel-hair will answer the purpose. (2) The mediums used and sold for mixing with the colours are various. A good and inexpensive one is gum dammer dissolved in turps. This gum may be got at any large chemist's at 1d. or 2d. per oz. Put the gum in a bottle and pour on turps to an inch above it. When dissolved, strain. Thin, if required, with more turps. (3) Prepared boards may be bought at any good artists' colourman's. (4) The paper stumps alluded to are doubtless for crayon and charcoal drawing. The large artists' colourmen, such as, say, Winsor & Newton, Rathbone Place, Oxford Street, W.C., issue illustrated and priced lists of all materials and appliances sold by them. W. C. should apply for one of their lists, which will give him much of the information of which he stands in need. A considerable discount is allowed to artists off list prices.—S. W.

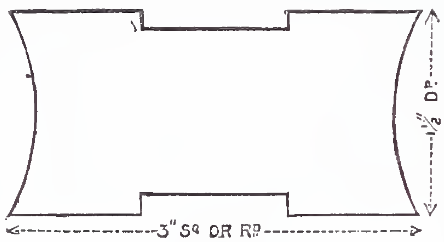
Cabinet in Fretwork.—H. H. (*Manchester*).—For a novice as you are in fretwork—although being skilled in the use of tools, you would probably succeed better than an ordinary amateur—I should not advise you to try the cabinet design issued with No. 1 for your first work, chiefly because it involves more labour than most pieces of its size, and unless absolutely well done would fail to be effective. Why not try the coffee table design in No. 30, or the little paper tray in No. 21? The design for an overmantel in No. 2 might be ornamented with some of the Japanese motives in Nos. 9 and 14. For instance, some of the storks (Figs. 3 and 4), or the other birds, might be cut in thin panels of the doors; the pattern of the paper tray on page 328 might be adapted for a cornice rail. If neither of these suggestions meet your wishes, there are two or three designs to appear shortly that will, no doubt, fully do so. For inlaying, the simplest way is, perhaps, to cut the pieces carefully out of a thin sheet of light wood, then to stain the portion from which they were cut, and replace them. Of course, the pieces themselves may be dyed various colours (with Judson's dyes) to simulate real marquetry, if you care for that effect. Another plan is to paste two thin layers of different wood together with a rather thick piece of brown paper between. Cut carefully with a fret saw, and reverse the pieces; thus if walnut and white holly be chosen, you will obtain a light pattern on a dark ground, and *vice versâ*. Bemrose's publish a book on Buhl Cutting and Inlaying; but so far as my memory serves, it was not particularly useful to me; perhaps others would find it all they wished.—E. B. S.

Gasalier Fitting.—G. S. (*Clapton*).—The first and most important thing to be done in taking down the above, is to turn off the gas at the meter, then take off the globes and triangles, next the weights, and you will then find that the outside stem with the arms, and a small inner tube attached, will draw off, or, if you are not careful, fall off. Take this down steadily, and pour out any water you may find inside. You will now notice that a single pipe remains connected at the top with a ball and socket joint; undo this joint; and all you have now to do is to unscrew the ceiling plate. If in doing the latter you notice how it is fixed to the ceiling, and how joined to the compo pipe or gas barrel above, you will have no difficulty in refixing it in any other position, and a little consideration after you have it down will at once show that the water is necessary to make the sliding joint gas tight. The only other thing of importance to do, is to be sure you pour some water in the top of the stem after you have refixed the whole before you turn on the gas. A practical gasfitter would not take the whole thing to pieces unless it was very awkward, but would unscrew it from the ball and socket joint, after removing the globes. But if you go step by step as I have described, you will understand better what you are doing. Again, let me remark, be sure not to turn on the gas before you have made the sliding joint gas tight, by pouring as much water as the stem will hold, without running over, when the gasalier is either up or down.—E. D.

Photographic Studio.—F. T. R. (*Retsbyl*).—Before the form of a studio can be decided upon, the surroundings must be taken into consideration. Good work can be done either in "lean-to" or detached glass rooms, the size and form being regulated in a great measure by the amount of money to be spent upon them, and space at disposal. The following leading conditions are generally considered imperative to good work of the usual kind:—The length of the studio should not be less than 30 ft., the width and height 12 or 14. An unobstructed north light tends to uniformity in results, on account of its freedom from direct sunshine and a generally more even illumination; a clever operator will turn out good work from a studio with any aspect. The cheapest form is the lean-to, as one side is supposed to be already built. The most convenient is the ridge-roof detached studio. It is impossible, in the space at disposal in these columns, to give full directions for building one. To sketchily describe a ridge-roof one, begin by laying down a framework the size of the area of the building, supported 12 or 18 in. above the ground on brick piers; for dryness' sake board it over with stout planks supported on battens a foot apart, and made as free from vibration as possible; on this erect the framework. Board up both ends, and about 6 feet of each side from the ends, supposing the studio to be rectangular, with a ridge roof, and one side and one half the roof may be opaque, the rest glazed; a door or doors being made on the boarded-up side, the glass is put in on the ordinary greenhouse plan, each pane overlapping the one below it; good colourless 21-oz. glass is best. The interior may be canvased and papered, and a background on roller at each end. The more steep the pitch of the roof, the less liability to leakage and accident from storms. There have already been published many designs for building glass rooms, which F. T. R. would do well to consult. A cheaply-made photographic studio is little different to a greenhouse in putting together. The fewer the sash bars and better the glass the more light. Provision must be made to ventilate it well, or unless this is properly managed the heat in summer is almost insupportable; it goes without saying that the larger the place, the more comfortable it is in this respect. F. T. R. will do well to consider the comfort of his customers in the construction almost as much as other conditions.—E. D.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Toughened Glass.—ONE IN A FIX (*Tunbridge*) writes:—"Would any reader give me a few practical hints upon toughened glass making, also what kind of pot and furnace is used for small work? I want to make a few articles of great strength in solid glass pressed to shapes required for experi-



Glass Mould.

menting. I believe the moulds are cast iron and made in parts. How are they fastened together to stand the pressure? What is required to make the mould leave the rough sides of glass? A sketch of parts wanted will greatly oblige, I enclose rough sketch. I want them round and square."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Rubbing down Oilstones.—BRUM (*Keighley*) writes in reply to A. G. (*Newcastle-on-Tyne*) (see

page 619):—"About the easiest way of rubbing an oilstone down is to hold it against the side of a revolving griudstone, using plenty of water."

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—BOILER; W. R. S. (*Brixton*); H. A. C. (*Plaistow*); A WOOD CARVER (*London, W.*); WATERPROOF; W. E. R. (*Southgate*); C. T. (*Kent*); SEMPER PARARE; C. N. (*Yeovil*); J. W. (*Ashton-under-Lyne*); E. W. (*Sheffield*); T. E. B. (*Walkden*); D McD. (*Paisley*); C. J. D. (*Brixton*); E. J. (*Liverpool*); W. D. (*Newcastle-on-Tyne*); A. S. (*Cork*); T. L. (*Sussex*); CONSTANT READER; W. H. B.; J. F. B. (*London, E.*); A. M. (*London, W.*); M. M. (*Glasgow*); W. F. C. (*Clifton*); A. S. H. (*London, S.E.*); W. B. (*Huddersfield*); J. H. N. (*Sunderland*); F. B. (*Swanscombe*); J. J. (*Bristol*); H. W. G. (*Bucks*); F. H. (*Leith*); C. S. (*Radford*); W. H. H. (*Bradford*); E. B. (*Derby*); N. W. (*Clapham, S.W.*); E. L. R. (*Oxford*); A. A. (*Coventry*); M. BROS (*Rawal-Pindi*); D. M. W. (*Kelso*); R. M. (*Morpeth*); I. W. B. (*Southport*); G. E. S. (*Berkeley*); J. Y. (*Derby*); H. M. (*Wolverhampton*); R. J. L. (*Salisbury*); G. H. (*London, S.E.*).

Trade Note.

IT has been agreed to erect an international monument to James Watt, in Greenock, the illustrious engineer's birthplace. Subscriptions towards the project had been promised from London, and other large centres in Great Britain, America, and other parts of the world. The Greenock Philosophical Society has taken the matter in hand, along with an influential committee under the auspices of the Greenock Town Council. The form which the memorial will take has not yet been decided, but it has been suggested that it should be either a well-equipped technical school in Greenock, or a colossal tower on a prominence which would command the attention of every passing ship on the Clyde.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 51.] SATURDAY, MARCH 8, 1890. [Price One Penny.

A JACOBEAN SIDE-TABLE WITH LOCKER.

BY MARK MALLETT.

That decorative and useful piece of furniture for constructing which drawings and instructions are now offered, is, as regards its original, of the James I. period. The type is a somewhat unusual one, for though the writer is a tolerably inquisitive student of English seventeenth-century furniture, he has met with two examples only—one in Dorset and the other in Warwickshire. The professional and amateur worker may alike find it worth the labour of reproduction.

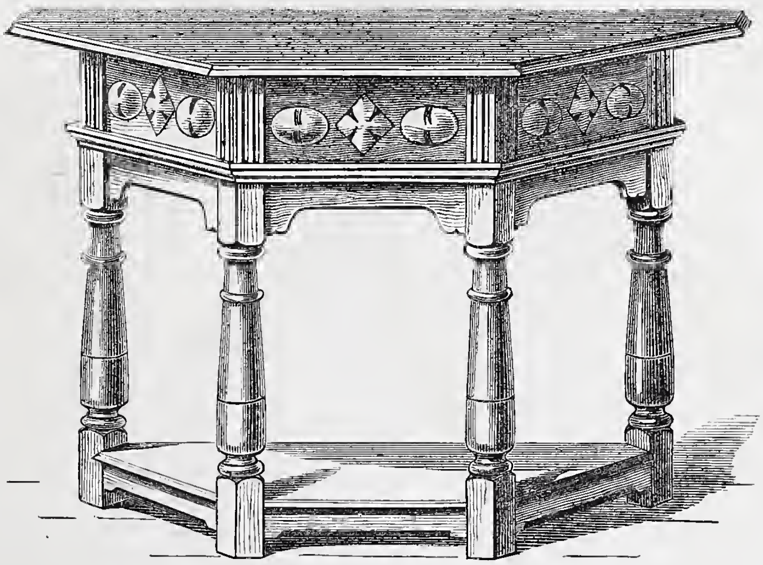

Fig. 1.—A Jacobean Side-Table.

Unlike most of the articles of that age, this table is without any carved decoration whatever, the ornament being entirely *appliqué*. As regards its construction, its peculiarity is that its top is made to open, and thus give access to a kind of locker, fitted with handy compartments of various sizes. The material of the original article is oak.

The dimensions of the table drawn are:—Height, 2 ft. 6 in.; breadth of top, 3 ft. 9 in.; projection of top, 1 ft. 6 in.; breadth of frame of table, 3 ft.; projection of frame, 1 ft. 2 in.; and depth of locker, 5 in. A general perspective view is given in Fig. 1, which is on a scale of about 1 in. to the foot. All the remaining diagrams are on a scale of $1\frac{1}{2}$ in. to the foot.

From Fig. 1 it will be seen that the supports are pillars of a pattern well known in Jacobean work. In the judgment of the writer, these pillars have merit not merely as being characteristic of the style, but also as having in their strength and solidity that kind of beauty which comes from fitness. Opinions differ, however, and some may think them too heavy; if so, lighter and more ornate turning, or even twists, may be substituted for them without any great prejudice to the general effect; and into the bases and upper parts of the pillars the framework, which is of 1-in. oak, is mortised. The frame pieces should not be less than 1 in., if the solid character of Jacobean work is to be kept; indeed, $1\frac{1}{4}$ in., when planed down, is scarcely too thick. The pillars can be cut from 2-in. plank.

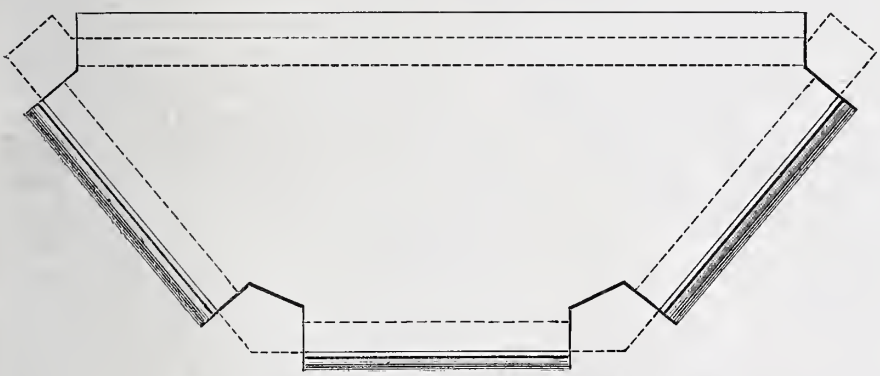

Fig. 2.—Foot-Shelf supported on Rails connected with Legs.

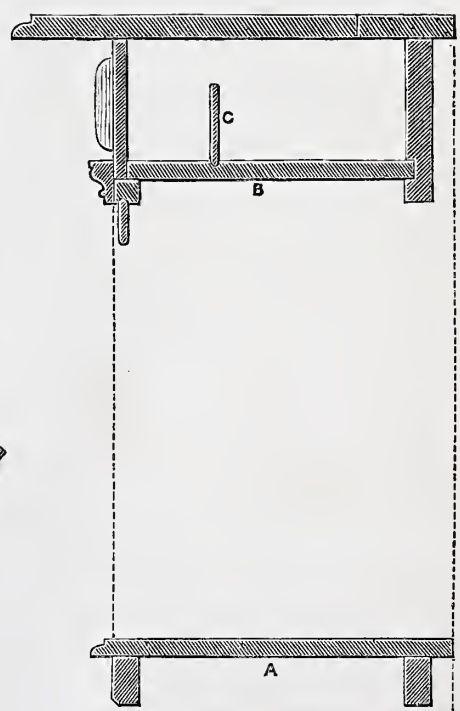

Fig. 3.—Vertical Section—A, Foot-Shelf; B, Bottom of Locker; C, Partition.

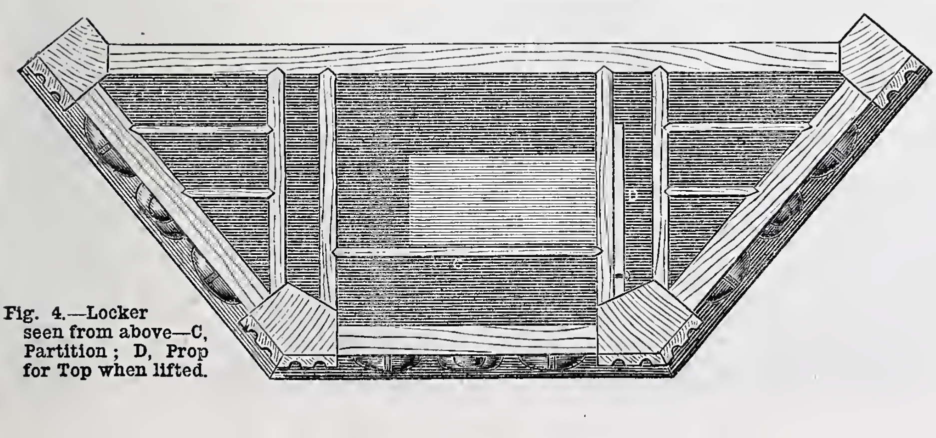

Fig. 4.—Locker seen from above—C, Partition; D, Prop for Top when lifted.

Fig. 2 shows the foot-shelf which rests on the bottom framework, beyond which it projects some $\frac{3}{4}$ of an inch. This foot-shelf is lettered A in the section Fig. 3; and the frame on which it rests is indicated by dotted lines in Fig. 2. It is of $\frac{1}{2}$-in. board, and its edges are moulded, as shown, except at the back. This foot-shelf will form no bad place for the display of artistic pottery—three vases or other articles, a taller one in the centre and lower ones at the sides, will show well upon it.

Fig. 3 is a section through the centre of the table. In it may be seen how the bottom of the locker, marked B, is supported by the framework of the upper part. But the arrangements of the locker are more completely illustrated in Fig. 4, where they may be seen as from above, before the top of the table has been fixed in place. This locker is divided by partitions into compartments of convenient size for papers or other small matters. The largest compartment is 11 in. long by 7 in. broad, and the whole locker is 5 in. deep. The more important partitions—those from back to front—are of $\frac{1}{2}$-in. board, and about $4\frac{1}{2}$ in. high; the subdivisions are of thinner stuff, and for them a height of some 3 in. is sufficient, as shown at C, Fig. 3.

At D, Fig. 4, is shown a strip of wood attached by a screw to one of the partitions. It is for the support of that part of the table-top which forms the lid of the locker, when it may be desired to prop it open. To prevent all danger of slipping, it may not be amiss to notch like a rack that part of the lid which rests upon it.

In this same diagram (Fig. 4) is to be seen something of the relative relief of the different pieces of applied ornament. These pieces are in a general way simply glued to the surface. Among the furniture makers of the seventeenth century it was rarely usual to trust the effect of their work entirely to *appliqué* decoration. They more frequently used it in combination with carving or inlaying, or both. *Appliqué* work, however, survived carving, for we find abundant, and some of the best, examples of it dating from as late as the earlier part of last century, and from a period when carving had passed out of fashion. The example before us is, as regards ornament, anything but an elaborate one. The two carbuncles on each side are, of course, turned in one and sawn through. The lozenge between them is sawn out and worked by hand. The fluted pieces at each end are also readily worked by hand; in restoring the original of the drawings, the writer had to supply one of these pieces, and found it could be quickly worked with the gouge.

In Fig. 5 we have the top, $\frac{3}{4}$ of an in. in thickness, and moulded at all its edges except the back one. Access to the locker necessitates that it should be in two pieces, of which that at the back—the fixed one—is 4 in. wide. If, however, any person making such a table should object to such a division in the lid, an alternative is open to him—he may omit the locker, and instead have a drawer on the front side. More than one drawer he could not well have; and this would, of course, involve some loss of space, and make, on the whole, a less useful article of furniture than the original, which will serve many of the purposes of a bureau.

Indeed, to the writer, the locker appears so characteristic a feature of this table, that he would not willingly sacrifice it. An ingenious combination of purposes, analogous to that shown in this table, is not unfrequent in early seventeenth-century furniture. The writer has met with joint-stools of the Jacobean period, the tops of which, by removing a secret fastening, could be made to open and disclose unexpected receptacles within. Such receptacles were, no doubt, useful in days when portable property was even less secure than in our own. Another instance with which he has met was an arm-chair, of much the same date, the back of which, when turned down on the arms, made a circular table some 3 ft. 6 in. in diameter. A chair-table like this, or one on somewhat similar lines, would not make an unattractive subject to amateur carpenters, and possibly a corner may at some time or other be found in WORK for drawings of one.

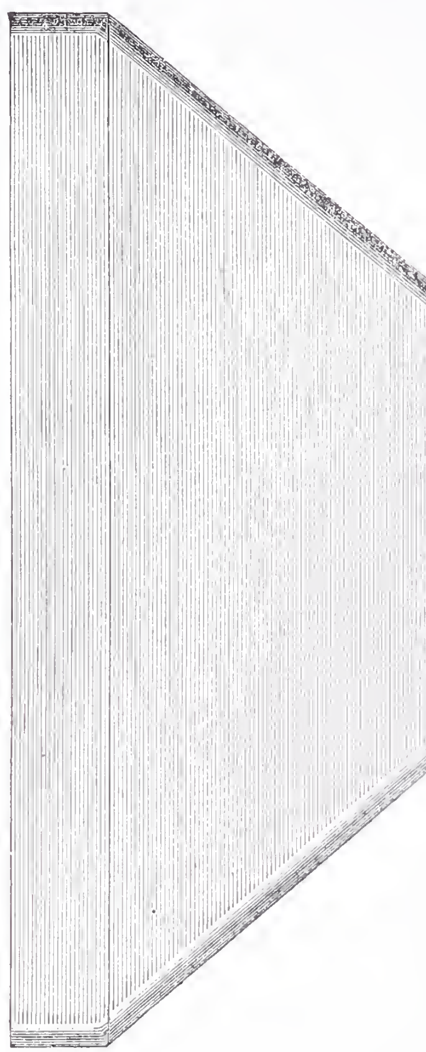

Fig. 5.—Top of Table, showing Joint for lifting Top.

The original of our Jacobean side-table is, like most of the furniture of the age in which it was made, formed wholly of oak; and oak will be the best material for any one who attempts an exact reproduction of it. A pretty table, however, on much the same general lines, but more lightly made, might be constructed in pine, and ebonised—the amateur joiner will probably prefer to work in the latter less costly and more easily wrought wood.

A suggestion may be added for the benefit of any one making such a table as this in oak and wishing it to harmonise with other oak furniture which is carved. He may gain that end with little labour by running a carved enrichment—some Jacobean variety of the "egg-and-dart"—along the moulded edges of the table-top and foot-shelf.

HOW TO MAKE A PIANO.

BY "NIL DESPERANDUM."

REGULATING, TUNING, AND TONING—CONCLUSION.

TAKE out the keys and place them on your bench; then take a thin piece of wood about an inch wide, and wrap round it a piece of fine glass-paper, and rub over the wood of the keys, behind the ivory or sharp, cleaning one at a time; then brush the dust off them; if you see any on the key bottoms, remove it. Between the balance and front rails fit a piece of thin wood to prevent the light being seen through the spaces of the keys. Now, where the ends of the sharps were cut off, black with ink about an inch wide; also black the lower part of the sharp from this line. While the keys are out, take off your damper rail carefully, and by moving each hammer to the string, see that each hammer strikes it fair; if the shank has cast to one side or the other, as shanks do sometimes, you can alter it by warming an old file, or flat piece of steel, and hold it to the side you wish to bend over. Now you can see that the bridles or tapes of your action are properly adjusted; put one finger under the lever and raise lightly, and there ought to be $\frac{1}{16}$ of an inch play between the top of the fly and the hammer butt; if there is not, you can make it so by bending the bridle stay either backwards or forwards. Now take the action out and put the keys back in their place, and take each key separately, and see that it works free; if not, ease it with your file, but do not make it loose; if you find it a trifle loose, you can tap it gently with a hammer over the hole; this will tighten it. Having done this, put the action in its place and see if there are any pilot screws which need turning up, as in the finishing. Now look over the keys and see that they are straight to your straight-edge, then tap on the keys with your straight-edge, and those that are high will move; take a shaving off these and make the low ones level with tissue paper. The spaces of the keys must now be adjusted, then the action must be regulated or set off. I will now describe what is meant by this: if the reader will kindly look at the action, he will find that through the fly of the hopper there is a wire, with a button on the end; as the key is depressed, this button rests on the slide rail, this being on the bevel; as it rises, the fly is pushed forward from under the hammer, allowing the hammer to fall into check. This is accomplished in the following manner. As the hammer moves towards the string, the check follows it, and when the hammer falls, the check is there to receive it, holding it firmly by the check arm. Make a hook, so that you can turn the wire that has the escapement button on. Now sit down at the piano, and commence with the first note in the treble, press the key gently down, and watch the hammer; if you turn the escapement button to the left, you will find that the hammer will bump against the string; therefore it damps the tone, or, as it is called, blocking. Now turn the escapement to the right, and you will find that the hammer escapes from the string; the check allows the hammer to fall the requisite distance from the string. Allow the hammer to go up to the string within $\frac{1}{16}$ of an inch, and allow it to fall, after it has struck the string, about $\frac{3}{8}$ of an inch. Regulate the check, to catch the hammer at this distance, by bending it forward or backward. When the key has taken the hammer to the string, it ought to rest on the front baize; if it does not, the touch is a little deep, and that means loss of power; remedy this by placing a piece of brown paper under the baize. If the touch is too shallow, and the key does not carry the hammer far enough, you can strike the baize with a hammer to compress it, so that the key carries the hammer further. Regulate every note in this way. Now put your damper rail in its place, and see that it works without noise. Put your foot on the right or loud pedal and press it down, so that it removes the dampers clear off the strings; then put a small block under the front of the rocker to prevent it going down further than is necessary; glue a piece of cloth on the top; also glue the bottom to the bottom board of the case. Now serve the celeste, or left pedal, in the same way, so that when the foot is pressed on the pedal, the hammer strikes the felt or flannel; stop this with a block also.

You now proceed to tune the piano, but before you do so, you will have to make a wedge; this is made of a thin piece of wood or cane, about a ¼ of an inch wide, with a covering of leather at each end. When the reader chipped the strings, it was only necessary to chip one at a time, but now the hammer strikes two and three strings at one time, it is more convenient to damp either one or two of them in tuning. It is for this purpose that the wedge is used. The same process is adopted in the tuning as in the chipping up, only that the action being in, you will be able to hear the notes more distinctly. You sit down at the piano (and in a quiet room if possible), and put your tuning hammer on one of the pins of pitch C. Now place your wedge between the string you are not tuning and the next note; this holds the wedge in position, and damps the string or prevents it vibrating while you tune the other. The wedge is about 7 in. long, and you put it between the hammers a little further on than the note you are tuning, so that it is at an angle; this is so that the hammer of the note you are tuning does not strike the wedge; a little practice at this will soon make it easy. While the chipping up is rough tuning, until the piano has been tuned two or three times it will sound very rough. Pull the string up until it is in unison or sounds the same as your tuning fork. Now take your wedge out, and you will find it sounds out of tune. Put your tuning hammer on the other pin of the note and pull it up until it is in unison with the other string; listen attentively, and pull the string up gently, so that when the note is struck, it sounds like one note without beats. This is the way to tune the unison. Practise this well until you are proficient, then try to tune the octave; this is the same note C, an octave nearer the bass end of the piano. When the note and its octave are struck at the same time (when in tune), it sounds as if you had only struck one note. Do not turn the wrest pins back if you can possibly avoid it, as this tends to loosen the pins. If you pull a note slightly sharp, give it several sharp blows; this will make it a shade flat. If you can get access to a piano, you will be able to try the scale and octaves. If you do not know the notes on the piano, I may say that the C is the white key which comes before the two sharps, then towards the treble the notes would follow in rotation, so: C, C sharp, D, D sharp, E, F, which is the white key before the three sharps, then F sharp, G, G sharp, A, A sharp, B, C; this forms the octave. Having tuned the octave C below pitch C, move your tuning hammer to the G below, or towards the bass; damp one string of the note, then strike C and G at the same time, and pull the G up carefully and slowly, listening attentively, and although it may sound rough and discordant when you start, with a great number of beats which sound like woo, woo, woo, you will hear it gradually coming into tune, and it will sound pleasant to the ear, and without a beat. Take out the wedge and pull up the unison, then move to the D above, or towards the treble; repeat the same operation as before, and so on through the scale, a description of which was given in the paper on stringing and chipping up. The thick end of the wedge is used for the bichord notes, the thin end for the trichord. In tuning a trichord note, you would put the thin end of the wedge between the two treble strings of the note, that would allow you to tune the first string; then use the thick end to tune the middle string of the note, and draw the wedge out to tune the third string. The pianoforte has no E sharp, or B sharp, so this deficiency has to be made up by tuning

all the fifths a wave sharp, and the fourths a wave flat, towards the bass. To be able to tune perfectly requires a large amount of practice, and tuners' ears in time become sensitive to the slightest discord. No doubt the reader is well aware that there are some persons who have no tune in them, therefore it would be impossible to teach them tuning. I have known some persons during my lifetime who, when they have made an attempt to whistle, or sing a tune, have made some awful discordant noises, while they were totally ignorant of having inflicted pain on those who possessed a sensitive ear, believing they were singing or whistling in perfect tune. They say, where ignorance is bliss it is a folly to be wise, but I think in this case it would be a kindness to tell them not to sing again, and put an end to their bliss. I worked with a man at one time who had never been known for years to hum or whistle a tune; I expect some one had put an end to his bliss. I think I have said enough to give the amateur a start in tuning his piano; the rest depends on practice and perseverance.

There is one other matter that ought to be attended to now—that is the toning: this is making the inequalities of the tone more equal. I will explain to the reader what is meant by this: one note, if the felt on the hammer is too hard, may sound like a tin kettle, while another may seem much softer; to remedy this, you must prick the felt at the point of the hammer with a sharp needle, or two or three held in a piece of wood; this softens the tone. Now, in the extreme treble, it is just as well to have it sound bright, or brilliant as it is termed; this can be accomplished by passing a warm flat iron over the points of the hammers; try the heat of the iron on a piece of paper, so that you do not burn the felt.

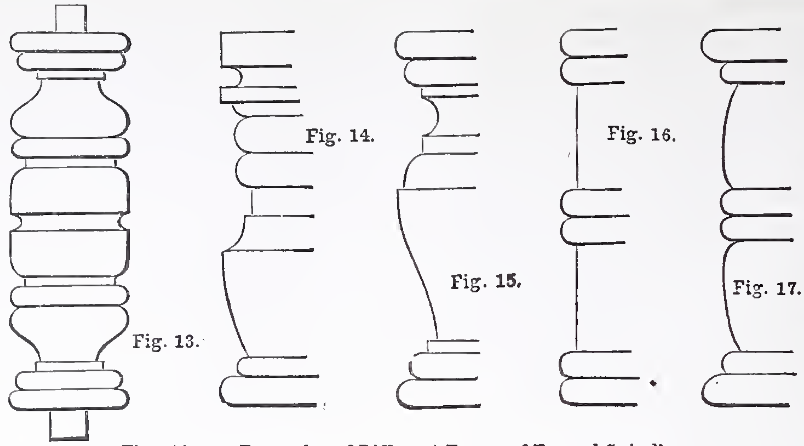
Your piano is now complete; and I hope those who do not wish to make a piano, may have found in the perusal of the papers on this subject something to interest and edify them. I am aware that a great many wrong impressions prevail with regard to the manufacture of the pianoforte, and I hope I have dispelled them. As the church organ is sometimes called the king of instruments, I would claim for the pianoforte the title of the queen of instruments. For the home, it will always be a favourite; whether for sacred, dance, or secular music, it possesses qualities which commend it to our esteem. And as the education of the people progresses, so will the manufacture of the pianoforte, as a knowledge of music is thought to be indispensable in our modern schools. To those who intend to make a piano, I hope I have made everything so simple, that they will readily understand it. Should any difficulties arise, or the reader not see his way clearly, I shall be most happy to set him right through the columns of "Shop."

A CARVED BUREAU.

BY D. ADAMSON.

SHERATON'S STYLE—EARLY ENGLISH STYLE.

To put theory into practice, let us take a drawer front—it can serve no good purpose to give an illustration showing the whole of the bureau—and see how it may be treated in a style typical of Sheraton's, merely observing that the objectionable cross-banding has been done away with. Let us then refer to Fig. 18, showing part of a drawer front, the main portion of which, by the way, we may regard as mahogany or rosewood; there is the familiar inlay, which has so often been reproduced, representing a series of flutes or beads converging to a common centre. Such pieces of inlay can easily be made by those possessing the necessary patience, but as they are somewhat tedious and by no means ornamental unless neatly put together, it may be satisfactory to know that they can be obtained through most cabinet makers who make a display of inlaid furniture. More elaborate inlays may be used if preferred, but it would take too long to describe their mode of construction here. Suffice it to say, as the process of marquetry cutting is very little understood by those who do not follow it as a profession, that full instructions have lately been published in the "Art of Fret Sawing and Marquetry Cutting." Beyond the mahogany veneer we have a stringing of a light wood, such as box. These stringings are sold at such a cheap rate, that it would be merely a waste of time for any amateur to prepare his own. Much skill is requisite to do it properly, and besides the work is purely mechanical. Next to this stringing, which is very narrow, say $\frac{1}{16}$ in. wide, we have another, a broader one of black, and beyond this a band of satin wood, or if preferred as being less costly, boxwood, between which and the outer border of mahogany the thin black and white stringing may be repeated. It will be noticed that the stringings, etc., must be mitred at the corners, but as they are very narrow no great difficulty ought to be experienced in doing this neatly. The same cannot, however, be said of laying them and the veneers, an operation which might, perhaps, deter the amateur artisan from attempting to form a Sheraton bureau unless explained to him. But as to give anything like a full explanation would be to forestall an article on veneering, which will shortly appear in these pages, the novice is referred to it.



Figs. 13-17.—Examples of Different Forms of Turned Spindles.

Early in the present century a marked decadence in the artistic features of furniture is very perceptible. We have already noticed this as evidenced in the later productions of Sheraton, whose later works may be taken as a sufficient illustration of the debased taste which during his short career had set in. It is difficult to believe that a man of his ability could possibly have fallen so much under the influence of popular fashion as to design some of his later works, which he seems to have been conscious were not so good as his earlier efforts. However, whether he originated the degraded style or merely followed the lead is beside the question. There can, however, be no doubt that for fifty—or might the time not be extended to seventy?—years from the beginning of this century, our domestic furniture was possessed of few if any artistic features which are deserving of perpetuation.

The workmanship might be good—indeed much of it was good—but any pleasure which could be experienced from this quality is lost in view of the utter want of any artistic merit both in decoration and structural design. Truly, so far as beauty or sense of ornamentation is concerned it was a desolate age, and those who pay any attention to such matters may well be thankful for the great improvement which has taken place in recent years. Perhaps the only class of men who have reason to cast a longing glance backwards to the good old times of bad or no art are manufacturers and designers of goods, such as furniture, which are influenced by artistic considerations. Anything then seems as if it served provided it were florid enough; but perhaps I am treading on the toes of some elderly readers who "can't abide them there straight things," so desist from further comment, beyond saying that though articles of furniture when perfectly plain might be worthy of regard, the same cannot be said of much that was elaborated by fanciful decoration. At any rate, there was no feature sufficient to characterise an epoch in furniture style, although here and there an enlightened designer might be found whose works cannot be indiscriminately ignored. Still, we may very well pass on to the present time.

As a result of the modern general renaissance in art, furniture soon feeling the influence became more simple in character than it had been for many years previously. Under the guidance of such men as the late Sir Charles Eastlake, the severe straight lines of the Early English style became the fashion. I must here point out Early English as popularly applied to furniture is altogether a misnomer, at least, if we regard Early English architecture as the standard, for the two present no decorative features in common. With more truth it might be called the *Old* English style, if by old we mean the woodwork of, speaking roughly, the sixteenth and seventeenth centuries. The term Early English is, however, a popular one, and as applied to furniture is so well understood, that notwithstanding writers have repeatedly called attention to its inaccuracy, it seems as though it would still remain in vogue, and it may as well be retained here.

Without going very deeply into the subject, let us then see what alterations will be needed to turn our bureau into an Early English one.

The prevailing characteristics of this style being straight lines, it will at once be perceived that in our original we have it already, with perhaps the beading round the edges of the drawer fronts omitted, and the mitred framing of the fall changed into an ordinary mortise and tenoned frame.

But probably along with severity and general plainness, scratched beads are equally associated in our minds with Early English, not to mention spindles. We all know how these were used a very few years ago. Spindles here, spindles there, and spindles everywhere. In moderation they are well enough, but really when they were brought in so very freely and indiscriminately, one began to get a little tired of them. In the bureau, fortunately, there is not the same temptation to use them in excess as with many pieces of furniture, for the only position in which they can be either ornamental or serviceable will be on top, where, in conjunction with top and bottom rails, they will form a very suitable guard to prevent papers, etc., slipping off. The guard may be either along the back alone or returned along the ends to the front. The latter will look better, but as the work is done in the same manner, the only difference being that there is a little more of it in one than the other, one description will serve for both. The illustration, Fig. 20, gives a general idea of the end of a spindled back guard, only without the return pieces. Analysing this, it will be seen to consist of an end piece into which are mortised two straight rails supporting the spindles. These will look better if placed moderately close to each other than if with a great interval between each, and two inches apart may be considered a fair distance at which to place them. In size they may be about a couple of inches long, and turned down from $\frac{3}{4}$-in. stuff, but it must be quite understood that considerable variation is permissible from these measurements. For one thing a good deal will depend on the pattern of the turning, a few suggestions for which are given in Figs. 13 to 17, the first of them being a spindle complete,

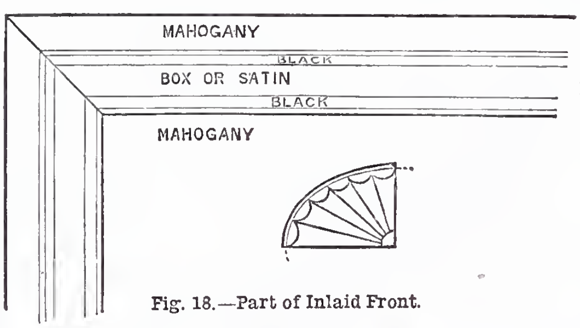


Fig. 18.—Part of Inlaid Front.

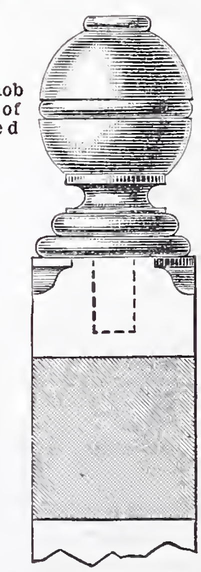

Fig. 19.—Knob at End of Spindled Guard.

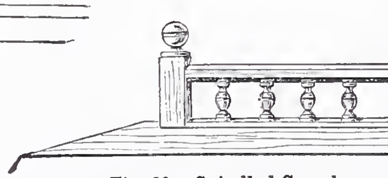

Fig. 20.—Spindled Guard.

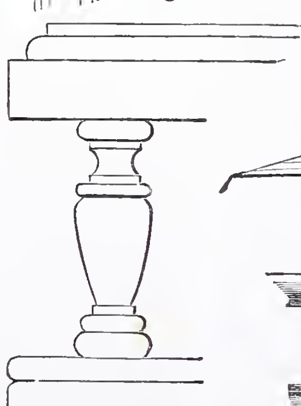

Fig. 21.—Alternative Mode of finishing Ends.

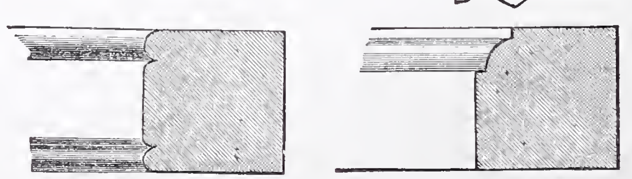

Figs. 22 and 23.—Top Rails of Spindled Guard.

and the others only showing the outline of members. From Fig. 13 it will be seen that the spindles are turned with a pin at each end, to fit into corresponding holes in the rails. As it would involve great waste of time to fit a piece of wood for each individual spindle into the lathe, the best way is to turn several on the same piece—the length, of course, of which will depend to some extent on the distance between centres, besides other considerations which the turner will well understand without them being specified. If the stick is of any considerable length, as it is only thin when turned down at the pins, a support attached to the lathe bed will be a necessity, but even without this several spindles can be turned on the same length. Great care must be taken to have all the spindles exactly the same length, so far as the show part is eoncerned. The length of the pins is of smaller consequence, as they can be cut shorter afterwards. They need not be more than $\frac{1}{4}$ in., that is on each spindle, not between two of these, though if they are not more than half this or $\frac{1}{8}$ in. they may still be used. Further directions will not be required about these spindles, and we may next turn to the rails.

Some care will be required in boring the sockets for the spindles; first, that the pins may fit them fairly tightly; and secondly, that the spindles may be perpendicular. To ensure the former, all that is necessary is to turn the pin down to suit the bit the holes are to be bored with, while to prevent any mistake in the latter, the holes may be made in both pieces at the same time. Perhaps it ought to be explained that the holes may be bored right through the bottom rail, but only sufficiently deep in the other to take the pins.

Both rails must be of the same width, which should be a little greater than the diameter of the spindles, so that they overhang these a trifle. In thickness $\frac{1}{4}$ to $\frac{3}{8}$ in. will do very well for the bottom one, but the top one will look better if it is a little stouter. It may be as much as $\frac{3}{4}$ in. thick without looking too clumsy.

Instead of leaving the edges square and plain in front, it will be better to finish them off in some way, .say by running a bead at the top or bottom, as shown in Fig. 22; or the upper edge may be moulded, and the lower left plain as suggested by Fig. 23.

It has already been said that these rails are to be attached to end pieces, which will next be described by mortise and tenon. The ends themselves are merely square pieces of wood, standing a little higher than the top rail, and at least as wide, or it will be better if they are a little wider on each face than the rail which abuts on them. The top end is turned up into a knob, and the bottom into a pin, though if preferred the knob, of which a suitable pattern is given in Fig. 19, may be turned separately with a pin which can be let into a hole bored for it in the end of the square piece, or it may be fastened with a double-ended screw. The pin or dowel at the other end of the square piece may also be let into it in a similar manner. In the bureau top holes are bored for these dowels to be placed in.

Fixing and fitting this part of the work is somewhat troublesome, but with a little patience all the spindles can be properly arranged between rails; the rails are then fixed into the end pieces, after which these are ready for fastening to the top. A little glue may be used to a spindle here and there, especially towards the middle of the rail, but if the upper one be stout it is not necessary. The mortises and tenons of course must be glued, and so must the dowels into the top. By this means the rail should be firm enough, but if any apprehensions are felt that it is not, glue may also be used to secure the bottom rail to the bureau, either along its whole length or only at intervals.

If the spindle guard is to be at each end, the mode of procedure is exactly the same, the rails being fastened to the square uprights, another of which will, of course, have to be at the front ends of each return.

As a variation it may be suggested that the finish in front might be as shown in Fig. 21, when each rail stops short without any terminal upright, and is merely rounded off at the ends to correspond with whatever beading or moulding is on the sides of the rails. By the way, the beads or mouldings should be on both sides of the return pieces, unless the bureau is to stand in a recess. The reason for this is so obvious that it will be unnecessary to explain the why and the wherefore. If, however, there be any reader who is unable to arrive at the reason without assistance, I can only say that I shall be happy to clear up the mystery for him in "Shop."

SIGN-WRITING AND LETTERING.

BY HENRY L. BENWELL.

Gilding Materials — Gold Leaf — Half Gold Leaf—Gilders' Size—How to Gild a Sign—Cushion and Tip Method—Transfer Gold Leaf—Dutch Metal—Bronzes, etc.—Advanced Text-Book for Further Study—Conclusion.

A treatise on sign-writing could hardly be considered complete without a description of the method employed by writers for gilding letters and ornaments with gold leaf. I can only give a description of the process as it is at present used in every-day practice, throwing out, perhaps, a few useful hints here and there as the result of my own practical experience in the work. It will thus be seen that I have nothing new to tell the practical workman, and as I am, therefore, writing for the novice alone, it will be necessary to be as plain-spoken and explicit as it is possible to be in describing a somewhat difficult process.

It will first be necessary to explain the uses of the tools and materials used by the sign-writer in gilding letters, only mentioning here those that are actually used in letter work, as there is no space to treat upon gilding in general in these papers.

The most important item is a suitable surface to manipulate the gold upon, and this is to be found in the gilders' cushion (Fig. 83). This is a wooden slab about 8 in. by 5 in., covered with a soft leather, and padded between the wood and the leather. A piece of parchment is tacked round one end, and half round the two sides, as shown in the illustration. This is to prevent the gold leaf from being lifted off the cushion, as the slightest movement of the air is sufficient to carry it away. Under the cushion will be found a leather loop; through this the thumb is inserted, being held in the left hand. There is also a smaller loop for holding the palette knife when not in use.

The knife (Fig. 84) consists of a long blade in a handle, and it has a hard, smooth, but not sharp edge. It must be kept clean and bright, otherwise it will tear the leaf instead of cutting it. It is used to cut the gold to the required size and shape.

The "tip" (Fig. 85) is a thin layer of camel's hair glued between two pieces of cardboard, and is used for lifting the leaf from the cushion, and carrying and attaching it to the spot to be gilded. It is 4 in. wide, and varies in length, the most useful being 1 in., $1\frac{1}{2}$ in., and 2 in.

The gilders' mop (Fig. 86) is either flat or domed; it is used to dab the gold with, in order to make it adhere firmly to the prepared surface.

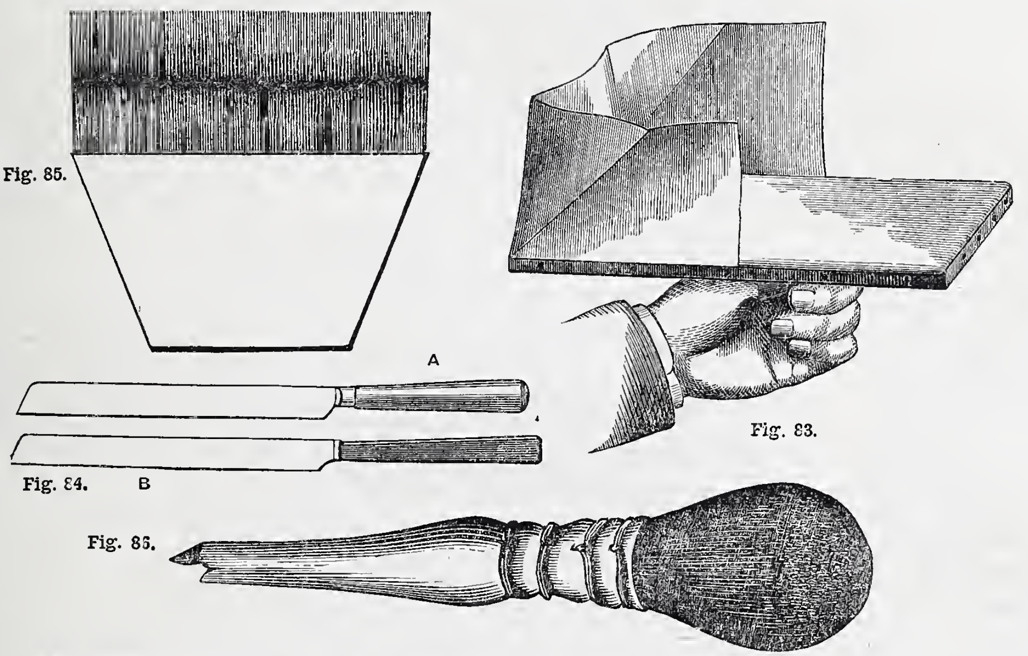

Fig. 83.—Cushion for Gold Leaf. Fig. 84.—Knives for cutting Gold Leaf—A, Knife with Balance Handle; B, Plain Knife. Fig. 85.—Gilders' Card Tip. Fig. 86.—Gilders' Mop or Dabber.

These are all the important tools that are really required, but a variety of sable, camel's-hair, hog's-hair, and "skewing" brushes will come into request in actual practice. Some powdered chalk must be tied up securely in a piece of fine muslin to make a pounce bag for dusting on the painted surface. Sponges, dusters, and other requisites should be kept specially for this work, and the whole of the tools and materials are best kept in a compact tin box.

The materials used for gilding, or for the imitation of solid gold, are—1, genuine gold leaf; 2, adulterative ditto; 3, Dutch metal; and 4, bronze powders.

In genuine gold leaf, there is always a certain amount of alloy, as pure gold is too ductile to be worked between the gold-beater's skin without it. It is sold in books of twenty-five leaves at about 1s. 4d. each, and gilders' work is measured and estimated by the "hundred" (leaves). Gold leaf must be kept in a dry place; if allowed to get damp, it will be impossible to remove it from the book without tearing it to pieces. Damp has also the power of tarnishing the leaf, and if any is discovered in this condition, it should never be used or it will spoil the work.

Gold leaf should fall freely from the book on to the cushion by a gentle breath from the operator; if it does not do so it is damp, and should, therefore, be placed in front of a fire for an hour or so to dry it. There are three shades of gold leaf sold—1, very pale; 2, medium or yellow; and 3, deep gold. No. 2 is the best for the sign-writer; it looks the best when varnished, and is the most durable if left unvarnished. It also stands the best against atmospheric influences when used on outside work, which, of course, comprises sign-writing.

Upon inquiry, I find that Messrs. Brodie and Middleton sell a "half gold" leaf at 5d. per book, which appears to be a very good article for the price charged. It is much thicker than ordinary gold leaf, and is, therefore, easier for the novice to apply, and it wears quite as long as the more expensive article. The same firm also make a special writer's gold size, which is very pale and clear, and of excellent quality.

There is now a cheap form of gold leaf upon the market known as the Venetian Ducat Gold Leaf, and sold at 7s. 6d. per thousand; it requires, I think, a special oil size and enamel, the latter being required for coating it after it has been applied to the surface to be gilded. It is then claimed to be permanent and washable, but although I have never seen a sample, I am inclined to the belief that, after all, it may be only a better sample of Dutch metal. It is made and sold by T. Pavitt and Sons, 70, Southampton Row, W.C. Dutch metal is a mixture of copper, brass, etc., and is made on the Continent. It is largely used in theatres for pantomime and burlesque scenery, hence the writer's acquaintance with it is pretty extensive. It is also used for gilding Christmas articles, and any kind of cheap and temporary work. It may be used by sign-writers and others for any temporary purpose, but soon turns black unless protected with a coat of patent knotting. Gold bronze powder may also be mixed with this, and applied to any surface, and will stand for years without tarnishing or getting discoloured.

Dutch metal is 1½d. per book at any large London colour warehouse or theatrical store. I now come to a somewhat modern article of convenience—I mean "transfer gold leaf." This is a perfect godsend to the sign-writer when working out of doors in windy weather. It is prepared as follows:—Procure a sheet of strong white tissue paper and three pennyworth of white wax, lay the paper upon a drawing board, and rub it all over—on one side only—with the wax. This must be well done, so that no small portions of the paper are missed; this can be ascertained by holding the paper sideways to the light, when the waxed surface should have a glossy and even appearance. The paper is now cut up into squares a size larger than the leaves of gold; the wax side of the paper will now have a slight amount of tackiness by which we are able to transfer the gold leaf by adhesion. The book is carefully opened, and a piece of wax paper is laid upon the gold and slightly pressed down with the hand, and this is continued right through the book until all the leaves have been provided with a sheet of waxed paper. The book should now be placed under some gentle pressure and it is ready for use. The method of using it will be described further on in this paper.

Letters for gilding are written in oil gold size, procurable at any colour shop. There is a slow and a quick size; the former is prepared by grinding up fat linseed oil and yellow ochre; for a quick gold size, a quick-drying varnish with a little oil gold size added to it to keep it tacky is a good preparation.

By regulating the quantity of oil put with the varnish, the mordant may be made to dry in three or four hours. Japanners' gold size and picture-frame-gilders' size may also be used for lettering.

Having enumerated the few necessaries required for letter gilding, I will now take the student through the process of writing and gilding a sign in simple unshaded letters on a black ground. The first thing to do is to so prepare the painted surface of the sign, that the leaf will be prevented from sticking anywhere except upon the sized portion, *i.e.*, the letters.

A sign which is to contain gilded letters which are afterwards to be varnished, is always given a coat of "flatting" as a finishing coat, and on this surface there is not much chance of the gold adhering anywhere except upon the letters themselves. If the edges are not sharp and clear, however, the sign just round the letters must be "egg-sized." But there are a great many people who will not have their gilded letters varnished over, as it takes so much off the brilliancy and richness of the gold, and in this respect I concur with such people. In such case, the sign has to be painted, varnished, and finished in every way before the letters are put on, and so we have to be careful how we work, or we shall spoil our own work and other people's too. The varnish, which should be of the best and hardest drying quality procurable, should be allowed to set quite hard; it can very well be left for a week after being applied to the sign. When hard, we commence by removing every trace of dust and sponging the board over with cold water; this will remove a certain amount of greasiness from the varnish; when dry, again dust, set out the letters in pencil, not in pipe clay, and then dust round with the pounce bag containing the powdered chalk. This need not be done to any unnecessary extent, as one frequently sees to be the case, but should be carefully applied to the spaces between the letters, and for an inch or two top and bottom of the letters. I need hardly say that this chalk is to prevent the gold from sticking anywhere but to the letters, and giving to the same a sharp, clear edge. A very slight dusting should be sufficient, and it must not obliterate the outline of the letters. Should any chalk grit get upon the letters, it must be carefully dusted off with a small brush before applying the size, which we are now to get into a workable state. The oil gold size sold in the little jars by oil and colourmen is generally too thick for use, and, therefore, requires thinning to the proper consistency. Brodie and Middleton sell it both "thick" and "ready for use." Taking as much as we require for immediate use from the jar, we thin it down with a little boiled linseed oil, and strain through a fine piece of muslin into a small jar for use. The slow-drying size is laid on one day and gilt the next, but if we require to apply the gold leaf on the same day as the size is applied, then we must use one of the quick-drying mordants already mentioned.

The method of pouncing the sign with chalk is a somewhat dirty and untidy method of working, although it is the one in general use; many of our best writers, however, use instead, egg-size, which is prepared in this way:—A nice fresh egg is pricked at both ends with a large pin, and the white of the egg only is blown into a cup; this is diluted with a little water, and the whole whisked up into a froth with a clean new sash tool. This is now applied to the sign and well worked over the entire surface, and if properly done, will prevent the stray particles of gold from sticking upon any part of the board. After the gilding is completed, the egg-size is washed off with a sponge and warm water.

Having thus prepared our sign and gold size, and marked the letters out, we take a suitable sable pencil and line and fill them in with the size, and leave it to get nearly dry. The great point now to be decided upon is, when is the size ready to take the leaf. This is somewhat difficult for the novice to decide. In the first place, if it is too moist and tacky, the gold will sink right into the size, and lose all its brilliancy, besides showing every joint and looking dirty in places. Secondly, if it has got too hard, it has lost most of its tackiness, and there is not sufficient left to cause the gold to adhere properly. The beginner generally fails from the first cause, but he is just as liable to err in the opposite direction if he allows too long an interval to elapse between brushing on the size and applying the gold leaf. The state of the atmosphere has, of course, a lot to do with the drying, and the drying qualities of the size vary in a great degree; so, as no two cases are alike as regards time of drying, a sharp eye must always be kept upon the work. I cannot give more explicit directions, beyond saying that a very slight tackiness will cause the gold to adhere, and this is all that is required.

Taking for granted that the size is now right, we proceed to apply the leaf, and as many signs are painted and lettered in the shop, we will first attempt the work indoors where no one can see our failures, or make us nervous by looking on. This is the tip and cushion process. Taking up the book of gold leaf, we open the first leaf, and breathing very gently at the edge of the leaf, and holding the book at the same time close down to the cushion, we cause the leaf to fall upon it. About four leaves are quite sufficient for the novice to take out at once, as he will be sure to waste the lot, and a few books besides, unless he has an "old hand" beside him to give him personal instruction.

Some, however, are bound to be self-taught, or not at all, so instead of paying for a tutor, they have to pay for experience, which comes to the same thing.

We now take the cutting knife, and wipe it to free it from moisture, and gauging the width of the letters, we cut the leaf into suitable sizes. A little dexterity is required in using the knife, and the quickest way to attain it is to get a practical man to show you "how it is done." We next take the "tip," and drawing it lightly through our hair, we lay it upon the leaf lengthways, and gently carry it from the cushion on to the sized letter; this operation is repeated until the whole of the letter is gilded, when we apply a slight pressure by dabbing it over—very lightly—with a piece of cotton wool, the mop, or the dabber, according to fancy. The whole of the letters are treated in this way until the job is finished. It is very seldom this method of gilding can be employed in the open air, but if it can, it is certainly best, as the gold leaf can be laid upon the size without pressure, which adds very much to its brilliancy, but when the gold is laid on from tissue paper or from the book, a certain amount of pressure must be used, and this is liable to disturb the size, and press the gold into it, and cause very uneven work.

We now come to outdoor gilding, and in this, writers of the old school simply take up a book, turn back the paper leaves, and without any cutting, place the leaf direct against the sized letter; this, I may say, is a very wasteful way of going to work, as if there is the slightest wind a great deal of the gold is wasted. The slightest movement in the air renders it very difficult to proceed in the way mentioned, and for this reason, when gilding with the tip or without it out of doors, the sign-writer is generally surrounded with a large coarse sheet to shield him from the evil effects of the wind.

The easiest of all methods in gilding is with the transfer gold leaf, the preparation of which I have already described. The work is very simple, as the leaf is now so easy to handle; this is the way to do it. Open the book at the first page, and take out the tissue square (with the metal attached) with the left hand, place it with the gilded side on to the letter, and with the right hand gently and lightly rub it with a piece of cotton wool, but only on that portion which you wish to adhere; now remove the tissue and apply what leaf there is left to another portion of the letter until all is used up.

As the tissue is transparent, it is very easy to see how much gold is used each time, so that every particle can be used up for odd corners and soon. And, moreover, there are no ragged edges with the gold flying all over the place as in the old method. Always save the tissues, as they may be used over and over again with an occasional re-waxing. As regards the application of Dutch metal, I presume that the ordinary oil size may be used as in gold leaf, but for theatrical purposes we use a preparation called madong, and this is how we make it. "Take equal parts of pitch, Venice turpentine, resin, beeswax, and Russian tallow (all to be had at the colour shop), put them into a madong pot and melt them together, but should the mixture work too stiff and thick, add more wax and tallow. The more tallow that is added, the more pleasantly it will work, but if too much is added, it will never harden sufficiently to work upon. It can be used harder in hot weather than in cold, as the heat keeps it 'tacky.'" Apply hot with a camel's-hair brush.

I need hardly say that this must not be used upon a sign-board; I give it to the sign-writer as a valuable secret recipe—secret no longer, perhaps—by which he will be able to gild letters upon canvas and other material for all temporary decorative purposes.

Writing with gold powder or bronze is hardly worth mentioning here I fancy, although I have used a great deal for room decoration, which has kept bright for years when applied by my own process. There is, however, real gold powder to be obtained, the price of which is 7s. 6d. per pennyweight, and pure silver powder at 14s. per ounce, or 1s. per drachm. Bronzes of all shades and colours run upwards from tenpence to two shillings per ounce. Bessemer's gold bronze, as used by the *Graphic* newspaper people, may be had at 4s. 6d. per pound direct from the manufacturer, and this is what I always use myself with good results.

There is a great deal more to be said and learnt upon the art of gilding letters, sign ornaments, Royal Arms, medals, etc., and all this is fully set out in Mr. Sutherland's "Art and Craft of Sign-Writing." As regards these pages, however, my readers must now rest content with what I have given them upon this interesting branch of the letter-maker's art.

I am now, through stress of space, obliged to bring these articles to a conclusion, but I have far from exhausted my subject. I would remind the student that he must not stop where I have left him, but keep going on and on, till he reaches that ambitious goal, perfection.

In conclusion, I can honestly recommend, as an advanced text-book, "The Art and Craft of Sign-Writing," by Mr. W. Sutherland, price 21s. This book measures 18 in. by 13 in., and contains twenty pages of alphabets (some in colours) and designs for sign-writers. Also coats of arms and shields, emblems for church and other decorations, with full instructions as to all methods and processes. Altogether, it is the most complete work published upon the subject with which it treats.

ELECTRIC CLOCK FITMENT.

BY H. J. L. J. MASSÉ.

After reading Mr. Bonney's article on "Electric Alarms" in a recent number of Work, I thought that some readers might perhaps be interested in another electrical clock fitment.

My drawing-room clock is an old Louis XIV. eight-day upright, with a movement made in Amsterdam nearly two hundred years ago. As a time-keeper it is practically perfect, and being in want of a striking clock on the bedroom floor, it occurred to me to fit up a single-stroke electric bell in connection with the old clock downstairs. After purchasing a single-stroke electric bell, two Leclanché batteries, a switch, and some wire, I set to work.

I did not wish any of the wires or fittings to show in the drawing-room, so I carried the wires from the back of the clock-case along the wainscoting, pushing them underneath where I could, then out into the hall up along the mouldings of the door-posts, and along the edge of the stairs, as invisibly as possible, till they reached to the electric bell, which I had fixed on the top of my bedroom door.

Of the method and the rationale of connecting the wires to the battery and the bell it is not necessary to speak, as all requisite descriptions have been given in previous articles. It will be enough to say that the circuit is only completed when the hammer of the clock rises preparatory to striking the hour. One of the insulated wires is securely fixed on to the thin metal rod which forms the handle, so to speak, of the clock hammer, and a portion of this wire (about half an inch or so) is laid bare, care being taken to so fix it that it does not touch the clock anywhere. The other end of the wire is fixed on a small bracket, at right angles to the wire on the hammer, and has likewise a small portion laid bare. When the hammer is raised to strike the hour the two bared portions of wire touch; the circuit is then completed, and the electric bell strikes upstairs.

The batteries—of which there are two, a No. 1 and a No. 2 Leclanché—are on two small brackets fixed to the back of the clock case, where they are, of course, invisible, as the clock stands across a corner of the room, though they are easily accessible

I found that a single cell Leclanché was not sufficient to do the work alone.

The switch is fixed upstairs, so that the clock may not strike upstairs during the daytime, or whenever its striking would seem to be undesirable.

At the present time I am endeavouring to find a means (electrical, of course) of pulling the cord which makes the clock repeat. This would enable me to tell the time at any hour of the night without the necessity of striking a light, or, what is worse, especially in winter, of getting up to see the time.

THE KALEIDOSCOPE: ITS CONSTRUCTION AND APPLICATION.

BY THOMAS RICHARDSON.

The Optical Portion—Use of the Instrument—Conclusion.

(*For Illustrations to which references are made in this Paper, see pages 424, 425.*)

Seeing that all necessary processes required in lacquering and polishing the exterior of the instrument have been frequently dealt with by other writers in the current volume, it seems superfluous to again revert to these matters here. We will, therefore, pass these by and concern ourselves with the interior, which should now have a coat of dead black paint; ivory black would be most suitable, made up thin, and sparingly applied to all surfaces except those in sliding contact.

The two pieces of patent plate glass required for the reflectors are 8 in. long, 2 in. wide, and $\frac{1}{12}$ in. thick, and previous to silvering the surfaces, all sharp edges must be removed by rubbing on a level piece of sandstone with water, all grit being afterwards cleared away by well washing and rinsing in clean water. Our next business is to make up the two solutions to be used in silvering. The first is prepared by dissolving 72 grains of nitrate of silver in $8\frac{1}{2}$ ounces of distilled water in a clean glass jar, capable of holding a pint or more. Holding the jar to the light so that you can see through the liquid, add slowly a few drops of solution of ammonia, when a precipitate will be formed; more ammonia must then be added drop by drop until the precipitate is *nearly* re-dissolved. Be very cautious in this latter particular, as if the ammonia is rashly poured into the jar the precipitate will suddenly form and as suddenly disappear. Filter, and after adding another $8\frac{1}{2}$ ounces of distilled water, label the jar—"Solution A."

The second is prepared by dissolving $15\frac{1}{2}$ grains of nitrate of silver in 17 ounces of boiling distilled water; whilst still boiling add 12 grains of Rochelle salts which have been previously dissolved in half an ounce of distilled water, the boiling being continued until the precipitate which forms becomes grey. Filter, and when cool, pour into a jar and label—"Solution B." If distilled water is difficult to procure, rain water, if caught in the country and filtered, will serve for the purpose. The boiling may be conducted in a flask on a retort stand, or in a porcelain dish covered with a glass plate, and heated on a stove. When these operations are complete, the two glass plates must be made chemically clean by rubbing them with a slip of wood dipped in strong nitric acid, the process being conducted in the open air to avoid inhaling the noxious fumes. The acid is then washed off with soft water and a solution of caustic potash applied in the same manner, after which alcohol or rectified spirits of wine is applied. Lastly, they are thoroughly washed in distilled water, and placed, whilst still wet, side by side in a clean dish, when equal quantities of the solutions A and B are poured over them and mixed by stirring with a glass rod. Six or eight ounces of each solution will be sufficient, and a meat dish will be found to be a suitable vessel for the purpose. If any suspicion is entertained as to its cleanliness, it will be well to subject it to the same searching process as described for the glass plates. At a temperature of 60° the silvering will be complete in two and a half or three hours. The glasses are then taken out, washed in distilled water, and when dry the surface may be polished with rouge, gently applied with a small pad of cotton wool. The reflectors may now be said to be in readiness for fixing in position, by applying a little cement to the backs in a few places where the glass is in contact with the slips of wood on which they rest, being careful to notice that the mirrors clear the case equally at each end, and also to refrain from applying pressure, but simply laying them on the supports at *i*, Fig. 2, and leaving them in that position for a day or so to allow the cement to harden; after which the slips at *h*, Fig. 5, may be gently screwed in their places, and the angle of the lower edges carefully adjusted by the screw at *f*, Fig. 2. A suitable cement for attaching the reflectors consists of 1 ounce of isinglass dissolved in $1\frac{1}{2}$ ounces of glacial acetic acid, the bottle containing it being placed in a little warm water when required for use.

Fig. 13.

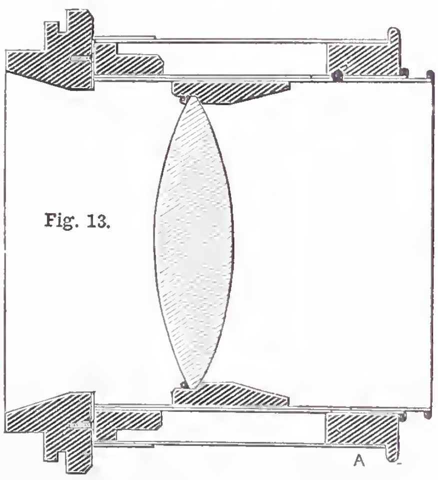

Fig. 13.—Sectional View of Objective.

Fig. 14.

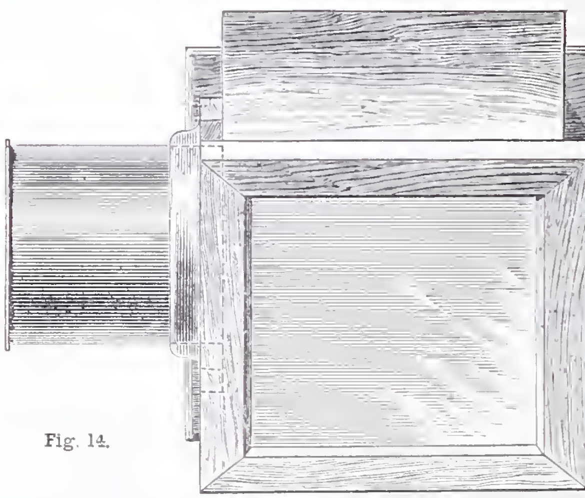

Fig. 14.—Plan of Camera Obscura for Use with Compound Kaleidoscope.

In replacing the sides of the case which have been removed to reach the interior, it would be an improvement to affix a pair of hinges and a catch to the side on the right of M, Fig. 2, to accelerate the process of cleaning the reflectors, which is effected by means of a camel-hair brush.

When satisfied that the working of the instrument is perfect, by testing it in the various movements of which it is capable, as described in the first paper, we may now bestow some attention on the construction of object-boxes. In these there is room for great diversity of form, according to the purpose for which they are intended. The object-box shown in section at z, Fig. 5, is intended for the reception of transparent objects which are attached by the cement already mentioned to the inner surface of the ground glass disc. When required for thin, loose objects, the space between the two discs is so reduced that it is impossible for one piece to slip behind another, and yet allow of perfect freedom of movement in the pieces. If it is desired to have two cells, one in front of the other, a disc of clear glass occupies the place of the ground glass disc; then a brass ring somewhat thicker than the objects in the second cell is laid in to support the disc of ground glass, and if deemed necessary, the ring of brass wire which secures the latter as shown in the section is replaced by a brass flanged ring similar in section to that which secures the lens in the eye-piece, as shown in Fig. 12. The process to be followed in making the object-boxes resembles that given in the case of the carrier, the outside being always finished first where the work in hand is so slight in character, as in this instance, for if the opposite course is adopted, on attempting to turn the outside, the work will bend and spring under the tool, and probably end by flying to pieces. To facilitate withdrawal from the carrier, they should be furnished with a round-headed brass screw at each side, in the same way as shown in the eye-piece (Figs. 8 and 9), the construction of which we will now pass on to consider. In the first place we must provide a ring, A, of particularly close-grained, hard mahogany, turned to fit smoothly in its bearing, being especially careful respecting the thickness of the tongue, so that when finished it shall be quite free from shake. To this ring is attached a dovetail slide, B, held by a piece at each side, secured across the grain by screws to the ring; the slide B carries an ordinary eye-glass which is mounted centrally, and secured by the cap, C. The opening in the slide under the lens is $\frac{1}{2}$ in. diameter, and to further close this aperture a diaphragm is provided at the back of the slide, having two holes $\frac{3}{8}$ in. and $\frac{1}{4}$ in. diameter respectively. The diaphragm is formed of a piece of thin brass, and is manipulated from the front by a small milled head, having a shoulder which bears on the slide, and the point is screwed and afterwards riveted or soldered to the diaphragm. In choosing the lens, it will be of a correct focus if print can be discerned or read clearly at a distance of 10 in. When finished, the eye-piece should have a deep mark cut on the upper edge, as shown by the crow's foot at D, Figs. 8 and 10, to indicate the exact position for entering the bayonet joint, after which a small pin or screw must be inserted in the grooves to act as a stop when the slide is exactly vertical, when it will be found that the latter requires grooving to clear the index above, and further, the ring requires cutting away somewhat to clear the diaphragm. There is yet another eye-piece to be made, as shown in Figs. 11 and 12, for projecting the picture on to a screen or camera obscura for copying. In this case the ring is heavier, and the screws which secure the guides on each side of the dovetail slide pass from the back, as seen in Fig. 12. The tubes required may be of brass, and may be procured of Messrs. Cotton & Johnson, 14, Gerrard Street, Soho, London, W., and secured to the woodwork by lugs of brass, soldered or riveted to the tubes. In the present case, however, they are formed of biscuit tins, the lid being firmly screwed to the slide while in the lathe, and perforated as shown in the diagram; the bottom is then removed with a file, and a short mandrel of wood is prepared to fit the tin tube, when the two lengths required are cut off truly at each end. The smaller tube carrying the lens is then reduced by dividing the seam with a knife, the mandrel being also reduced to take the two tubes, one within the other, after which the inner one is bound with wire at each end, and soldered afresh, the end being finished with a ring of brass wire to afford a hold of the tube in focussing, and the outer tube soldered to the lid. The lens, which is 2 in. diameter and 6 in. focus, is secured by a brass flanged ring, and mounted in a mahogany cell, turned to a tight, sliding fit within the smaller tube. The ring is then marked, and a recess cut as indicated by the dotted lines in Fig. 11, as adopted in the preceding case.

On precisely similar lines we must prepare the objective, shown in Fig. 13, but in addition, we require a larger tube and lid to form an extra draw, the difference in diameter being made up by a ring of mahogany attached to the inside of the larger tube at A, and a second ring fixed by screws to the outside of the middle tube. The lens is 3 in. diameter and 4 in. focus; it is mounted in a cell of mahogany, and held in position by a ring of brass wire. The camera obscura, shown in Figs. 14, 15, and 16, consists of a cubical box, whose interior measures 6 in. in every direction. It may be constructed of pine, and should be perfectly square. The ends are mortised into a baseboard, and shapen so that the top, which is left open, is inclined or tilted 30° from the horizontal line, the reason for this being that the picture

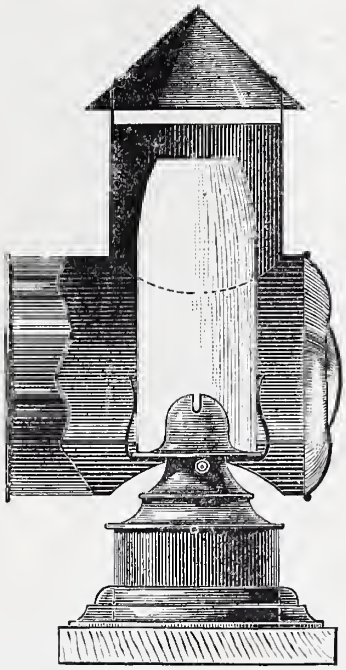

Fig. 17.—Lamp with Shade and Reflector for illuminating Objects.

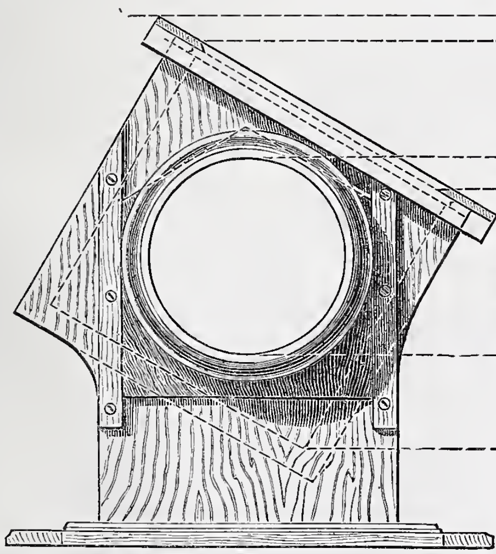
may be viewed without inconvenience by the observer seated in front of it, the kaleidoscope being placed to the left. On the front is an opening covered with a slide which carries a tube projecting over the tube in the larger eye-piece, to exclude extraneous light. Previous to nailing the ends to the sides of the box, a diagonal line is drawn from one corner of each piece to the opposite, and immediately below this line a slip of wood is screwed to each side. On these slips the mirror rests, and the image is reflected upwards on to a piece of ground glass, which lays, ground face downwards, within a shallow ledge, $\frac{5}{16}$ in. wide, which runs all round the top of the box, the ledge being of the same thickness as the square of ground glass. Over this latter is a frame of mahogany rabbeted or built up as shown, which holds the tracing cloth or paper on which the picture or design has to be drawn.



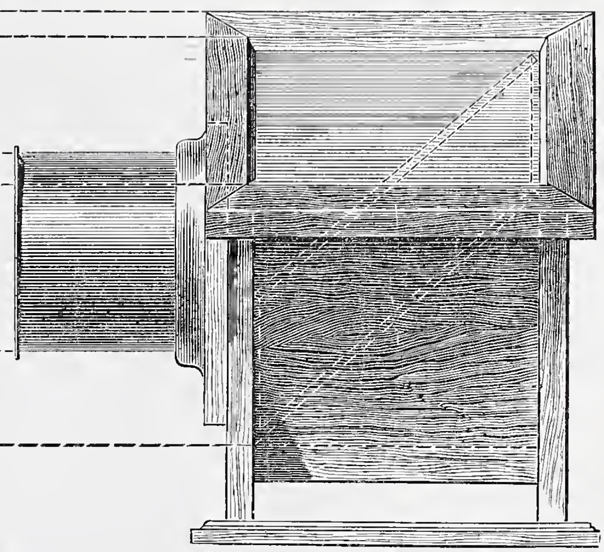


Fig. 15.—End Elevation of Camera Obscura. Fig. 16.—Front Elevation of ditto, showing Position and Angle of Mirror.

To intensify the light, and shade the eyes of the observer as much as possible, such a lamp as that shown in Fig. 17 will be found useful. It is furnished with a $\frac{3}{4}$-in. wick, and a silvered metal reflector, 5 in. diameter. The shade is of strong tin plate, and the lamp is mounted on a wood base, 6 in. wide and 8 in. long, which corresponds to the width of the kaleidoscope, so that on placing the instrument and any accessories not actually attached to the same, they may be kept central with each other on a board having slips screwed to its true face 8 in. apart, as shown in section, Fig. 15. All tubes in the optical portion should receive a coat of dead black, as advised in respect to the interior of the instrument itself.

An extremely useful addition to the object-boxes already mentioned is the oblong form. This is 10 in. or 12 in. long, and 5 in. or 6 in. deep, with a clear glass in front and one of ground glass at the back; it is placed in a slide in front of the objective, which projects the image of the objects arranged in the box, and illuminated from behind by means of the lamp.

By the exercise of a little ingenuity in the arrangement of the materials in the object-box, so that each colour harmonises with those in its immediate vicinity, and a careful adjustment of the light and focussing of the lenses, a series of patterns will be observed in the camera obscura which, by the brilliancy and the perfect harmony of their tints, will delight the eye of every beholder.

To assist the reader in the selection and combination of colours which harmonise with each other, I mention a few of the most important, viz.:—Red with green; yellow with purple; blue with orange; olive with orange; purple with citrine; russet with green; blue, red, and yellow; purple, green, and orange; olive, russet, and citrine. Space will not permit of my pursuing the subject further here, but the student is recommended to peruse the articles on this difficult subject in "Cassell's Technical Educator," by Professor Church, in which he will find it treated by a masterly hand.

The materials introduced into the object-boxes may consist of carved gems; lace; glass, either flint or crystal, plain, spun, or twisted; flowers; leaves; figures, cut out and cemented to the glass of the object-box; and when using the objective we may dispense with the object-box, and project the image at once on to the end of the reflectors, the most important thing being to have them strongly illuminated on all sides; sometimes they can be improved by cementing to mirror glass, and at others two lamps can be judiciously employed for the purpose, care being taken to exclude the direct image of the flame.

Respecting the application of the kaleidoscope to the arts, it is difficult to transfer the brilliant colours of some patterns to materials of a sober character, and therefore it appears most fitted for materials of a brighter and more reflective character, such as embroidering, and otherwise ornamenting in silk, and yet more especially in paper and glass staining and painting; and I cannot conclude these articles in a more excellent way than by quoting a passage from the writings of the talented discoverer of the kaleidoscope.

Speaking of the artist who forms windows of painted glass, he says:—"In this last profession, in particular, the application of the kaleidoscope cannot fail to indicate combinations far superior to anything that has yet been seen in this branch of art. From the uniformity of tint in the separate pieces of glass which are to be combined, the effect produced by the instrument from portions of the very same glass that is to be used for the windows may be considered as a perfect fac-simile of the window when well executed on a large scale."

THE SLIDE VALVE.

BY T. R. BLACKETT.

"Lap" and "Lead"—Eccentric Sheave.

The slide valve of a steam engine has been so often ably discussed that I have almost to apologise for writing a paper upon it. But, however, it is my intention to put the matter so plainly before my readers, that many who read this paper will know how to proceed, should they be called upon to set a slide valve.

Very few workmen, who build, and draughtsmen who design really high-class engines, are versed in the higher mathematical branches, hence my putting it in a practical light.

The parts of a steam engine move with geometrical precision with each other; thus every part must have some angular or linear relation with each other. Now such being the fact, why not do away with the time-honoured though time-taking custom of setting the slide valve before the eccentric is keyed on to the crank shaft? The proper angular relation of the eccentric to the crank is a right angle plus an angle obtained by the linear advance of "lap" and "lead."

By "lead" is meant the distance the steam-post is opened at the commencement of the piston's stroke. By "lap" is meant the distance the slide valve overlaps the opening edge of the steam-post at the end of *its* travel.

Let us take, for example, a common D slide valve (Fig. 1). We will suppose that it has $\frac{3}{4}$-in. "lap," and it is to be set with $\frac{1}{8}$-in. "lead" on each steam-post, with the travel or stroke of slide valve to be 4 in. We will now proceed to fix the eccentric, *for good*, in its proper place upon the crank shaft.

If a small shaft, we will put it on the surface plate or marking-off table, letting it rest in a pair of V-shaped bars.

The next thing to be done is to plumb the centre of the crank pin directly over the centre of the crank shaft; having done this, erect a perpendicular line from the bottom of the crank shaft, as shown in Fig. 2; next the total "lead" is $\frac{1}{4}$ in.; set the dividers to that radius, and mark off from the centre of the crank shaft *downwards* an arc cutting the perpendicular line *a* (Fig. 2).

Having done this, we take the total "lap," which is $1\frac{1}{2}$ in.; we set the dividers to that radius, and mark off downwards as before, from where the first arc cuts the perpendicular line to *b* (Fig. 2). We will now look to the stroke or travel of the slide valve itself; we find it is to be 4 in.; set the dividers to half that distance, viz., 2 in. Having done so, describe a circle from the centre of the crank shaft, which is called the travel circle. Here we take the scribing block, or, as some call it, the surface gauge; set the pointer or scriber at *b* (Fig. 2), and draw it along in a horizontal direction across the end of the shaft until it cuts the travel circle at *c* (Fig. 2). Now take a straight-edge and draw a line from the centre of the shaft, *o*, to the outside of

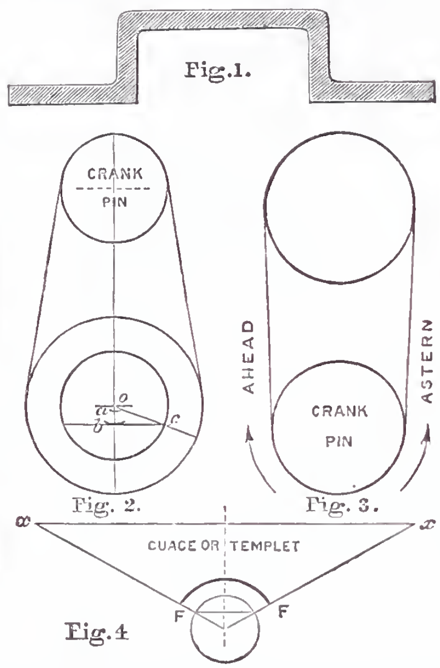

Fig. 1.—Section of D Slide. Fig. 2.—Plumbing Centre of Crank Pin over Centre of Crank Shaft, Centre Line of Eccentric. Fig. 3.—Plumbing Crank Pin for Marine Engine; Shaft to be Plumb, Pin down. Fig. 4.—Gauge or Templet; when tried upon Shaft for Marking Centre Lines, $x\ x$ to be levelled by Spirit-Level.

the shaft cutting *c*: this line produced along the shaft is the centre line of the eccentric sheave.

We have here the true geometrical relation of crank and eccentric sheave.

Although draughtsmen have for years followed this method of showing the position of the eccentric sheave upon the shaft, working mechanics have been loath to make use of the same method to fix their eccentrics, and keying them up for good.

But thanks to the advancement of education and science, we see old "rule of thumb" notions put to one side, and gigantic undertakings executed by practical mechanics on a scientific basis.

Again to our subject: the horizontal distance of the eccentric along the shaft, from centre of crank pin to the centre of the eccentric sheave, is equal to the distance from the centre of the cylinder to the centre of the slide valve spindle. I think that any one who makes himself master of the above facts, either the amateur making his model engine, or the professional workman in the workshop, who needs the instructions cannot fail to turn out an efficient engine.

In the case of a large marine engine, for example, where the crank shaft cannot be placed on a marking-off table, we have to plumb the crank pin *downwards* (Fig. 3), and make a gauge or templet (Fig. 4), constructing the same geometrical figure as described before, but showing both the ahead way and the astern way of the engines; the two lines, F F (Fig. 4), are the centres of the two eccentrics to be produced along the shaft. The thickly-marked lines are where the gauge is cut out to fit the shaft. The proper distance of the eccentric from crank pin is got the same way as the first-mentioned case.

When the eccentrics are keyed on, and the shaft is placed in position in the engine, the setting of the slide valve is now an easy matter, viz.:—Place the eccentric sheave on either of its centres, or, if you choose, put the engine on its "dead" centre; give the slide valve the required lead; our valve is now set.

These remarks are practical, and will, I think, be easily understood.

Marine slide valves are allowed more "lead" on the bottom steam-post on account of the obliquity of the connecting-rod, which I will describe fully in another paper, as well as the settling down by the wear and tear of the engines.

I have here endeavoured to set forth the vital parts of the steam engine, and should any amateur or his professional brother wish for further information, I shall be most happy to provide him with it, either through "Shop," or by post, if he will only pay the postage, as far as lies in my power. Having shown the proper place for the eccentric sheave, in my next paper, I shall consider the obliquity of the connecting-rod and its remedy; also reason of "lap" and "lead."

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

127.—Syer's Mitre Block and Saw.

It will doubtless be fresh in the memory of many of my readers that a full description of the appliance known as a mitre block, or mitre trap, was given in page 273 of this volume, and that its construction, and the mode of making one for one's own use, were clearly defined. To this paper, "A Mitre Block, and How to Make It," by David Denning, I must therefore refer all who wish for more than the necessarily brief notice I can give here in reference to the Mitre Block and Saw, which has lately been improved—I may say, perfected—following the general lines of the original appliance, and introduced by Mr. Thomas J. Syer, 45, Wilson Street, Finsbury Square, E.C., of the firm of Thomas J. Syer & Co., tool makers, etc., and dealers in all tools and appliances used in carpentry, joinery, and cabinet making, and Principal of the Finsbury Amateur School of Practical Mechanics. The mitre block is, as its name implies, a contrivance for mitreing joints, and available also as a means for squaring off the ends of pieces, such as door-rails, stiles, etc. Mr. Syer's mitre block possesses value in being exceptionally well-made, perfectly true, and admirable in action, the facility with which the movable block works, and its grip on the wood, that may be placed between it and the fixed block, being secured by the screw which is attached to it, and which is worked by an iron bar passing through the spherical termination at the outer end, as shown in the illustration given in Fig. 1. The projecting piece below the platform on which the blocks are placed supplies the means of securing the block in the jaws of the bench vice. The most attractive thing in connection with Mr. Syer's mitre block is the tenon saw that is supplied with it.

The construction of, and mode of handling adopted for, this saw will be understood from Figs. 2, 3, and 4, which show respectively the plan, the side elevation, and the end elevation of the tool. From these it will be seen that the

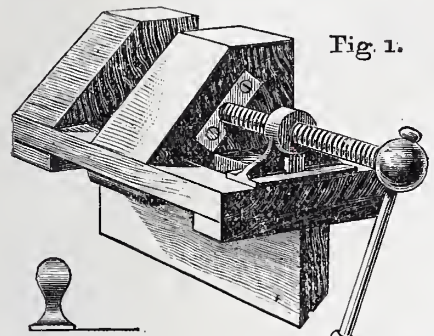

Fig. 1. Fig. 4.

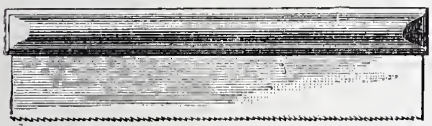

Fig. 2.

Fig. 3.

Fig. 1.—Syer's Mitre Block: perspective view. Fig. 2.—Plan of Tenon Saw, handled for Use with Mitre Block. Fig. 3.—Side Elevation of Saw. Fig. 4.—End Elevation of Saw.

saw blade is pierced with holes along the side opposite to the toothed edge, and that it is thus attached by screws to a handle extending the whole length of the side. This handle, being hollowed out on either side, can be grasped at any place along its length at the convenience of the operator, or can be worked from the end, near which is placed a hole (shown in Fig. 3) for the reception of the thumb. By this form of handle mitres can be sawn with the utmost ease, the surface of the blocks acting as a guide for the saw, which passes over them without doing any injury to them, as the heads of the screws are countersunk in the saw blade. The value of the saw lies in the fact that the blade is parallel to the guides over which it moves, and therefore makes a clean and true cut. This could not be done to the same extent, or so conveniently, with the ordinary tenon saw, as the thickness of the back would tend to throw the plane of the blade at an angle with the surface of the blocks. The price of the mitre block without the saw is 31s., or with the saw, 35s. The saw is supplied separately for 4s. 6d.

As a matter of course, the drawings of the saw given above will prove highly suggestive to many workmen, both in professional and non-professional ranks, and doubtless there will be many who will handle an old tenon saw in the manner shown above, after despoiling it of handle and back. I shall be glad to hear from any workman who may attempt the operation and prove successful in it. I can assure him he will find the saw a very useful one.

The Editor.

I.—Letters from Correspondents.

Wood Mitre Cramp.—J. S. A. (*Edinburgh*) writes:—"With reference to G. R.'s reply to J. C. (*Blackburn*) in No. 38, page 605, of Work, I give the following as a very simple and useful form of wood mitre cramp. Get a piece of birch or any other hard wood 1 in. square, and any convenient length, mark off with a square four pieces ¾ in. each; then make four holes through the corner (Fig. 1), saw off the four pieces, and shape them, as in

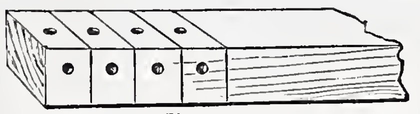

Fig. 1.

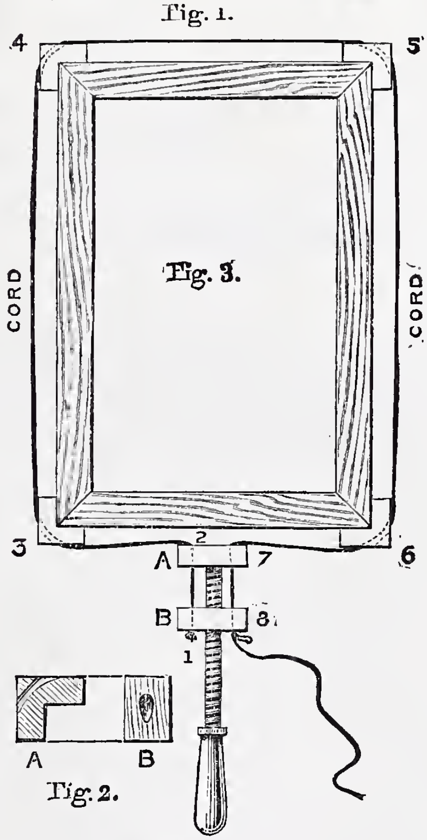

Fig. 3. Fig. 2.

Wood Mitre Cramp.

Fig. 2. Take a square piece out of the corner of each (A, Fig. 2), and shape the holes so that a cord will pass through easily (B, Fig. 2). Then you require a wooden screw, which you can get from any turner or joiner for a few pence, if you cannot make one for yourself. Fig. 3, I think, will explain itself. A is a piece of ½-in. birch 2 in. by 1½ in. In the centre there is a hole half-way through, into which the point of the screw fits, and on either side there is a hole for the cord to pass through. B is a piece of the same size which forms the nut of the screw, having two holes for the cord as in the other piece. Now get a piece of strong cord (not too thick), put a knot on one end, and pass it through the holes, beginning at 1 and finishing at 8. Glue your mitres, and lay the frame in position on a table; place one of the little blocks on each corner, keeping the screw at the side next you; then draw the cord tight, and put a running knot at 8, Fig. 3; then screw up, being careful to notice that your mitres are all fitting in properly. The frame must now be left in the cramp until the glue is dried, when it can be taken down and nailed with case."

Mail Cart Wheels.—J. J. K. (*Ireland*) writes:—"I am making a mail cart according to one of the designs in No. 30 of Work, and when I had the body made I got a pair of wheels from the Victor Cycle Co., Grimsby (as advertised in your Sale and Exchange column), for 7s., and I must say they are the best value I have ever seen, and send you the particulars for the benefit of my fellow-readers, who might be making mail carts. They are as follows: 23½ in. in diameter, rubber tires, axle, brass caps, washers, pins, etc. They set off my cart to perfection."

A Correction.—F. A. M. thanks Brum (*Keighley*) for the following:—Errata, Milnes Lathe, page 618, lines 21 and 23 from bottom, for "withdraw spring D" read "spring G"; for "arm D D" read "arm B B."

Useful Scroll Saw.—Artist in Wood writes:—"One of your correspondents says the useful scroll saw will not work; it is not likely it will work if a watch spring saw is the thing that is wanted. It is for cutting board, not thin fretwood."

Combination Bedroom Suite.—J. S. writes in reference to F. C.'s remarks (p. 684):—"Before reading your letter I had replied to T. B. R., and perhaps by this time you will have read my letter, wherein I state my objections to a drawer for basin, etc. Although 'two heads are' said to be 'better than one,' it depends upon whether they work together, or follow one another. Personally, I could not tolerate a partner, and I am afraid, if I had one, that one head would be worse—by a few punches—than the other; but I read such letters as yours in the spirit in which they are doubtless written—friendly. Concerning the suggestion of giving a summary of the total amount of wood required, very few writers do this, as space must be taken up, and any one with a small amount of arithmetical ability could manage it himself, as sizes of every part are always given. It would be almost useless to mention the cost, as Work pokes its ever-welcome nose into districts so far and wide apart that prices are bound to be different in some of them. You will have seen that I said it would cost nearly as much to make one of the robes as to purchase a complete bedroom suite. The bottom side drawer front can be either 'mocked' or panelled. Why should the latter prevent dovetailing? The framing would have the same solidity as a whole board. Front drawers certainly do show bevels, and I intended in my written article to say that if made so, a small piece of wood would have to be fastened to the front of job on to which to hinge towel-rail. Certainly the risk is always at hand of the glass door falling downwards, but just as certainly is the risk always at hand of the whole article tumbling together, if not properly and strongly made. I have remarked in an article the Editor has in hand that it is difficult to understand sometimes how designers and inventors obtain their ideas. It will perhaps surprise you to know that the main features of the article under consideration 'came to me' at about three o'clock one summer's morning, after a fruitless endeavour to court and wed sleep. This is not always the case, but I should advise no one to start on this plan. About the thicknesses it would, no doubt, have been better had I stated some parts as being thicker than others, but it was not on account of ignorance. Some time ago I sold a design (the Editor has seen a copy of it) to a manufacturer, who made several of them. It was a differently constructed affair to the present one, and was 5 ft. 6 in. wide, although answering the same purposes. I have seen one or two that he has made, and it struck me, when I 'got up' this one for Work, that thinner stuff would answer the purpose for it. However, the idea doesn't seem to be relished. In a seaside hotel, in a gentleman's office, in the green room of a theatre, etc., the slight inconvenience of not being able to wash the hands often would be counterbalanced by the convenience of washing the whole head once or twice per day, without having extra furniture for the purpose. To avoid the effect of wet, why not paint the inside of the panel (as I said paint the outside of article) in an enamel which would stand either hot or cold water? The trouble of wiping the panel must not be considered. If you leave the panel open all day, and your clothes thus exposed to dust, etc., you will be able to wash your hands oftener; if you close the panel you cannot be accommodated with washstand, but your clothes will be free from dust. In conclusion, I must thank you for your letter, and ask you to criticise any other articles of mine if you see any faults."

II.—Questions Answered by Editor and Staff.

Book on Organ Building.—E. B. (*Longton*).—"Organ Building for Amateurs," published by Ward, Lock & Co., Salisbury Square, Fleet Street, E.C., price 3s. 6d., will give you all the information you require.—M. W.

Lathe.—J. E. (*Liverpool*).—Much has already appeared in Work upon working the lathe, and from time to time further papers will appear. Any specific question on how to use the lathe will be answered in this column if you will put such.—Ed.

Protection by Patent.—A. E. S. (*London, E.C.*)—The Patent Office protections cover Great Britain and Ireland and the Isle of Man. The Government stamp upon an application for a Provisional Protection is £1. Great care should be exercised in preparing specifications, which must be written in duplicate upon the properly authorised forms, and accompanied by the stamped application form. If you merely protect a shape or design, it is probable that you may require protection under the Designs Act, and not under the Patent Act. Should you obtain Provisional Protection under the Patent Act, it stands good for nine months from the date of the application, when the complete patent must be applied for, which will remain in force for fourteen years. The protection for a design is only given for a period of five years.—R. & C.

Bronzing Fishing Tackle. — BRONZING (*Leeds*).—I am sorry you have been kept waiting, but your letter inquiring about the bronzing of fishing tackle, etc., must have miscarried. The subject has, however, been brought forward in these columns in answer to other correspondents. Chloride of antimony applied to perfectly clean and polished brasswork will produce a charming violet steel colour, which I consider most suitable for fishing reels, rod mountings, etc., but whether the makers of such articles, or the connoisseurs among the fishing community, would approve, is another matter. Try it, however, before you decide. The brass should be turned up quite bright in the lathe, or "dipped" in the usual way, then heated moderately, and the chloride of antimony liquor applied with a rag until the work is evenly coloured, when it should be polished with a perfectly dry soft cloth and lacquered with clear—*i.e.*, colourless—lacquer. —OPIFEX.

Wheel Gearing.—G. R. (*Durham*).—The data you give are altogether insufficient. To design the wheels it is necessary to know the amount of force to be transmitted in order to determine the sizes of the wheel teeth, and of the driving chains and other parts. The ratios of the diameters of wheels to get the desired increase of speed will be as under:—Assuming the wheel, of which the circumference is to run at 40 miles an hour, to be 6 feet in diameter, it will make 200 revolutions a minute nearly. There must be a pinion on the shaft geared to a wheel 5 times its diameter on the next shaft, which must carry a pinion geared to a wheel 4 times its diameter, carrying a pinion 2½ times its diameter fixed on the shaft, which is to revolve 4 times a minute. If you let me know the class of machinery, if the size of the first or last wheel is settled, and the power to be transmitted, I can give you definite information from which you can work. Four revolutions a minute is remarkably slow for any kind of machine, except, perhaps, a water wheel.—F. C.

Magnetising Steel.—FLAX SPINNER (*Longton*). —In your former letter, sent me in July last, you asked for information respecting the means to be employed in developing the greatest power in an electro-magnet. From your letter just to hand, I gather that you wanted something different altogether. Why, then, make a mystery of your real wants, and enjoin me to secrecy? There is no secret about magnetising horseshoe magnets, or remagnetising them when they have lost their magnetism. You won't get a patent for the process. Make a pair of hollow bobbins, with holes in them to fit the legs of the magnet. To develop the greatest power in the magnet, wind on these enough No. 20 cotton-covered wire to make the whole three times the diameter of the hollow core. Wind one bobbin from right to left, and the other in the contrary direction. Connect the two together when on the legs of the magnet, and send through them the strongest current at your command. The current from your 10 Walker cells in series will develop considerable power in the small steel magnets. See also replies to C. E. B. E. (*Ebbw Vale*), V. R. (*Liverpool*), and ANXIOUS (*Liverpool*). I do not forget to answer the letters of correspondents. Every letter received has my prompt and careful consideration, but my replies cannot get into print as soon as you expect them.—G. E. B.

Magnetic Exploder.—A. C.—I do not know the conditions necessary to effect the explosion of benzine vapour by means of a magnetic exploder, so cannot tell you how to make the instrument. I hope to give an illustrated description of a small magnetic dynamo in a future number of WORK, and this may possibly suit your purpose, as it will make a wire white hot, and give sparks. I cannot give you any idea here in a few words how to make the machine, so must ask you to wait until I can explain it in detail.—G. E. B.

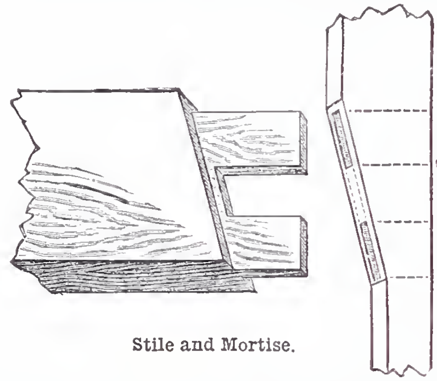
Shocking Coil.—J. B. P. (*Irthlingborough*).—Have you not heard that "everything comes to those who wait?" The coils will come by-and-by, and I hope the coil-makers are not tired of waiting. I have not forgotten them, nor my promise to them, but I wish to deal with the subject thoroughly when I set about it, so must first clear the bench of other jobs lying about on it waiting to be done. Dyer's book on "Coils" is a good, cheap book on the subject, costing only a shilling.—G. E. B.

Cleaning Engravings.—W. C. (*Somers Town*). —Put the soiled engravings in a bath of pure soft water—a flat porcelain tray or dish is the best receptacle; when thoroughly saturated, remove the pure water from the bath and add a bath of chloride of lime, which should be prepared by straining a strong solution of chloride of lime through muslin; watch the bath carefully, as the whole secret lies in *when to stop* the action of the lime: a few minutes will usually suffice, then rinse thoroughly in pure water, dry or strain.—F. B.

Repoussé Work.—J. L. R. (*Guernsey*).—All the necessary tools and materials for repoussé work may be obtained from Mr. Gawthorp, 16, Long Acre, London, and a useful little book of hints (6d.) for amateurs.—G.

Plating German Silver. — STRIPPER (*Soho*).—If your bath plates brass and copper well, and in a condition suitable for burnishing, but fails to deposit an adherent coat of silver or German silver, it shows either that you have not enough free cyanide in your solution to properly plate German silver, or you do not get each piece well coated before the other metals are put in the bath. Plate the German silver articles by themselves, and put in a small piece of cyanide just before immersing the articles in the bath. Also bring the anode a little closer to the articles at first, so as to get them quickly struck with a thin coat; then move it a little farther off whilst finishing. See to it also that the surfaces of the articles are slightly roughed in the acid pickle before being quicked in the nitrate of mercury solution, and transferred to the plating bath without loss of time, as German silver soon oxidises after it has been pickled, and the slight film of oxide would be enough to cause the deposit to strip under the burnisher.—G. E. B.

Door for Greenhouse.—W. H. (*Battersea*).—The framing of the door is made narrower at the upper part, to take away the heavy appearance which it would present if the stiles were kept the same thickness all the way up. The door stiles are first set out and mortised, then the upper part is cut down to the required width, stopping at the top of the belt rail, then bevelling off to the bottom of the belt rail. You will be unable to plane right up into the corner of the angle, and must use a chisel to finish off that part, taking particular care to keep the edge of the bevel quite square, as if it is unevenly done you will never get your joint to fit



Stile and Mortise.

closely. The ends of the belt rail are shouldered on the bevel to fit the stile. The accompanying sketch should give you an idea how to manage the work, the bevel of stile and mortise being shown, also the mode of cutting the double tenon, which you will notice is rebated at the under edge to allow for the grooving of the lower part of the framing to admit the panels. The upper edge has no rebate. The dotted lines on the stile show the position of the mortises. As you have succeeded so far with the building of the house, I hope you will not stick at the making of the door, but if you find any further difficulty I will be glad to help you out of it if I can.—G. LE B.

Porous Cell for Battery.—A. N. (*Waltham Cross*).—If you cannot get these cells in your neighbourhood, they can be sent by parcels post by Mr. Dale. See his advertisement in WORK, and write to him.—G. E. B.

Browning Gun Barrel.—W. B. (*Kent*).—For two recipes for browning a gun barrel I refer you to replies which have already been given in WORK: but, in case you might prefer a more elaborate process than that recommended to Paddy Brown, you can try the following, which is from the U. S. Ordnance Manual, as quoted in the *Scientific American* of September 21st. "Spirits of wine, 1½ oz.; tincture of iron, 1½ oz.; corrosive sublimate, 1½ oz.; sweet spirits of nitre, 1½ oz.; blue vitriol, 1 oz.; nitric acid, ¾ oz. Mix, and dissolve in one quart of warm water, and keep in a glass jar. Clean the barrel well with caustic soda water to remove grease or oil. Then clean the surface of all stains or marks with emery paper or cloth, so as to produce an even bright surface for the acid to work upon, and one without finger marks. Stop the bore and vent with wooden plugs. Then apply the mixture with a sponge or rag, and expose to the air for twenty-four hours, when the loose rust should be rubbed off with a steel scratch brush. Use the mixture and the scratch brush twice and more, if necessary, and finally wash in boiling water; dry quickly, and wipe with linseed oil, or varnish with shellac.—OPIFEX.

Coin Duplicates. — E. H. (*Plumstead*).—With reference to the first query in your letter, as to a publication which gives directions for making duplicates of medals, etc., I am sorry I cannot inform you, and hope that if any of our readers know of such a book they will let us know in these columns. I daresay that the method which I suggest is roundabout and clumsy, but I have found it answer very well, and so, hoping it may help you, give it for what it is worth. Half fill a shallow box or dish—I use a half-plate developing dish—with best plaster of Paris, in thick paste. Brush your medal over on one side with some of this paste. To guard against air-bubbles, lay the medal upon the surface of the plaster, press firmly and evenly until the medal is embedded, and the upper surface is flush with the surface of the plaster; see that the plaster touches the edge all round, and that it is not too thin and watery. Repeat these operations for as many medals as the bed will accommodate, leaving an inch at least clear round each. All this must be done as quickly as possible, as the plaster sets very rapidly; and it is better to make the experiment at first with one or two of the largest specimens. Now lay aside until the plaster is thoroughly set, and place in a moderately hot oven or before a hot fire to dry. When dry, with a sharp knife cut several angular grooves near the edge, say one on each of the sides; let these grooves be clean cut and V-shaped, and placed in such a way that they may not interfere with the medals, etc. Now dust very finely powdered blacklead over the face of the bed, and polish with a very soft brush, or rub lightly with the finger. Now mix sufficient plaster paste to fill the dish, etc.; paint over the medals as before, and pour in the plaster as quickly as possible; allow to dry thoroughly as before, and turn out carefully. The two portions of which the mould is composed may now be easily separated by gently prising at the line of juncture, when, if all has gone well, the medals, etc., may be removed—this very cautiously, so as not to crumble the edges —and we should have a perfect mould, the upper portion of which may be placed in exact position, being guided by the key grooves. The next step is to cut grooves from the edge of the medal to the edge of the mould—two for each medal, which are cut side by side, one to pour the metal through and the other as an air escape. Of course, half of each groove will be cut on each portion of the mould, and the groove for the metal should taper from the side of the mould to the edge of the medal, while the air vent need not be so tapered. Remove all particles of dust very carefully with a large camel-hair brush from the surfaces of the mould; place them together, and clamp them together. Place the mould in a hot oven, and get your metal ready. I use lead, tin, and bismuth, equal parts. Melt and well mix, and pour out into a bar; again melt, and it is ready for use. When the mould is hot—as hot as an ordinary oven will make it—hold it on edge, and very carefully pour in your metal; let stand in same position until cold. Open mould carefully, and the rest will suggest itself.—OPIFEX.

Sign-Writing. — TYRO (*Queensboro'*).—This is somewhat a pure matter of opinion, and you are quite as much right as you are wrong. It would perhaps have been better if you had added the letter "s" and made it read "Brightmans, Coal Merchants," when there could have been no doubt about the surname being in the plural number. At the same time, if a name is used to designate a firm of traders, such as in your own case, the very fact of you writing "coal merchants" conveys to the reader that there is more than one person connected with the firm, and consequently the whole is in the plural number. But, as I say, there are many to differ from me on this point, as with yourself. There are many well-known examples which you may point to in support of your contention, such as "Goy, Limited" (the word "limited" conveying the same information here as the word "merchants" in your case), or "Eastmans, American Butchers," a company which has a shop in almost every large town in the kingdom.—H. L. B.

Photographic Slides for the Magic Lantern. —JOHN BULL asks the following questions:—"How to make photographic slides for the magic lantern, and can they be made out of the plates?" Now, Mr. Editor, I do not want to develop into a growler in my old age, but will you allow me to say just a word in protest against such vague questions? It is a common fault with persons to ask questions in such a way that one is at a perfect loss to know what is wanted. I believe that the art of asking questions is one that few understand. Their want is palpable enough to themselves, but either they have not the power or are unwilling to take the trouble to place the idea—the word picture—before the mind of another. Now, I am not writing this in an unfriendly spirit, or through captiousness, but that our mates in the "Shop" may be induced to state their wants clearly, as it will save much time on the part of those who desire to help them, and very often much space in WORK—which is even of greater value. Now to refer to the question, I must presume a great deal: first, that J. B. can take a negative, etc. To take a transparency, make a wood tube, 5 ft. long and 3¼ square inside measurement. Half an inch from one end glue four very small angle pieces in the corners, so as to form a ledge for the negative to rest on, with the picture side towards the end. Now lay a wet plate on this, but separated from it by $\frac{1}{16}$ of an inch, with the prepared surface towards the negative; fasten this in its place by any mechanical means that may suggest itself. Seeing that the end is light-proof, bring it into the light, and tilt the tube towards a north light if possible. Length of exposure must be determined by experiment—say five seconds; develop in the usual way. If I have not guessed the right answer, please ask again, and state distinctly, and I will try to give the needed information. As to the second question, "Whether they can be made out of the plates," I must treat it as a conundrum, and give it up.—O. B.

Electric Breast Pin.—QUOCUNQUE JECERIS STABIT.—An electric breast pin is made up of a very small incandescent electric lamp set in an ornamental metal setting, much as a stone would be set in a scarf pin or brooch. The tiny globe of glass, the size of a large pea, is very fragile, and can only be fixed by a skilled workman trained to do such things. Connection is made with the two tiny terminal wires of the lamp, at the back of the brooch, with a small flexible two-wire cord, leading to a small battery kept in the breast pocket of the coat. The lamp itself will, probably, cost you 5s., and you can get the pins for 7s. 6d., so it would be scarcely worth your while to attempt making one yourself, for you would run the risk of breaking one or two lamps in the attempt. Respecting the battery, see replies to ASCA (*Newcastle*), VENUS (*Norwich*), and H. E. (*Leicester*). Small accumulator cells are sold for the purpose at £1 each.—G. E. B.

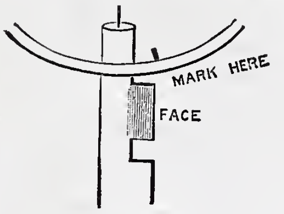
Telephone Magnets.—D. A. C. (*Aberdeen*).—I am very much pleased to find that my article on the telephone has been appreciated, and that it seems to have raised an interest in this subject among the readers of WORK. The magnets which you inquire about, and suitable for your purpose, can be had from Messrs. King, Mendham & Co., manufacturing electricians, Western Electrical Works, Bristol. The size is 5 in. by ⅜ in. (the form is round), and tho price is 10d. each; if fitted with adjusting screw 4d. each extra. I am sure you would be able to purchase such magnets in Aberdeen. If you cannot get them the exact size and make, take the nearest thereto, and make the other parts to suit. Why not make them yourself?—W. D.

Fret Saw and Lathe.—MENDICUS (*Newcastle-on-Tyne*).—As a rule combination tools and appliances are not so satisfactory as those which are simple, and I do not think you will find fret saws and lathes any exception. The combinations, however, are by no means useless, for very fair work can be done with them. The principal objection I have against them is that the lathe is of small size and power. The Goodell and Companion lathes are the best in this respect, but the sawing arrangement is not of the best. If you want a really good fret-sawing machine there is nothing to equal the Britannia Co's. No. 8. This, however, has no lathe attachment in the ordinary way, though the manufacturers will supply one when desired, and from the unusually heavy flywheel of the No. 8 you will be able to manage any turned work which could reasonably be expected from a small lathe. I should, however, strongly recommend you to have lathe and fret saw as separate articles, for though at somewhat extra cost you will secure far greater efficiency. The same company's *multum in parvo* lathe is a really practical one at a small price. Let me say that you are not altogether correct in stating that the finest class of fretwork cannot be undertaken without the aid of a machine. As a matter of fact the finest work—viz., that in connection with inlays of veneers—is done with the hand frame. A good machine is quicker and more powerful than this, but that is all.—D. A.

Medical Coil.—W. B. C.—(1) A 3-in. coil should have a core 10 in. in length by ⅜ in. in diameter, and be wound with 2 layers of silk-covered No. 16 B.W.G. copper wire, weighing about ½ lb., as a primary. The secondary may be wholly of 4 lbs. No. 32 silk-covered copper wire, or made up in 3 powers, with 1 lb. No. 32, 1½ lb. No. 34, and 1½ lb. No. 36. (2) Chromic acid is preferable to bichromate of potash, because it does not deposit crystals in the pores of the battery plates. 3 oz. of chromic acid in a pint of water, acidulated with 3 oz. of sulphuric acid. (3) Dyer's book on "Coils" will give you a tolerably general idea of their construction, but I cannot recommend a book treating specially on medical coils. This part of the subject will, however, come up for treatment in the next volume of WORK, when we deal with induction coils.—G. E. B.

Switch for Electric Time Alarum.—ONE IN NEED (*Coventry*).—I must refer you back to the illustrations, Fig. 13 and Fig. 14, on page 497. Cut out a round piece of hard wood, 4 or 5 in. in diameter, and hollow it on one side, as shown in Fig. 14. Smooth and polish the other side. This will form the base of the switch. Now make an arm of spring brass, 2 in. in length by ½ in. in width, and a thickness of about ⅛ in. Drill a hole in one end to receive the pin in which it is to be pivoted. Drill a similar hole at the other end, and rivet to that end of the arm a button of bone, hard wood, or of brass. The pivot on which the arm moves should be in the form of a small brass bolt, with a nut to tighten it on the underside of the base. Pass this through the arm, then through a small brass collar to raise it from the base, then through the base in the centre. Next cut out two thin and narrow strips of brass to the shape shown on Fig. 13, and turn up a tiny piece of each to form stops; drill holes in each to receive small brass screws, and fasten these to the board. One of these strips is connected by a small bolt, or brass screw, to one end of the line wire, as shown at Fig. 14, and this is marked ON in Fig. 13; the other strip is merely a rest for the arm when we wish to switch the bell off. The other end of the line wire is secured to the nut of the pivot bolt, as shown at Fig. 14. The arm forms the connecting link or bridge between one wire and the other, and by moving it to the right the bridge is broken and the bell switched off. The switch may be put in any part of the circuit between the bell and the clock, or between the clock and the battery, wherever convenient to you. You have only to cut the wire at the spot where you wish to fix the switch, and connect the bared and cleaned ends to the two parts of the switch—one to the arm pivot and the other to the screw of the brass stop. You may make the base square if you like, and may fix all the wires to the face of the base instead of the back; but this does not look neat, otherwise it will work equally well. Respecting the lattice arm, the pillar (Fig. 7) is screwed into its foot (Fig. 8), and the lattice arm is pivoted to the top of the pillar. As these parts are therefore in metal contact with each other, you have only to fix one of the wires to the base of the pillar by means of one of its screws.—G. E. B.

Watch Repairing.—AN AMATEUR.—Thanks for appreciating "Watch and Clock Cleaning," and your patience in waiting. To loosen cylinder, have a piece of iron—smooth—with a hole in it that will just take cylinder; now have small hammer ready and very small punch—say a stout needle, point just off, if nothing better; warm by holding over gas jet with your tweezers, then pop it into hole and tap it out all round. In refitting new cylinder, have correct depths for pivots, and be sure height of escape part is right so as scape wheel will clear it. Before taking out you should make a mark upon balance rim, for the face of cylinder scape part, as in the accompanying illustration. So in replacing you will have no trouble about the three holes you set it in beat, or the next who may clean; you understand what I mean. When cylinder is ready to fix, and a neat fit, and all is set right to receive brass collet for height, etc., place it on, and heat it over small gas flame and touch it with shellac; it will be secure enough if hot enough to penetrate, but not too hot to alter tempering. Names of all parts are with each article. Repair prices I would not like to be printed; I should upset a hornet's nest.



Balance Rim, etc.

Enlargements.—A. S. (*Sheffield*).—With the enlarging camera described in No. 13 of WORK, you can enlarge up to 12¼ in. by 10¼ in. To make pictures from ½-plate negatives to the size you want—viz., 24 in. by 19 in.—you will have to increase the size of the back and front of the camera to suit, and increase the length of the baseboard to 6 ft.; the sliding boxes that carry the lens must also be lengthened—say, about 3 in. more than the size given. The lens used in taking the negative will be the most suitable for use in the camera, and in making such large pictures you must use a small stop to preserve the sharpness of the image. Use a focussing glass, as it is difficult to tell by the eyes alone when the image on the ground glass is quite sharp; and if you cement a small circular piece of thin glass (such as is used for covering microscopical slides) to the centre of the ground glass screen with Canada balsam, you will be able to get accurate definition by focussing on it. Use pine in preference to red deal, it is much easier worked. All the details of the camera remain the same as described in No. 13, and the manner of construction will be exactly similar, with the exception of the increase in the sizes of the parts I have mentioned. I am sure you will find much pleasure in the use of the apparatus, as you will be able to produce by its aid very fine wall pictures, that is, of course, supposing that you have suitable negatives.—G. LE B.

Polishing Boxwood.—E. C. (*London, N.*).—I must repeat once more that unless inquirers will state clearly and fully what course they have adopted whenever results of polish are not satisfactory, it is quite impossible to do more than surmise what is wrong. Numerous causes might be named as the reason of your failure to get a good surface, and very likely none of them might be the correct one. Describe your process, and then I shall very likely be able to tell you how to improve. In the meantime I can only suggest that you have used your rubber too wet. If this is not so, I cannot assist you at present, owing to the very limited data to go upon. To spirit off use a clean rubber moistened with spirits instead of polish, but if you have not got a good body on it is hardly worth your wasting time in spiriting. Glaze certainly gives a common-looking finish, especially on a badly-prepared surface, but so would spirit.—D. A.

Polishing Baywood.—SALFORD LAD.—I do not know of any wood called Spanish baywood, but I am inclined to think you have misnamed it, and mean simply Honduras-mahogany or baywood. This is commonly used in your trade, the choicer Spanish mahogany being more employed where appearance has to be studied, as in furniture. If you will refer to No. 31 of WORK you will find the particulars you want are given in the middle column of page 493.—D. A.

Turkish Bath Making.—R. S. H. (*Dover*).—There is no occasion for anything elaborate. You can make a really serviceable portable Turkish bath without a mortise, tenon, or dovetail in its construction, nor are framed panels at all essential. All you have to do is to use nails instead. You probably know how an ordinary packing case would be made. Well, look upon your portable bath as a packing case, and with the knowledge you already have I hardly think you will require any directions beyond these few hints.—D. A.

Staining to Walnut.—W. G. (*Dalston*).—Having enamelled your washstand I am afraid you will not find it at all an easy matter to make a good job of it by doing as you propose—viz., staining it walnut colour. I certainly would not advise you to try this, as the result will probably not be satisfactory. If you want it walnut colour I should recommend you to paint (enamel) it. If, however, you wish to stain you must first remove the present coating. This you can do by scraping on any parts which can be got at by the scraper, and washing with strong soda and water. Why will the plane not take? After having removed the paint in whatever way may be most convenient, you must apply the stain in the usual manner, but it is more than likely that the stain will not be even. I have now told you what may be done with the best chance of success, but I cannot advise you to undertake the work. If you can give the date of former letter possibly it may be traced, but as it has not been answered, it is not at all likely it ever came to hand. You will easily understand it is hardly possible to look through the correspondence for a few months back without having an idea of date and subject.—D. A.

Upholstery in Morocco.—CAB HAMMER (*Cork*).—Whoever recommended you to use vinegar to enable you to put morocco leather on arms of couches and round frame furniture, without showing any wrinkles or creases, has either been "taking a rise out of you," or did not know anything about the matter. The backs of particularly obstinate skins are occasionally moistened slightly with water in order to make them yield, but this practice should not be adopted by any but a thoroughly skilled worker, who would hardly do it if he could effect his purpose by other means. Only skill can enable one to do as you desire, and it is utterly impossible to give instructions which can meet every case. I may, however, just indicate that judicious cutting of the skins, placing the tacks very close together, and manipulative neatness are important factors. If you have any special piece of work you are in difficulty about, and will let us know full particulars of shapes and sizes, I shall be happy to give you any assistance that may be possible. This will be of more assistance to you than pages of general directions.—D. A.

Zincography.—J. W. S. (*Sheffield*) inquires how to produce a zincotype. To enter into all the necessary details of manipulation and instructions for overcoming the difficulties likely to arise, would exceed even the ordinary length of our articles. Briefly, however, tbo process is as follows:—The subject should be drawn upon litho-transfer paper, or pulled from an engraved plate and put to stone, rolled up, washed out, brought up with a roller and again washed out, after cleaning and etching, and a transfer pulled. Then, upon a perfectly clean polished zinc plate, cut to size of job in a copperplate press, put down the transfer, and roll it up with a litho roller, and etch as if for printing from zinc. Then feed the job with an acid-resisting varnish, put the plate into a trough upon rockers, and bite it with weak nitric acid and hydrochloric acid mixed; the lines will be left in relief slightly; rinse well in pure water; dry upon a hot plate. Roll up when cool, but not cold, with a flannel roller, with a mixture of Brunswick black varnish, or other acid-resisting substance; paint sides of any lines which seem undercut by the acid. When dry again, place in the rocking trough—which must be kept moving, so that the acid washes away all oxide—using acid rather stronger, repeating the operation, drying, rolling up, etching, and rocking, until the plate is deep enough. In those parts where the lines are close together, at each drying care should be taken to paint them out as soon as they are deep enough, or the acid will eat underneath them and break them away. Then with terebine or turpentine wash off the varnish, cut out entirely all large white spaces with a fret saw, and mount upon a mahogany mount to type-height with small screws, countersunk at the edges of the zinc. There is a very useful treatise by Josef Bock, published at 2s. 6d., which fully explains the processes and gives the best formulæ. It may be had from the publishers of Wyman's Technical Series, 65, Chancery Lane, E.C., or by order of any bookseller.—J. W. H.

Mounting of Drawings.—T. A. W. (*Kilburn*).—For the proper mounting and straining of drawings, maps, engravings, etc., two things are absolutely essential—(1) good paste, and (2) cleanliness in handling; it is also advisable to practise your hand upon some small unimportant work before attacking anything large and serious. In preparing your paste, which must be free from lumps and about as thick as new milk, add a lump of alum as big as a walnut, then stir to boiling, but be careful not to allow it to burn; then squeeze through canvas. A plain wooden frame for straining is now necessary, or, if the drawing is to be framed afterwards, a permanent wooden strainer; in either case the wood should be about 2 in. wide. Obtain some plain, unbleached calico, about 4 in. longer and wider than your strainer, damp the calico with a sponge, then paste 1 in. all round, and, after laying the strainer, or frame, face down on calico, turn the pasted edges over frame; let this dry. Afterwards moisten with sponge and clean water the paper you intend to mount, sponging evenly all over, so that it is quite *damp* but *not soaking wet;* then paste about $\frac{3}{4}$ in. all round the border, take your frame with strained calico upon it, and lay it face downwards on the paper to be mounted, which it will take up; then with your hands, or a clean linen cloth, carefully press the pasted border all round, and leave to dry *slowly;* then you will find it strained as tight as a drum head, and you can either frame it in the ornamental frame you intend for it, or, after making a drawing on the strained paper, with a penknife cut it all round and release it from the strainer. Should this not be sufficiently clear, I shall be pleased to answer any further questions you may submit.—F. B.

Lathe Tackle.—J. R. (*Richmond*).—Glad to hear you have got so far. You should add the taper-screw to your set of chucks, which you can make by fixing a common joiner's screw into the centre of a small face-plate, putting it in so that it cannot turn round when the wood is screwed upon it. To turn wood you require two chisels and two gouges, say a 1-in. chisel and a $\frac{1}{2}$-in. one; a $\frac{1}{2}$-in. gouge and a $\frac{1}{4}$-in. one will do to begin with. *Don't* have a grindstone to run in the lathe; you would have to take out your work every time you want to use it, and it would splash with dirty water all your lathe and tools. I cannot recommend anything cheaper than a 20-in. stone in a wood trough, with treadle; this costs 20s. A less stone than this has not enough momentum to do without a fly-wheel.—F. A. M.

Glass Embossing and Lettering.—LETTERING (*Farnworth*).—For outlining on glass use black japan or Brunswick black. An imitation frosted ground surface is secured by coating glass with a thin layer of white paint and working a dry brush upon the surface. Black japan and deep vermilion also make good backgrounds, but, of course, a "figured gold" groundwork is the most chaste of all in appearance. Epsom salts in solution, when applied to glass, give it a natural frosted appearance when dry, but this dodge is not of a very permanent character.—H. L. B.

Book on the Lathe.—A. C. (*Oldham*).—The Britannia Company's book is to be obtained from Britannia Company, Colchester. Cash can be remitted by stamps, or postal orders, or cheque, or coin in registered letter.

Repairing Broken Pivot.—B. P. (*Birmingham*).—I am pleased to see you and others appreciate my humble efforts; all descriptions in print so far have been too scientific for amateurs: of course they do not intend to convey information to the masses. Take your pinion with the pivot broken, and in a small size gas flame, soften it, file off level, and proceed to drill in the centre; but you cannot have a centring tool, so do the best you can. In drilling, if you move ever so few turns as much around your work as possible, this will keep you in the centre, and when you are sufficiently deep enough dress up a piece of steel softened about same as pinion. When it fits tight to the drilled hole, temper it; now hard solder it. I see you know how: but the next difficulty is to turn the pivot. I see you have one. Now dress up pivot, and get correct depth; this you must be very particular about. Polish the pivot well, and I think your difficulty will vanish. But is it not much cheaper, if you call your time of any value, to have a new pinion put in? In either your first or second mentioned job, it will only cost you 2s. at Barton's, Church Street, Liverpool; or Reid's. Basnett Street, Liverpool; or Morris Cohen's, Kirkgate, Leeds, all watch tool, etc., shops. Don't act green, but as if you were in the trade. Case-harden by making a fire of leather scraps, which are most exceedingly hot, and place your steel bar with wire affixed in centre until thoroughly heated, then plunge in coldest water you can get. I think you will not have any trouble in bending after that.—J. S.

Regilding Frame.—W. L. B. (*Hucknall*).—No; vellum size will not answer your purpose; we find bronze turn colour under any circumstances; it will retain its colour the longest, however, if you get the best bronze powder, and mix well with your varnish, and apply with camel-hair brush, as gold paint. Frame makers gild in the ordinary way with a Dutch metal leaf, and then varnish; this will keep for years. The cheap German frames sold are all gilded with this leaf; some, however, are gilded with silver; the best quality ones and coloured lacquer retain their colour. I have some which I have had in my house twelve years, and they are still very good.—G. R.

Index to WORK Volume.—D. A. B. P (*Hammersmith*).—You and every reader of WORK will have an opportunity of possessing an index, as one will be published after the issue of No. 52.—F. J. C.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Brush Making.—T. S. (*Wellington, Salop*) asks:—"How brushmakers make the one end of Mexican fibre to represent the flag on bristle; whether it is a dye, and what it is composed of?"

Re-waxing Meerschaum.—TOBACCONIST writes:—"Will any reader of WORK explain the process of cleaning and re-waxing meerschaum pipes, as done for the trade?"

Cutting Music for American Organette.—AMATEUR MUSICIAN writes:—"I beg leave to ask (through 'Shop') of your musical correspondents for instructions how to drop in chords when cutting the notes of a tune, such as marches, waltzes, songs, etc., on the paper for an American organette. I can cut the notes, and their octaves (or unisons), but there is not melody enough without occasional 3rds, 4ths, 6ths, etc., and where to drop them in I am not able to decide. Is there a fixed rule for doing so, and if so would some kind reader be generous enough to say what it is, as I am sure many of the readers of WORK would be glad to know how to add chords in the key of C for their organette. I have a list of these chords now before me, but cannot use them in their proper places, and I care not to purchase sheets of music for the instrument when I can make them, minus the chords. I have made the instrument myself from the patented one, and, in fact, improved it, and if I could complete the dropping in of the chords it would be a real good job. But as it is patented, I must keep silent on that point."

Springs for Artificial Legs.—R. F. (*Landore*) writes:—"Will any reader kindly inform me through 'Shop' where I can obtain springs for artificial legs and steels for trusses?"

A Simple Incubator.—NEMO (*Ospizio, Malta*) writes:—"In WORK for December (see page 654) I find described a simple incubator in reply to B. F. (*Liverpool*) (see page 302). May I ask how long the incubation takes place?"

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Fairy Bells—R. F. writes in reply to SUBSCRIBER (*Bristol*) (see page 654):—"Bottom and sides are of $\frac{5}{8}$-in. pine. Wrest-pin blocks are of beech $1\frac{1}{4}$ in. wide by $\frac{3}{4}$ in. deep. Lower block, the front edge of which acts as bridge, is $1\frac{3}{4}$ in. wide, and shaped as shown in diagram. Under this and outside the bottom is hitch-pin block $\frac{3}{4}$ in. by 1 in.

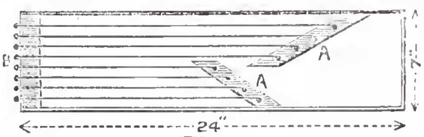


Fig. 1.

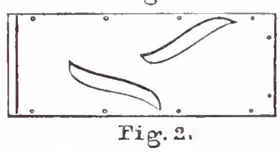

Fig. 2.

Fig. 3.

Fairy Bells.

Cover, which is made to take off, is of $\frac{1}{2}$-in. cedar or mahogany. Wrest pins are ordinary piano pins, and hitch pins are round-headed $\frac{3}{4}$-in. screws. The first four strings are of No. 11 steel wire, next two 12, last two 13. Strings must be wound round pins so as to quite clear blocks. The cover may be made to slide in and out, and is preferable this way."

A Steel Flux.—J. H. D. (*Luton*) writes in answer to G. H. S. (*Manchester*) (see page 670):—"You will find the following a good flux for welding steel: 1 part sal-ammoniac, to 10 parts borax, pounded together, and fused over the fire in an old tin until clear, when it is poured out and allowed to cool, afterwards reduced to powder, and used in the same way as any other flux would be used."

Pill Making.—CHEMICUS (*Tynemouth*) writes:—"In answer to J. C. (*Carlisle*) (see page 494) for the addresses of makers of machines: Kneading machines, Werner and Pfleiderer, 88, Upper Ground Street, Blackfriars Bridge. For piping, cutting, and finishing machinery, Mr. J. W. Pindar, 75, New Church Road, Camberwell."

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—AN OLD SOLDIER; W. W. (*London, S.E.*); STANNUM; H. S. (*Tunbridge Wells*); J. R. (*Dundee*); W. W. (*Newcastle-on-Tyne*); H. C. (*Newcastle-on Tyne*); G. K.; S. R. (*Withington*); W. R. (*Fife*); W. L. D. (*London, S.W.*); BRITANNIA CO.; SKIBOO; W. C. (*Manchester*); A. J. E. (*Worthing*); M. A. T. (*Cambridge*); F. H. F. (*Kensington*); W. S. C. (*North Shields*); W. J. (*Swansea*); B. S. B. (*Warwick*); A FREEMASON; R. G. R. (*Blair Athole*); J. H. T. (*Manchester*); S. C. R. (*Derby*); E. H. (*Clerkenwell, E.C.*); J. S. S. B. (*Dublin*); W. S. A. (*Aberdeen*); F. H. (*Streatham Hill*); C. W. (*Andrie*); A WOULD-BE INVENTOR; F. A. Trade Notes and Memoranda.

THE following particulars, which have been supplied by Mr. Leader Williams, as to the mechanical appliances at present employed in the construction of the Manchester Ship Canal, will be of interest. There are no less than 96 steam navvies, including 3 German, 4 French, and 58 Ruston & Proctor's navvies. There are 166 locomotives and 5,874 wagons, whilst 213 miles of temporary railway have been laid down. There are 162 steam cranes, 127 portable and other engines, 186 steam pumps, and 40 pile engines, on various sections of the works.

PETROLEUM motors are being simplified and improved to such an extent that they may now be ranked amongst the useful small motors. In one manufactured by Messrs. Altman & Company, of Berlin, ordinary common lamp petroleum is used with great success, and a number of these little engines, varying from one to four horse-power, have been running for over a year in different parts of Germany and Russia, whilst in Belgium a company for their construction has been formed, and the works, situated in Brussels, are in full swing. Insurance regulations constitute one of the formidable obstacles to the introduction of this class of motor in England.

THE supply of electrical accidents in the United States is being recorded. The latest report is about a damp horse smelling a damp lamp-post, and is not so impossible as usual. In the interests of electrical progress in Great Britain, it would be well to allow a technical man to see these telegrams before they are published, for no one knows how much damage may be done to a cause by the spreading broadcast of a number of reports apparently prejudicial to its interests.—*Industries.*

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

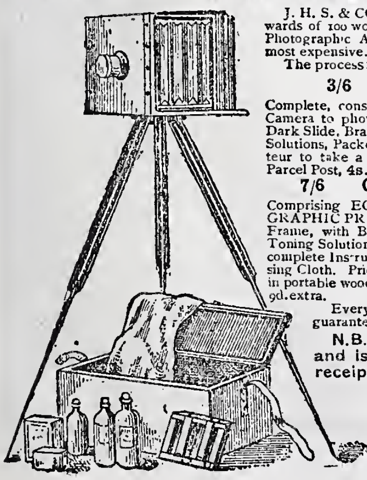
J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.

MANUFACTURERS AND IMPORTERS OF **PHOTOGRAPHIC APPARATUS AND FRETWORK MATERIALS.**



J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.

The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price 3s. 6d., or securely packed by Parcel Post, 4s.

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price 7s. 6d. Securely packed, post free, 8s. 6d. If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.

Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

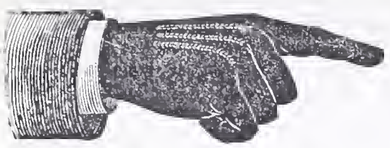
Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

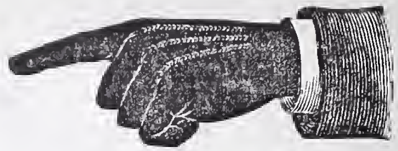
JUST PUBLISHED, NEW CATALOGUE of Machines, Saws, Designs, Wood, &c., 56 pages, 600 Illustrations, with Instructions, 4d., post free. Good Fret Saws, 1s. 4d. per gross; best ditto, 1s. 9d. per gross.

Eclipse Design, No. 102.

Wall Bracket. Price 5d.



NOTICE!!



WE are *bonâ-fide* Makers of 300 Varieties of Lathes and other Engineers' TOOLS, many of which were designed for the British Government. Six Varieties of Fret Saws. Numerous Prize Medals. Our new Fret Machine, No. 8, cuts metals or ¾-in. wood: it is having a capital sale. Send 6d. for Catalogue; 2d. for List of Second-hand Tools. New and valuable Book on Turning, 3s., post free. Cash or Hire Purchase. You are invited to call and inspect a Large Stock of above at

BRITANNIA CO., 100, Houndsditch, London.

ALL LETTERS TO BRITANNIA WORKS, COLCHESTER (ENGLAND).

SIZE 44 X 12 INS.

DISEASE EXTERMINATED from the System, and every form of Nervous, Muscular, or Organic **WEAKNESS** speedily overcome, without Poisonous Drugs or Quack Medicines.

Invalids should know that there is positively no Nerve Tonic and Health Restorative agent on earth so valuable and harmless as Nature's own remedy, "ELECTRICITY."

MR. C. B. HARNESS,
President of the British Association of Medical Electricians,

Confidently recommends all Sufferers from RHEUMATIC and NERVOUS AFFECTIONS, LIVER and KIDNEY DISEASES, LADIES' AILMENTS, or any form of Local or General Debility, to wear his Patent

ELECTROPATHIC BELT.

Thousands of Testimonials.

WRITE FOR COPIES.

HARNESS' ELECTROPATHIC BELTS

Sole Proprietors: The Medical Battery Co., Ltd., 52, Oxford Street, London, W.

ALL who wish to be **Healthy** and **Strong** permanently should wear one of these comfortable Appliances.

They are guaranteed to produce a mild, soothing, invigorating, imperceptible current of Electricity which speedily vitalises every Nerve, Muscle, and Organ of the Body.

They Prevent and Cure all NERVOUS AFFECTIONS, and are invaluable in cases of RHEUMATISM.

Sufferers should call without delay, and inspect the *Thousands of Testimonials* received from all classes of society.

CONSULTATION FREE *of Charge, personally or by letter, on all matters relating to Health and the application of Curative Electricity, Massage, and Swedish Mechanical Exercises. If you cannot call, write for Descriptive Pamphlet and Private Advice Form.*

Note Address—THE MEDICAL BATTERY CO., Ltd.,

52, OXFORD ST., LONDON, W.

(Corner of Rathbone Place).

All Communications treated as STRICTLY PRIVATE & CONFIDENTIAL.

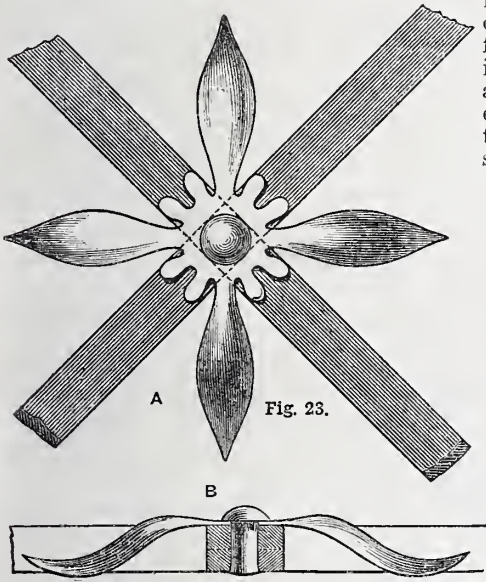
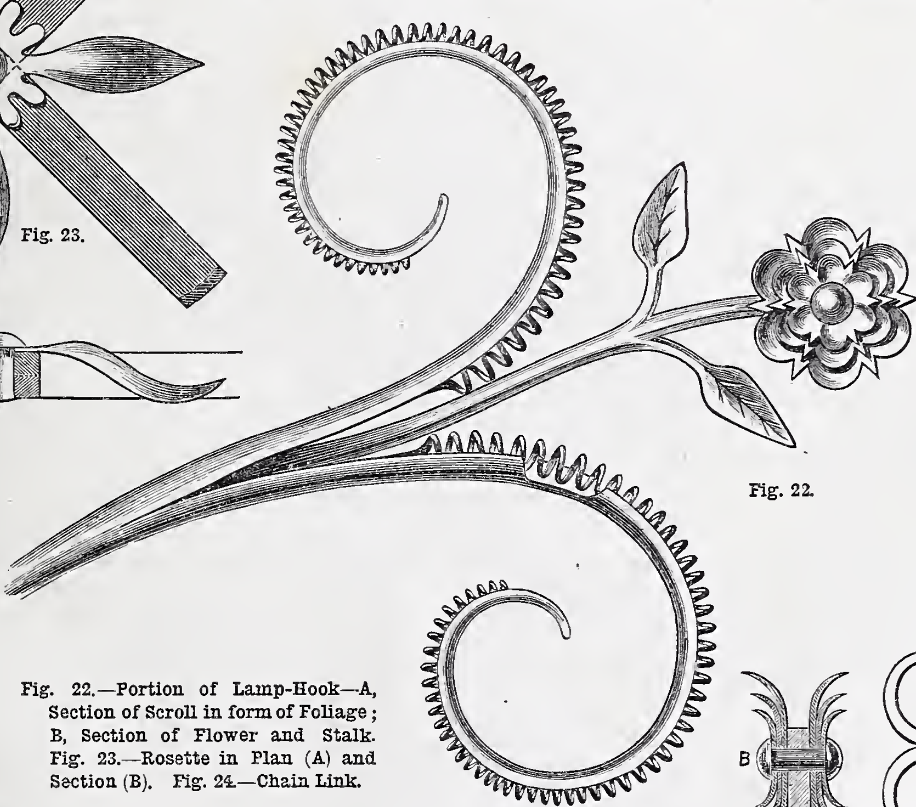
SMITHS' WORK.

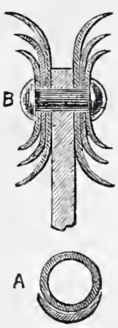
BY J. H.

ORNAMENTAL WORK OF THE MIDDLE AGES.

THERE is a large quantity of ornamental work remaining from the wreck of the Middle Ages which cannot properly be classified, but which is characterised by much redundancy of detail. Locks and keys, ecclesiastical furniture, and articles of domestic use, abound. The briefest possible notice of some of these must conclude this preliminary section on mediæval work.







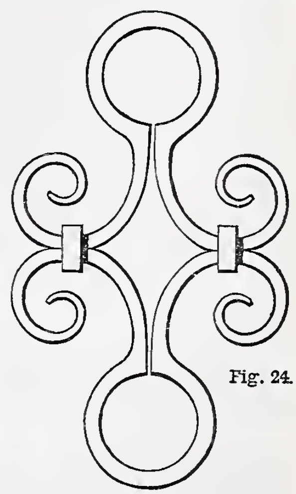


Fig. 22.—Portion of Lamp-Hook—A, Section of Scroll in form of Foliage; B, Section of Flower and Stalk. Fig. 23.—Rosette in Plan (A) and Section (B). Fig. 24.—Chain Link.

Some of the locks and keys which survive are worth careful study. The latter are for the most part filed out of the solid. Some specimens of the old French smiths, preserved in the Hôtel de Cluny, Paris, must have cost an almost incredible amount of labour. There are a good many figured in an old and very scarce book of a French smith, Mathurin Jousse, and several chapters are therein devoted to their description.

A method commonly adopted in the construction of some articles where cheapness was sought after without the sacrifice of beauty was this :—An open-work pattern was marked on sheet iron and punched out, and the edges filed square. This was laid upon another sheet, and foliations or other ornaments were marked through the interstices of No. 1 upon sheet No. 2. When No. 2 was cut out, this was laid, perhaps, upon another sheet, No. 3, which was then also marked, the operation being repeated if necessary upon several sheets in succession. These, being all perforated, were laid in relative superposition and riveted together. Sometimes beads, rosettes, or other ornaments were attached to the face. Many examples of such work occur in door-handles, locks, and escutcheons, and I may remind the reader that very pretty effects have also been produced by the twisting of bars, both of round and square section, to form door-handles and knockers.

Many of these thin-plated articles would scarcely come within the range of smiths' work. There is little difficulty in their execution, being for the most part cut or stamped without any bending ; yet there is in many cases a good deal of raised work combined therewith, semi-human and grotesque figures as well as foliage being beaten up with punch and hammer into full and perfect relief. And there is, besides, much engraved work which requires time. Nowhere, perhaps, does the contrast between mediæval and modern work appear in stronger contrast than in the relative amount of detail put into them. The quantity of work turned out in a given time, so vital a factor in our modern competitive production, scarcely appears to have affected the craftsmen of the Middle Ages. The ideal of work was of a loftier character then than it is now, and Brummagem wares are as far removed from those of Limoges and Nuremberg as the quantity turned out in the first exceeds that produced in the latter. The wares of the one fulfil the purpose of the hour, those of the other endure for centuries.

There is a coffer or deed-chest at the South Kensington Museum which is a curious example of German work. It is dated 1716. The coffer is made of iron, and is almost covered with elaborate repoussé and open scroll or foliated ornament. It is stiffened with straps, also highly ornamented, is provided with stout handles, and stands on handsome curved legs. But the most curious portion of the deed-chest is its lock, which is placed in the centre of the top of the cover. There are a large number of stout knobs studded over the cover which might be supposed to be for purposes simply of ornamentation. But there is just one knob near the lock, to the left hand, which must be turned and unscrewed in its hole before the keyhole can be exposed. Also another knob in front of the lock has to be pulled backwards to release a spring which presses against the cover of the lock. When these two operations are performed, then the cover of the lock can be lifted and turned aside, exposing the keyhole in the bottom of its little box. It is an ingenious and interesting specimen of an early burglar-proof safe.

A somewhat unique piece of work is shown in Fig. 22. It is a portion of a lamp-hook of seventeenth-century German make. This floral ornament consists of lanceolate leaves with tendrils laying in and partly enclosed by the leaves. From the axils of the leaves the flower-stem comes out, the flower containing three whorls, and it is double, back to back (B). But the noteworthy point is the beautiful manner in which the tendrils are twisted. It appears to me as though the tendrils and leaves were swaged from a divided rod, though they may certainly also have been welded at the axil. But there is no union of the two all along the course of the leaves; one simply lies within the other (A). More than this, the convolutions diminish in diameter, and the diameter of the rod also diminishes.

Rosettes are frequently employed for the purpose of covering over unsightly joints. These are generally punched from a single piece of plate and united with a central rivet terminating in a knob in front. Fig. 23 is from an Italian trellis centre of the seventeenth century, and shows a flower concealing the union formed by the crossing of $\frac{3}{8}$-in. square rods which form the panel.

There is an implement in the South Kensington Museum of French make and sixteenth-century date, used at the ceremony of cutting a first sod. It is called a pickaxe. But it is a double-ended implement. One end is shaped like a pickaxe, the other like an adze. The blade is pierced with holes and incised with two shields, one representing a similiar instrument, and the other charged with a fleur-de-lis. On the sides of the socket for the handle are masks.

A specimen of a chain link of Venetian make of the seventeenth century is shown in Fig. 24. Each link is made of two pieces curved and united with belts. There is a hook at top, then five successive links like the figure, then a large expansion of a different pattern, afterwards six more links and another expansion terminated with a bottom hook. This was probably used for the purpose of suspending a lamp.

It does not matter how commonplace were the uses of utensils, they were nevertheless wrought into beautiful forms, and decorated profusely with ornament. Stands for braziers are treated thus; hammers, carpenters' braces, pincers, nutcrackers, corkscrews, laundress's flat-irons, andirons, and many other articles commonly reputed base and vulgar, are made beautifully artistic.

Much of the art work of the Middle Ages is lost to us, having been destroyed by change, cupidity, revolution, and various political events. It may be safely averred that in the most favoured lands more has been destroyed than preserved. France has especially suffered, thousands of monuments which have been described and figured having been swept utterly away.

We cannot properly comprehend how much is involved in the mediæval smith's work, except by a broad study of the whole artistic craft of the Middle Ages. Abundant examples occur of men who were workers in gold, silver, and iron—canons of cathedrals ("artist canons," as they are termed)—men who wrought for the love of Mother Church, and remained poor at the same time that they enriched her churches and shrines with works of marvellous beauty. The smith's work was only a single branch of that art which was offered as a tribute to faith. Months and even years of loving labour were often bestowed upon a single article, and the names of very many of the artist craftsmen survive after the lapse of ages and revolutions. Need we wonder that the baser metal, iron, was wrought into such wondrous forms when we know how the same artists had wrought or cast still more delicate forms in the precious metals, or had been intimately associated with those who had fashioned the candelabra, lecterns, chalices, monstrances, reliquaries, and so forth, employed in the service of the great Church?

It is said that the church of St. Sophia at Constantinople possessed at one time no less than 6,000 gold candlesticks, two of which weighed 100 lbs. each; twenty-four copies of the Evangelists with golden covers, each weighing two quintals; and seven massive gold crosses of one quintal each.

Eloi in France, 588—659, was, like Dunstan in England, first a goldsmith, then courtier, minister, bishop, and saint. He founded two establishments for the education of artist canons, a class of men common in the cathedral establishments about the tenth century. It is related that Geoffrey de Champallement, Bishop of Auxerre, instituted three prebends in his cathedral for artist canons. One of these was to be a goldsmith, the others a painter and a stained-glass worker. Many of the monastic orders made it their boast to encourage the liberal arts. The cathedral and monastery were thus nursing mothers to the arts in a turbulent age. St. Dunstan, 925—988, who was monk, goldsmith, blacksmith, and royal minister, is an illustration of the union of craftsmanship with learning.

"Up to the middle of the sixteenth century," says Wyatt, "the artist and the workman had been one and the same, and alike honoured, hence much of the rare old excellence. After that period the artist became a patrician who designed, the workman a plebeian who executed. Hence at once arose an estrangement, which gradually widened until the artist made all his designs after some vague general model of a *beau ideal*, and the workman, having only his assistance on rare occasions, dropped into a jog-trot habit of collecting stock commonplaces, which at last degenerated into a system of mannerism and copying, taking the place of design altogether, and raising up a formidable barrier to all modern progress in the industrial arts."

A treatise on iron work, the first of its kind, was published in 1627 by one Mathurin Jousse. It treated of tools, of which he enumerates thirty varieties, and of processes in detail. He gives a description of locks, some of which he says took two years to make; the making of padlocks and of keys, the union of iron by melted brass, and of silver and brass (silver solder), the making of bellows, screws for vices, files, the tempering of steel, and much besides. There are sixty-nine chapters in all. Some of the woodcuts in this work are extremely quaint.

The ornamental section of smiths' work might well appropriate a much larger share of attention than I have been able to give to it; but forming as it does only a portion of a series having a much wider range, I now leave it to enter on at some future time the treatment of the modern practice of smiths' work. This will deal with practical work in the forge with hammer, anvil, and gauge, and with boiler making.

PLAIN AND DECORATIVE HOUSE PAINTING.

BY A LONDON DECORATOR.

House-Painters' Brushes, Knives, etc.

Throughout a varied and extensive knowledge of the house-painting trade, its employers and operatives, the writer has been much impressed by one fact in connection therewith—namely, the very limited amount of knowledge possessed by the average individual, whether master or man, as to the nature, right construction, and desired qualities of their brushes.

Without engaging ourselves with a lengthy disputation upon the political economy of the trade, a few moments' consideration will show the great disadvantage attending this lack of knowledge, as well as the cause of it also.

In no other branch of trade is it usual for the employer to supply the artisan with tools, and no custom, I believe, has been more harmful to the independence and self-respect of operative house painters as a body than this "handing over" and "receiving back" the tools with which a worker earns his daily bread every time he obtains a fresh job. Good brushes are as indispensable to the house painter as are reliable and well-tempered tools to the joiner or cabinet maker. Where, then, comes in the wisdom of such an arrangement, which, if adopted by a master worker in wood, without doubt would be considered both absurd and impracticable?

Such, however, is the case. The master-painter, or his *clerk*, or *manager*, and sometimes, but not *very* often, his practical foreman—since the latter would probably purchase good brushes, which are, naturally, *not* the cheapest—select the articles with which a season's work will be executed; and, in nine cases out of ten, they will be the *cheapest* of the "A 1," "Superfine," "Extra strong," or some such similar lying appellation the vendor or traveller pleases to term them. I do not assert this as being characteristic of the trade anywhere and everywhere; but such, undoubtedly, is the case in the provinces and small towns, where the *spreading* of paint is the most important factor of the trade's existence.

The immediate purpose of this paper, however, is not to consider the circumstance and customs attending the purchase and use of house-painters' brushes, but to describe the particular kinds with which the painter has to work, and to further afford herein some measure of advice as to price and quality for the guidance of purchasers.

The *best bristles* used in making painters' brushes are imported from Russia. The hairs of the hog and wild boar are noted for their strength and size, growing from two and three to some nine inches long. St. Petersburg, Kamschatka, and the "wilds of Siberia" contribute a large proportion of the immense quantity used for brush making annually. The quadrupeds "shed," or rub off, a goodly number of their bristles during the summer time, and these, when collected into a sufficiently large bundle, are sent by the peasantry from all parts of the country to such trade centres as those above mentioned. France and Belgium also contribute a small proportion of bristles to the market, and Germany not only sends us the hair, but a great quantity of the cheap and "rubbishy" brushes I have alluded to.

The *value* of *hogs' bristles* naturally depends upon their suitability for brush making—their length, strength, elasticity, and also colour. Not only is it so with house painters, but also with all descriptions of brushes, *white* bristles are commonly preferred; probably under the impression that adulteration therewith is less prevalent than with grey or black-haired brushes. Bristles are quoted on the market at "per cwt.," and the vast difference which may be found in the price and quality of two ordinary-looking paint brushes may be gathered from the fact that the price of genuine bristles ranges from about £10 to nearly £50 per cwt.

With the growing demands and requirements of the painting and decorative trades, the supply of the best and most serviceable bristles and brushes scarcely keeps pace; hence the industrious German trader finds a splendid market here for the showy-looking goods with which the trade is now inundated.

The *adulteration* of brushes is carried on to a vast extent, and principally by the aid of American fibre and horsehair. So well are these articles manipulated and mixed with the bristles that a thoroughly practised and practical person alone can discover them. Of the two, the horsehair is most difficult to detect by examination, since the difference between that and poor bristles is but one of a little elasticity. When there is, however, any quantity of fibre mixed with the hair the loss of "spring" in the brush is very noticeable. The appearance of the fibre is also more open to question; it is neither so smooth and finished-looking as hair; whilst the difference in burning of a vegetable fibre, which will leave a grey ash, and the peculiar smell attending the burning of hair or bristle, quickly decides for us its nature. This, however, is no test between bristle and horsehair —experience alone can decide the latter.

The *principal brush-making firms* of London, and those whom any reader of WORK (employer, operative, or amateur) can apply to with the certainty of getting genuine brushes of superior quality—providing he pays a fair market price for them—are Messrs. G. B. Kent & Co., of Great Marlborough Street, London, W. (whose goods I place before any makers for excellence); Messrs. Crowden and Garrod, of the Borough, Southwark; and Messrs. Hamilton & Co., of Greek Street, Soho, London.

In arranging the accompanying illustration of this subject, my aim has been chiefly to impress by its assistance the peculiarities of each class or make of brush upon the memory of the reader, and this without any consideration of the exact size or scale. Figs. 1 to 10 include most of the descriptions of brushes in ordinary use for painting and varnishing, and all these the earnest worker should be familiar with. The first figure will convey a fair idea of the appearance of a "good honest paint brush" in the form it is purchased in. The bristles are about 6 in. long from the binding to the point, and each brush requires tying up with string some two or three inches higher before it is used for painting with. As the brush wears down the string binding is untied, until eventually the extra "bridle" is entirely dispensed with. Fig. 2 is a similar article, but, as its name implies, made in an oval shape; and upon these lines the brush is worked. Fig. 3 represents a make of brush much used in the provinces, and in which shape quantities of cheap brushes are made. All three above mentioned are usually sold in four qualities of bristle, "Lily," "Yellow Middle," "Grey," and "Black," of which the first and whitest is the best and most expensive. The prices of each for the full size article would be about 5s. and 4s. 6d. for the first two qualities, and about 4s. for the last two, respectively. Although good hair makes a good brush in all of them, the first I believe to be the best in the hands of a thorough tradesman; and this shape is mostly used at the West End decorators' shops.

Fig. 4 shows an English paint *tool*, a small, round-handle brush, the shape of which is never altered; the small sizes are called "sash tools"—that is, for painting the small bars of a window-sash. They all require tying up shorter for using in oil paint, and the price of a good medium size tool is from 1s. to 1s. 6d. The German paint tool (Fig. 5), both for wear and quality, compares very unfavourably with the former; and although they can be bought so low as 50 per cent. less than a good English tool, they are dear at that to any worker who buys a brush to use and keep, and not to spoil. Fig. 6 represents a tool of recent date, purposely made for sash-cutting, at prices from 1s. to 1s. 6d. each; it is an assistance to quick and clean sash-painting on factory premises, etc., where there are great numbers of window-panes, but for ordinary work the string-tied sash tool will suffice. Figs. 7 and 8 are usually termed "fitches," consisting of short bristles bound in tin, with long red handles. They cost from 2d. to 2s. each, according to size, and are much used for all kinds of decorating and gilding; and nearly all workers in paint, "artistic and otherwise," find them indispensable. Fig. 9 is a somewhat similar brush, useful to gilders, scene painters, etc., as well as decorators.

Painters' Varnish Brushes are usually old and well-tried tools that have been "worn-in" with painting, and these cannot be improved upon for professional use if properly cleaned and looked after. Figs. 10, 11, and 12, represent brushes specially made for varnishing; the first, shown edgewise, it will be noticed is ground down to the shape of a partly-worn paint brush, and costs from 2s. to 4s. Fig. 11 is a shape one occasionally sees used by the operative house painter; why this shape was purchased for *his* work I suppose nobody—not even the employer who purchased it—could say; certainly not by reason of its suitability. This and Fig. 12 can only be used to advantage on the finest work, and on broad, flat surfaces; and, as before said, nothing can touch a "good old paint brush and tool" for house-painters' varnishing purposes.

Dusting Brushes are such as no clean and good work can be done without. Fig. 13 shows the best shape of brush for this purpose, at prices from 4s. to 5s. each. Somewhat similar in shape to Fig. 1, it is yet rather larger, and the bristles are much longer and spreading, so that dust and dirt can be brushed out of any crevice and corner with ease. I have seen brushes like Fig. 3, made only for painting, repeatedly used for this purpose, and when by such unfair knocking and usage the hairs come out, the maker is often blamed without reason.

Figs. 14 and 15 are more decorators' than painters' brushes. The first is used for stencilling, and the latter for running lines with the aid of a bevelled edge straight-edge. The prices of these tools, like all brushes, depend upon the size, but a useful brush of either kind can be bought for 6d.

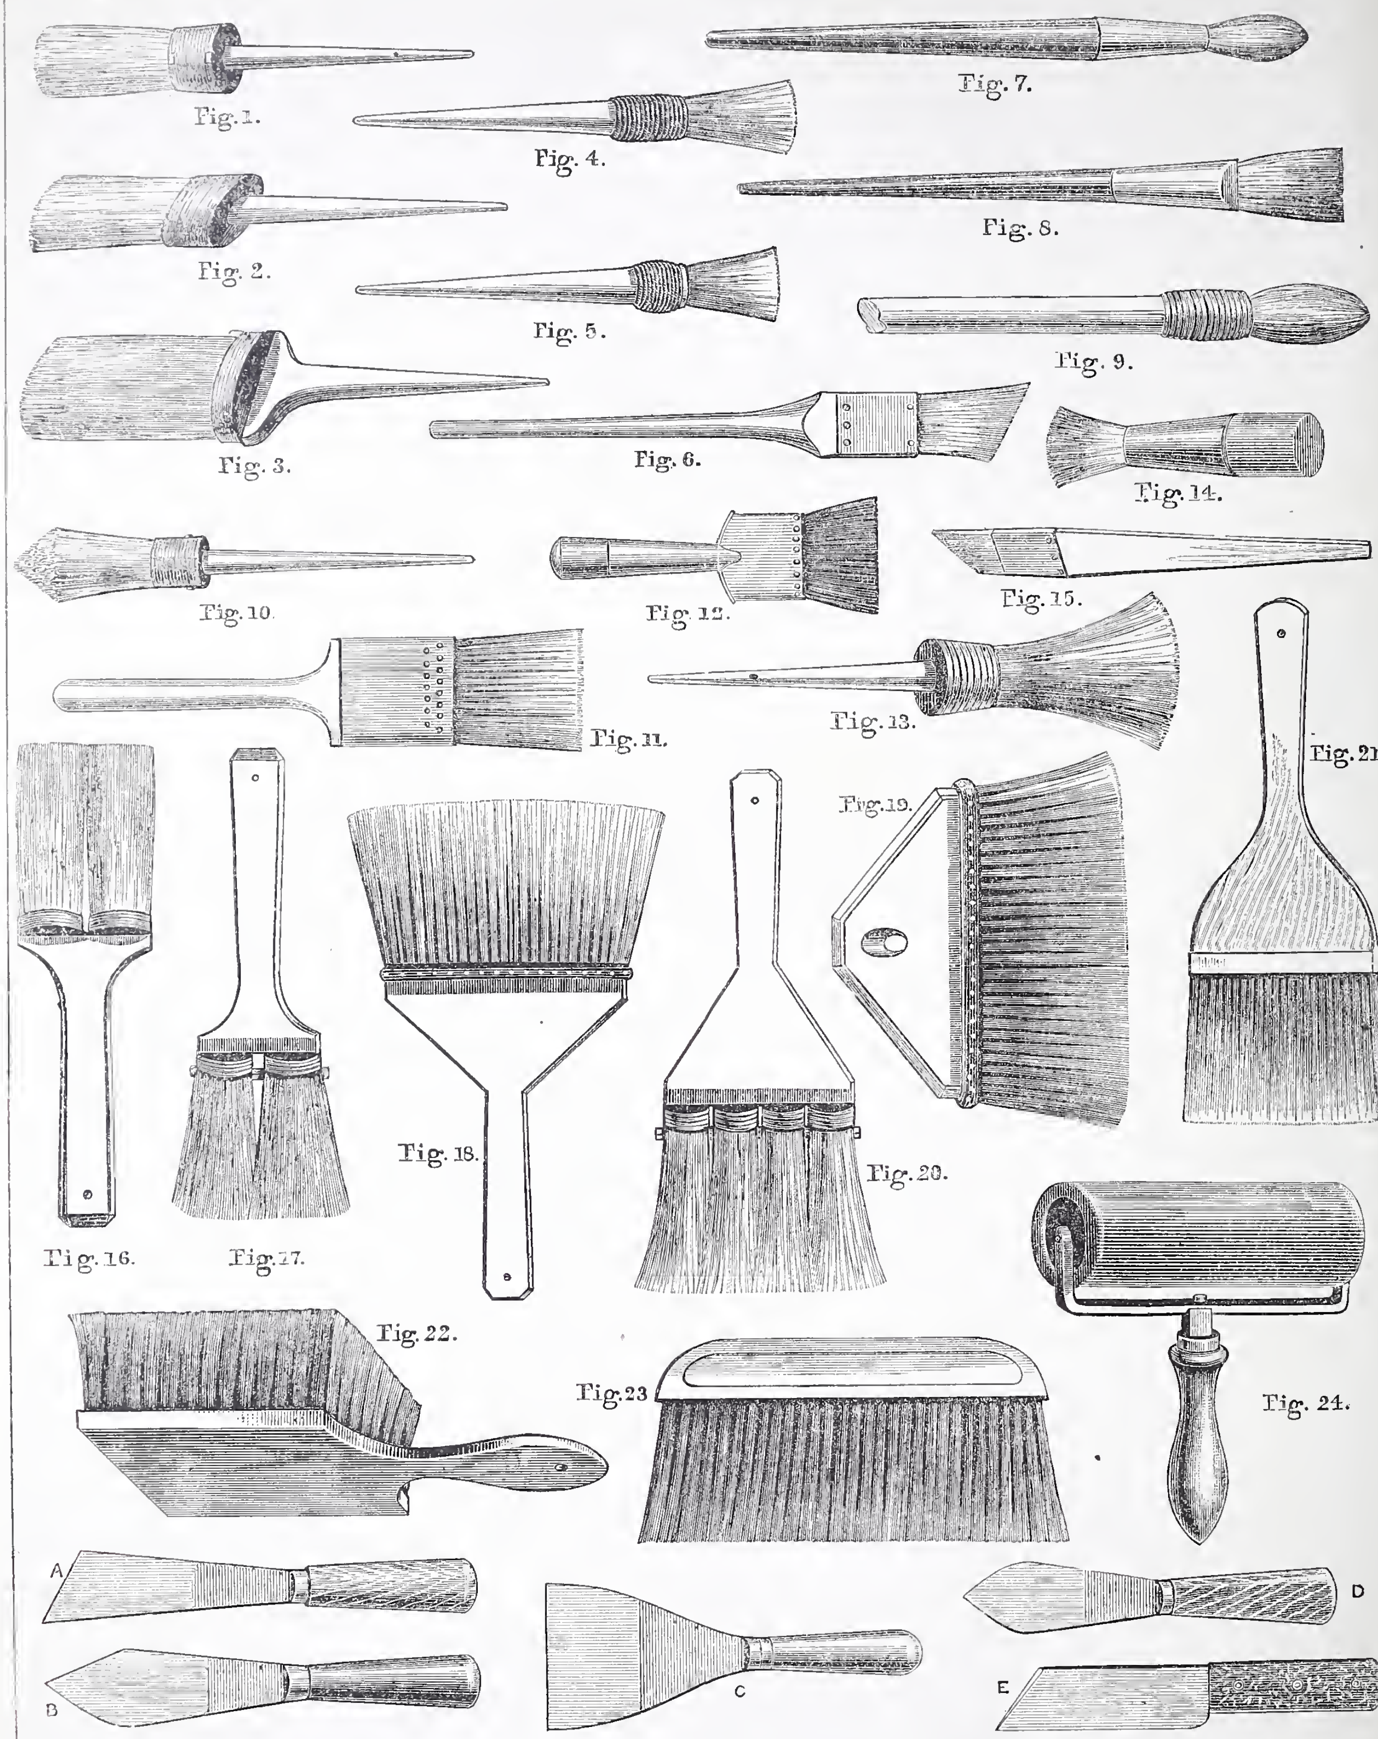
From 16 to 20 we have a variety of larger brushes specially made for distemper painting and preparation. Fig. 16 is the distemper brush for the best kind of work, and such as is used in London and the chief decorative centres. They are also known as "two-knot stock brushes." The best and finest are made with yellow and grey bristles, which are about 6 in. long, and cost from 6s. to 9s. each, according to size. They are without doubt the most suitable size and shape for spreading properly prepared "jellied" distemper. Fig. 17 represents a most useful brush, made of black hair and fibre, for washing off old distemper from ceilings and walls, the prices of which are from about 3s. to 4s. 6d. each. Fig. 18 shows the distemper brush very general in the west of England and other provincial parts, where it is commonly known as a "paddle" brush. Its broad, thin make tells plainly how little jellied distemper is understood and used in parts where the "paddle" is called for, since nothing but a wash can be spread with them. They are always made with grey or black hair, and cost from 4s. to 6s. each. Fig. 20 is a good shape and make for a practical man, but rather too heavy and clumsy for the best work; the price of this corresponds with the preceding brush. The four kinds just described are always made with handles, as shown; Fig. 19, however, corresponds closely with Fig. 18, but is made for affixing a long handle thereto.

In some parts of the country this "limer" is the principal ceiling brush used—I need scarcely add that in such quarters decorative art has not reached a very elevated position. A practised hand can get over a tremendous quantity of sizing and distemper washing with them, and they save erecting the scaffold also. They are, if of the best kind, as expensive as the "ground stock," Fig. 16. Fig. 21 represents a good pasting brush, and useful for distemper work also, costing about 4s. 6d. each.

Stipplers are the most costly of painters' brushes. Fig. 22 shows one with handle at end; they are also made with handles on the back and reversible handles. They are used for obliterating the brush markings, in "flatting" and other processes, by a beating action, executed evenly and carefully after the paint is applied and roughly distributed. They require careful attention to keep in order, and should, directly after use, be washed with plenty of soap and warm water, without wetting the "stock" or wood. When all the paint is removed, rinse in cold water, and accelerate the drying by beating on a dry cloth or wash-leather. The price of a stippler 8 in. × 6 in. is about 13s.; 9 in. × 7 in., 17s.; and a small size, 6 in. × 4 in., would cost 7s. or 8s.

Paperhangers', or *Papering, Brushes* are shown at Fig. 23; these are made for fixing new paper to walls, just as a cloth is used by the novice or amateur. The shape of the back is somewhat similar to a spoke-brush —long and thin, so that the hand can grasp it comfortably. Paperhangers use such a brush for the bulk of their work; but for "satin" goods and very delicate papers the roller (Fig. 24) is substituted for the brush, and with which the paper is rolled into close contact with the wall. When newly purchased it is usual to cover a roller neatly with a couple of thicknesses of flannel.

Of the *knives* most used by the house painter, I have shown five. A represents a *chisel knife*, or it may be termed a *stopping knife* with chisel point. B shows the most useful shape of *stopping knife*, with which holes and indentations of woodwork, etc., are filled with putty. C is the "chisel knife" proper, but as often termed the *broad knife*; this is used for stripping and scraping old walls, filling up woodwork, stopping plaster walls, etc., and is a very useful tool. D and



HOUSE-PAINTERS' BRUSHES AND KNIVES.

Fig. 1.—Ground Paint Brush. Fig. 2.—Oval Ditto. Fig. 3.—Copper Bound Ditto. Fig. 4.—Sash Tool (English). Fig. 5.—Ditto (German). Fig. 6.—Sash-Cutting Tool. Fig. 13.—Dusting Brush. Fig. 14.—Stencil Tool. Fig. 15.—Lining Fitch. Fig. 16.—Ground Distemper Brush. Fig. 17.—Washing-off Brush. Fig. 18.—Nailed Stock. Fig. 19.—Limer. Fig. 20.—Scotch Stock. Fig. 21.—Pasting Brush. Fig. 22.—Stippler. Fig. 23.—Paperhanger's Brush. Fig. 24.—Paperhanger's Roller.

E are more properly *glaziers' knives* than house painters'; the first is the *putty knife*, indispensable for glazing sashes, and the latter, the *hacking knife*, for hammering out the old hard putty previous to reglazing. All these, with the exception of C, cost from 9d. to 1s. each; the broad knife is worth from 2s. to 3s.

Brushes are by far the most important of the painters' tools, and I have given my chief attention to them in this paper. Space does not permit of my introducing herein a number of other articles used in the trade; but where possible they will be illustrated in each lesson as they are required for practical purposes described in such. The present article closes the first and elementary part of this subject. In Vol. II. the imitation of woods, marbles, etc., will be practically taken in hand, accompanied with illustrations of tools and processes—so far as such, in "black and white," can assist the student.

A CARVED BUREAU.

BY D. ADAMSON.

Drawers, Mouldings, etc., in Early English Style—Conclusion.

We have still to consider the stamping of the Early English character, if one may call it so, on the drawer fronts, etc. This will be managed by beads and mouldings, or by one without the other. Let us take beading first. As no doubt every one is aware, this effective and easy way of breaking a plain flat surface is managed with a scratch or router, the blade of which is simply worked backwards and forwards on the wood till the bead is formed. A simple form of this tool and its use having been recently the subject of an article in these pages, it will be unnecessary to dilate on it here.

Two rows of beadings will be enough for each drawer front, on which they are to be scratched horizontally, only right across, at a distance of about an inch from the top and bottom. A row composed of three plain beads, as shown in Fig. 24, will be very suitable, but there is no reason why the beading should be so uniform if any other pattern be preferred. For instance, any of those illustrated in the article above referred to will do equally well.

In addition to the drawer fronts, the bearers may be scratched in a similar manner, and not necessarily with the same beads. A bead on each edge rounding off the angle, and a hollow between, as in Fig 25, will look very well, and the same may be said of the "sunk moulding," shown by Fig. 26. In both these instances it will look better to set the front back, or within the bearers a little, as suggested in the illustrations.

It will also occur to the reader that the front edges of the ends may be finished off in a similar manner to the bearers. With the outer edges no difficulty can occur, but there may be some hesitation about the others, so it will be seen at once that the moulding or bead cannot be run through the joints of the ends and bearers. They might be worked through, but the effect would be very unpleasant, and I do not think the method would be approved of by any one accustomed to good cabinet making. The better plan, if these edges are to be moulded, will be either to stop the bead before it reaches the bearer, or work it up to a mitre with that on the drawer bearers. In either case, the bead or moulding will have to be finished off at the end with carving or other cutting tools, as the scratch will neither work a clean stop nor yet effect the mitre.

The front of the fall may also be treated with scratches on the framing, the beads terminating with the ends of the frame pieces, *i.e.*, they will not be run across cross grain, but be stopped at the joints. Of course if the framing is mitred, the beads will be formed also to a mitred angle, but, as has been said, a mitred framing is hardly in consonance with Early English. If the panel of the fall is sunk within the framing, it, too, may have two or three rows of beading scratched along it; and the same may be said even if it is flush, though I almost hesitate to recommend beading in this case. Beads may also be run from top to bottom on the ends of the bureau, though, for my own part, I should prefer them plain; but if they should be preferred, try to utilise them by concealing any join that may have been necessary. This can easily be managed by arranging the cutter so that the line of the joint is just between two beads. Three or four sets of beads at regular intervals between will be quite enough for each end.

Now for mouldings. The only parts of the work to which these can be applied successfully are to the edges of the drawer fronts, and round the inner edge of the fall framing. Many suitable patterns of mouldings may be found, from the simple one shown in Fig. 5 (page 738), to the more elaborate outline given in Figs. 27 and 28. It will not do to have the mouldings too large and heavy-looking, but as so much depends on personal ideas of excess in this direction, nothing definite can be said beyond that I consider the sizes shown in the last-named illustrations suitable. It must not, however, be taken that for all mouldings, whatever their outline, these sizes are best. It would, for instance, look clumsy were the moulding in Fig. 5 to be enlarged to it, and, of course, no one would think of using an architrave moulding for drawer fronts, such as those under consideration. With these remarks the size of mouldings may safely be left to the reader's discretion.

Whatever the pattern, they are to be neatly mitred at the angles and attached to the fronts of the drawers flush with their edges, making, as it were, a kind of projecting moulded frame on the surface of each front. Any beading that may be required on the fronts must be done before the mouldings are stuck on. Glue alone ought to hold them securely, but a few brads or wire nails, driven in where they will be least perceptible, may be used as well. The nails should be well sunk, and

the holes filled in with stopping. As these will only be small, probably a little shellac melted into them will do very well. Figs. 27 and 28 show that the drawer fronts are set back, so that the mouldings, when the drawers are closed, do not project beyond the bearers, but are rather within them.

If the fall panel be sunk, the same mouldings may be placed round it on the edges of the frame, the corners being mitred. With a flush panel the mouldings must be modified, so that they can be stuck on to hide the joint. A suitable moulding for the purpose is shown in Fig. 29. I must frankly say that I do not like this alternative, and it will be far better, if mouldings are to be employed, to have a sunk panel.

Possibly it may be wondered whether no carving is admissible. If so, it may be said that, as a rule, it is not found on ordinary Early English furniture, but at the same time there is no valid reasou why the bureau should not be adorned with it if the maker wishes. As regards the scope of consideration of Early English design, it is, however, unnecessary to do more than say that carving, when resorted to, is usually unimportant. It may, however, not be out of place to say that as the source whence the Early English of modern furniture sprung is clearly the Tudor and allied styles, that carving inspired by them can scarcely be considered out of character. Carving is uot necessary, but it may be added as perhaps the clearest way of expressing the matter, that I think the majority of us would be rather inclined to class a bureau nominally in the Early English style with such carving as oue generally sees as a "Queen Anne." This will be the next to be considered, but before doing so attention may be called to the rich effects which may be got by a judicious use of the beads and mouldings alone.

Something should also be said about the plinth. That in Fig. 1 (page 600) would be more appropriate, and would do very well with a plainly beaded bureau, but a suitable moulding along the edge, instead of a bevel, would be better still, especially if mouldings are used on other parts.

It is possible that some readers may object to stuck-on mouldings. Many of our leading writers on, and critics of, modern furniture do, and not without a certain show of reason sometimes. Their arguments are mostly based on theory, and were it my intention to show how furniture might be got up in the most costly manner, without considering whether it would practically be any better either in appearance or usefulness for the superfluous expenditure, nothing would have been said about mouldings, or, rather, the directions would have been for them to be worked out of the solid. As it is, my wish is to help novices to construct good every-day pieces of furniture without any unnecessary labour, and to take full advantage of methods of construction which practical experience shows to be satisfactory. Those, of course, who fancy any process of either decoration or construction which I have advocated is wrong may leave them alone, and substitute others if they prefer to. I do not profess to teach those who are satisfied that they know all about everything connected with woodwork, for most of them cannot learn much—not even that there may be more than one way of doing anything. If possible, the style known as Queen Anne is even more vague than the Early English when furniture is referred to. It is almost impossible to define any lines of demarkation between the two which shall convey, without an exhaustive treatise on them, a clear idea. In very distinctive designs, of course one can do so; but the two styles are so merged into each other that it is not easy to say positively of many details that they belong exclusively to one or other. Thus in the mouldings mentioned when treating of the Early English bureau, we have met the Queen Anne style half-way, for many would feel disposed to classify a piece of furniture on which they occur as Queen Anne. Nevertheless, we may get some characteristic bits which may very well entitle even a plain piece of furniture like our bureau to be called a specimen of the modern version of Queen Anne furniture.

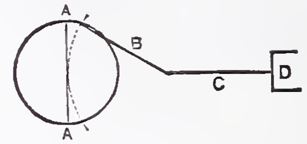
Let the mouldings be retained, even the beads if you will, but add a few carvings in the form of semi-conventionalised foliage, flowers, etc. I cannot commend the heavy swags of fruit and garlands of flowers which one often sees used, as they seem to be dangerously bordering on the strange devices which were in vogue immediately before the present Renaissance; there is, however, no reason why, in a modified form, such things should not be used. For instance, a little conventional drapery or a festoon may be carved on the drawer fronts, as suggested by the accompanying illustrations, Figs. 30 and 31. These will be quite enough to guide the carver, but it must be remembered that they by no means indicate the extent to which Queen Anne details may be applied when the construction will allow of anything more elaborate. It would be a comparatively simple matter to design a bureau with a very considerable amount of Queen Anne detail, but to do so it would be necessary to depart from the object of these instructions, which, it will be remembered, is to show how the original plain bureau, without altering its general shape or construction, may, in some measure, be invested with the features of various styles. I trust this has now been done in a way that may be suggestive to the novice either in making or designing, and, accordingly, take leave of this part of the subject, reserving any further remarks which may be considered advisable till a future opportunity, when perhaps sundry points, such as internal fittings of the upper part, secret drawers, slope for writing on, etc., may receive the attention they deserve.

THE SLIDE VALVE.

BY T. R. BLACKETT.

OBLIQUITY OF CONNECTING ROD, ETC. ETC.

IN order that the slide valve will do its duty in a proper manner—viz., to admit, cut off, and exhaust the steam at the required part of the stroke—we must have a connecting rod of sufficient length to give a proper balanced action to the engine. In explanation of the above, I may briefly state that while the piston only moves through a distance equal to twice the stroke in oue revolution, the crank-pin describes a circle exactly 3·1416 × by the stroke. Here is the proper relation between piston and crank. In the case of an ordinary horizontal engine, we have a connecting rod, one end of which takes the cross-head and the other the crank-pin, thus at every forward and backward stroke of the piston it changes the linear motion to a circular one. It will be seen by examining Fig. 5, where we have a very short connecting rod (exaggerated to point out the matter clearly), that while the piston is at *its* half stroke, the crank has not yet reached *its* half stroke or half centre. Now drop the connecting rod to the bottom half-centre, and we see that it crosses the centre of circle described by the crank-pin, as shown by the dotted lines in the figure. To overcome this obliquity of the connecting rod, it is necessary that it must be as long as possible—about two and a half times the length of the stroke. I have designed, during the last fifteen years, a good number of horizontal engines, and have giveu from $2\frac{1}{2}$ to 2·6 times the length of stroke for



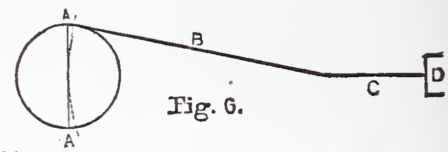


Fig. 5.—Diagram showing disadvantages of Short Connecting Rod. Fig. 6.—Diagram showing advantages of Long Connecting Rod—A A, Half Centre; B, Connecting Rod; C, Piston Rod; D, Piston.

connecting rods, and find, from actual practice, that that length answers well. If such a rod is made in proportion to the strain it has to bear, it will be found that there is no fear of buckling or bending, which some makers affirm against long connecting rods.

Fig. 6 represents by centre lines connecting rod of proper length, with an arc, shown by dotted lines through the centre of circle described by the crank-pin.

By giving a slide valve "lead," we give it not only to the steam port alone, but to the exhaust port also; in other words, it causes the exhaust port to close sooner than if we had given the steam side no "lead" at all. Hence we see "lead" is intended to give a "cushion" to the piston at the end of its stroke. If there was no cushion we would be sensible of the fact by a series of raps or blows at each end of the piston stroke, which, in the case of a high-speed engine, would be most unpleasant. In very large engines whose number of revolutions do not exceed forty per minute, I have seen the slide valves set with "lead" equal to the thickness of a piece of note-paper.

I would advise any one who intends to make himself master of the slide valve to construct a wooden model with crank and eccentric sheave, slide valve and rod, also a slot for a piece of wood to represent the piston in the cylinder. He will then be able to see more clearly than if he had only to depend on his memory. Similar models are used by "demonstrators" in our principal engineering schools.

Should any reader wish for further information regarding a wooden model, I could give it in "Shop." My reason for not giving it here is that every one who intends to master the slide valve will be able to rig up a rough model good enough for his purpose.

Now, with regard to "lap," it is put on the slide in order that we may work steam expansively. For instance, we wish to cut off steam at half-stroke, with our boiler pressure at 30 lbs. per square inch. Now, having cut off at half-stroke, we have the cylinder half full of steam at a pressure of 30 lbs. per square inch; thus it stands to reasou that when the piston has reached the end of its stroke, the steam in the cylinder will have expanded to twice its volume, but diminished to half its pressure—viz., 15 lbs. per square inch. This is called the expansive working of steam. I have given the above as a sample case. We might have an engine where we wished to cut off at one-quarter of the stroke with a higher boiler pressure. But with regard to "lap," in designing our slide valve there is a good rule, which, I am sorry to say, I cannot give in a simple form, so that our highly skilled, but not highly mathematical, workman could understand at a glance. It is this:—

From the length of the piston stroke subtract that part of the stroke at which it is intended to cut off steam; divide the remainder by the piston stroke, and extract the cube root of the quotient, which multiply by half the stroke of valve, and from the product take half the "lead." The answer will be the exact "lap" required. This may appear a complicated rule, but it is none the less accurate and mechanical.

SIGN-BOARDS.

BEING HINTS ON THEIR CONSTRUCTION FROM A CARPENTER'S POINT OF VIEW.

BY B. A. BAXTER.

In all woodwork, or, indeed, in all work, it is of great benefit and value to observe and remember any apparently small details in treatment of material by those who have experience.

We can scarcely go into a timber yard without observing that the ends of the choicest logs and stacks of boards are covered with some paint or composition to prevent gain or loss of moisture taking place at the end of the plank. The merchant wishes his wood to dry, but he prefers that it shall dry as equally as possible. The structure of wood is very much like an assemblage of tubes bound together, and the timber merchant knows that it is better that the ends of the tubes shall be sealed up, and that the drying shall take place on the larger surfaces.

For the same reason he keeps his choice timbers out of the direct rays of the sun. Rapid and partial drying means unequal and violent contraction, and this leads to cracks and shakes in the wood.

Apply this to sign-boards, and we may generalise that end grain should be exposed as little as possible, and that, where it can be, it is to be painted as effectually as circumstances allow.

If an experienced carpenter were asked to describe a cheap and yet a serviceable sign-board, I think he would say, "Have a frame made the size required, dovetailed at the corners, having a thickness at least equal to the proposed board or greater, and about three times its thickness for the breadth of framing, say panel of 1-in. stuff; make a dovetailed frame of $3\frac{1}{2}$ in. by 1 in., or $1\frac{1}{4}$ in. Let the ledges which cross the board be mortised and tenoned into the frame as in Fig. 1. In order to avoid weakening the frame, these mortises should be near the centre of its width, and the shoulder behind the ledge (what is generally called a 'bare-faced tenon'); let the board itself be fitted easily into the frame, and screwed from the back through holes in the ledges, all the holes except those in the centre being elongated to allow for a trifling movement."

The end grain of the board having been painted well before fixing, a moulding can now be fitted in the angle formed by the face of the board and the inner edge of the frame, and fixed to the frame and not to the board. This plan will ensure a durable and an economical construction.

As to the kind of wood, I can only suggest mahogany or pine. I could not recommend pitch pine, because, though very durable, it is generally so full of turpentine that it spoils the paint if exposed to strong sunshine. In all cases, avoid sap in pine.

In these days of gigantic advertisements, some mention of the covered notice and sign-boards is necessary. A prepared canvas for the purpose is to be had, and is made in very large sizes by the floorcloth manufacturers, which stands well—if only the frame has enough muntings to prevent the canvas vibrating like a sail under the influence of the wind.

Frames for these signs should be made of yellow deal from $3\frac{1}{2}$ in. to $4\frac{1}{2}$ in. wide, and $1\frac{1}{2}$ in. to 2 in. thick, mortised and tenoned together like a door without panels, painted well before canvas is put on, and moulding applied to edge, either rebated or a piece screwed on to edge of frame, forming square of moulding.

The heart side of a sign-board panel is the best for the face side, but the workman always will do the reverse if unnoticed, as the outside is easier to clean off. Particularly should this be observed when, as in some signs, there is a prepared canvas glued upon the wood like a veneer. This is an excellent plan for curved signs.

Frames for glass signs may be made like Fig. 2, but with a moulding like Fig. 3.

There should be a soft cloth or felt behind a glass fascia upon the wooden back to prevent injury to the painting and gilding, which is, of course, at the back, and special care should always be taken to prevent the entrance of rain.

GESSO WORK.

BY E. C.

THE DECORATION OF PICTURE FRAMES.

THE illustrations in this, the concluding, paper on gesso work are intended to supply designs for the decorator of picture frames. Never was there such a demand for medium-sized and small frames as at the present time. Fancy frames are required for etchings, autotypes, and photos innumerable; and it seems almost impossible that there should be too great a variety of these. The plain white enamelled frames and those of brocade and of satin have had a long run, and gesso decorated frames may well now become popular. If any of the readers of WORK wish to make a profit on such articles they will need to attain great facility in producing decorations at rapid speed. Amateurs are proverbially slow workers; they are more given to perfecting details and finicking over "finish" than to attending to effects, which after all is the main point in decorative arts. Now, the outlines should be kept true and sharp, but the modelling of the foliage will not need the same amount of care and labour bestowed on it as a figure on a panel. It can be quickly done either with or without the aid of cotton wool.

A word on the subject of "relief" to amateurs. I find that the least experienced amongst them often fall into the error of supposing that high relief is effective. To a certain extent it is, but we must bear in mind the purpose of our decorations. There is no true art in subordinating the picture or photo, which should be the centre of interest, to the ornamentation of the frame; therefore the design should be kept in rather low relief, and the colouring should be quiet in tone. The latter is more important if the photo is coloured; for etchings, too, I like subdued colouring in the frame, but for plain photos a bright frame is far from objectionable.

I will take Fig. 2 of the illustrations first for consideration, and suggest several ways in which it might be treated. I should choose that the frame should have rims slightly raised at both edges, so that the part to be decorated may appear sunk. It should be of walnut, rosewood or dark oak, or of some light wood stained to resemble one of these. Now for the design. Raise it a little above the wood surface by applying two or three coats of gesso; model the gesso with a brush, especially noting the tips of the leaves that turn over. Enrich it with gold lacquer only; for instance, the stem connecting the foliage that runs through the whole design could be touched with gold lacquer on both sides, leaving the most raised part white. Then the back parts of the leaves that turn over can be lacquered, and if veins of leaves are introduced they should be raised and the sunk portion on each side lacquered. A second mode of working would be as follows. Coat the design with gesso, keeping it quite flat. Cover the whole of it with gold lacquer, and silver the stems entirely and tips of leaves that turn over. This makes a lovely decoration with rosewood background. Again, instead of the background being of wood it could be coated with gesso and then lacquered green, or blue, or copper red. The rims in this case ought to be gilded. Yet another plan would be to carry out the gesso decoration entirely in blue and gold, and to silver the background. The design silvered, and just relieved with metallic blue, on a rosewood background would be admirable.

I should feel inclined to treat Fig. 4 somewhat differently. If this design were done in plain gesso it would look a trifle heavy on a dark wood background, so I should introduce several colours and get a rich harmonious effect. First gesso the ground all over; on this raise the design and model it. Then tint the flowers and buds red, accentuating the folds of the buds, and giving roundness to the petals by adding touches of gold. Colour the leaves a soft bluish green and throw up the veins with gold. Lastly, gild the background. This will prove a handsome frame decoration well suited for a good-sized photo or etching.

Whiteframes are much admired now for etchings. I do not mean alone the enamelled ones, but those of more uncommon style that are patronised by artists. I remember last season seeing an etching of a ship at anchor. It was a slight, sketchy production, no attempt having been made at elaboration; a few lines suggested the sea, but the effect was excellent. This was framed with a broad oak band painted white, and at one corner was a raised gilt anchor. The wood was not planed, but showed notches and cuts beneath the paint. The whole, viewed at a short distance, assumed a soft silvery-grey tone that was very charming. Now, I consider that Fig. 4 would answer well for such a frame. Say the whole ground is gessoed and left untouched with colour. The gesso is of a pleasing ivory-white tint, and the surface is smooth and appears polished. Raise all the design in gesso, but the buds and flowers may be in rather higher relief than the bordering leaves. Outline the design with gold lacquer, vein the leaves and mark out the petals with the same. Thus a chaste white and gold decoration will be obtained that will not clash with the most delicate etching.

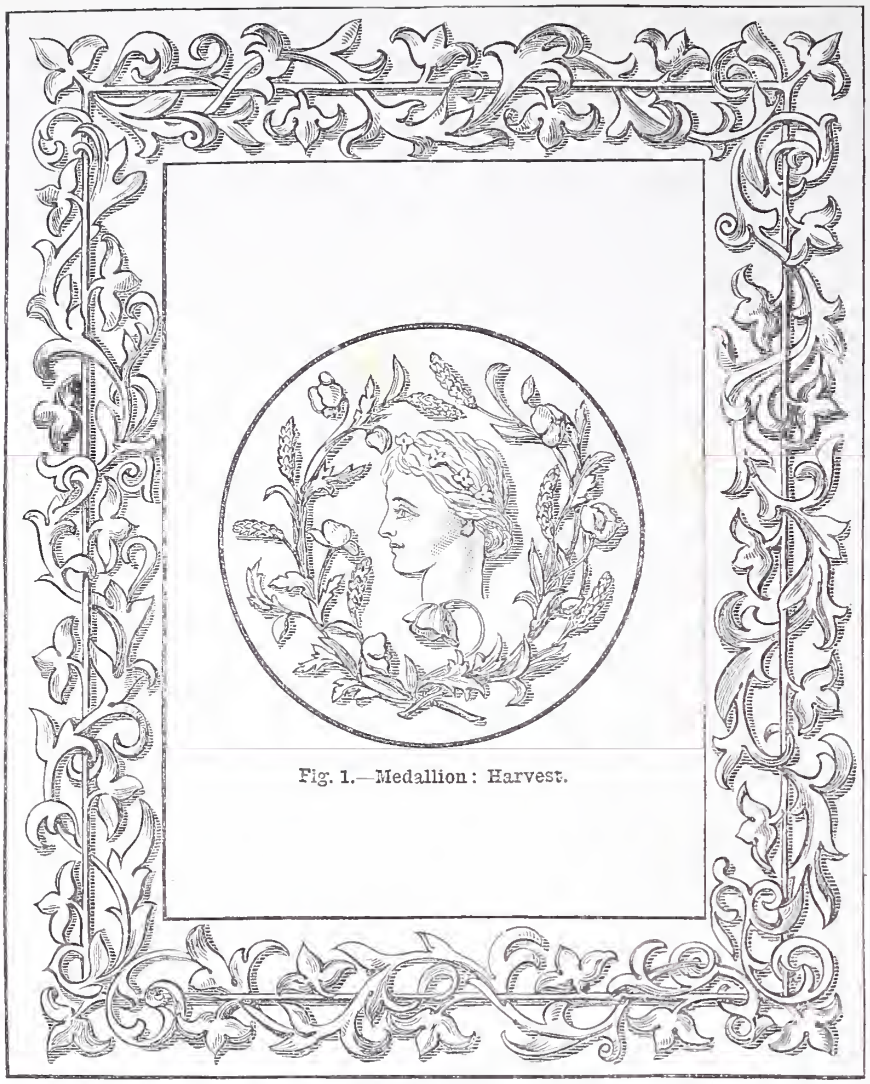

Fig. 1.—Medallion: Harvest.

Fig. 2.—Photograph Frame in Gesso Work on Flat Surface.

I would have no rims to this frame, and the etching should have a simple mount of white cardboard. Instead of the gold lacquer, brown oil colour could be suitably employed on a frame intended for a sepia drawing. A good mezzotint would be admirably set off by the white and gold frame.

The dragons shown in Fig. 3 will bear to be in higher relief than the conventional floral designs we have so far been considering. They should be well modelled and then coloured according to the worker's fancy. Here we have great scope for showing our skill in colouring. Rich, brilliant effects may be created with metallic colours, and such a design as this allows of uncommon harmonies. The ground should be of gesso, coated, let us say, with copper red, sprinkled with gold powder after the Japanese lacquer style. The dragons might be of gesso touched up with gold, the latter being used more strongly in the tails, on which strokes of gold may be closely laid, and the ears, eyes, mouth, and all outlines may be given with gold lacquer. Green and silver, or blue and silver, might be substituted for the red and gold. Or the dragons might be done with metallic blue, shaded into gold, in which case the background would be silvered.

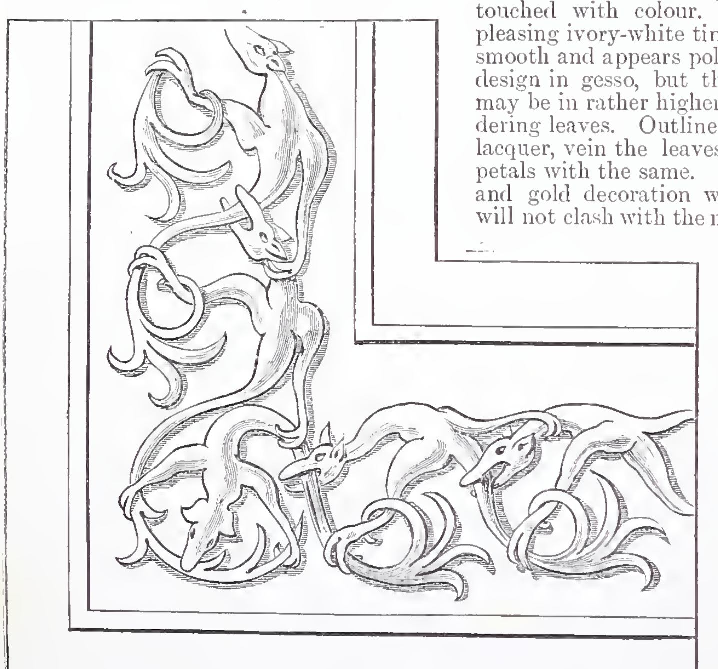

Fig. 3.—Corner for Picture Frame.

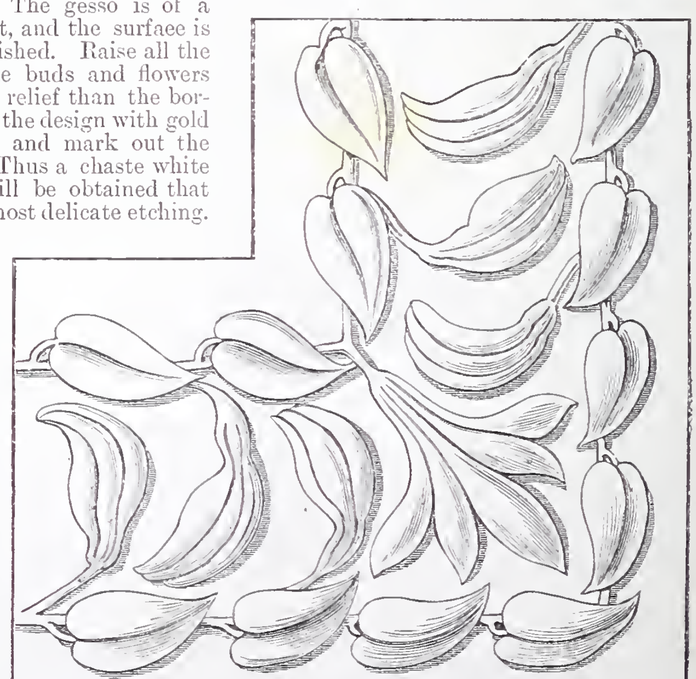

Fig. 4.—Corner for Picture Frame.

The background of floral designs may occasionally be enriched by short strokes in gold being laid on with the brush, so as to form a series of broken lines. These lines should be repeated every eighth of an inch or so. On panels, the intervening spaces between the lines gradually increase until the distance between the upper ones measures an inch or more. Sometimes the lines become more broken and cease altogether, to be resumed at a long interval towards the top of the panel or the frame. The medallion (Fig. 1) may well be coloured in a more naturalistic manner than the frame decorations; still, we must not overlook the fact even here that effect is the main end to be kept in view. The head is to be modelled in gesso, the shadows given in brown only, and the hair to be slightly marked out in tresses with brown, the wreath of marguerites to be touched with gold; this will make it appear like a sculptured head. Some might prefer to tint the face with oil colours and to colour the hair auburn; then the flowers wreathed around the head should be white. All this is just a matter of fancy. The background I suggest is blue, gradually merging into gold at the top. The garland of flowers should be done in metallic colours—scarlet for the poppies, gold for the wheat-ears, and green for the poppy leaves and stems. The blue of the background should also be metallic, oil colours being reserved for the head.

I am convinced that all who study the art long enough to become proficients will be delighted with the result of their work, and they will not consider that the time spent over it has been in any way lost.

OUR PRIZE BOOKCASES.

III.—A Bookcase in Carved Work.

(For which the Third Prize of Half-a-Guinea was awarded.)

The bookcase, of which illustrations are given herewith, was the last of the three that were chosen as being most worthy of the prizes offered in the recent prize competition for the fitting and appropriate receptacles for the 208 volumes that form the series of best books by the best authors known as Cassell's National Library. These bookcases, it may be said, were chosen on the one part for their fitness for the purpose for which they were designed, and on the other as being types of different modes of treatment, each good in itself, but offering a striking contrast to those with which it was brought into juxtaposition.

With regard to material, the bookcase now under consideration is to be made in fumigated oak of a rich colour, the darkened hue in imitation of old oak being obtained, in one way, by exposing the wood to the fumes of ammonia, exposure in a stable where there are many horses being sufficient to produce the desired result. The lower part, as shown in Fig. 2, is fitted with two small drawers, the front of which is shown on a larger scale in Fig. 1, the front elevation and end elevation being exhibited in Figs. 2 and 3. These drawers will be found useful for pens, pencils, paper, and other small articles. The top shelf may be utilised for the display of bric-à-brac and the lower one for pottery.

The carving is to be boldly executed and the ground stamped. The details given in Figs. 4, 5, and 6, the plan of the top shown in Fig. 7, and the section of shelves on the line, A B, in Fig. 2, exhibited in Fig. 3, will explain themselves, and there is no occasion to do more than suggest a few sizes for some of the parts, as for example: uprights, $1\frac{3}{4}$ in. square; panels, $\frac{3}{4}$ in. thick; stiles, $\frac{5}{8}$ in.; shelves, $\frac{5}{8}$ in. thick, and carved on the edge as shown in Fig. 2. For making the drawers, the reader cannot do better than refer to the instructions given on this subject in "Lessons from an Old Bureau," and reference may also be made to page 233 of this volume for the method of making a bookcase.

The double rack work shown in Fig. 6, for taking supports for the ends of the shelves, might be dispensed with, the books being all of one size; but if the reader prefers to have movable shelves, he should look at page 233 of this volume, to which reference has just been made, and in which the method of making this arrangement is fully explained. The necessity of making a working drawing to scale, of a larger size than that of 1 in. to 1 ft. adopted for the illustrations here given, with the exception of Fig. 1, cannot be too strongly insisted on; and the carved work for the drawer fronts as shown in Fig. 1, the top and bottom of the bookcase, the edges of the shelves, the sides of the uprights, the pillars at the bottom, the finials at the top of the uprights, as shown in Fig. 1, and the panels at the exterior of the sides, as exhibited in Fig. 2, should all be carefully worked out full size before the workman commences the work of ornamentation with the carving tools. The scallops under the top and three shelves in Fig. 1 are intended to represent leather, attached to the under part of the shelf to prevent in some measure the access of dust to the top of the volumes.

WAX POLISHING.

BY DAVID DENNING.

THE difficulties attached to French polishing any piece of wood, of whatever kind, are sometimes so apparently insurmountable to those who have not been properly instructed in the art that many a novice, after his first attempt at polishing, is almost inclined not to risk injuring whatever he may have made by polishing it. Such a feeling is excusable. He sees the thing in the white—as an unpolished article is technically called—nicely finished and clean. He knows well enough that if he could only polish it satisfactorily its appearance would be considerably enhanced, but remembering that his intended improvement may result in an unpleasant-looking surface, he reluctantly gets someone else to do this part of the work. Of course, in trade circles the polishing, as a matter of fact, is done by a polisher, but in small shops, and especially by amateurs, the desire is to do all the operations oneself.

Now, though no method of finishing more enhances the beauty of most furniture woods than French polishing when well done, there are processes which, though not capable of being brought to such perfection, are much simpler. Among these is the subject of the present article, viz., "Wax Polishing." This mode of finishing is so remarkably easy, both as regards materials and manipulation, that it is hardly an exaggeration to say that the unskilled novice can manage as well as the most expert. It therefore seems a suitable process for the first of a series of articles in which the more difficult operations will be duly explained.

Perhaps something should be said about the kinds of timber which are suitable for wax polishing, or "waxing," as it is often called. I have used the word suitable, but it may be said that, beyond custom and fashion, there is no reason why any wood should not be treated in this way. That to which it is generally, or it may almost be said solely, confined is oak, especially after this has been darkened by fumigation with ammonia—a subject which will be more fully gone into in an article on staining. The appearance of oak so finished will be familiar to most readers who have paid any attention to furniture. The finish is comparatively dull, but there is an attractiveness about it which the more highly finished French polish does not possess for all eyes.

For old oak furniture—whether by this is meant genuine or imitation antique—no finish is superior to wax, though, as is well known, varnish is often used.

While mentioning varnish, it may be as well to explain that wax polish, though it may not give the same amount of gloss, is, if I may so express it, clearer and finer looking. Varnish clogs the wood, and is apt, to use a very expressive trade term, to give a "treacly" look to any piece of furniture finished with it.

Mahogany, though seldom wax polished now, may very appropriately be finished by this means, and it may be questioned whether, for many purposes, it is not superior to the dulled French polish so often seen.

As is very well known, the top of a dining-table is very apt to be rendered unsightly from hot plates or dishes injuring the polished surfaces. The heat burns or blisters the hardened shellac of the French polish, so that any method of finish which is not so liable to disfigurement is preferable; and one of these we find in wax polish. It ought *en passant* to be said that dining-table tops are usually (unless French polished) simply oil polished. This, however, is more tedious than waxing, which is, at least, as suitable for the purpose, and the readiness with which any accidental injury can be repaired renders it particularly useful.

Wood stained black, or the so-called ebonised finish, may also have wax polishing substituted for French. The result is certainly a closer approximation to the appearance of real ebony than when the work is ebonised in the usual way. Special attention will be devoted to the polishing of fretwork articles later on, but it will not be out of place here to say that by means of wax they may easily be made to look better than so many of them do when unskilfully French polished.

It has been said that any wood may be wax polished, but at the same time a rough classification may be made—one which, though not strictly accurate, will enable those in doubt to decide for themselves whether wax will be an improvement. I do not know whether it is a rule strictly observed—in fact, it may be said there is no rule on the subject—but there can be no question that wax answers best on the more coarsely grained woods, such as oak, ash, etc., and that pine and other light woods of close texture can hardly be considered to be improved by it—unless, indeed, they have been previously stained. As the reader will now have a fair idea of the capabilities, advantages, and disadvantages of wax polish, the making and application may next receive attention.

Probably there is no material used by the polisher, and prepared by him for his own use, in which a greater variety of proportions is used. One man likes the polish thin, so thin as to be merely a liquid; another prefers it to be in the form of a paste. As such great latitude is allowable, the novice may wonder whether certain proportions are not better than others, or whether some polishers are not using the stuff to disadvantage.

It may, however, be said that so far as actual finish—*i.e.*, gloss—is concerned, it matters little what the proportions of the ingredients are. These, it may as well be stated, are in the simplest mixture merely wax and turpentine. Others, such as resin, Venice turpentine, etc., are occasionally added, but provided the wax be of good quality, they are quite unnecessary, if not prejudicial. Resin, when used, is added with the intention of hardening the surface, and in some instances it may be beneficial, but only experience can teach when it will be. The learner may be quite certain that if he cannot get a good result from wax and turps alone, the fault does not lie in the absence of resin. Venice turpentine, though mentioned as an ingredient in some of the old receipts, is by no means an indispensable ingredient, and it may fairly be questioned whether it is of any use whatever. It rather savours of quackery, or the mystery with which some of the masters of arts and crafts appear in former times to have endeavoured to conceal their actual mode of working. I have known Venice turpentine to be employed in making wax polish, so that those who would like to try it may experiment on their own account, remembering that a very small quantity is recommended.

To prevent any misconception then, let it be clearly stated that wax and turpentine alone are all the materials necessary to make a good wax polishing paste, and that when anything else enters into the composition the mixture is one of a fancy character. This is not the place to discuss the qualities of beeswax which are offered for sale, and it must be left to the polisher's own decision what kind he gets. Some advocate the use of fine white wax, and possibly a slightly better finish may sometimes be got with it than with the ordinary yellow wax. This, however, is generally used, and the only occasions when I would suggest that it might not be so good as the lighter colour are when extreme purity of tone is required for a white wood. A perfectly white wood is, however, so seldom wax polished that, for all practical purposes, at present it may be considered non-existent.

It will readily be understood that the way in which the wax polishing mixture is prepared depends a good deal on the proportions of the materials. For a thin liquid—or should I not say a liquid polish?—it is sufficient to shred the wax finely, and then pour the turpentine over it, leaving the two till they are incorporated. The turpentine will, however, only dissolve the wax slowly, and a much more expeditious method is to melt the wax by heat, and then, before it has time to solidify, the turpentiue is poured into it. Naturally, when melting wax, caution is necessary, and on no accouut should the turpentine be poured into the wax while it is still on the fire. With ordinary care, there is, however, no danger, and I only suggest the possibility of a mishap for the benefit of those who might otherwise overlook the inflammable character of turpentine vapour. As I have so far purposely abstained from naming definite proportions in the desire not to hamper novices, it may be as well to say that if they find the mixture either too thick or too thin for their tastes, they may easily alter the consistency.

If it is desired to thin a mass, which is, say, as stiff as butter, a very moderate amount of heat will reduce it to liquid form, as the turpentine already in it facilitates the change. More turpentine is, of course, added while the wax is in the liquid state. On the other hand, it may be necessary to stiffen the mixture, and in this case some more wax should be melted separately, and the original polish added to it. The heat of the freshly melted wax will probably be sufficient to cause all the materials to amalgamate. It should, however, be noted that the wax in any case should be thoroughly melted before the turpentine is added, as a lumpy mixture is neither pleasant to work with nor yet conducive to good finish. When exposed to the air, the natural tendency of a wax polishing mixture is to stiffen, on account of the evaporation of the turpentine. A considerable time must, however, elapse before there is any appreciable alteration, and the fact that a change does go on, however slowly, is just alluded to, to remind polishers that if they have any considerable quantity of the mixture standing over, they must not expect it to retain its original condition unless kept in a closed vessel.

Now, just a hint for those who think that the more ingredients a mixture contains the better it must be, and accordingly are not satisfied unless there is a certain amount of resin in their wax polishing paste. Resin does not melt so quickly as wax, therefore let it be melted or partially melted, first adding the wax gradually, and, as the cookery books say, "constantly stirring." Whether resin be used or not, the mixture should not be applied till it is cold.

Although, as has been said, the consistency of wax polish varies considerably, it would hardly be fair to leave the novice in a state of perplexity about the comparative merits of different degrees of stiffness or fluidity.

Perhaps the best way to explain matters so that an intelligent conception of the polisher's aim may be arrived at, will be to suppose a piece of pure wax—that is, wax without any admixture of turpentine—is taken by way of experiment, and rubbed on a piece of smooth flat wood. A certain amount of the wax adheres to the surface, which, when friction is applied, becomes glossy or polished. The labour, however, is considerable, and however well dry wax may do on a flat surface, a very short experience will show that when mouldings or carvings are to be treated the difficulties in the way of satisfactory application are considerable. Well, the remedy is obvious: the wax must be softened that it may be got into all parts of the work. Melted wax, therefore, might do, but even in putting it on to the wood it becomes cold, and consequently reverts to its original stiffness. This necessitates the scraping or tedious removal of superfluous wax, for it cannot be too emphatically impressed on the novice that so long as wax is present on the surface in visible quantities, polish or gloss cannot be got. We have then to get the wax to a fair working consistency by means of some suitable solvent, which turpentine has been found to be. It is cleanly, inexpensive, and evaporates sufficiently quickly, besides mixing well with the wax. We can now see why some polishers prefer what others might think an excess of turpentine. If a stiff paste is used, the wax is apt to be deposited in excessive quantity in places, necessitating a considerable amount of rubbing to remove it. On the other hand, a fluid polish spreads the wax much more evenly, but no gloss can be obtained till the turpentine has either evaporated or been absorbed by the wood. Unless the polish has been "slopped on" over the work, this does not take long, so that, on the whole, a thin mixture may be considered preferable to a very stiff one. Enough has been said to enable any one to determine for himself whether to use a thick or a thin paste, but there are always a few who think—and very likely rightly—that as safety does not lie in extremes, but in the middle course, they would like to have some idea what this is in wax polish. Possibly here, again, opinions would be found to differ, but I should say that a paste of about the same consistency as butter in hot weather might be regarded as a medium. Of course, those who use a wax polish mixture which could be poured would consider this stiff, while others who add very little turpentine, or who believe in resin, would consider it thin. After all, it does not much matter whether a thick mixture or a thin one be used, the result depending more on the manipulation of the material than on the material itself; and how this is to be applied may next be considered.

In the application of wax polish we find almost as great a diversity of opinion, or rather variety in practice, as in proportion of ingredients. The great thing is to have the wax—the turpentine, it must be remembered, is merely the vehicle for conveying this—evenly and thinly distributed, and so long as this is done, it is of small consequence how it is managed. Some say use a piece of rag, while others prefer a stiff brush to rub the wax in with, and both get equally good results. After the wax has been rubbed in, the polish is obtained by friction; or to parody a well-known advertisement, the more you scrub, scrub, scrub, the more you rub, rub, rub, the brighter the polish will be. In this final friction it is essential that the cloth or brush used be perfectly dry, as if it is at all damp, no polished surface can be produced. In any case, the brush or cloth used to rub the wax into the wood should not be employed to give the finishing touches. These are best done with a perfectly clean rubber, and if I may venture to lay down rules when the process admits of so much diversity in procedure, I would use, say, three sets of cloths or rubbers. With the first the mixture is to be rubbed on the wood, with the second it is to be rubbed off till a fair amount of polish is got, while with the third the rubbing should be continued till the surface is as bright as it can be got. Very likely some might prefer to be told exactly what material the rags should be of, how long they should rub, and a whole host of minor details, but though these instructions may seem vague, I wish to make the various processes connected with polishing as clear as possible and to give them divested of all the needless minutiæ which are popularly regarded as inseparable from the polisher's art.

There are enough difficulties in the way of practising it successfully without adding to them by insisting on fixed modes of procedure, and so hampering the intelligence of the worker, who will scarcely need to be told that without common sense no directions, however precise, would assist him to any great extent. So far as has been deemed necessary, directions which should enable any one to wax polish wood successfully have been given, and this paper may very fitly be brought to a close by stating that hard dry rubbing, with plentiful use of "elbow grease," are at least as important as the wax and turpentine. Though more simple than the French polishing process, that with wax is more laborious. For the purposes of these hints on waxing, the Latin quotation, *labor vincit omnia*, may be freely—very freely indeed—translated into the vernacular as "labour brings the polish up."

OUR GUIDE TO GOOD THINGS.

⁂ Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.

128.—Erfurth's Patent Scaffold Holder.

In page 728 of this volume an interesting account of some ingenious steel ties for the connection of scaffolding was given by Mr. John Charles King, under the title of "Science in Scaffolding." This induced Mr. J. Charles Schroeder, 49, Ferntower Road, Highbury New Park, London, N., to send me a prospectus and working model, on a small scale, of Erfurth's Patent Scaffold Holder, a simple and apparently secure means of fixing cross-poles to uprights without having recourse to ropes. Mr. Schroeder writes:—"I would beg to draw your attention to a patent scaffold holder for which I am agent in the United Kingdom, and which I venture to think is of greater safety and efficiency than the contrivances shown in your issue of this date (No. 46, Feb. 1, 1890). I beg to enclose a circular giving diagrams and full particulars of this holder. The same is already in extensive use in various parts of the Continent, and has met with universal approval. A number of these patent holders are about to be practically tested during the coming season by a well-known firm of builders and contractors in London." Mr. Schroeder further informed me that the patentee is M. Erfurth, in Teuchern (Saxony), and that the holder is patented in England under No. 1389 (1888). It is asserted that weakness and complication in construction have been the chief causes of failure of those hitherto brought into the market, but that this patent holder is superior to them all, being of iron and wrought in one piece, and consisting of a saddle arm, clamp, and counter-arm—represented in Fig. 2 by the letters *c*, *a*, *b* respectively—each provided with a spur, or point, which are forced into the scaffold-pole and cross-piece under pressure of the cross-piece and the weight thrown on it, and which are indicated in the diagram by the arrows at the letters *a*, *b*, *c*. The holder is fixed to the standard or upright pole by pushing it on sideways at the desired height and turning it with a jerk, the saddle arms pointing in an upward direction. This can be done with one hand in a few seconds. It is not requisite to drive in the spurs with a hammer, as the holder fixes itself automatically. When the cross-poles are placed on the projecting saddle arms, their weight presses the holder against the standard in such a manner that the spurs enter the wood and prevent the holder from slipping, thus affording the greatest security. The simplicity of the invention does away with the necessity of repairs and renewal of parts, which are said to form the great objection to other holders. It is claimed that the saving in time and cost of erecting scaffoldings when the holder is used is considerable, compared with the cost when holders with screws, wedges, and chains, etc., are employed. Although the initial cost of this holder is more than that of ropes, yet, owing to the short time which ropes last, and their liability to be lost or destroyed, the saving in the end is great; and when the time and consequent expense necessary to the employment of ropes are taken into account, the amount saved by the use of this holder is very large. The strength and durability of these holders are such that they will last for many years, and, owing to their capability of being packed in a small space, their transport is easy and inexpensive. They can be used with safety on a pole much smaller in diameter than the holder, and, moreover, it does not hinder the standards and cross-poles being joined when necessary. It is made in three sizes, namely, No. 1, 7⅞ in. internal diameter, sold at 4s. 4d. each; No. 2, 6⅜ in., at 3s. 9d.; and No. 3, 4¾ in., at 3s. 3d. each. The advantages claimed, as stated above, are certainly considerable, and the holders themselves deserve thorough and careful testing.

NOTICE TO OUR READERS.

With the next number of WORK (*No.* 53) *will be issued,* FREE OF CHARGE, *a large* SHEET OF DESIGNS IN WOOD CARVING (*size* 30 *in.* × 20 *in.*), *consisting of Twenty artistic and elaborate designs for various articles of Furniture in the Elizabethan, Italian, Old Dutch, North German, French 15th Century, and Modern styles. The various designs represent Chairs, Mantelpieces, Cabinets, Chests, Cornices, Pateras, Panels, Borders, &c.*

An Index to the First Yearly Vol. of WORK has been prepared, and can be obtained by order from all booksellers, price 1d. It is included in the last Monthly Part of the volume (Part 12).

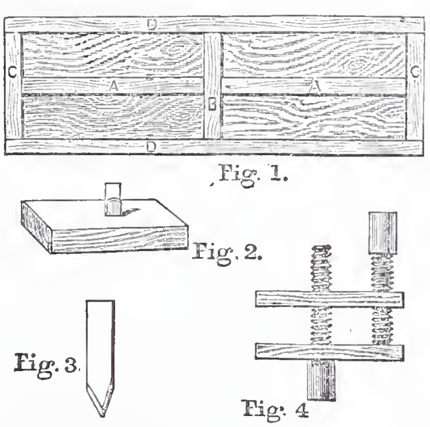
SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

I.—LETTERS FROM CORRESPONDENTS.

Steel Castings. — STEEL MOULDER writes:—"The reply to J. T. (*Newport*) (see page 701) is somewhat misleading, because it is not so very exclusive. Nor is the making of them so difficult. If J. T. wishes to produce small castings from a few pounds weight up to 1 hundredweight, he can entirely dispense with ganister and ground crucibles, and also with the costly process of drying the moulds, and instead of the moulds being more refractory, for such size as the above indicated it is just the opposite, because the moulds should be only just firmly rammed, and as little moisture as possible used. But for heavy castings your reply is about correct. This is my practical experience of all kinds of steel castings, extending for a period of twenty years in some of the principal firms of this country, and if J. T. would like to write personally to me, or through the columns of 'Shop,' saying what kind of castings he requires, I will gladly try to help him as to the best way to produce them, and if he is a moulder he will not find it so difficult as it appears."

Wardrobe.—ARTIST IN WOOD writes:—"Fig. 1 is wardrobe end veneered so as to show rosewood panels and ash framework; also how the veneers may be put on in least possible time and best of joints made. Lay the panels first, then with the cutting gauge and straight-edge cut out the groove, A, to receive ash veneer. Lay in this veneer, then with cutting gauge and straight-edge cut out groove B, and cut off ends of panel veneers at C. Then lay ash veneers, B and C. Now cut off sides of panels and end of rails, then lay the stile veneer, D. Cut

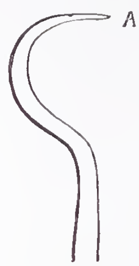


Veneering Wardrobe.

out all veneers with the cutting gauge and straight-edge. Do not use a plane except in fitting in veneers, A and B. Fig. 2 is the cutting gauge made of wood, with wedge to fix the steel cutter. Fig. 3 is cutter of cutting gauge filed to a point from one side only. It is made from a bit of thin steel. A bit of bow-saw blade will make one. Fix the straight-edge on the work with hand screws (Fig. 4). Wardrobe ends are not often veneered. I send this sketch to show your readers a proper way of doing all such-like work."

Painting Blackboards.—J. M. P. & Co. (*Nottingham*) write:—"We must take exception to J. F. K.'s description (see page 701) of the 'best' way of painting blackboards for the following reasons:—(1) The board will not preserve its 'dead' appearance after being used, but will become glossy. (2) The method he describes is as old as the art of making blackboards, and therefore should not be described as the 'best.' We are the inventors and makers of a composition for painting blackboards which will retain their 'dead' surface for years—indeed, until worn out—and we should be glad to send samples to any of your correspondents who may apply to us."

Hook-Turning Tools. — C. C. E. (*Lincoln*) writes:—"If our friend, F. A. M., had ever *worked* with hook tools, he would never have repeated, for the benefit (?) of TYRO (*Liverpool*), one of the very few mistakes to be found in Holtzapffel, Vol. IV. More than twenty years ago I procured Holtzapffel's tools, but as neither I nor any one else could use them I journeyed to Kingscliffe, to find that the tools were useless from two causes: first, the hooks were recurved as in Holtzapffel's book instead of being made like diagram, the point at A being prominent rather than curved back. Second, the stems are square instead of round. Hook tools, when properly made, are easily used, and will cut rapidly even into African black wood, but the rest must be *below* the lathe axis about 1 in. (not *above* it, as directed) and about 1 in. from face of work. Bore a hole, say, ¾ in. to nearly full depth to be excavated, and begin at edge of hole with a light cut, the edge of hook being almost horizontal. A little practice will give confidence as to price of tools. W. Green & Sons, turners, West Street, Kingscliffe, Northamptonshire, will supply small 'hooks' at 1s. 6d. each; large, 2s.; square 'hooks,' small, 2s.; and large, 2s. 6d.; long handles, 6d. each. A very efficient tool, doing partly the work of a 'hook' and 'square hook' combined, has recently been devised, but it is so much more difficult to use that amateurs had better let it alone."

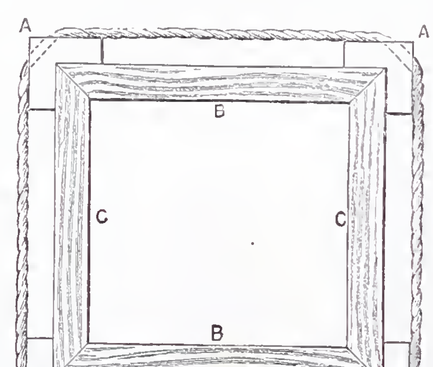


Turning Tool.

Sharpening Plane Iron.—DUMMY writes:—"I should advise R. H. (see page 651), and those who are inclined to follow his example, to forget an amateur's dodge and learn to sharpen a plane iron as it ought to be done, and not use a makeshift, slovenly dodge. In the first place, R. H. will find when the iron gets worn down he cannot continue to sharpen in the manner described. 2. He is wearing away the back part of his plane; and 3rd, he is not getting a true cutting edge. You will see by placing the plane in the position mentioned you get a bevel something like diagram, very stunted, and the iron would require grinding much oftener than it ought to do. To sharpen the iron, take it in the right hand, let the top of the iron rest against the thick part of the hand, the thumb round the edge, the two forefingers straight down the iron, the remaining two fingers round the other edge of the iron, holding quite firm. Put the iron on the stone, the bevel fitting the stone; now place the fingers of the left hand upon the iron, so as to give weight to it; proceed to sharpen; in doing so move the arms and not the wrists: the wrists must be held quite stiff, or you will roll the iron (as we call it). If your stone is in proper order, you will get a straight, smooth edge on the iron. Try it. If you endeavour to do as I say, common sense will soon show you your faults."

Plane Iron.

Mitre Cramp.—J. A. (*Wandsworth*) writes:—"Seeing in page 605 of WORK a query concerning the means of holding mitre joints, I send the following apparatus, which, though so extremely simple, is very efficient, and has a further merit with many that it costs scarcely anything. The



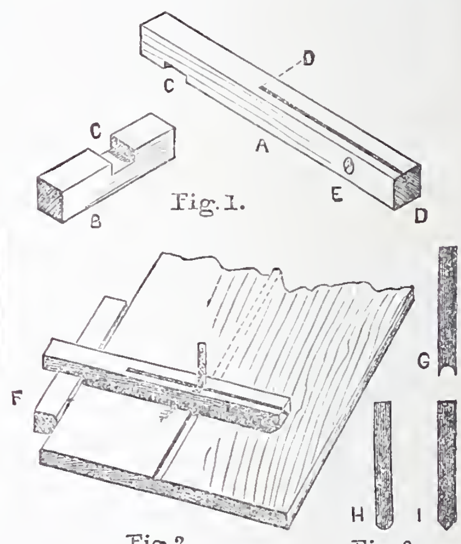
Mitre Cramp Apparatus.

sketch almost explains itself. The only things required are some wood (beech or oak) and some stout cord. Four pieces, A, A, A, A, are sawn out to the shape shown. If the inner angle is not a true right angle after being sawn, it must be made so by being pared with a chisel. Having made the opposite pieces, B, B, and A, A, the same length, and at the proper mitre angle, place them in position for gluing. Then tie the cord so that it will pass loosely round them, after which glue and tighten up the cord by means of the rod B. Before making the joints very tight, see if any of them overlap. If so, press them level with each other, and then tighten up fully."

Sign-Writing Charges. — B. J. (*London, W.*) writes:—"I send you prices of sign-writing about the West end of London:—Plain colour per inch, ½d.; sunken letters in three colours, per inch, 1½d.; each additional shade per inch, ½d., if properly executed. Gold, 4 inches and under, 1½d.; ditto, 8 inches and under, 1¾d.; ditto, 12 inches and under, 2d. Mouldings ½ inch to ¾, per foot, 3d. To the trade at one-third less than the above."

Saw Hammering.—R. H. (*Bolton*) writes:—"I notice, while perusing WORK (see page 715), that J. N. (*Sheffield*) is willing to instruct any one that is in need of information on circular saw hammering; if he will be so kind, I have a 33-in. circular saw, that is dished or concaved about $\frac{3}{16}$ of an inch, and through that cause it bears hard on the packing. I have sent it to the saw repairer's twice, and he asked me if I used pegs, and I said 'No,' but I use cotton banding lapped round a piece of pine stick, as most sawyers do. I am a practical sawyer, and I think all the pegs in the world would not make a dished saw run and cut true boards. He has hammered the saw, but still it is as bad as ever after it has run a short time in the bench; the same saw has worked for years, and done well."

A Useful Tool.—F. C. (*Leytonstone, E.*) writes:—"I send sketch of a very useful tool. It is not a novelty, and is by no means new, but it may be easily made by an amateur, and perhaps save a lot of trouble and expense, and, I believe, is not generally known. It may be made as follows.—Procure two pieces of hard wood, say 1¼ in. square—ash will do very well for the purpose—one piece, A, Fig. 1, 8 in. long, the other, B, 4 in. long. In A run a saw



A Useful Tool.

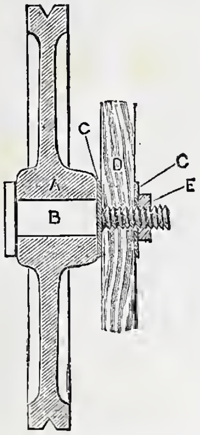
cut, D; this is to hold the cutter; notch them together as shown at C. E is an ordinary wood screw. Fig. 2 shows the finished tool, and the method of using it to work a bead in the middle of a board. The cutter is held in its place by tightening the screw, E. In Fig. 3, three forms of cutter are shown—G works a bead, H a flute, and I a V joint. They are easily made out of an old plane iron or a broken chisel. In using it is necessary to keep the knee, F, Fig. 2, tight against the work."

Dulcimers.—W. Y. (*Enfield Lock*) writes:—"On page 254, under the heading of Sounding Board for Dulcimer, W. S. M. (*Leeds*), in reply to DULCIMER, gives him some advice with regard to this instrument. W. S. M. is evidently a maker of dulcimers, and as I am about to buy one, should like to correspond with him."

Change Wheels.—F. A. M. sends the following errata *re* Change Wheels (page 734), line 9, "28 is brass gas;" also in line 8, for 28 read 26. Line 23 from bottom, omit "therefore," and put a full stop instead, beginning new sentence, As we have."

Wheels.—W. P. (*Withington*) writes:—"I have been waiting for G. W. (*Bournemouth*) to answer R. B.'s (*Largoward*) query in 'Shop' with regard to the address of firms where he might procure ready-dressed timber for wheel making. As no reply has been forthcoming, I append a few more names out of a number than those which I gave in No. 46, page 734, in 'Shop,' as being situated in Manchester, and which would be inconvenient for those living down south; anything in the wheeling line can be procured from Messrs. C. and B. Gadson, 11, Bushfield Street, London, E.; or Messrs. Thomas Whittingham & Wilkin, 135 and 136, Long Acre, London, W.C."

Parts of a Lathe.—S. G. D. (*Stroud Green*) writes:—"In the issue of WORK for December 14th I see an inquiry arising from a communication I sent you some time ago, and which you did me the honour to publish. Under the heading of 'Parts of a Lathe,' in 'Shop,' page 619, P. C. (*Bedfordshire*) seeks for further information about my temporary lathe attachment (I call it 'temporary' because by its aid I contemplate constructing a more elaborate and perfect accessory to the carpenter's bench). The wheel, A, is of cast iron, and its axle, B, is a bolt which is fixed to the bench, D, and secured by the nut, E, C C being washers; the accompanying sketch will make it clear. When I fitted up this attachment I had little time to spare, so put the wheel in the position that gave me least trouble to prepare the place for it. It would be a great improvement if the wheel was placed as near to the ground as possible, so that it comes well under the headstock of the lathe instead of behind it, and almost on a level with it, as is the case in the original arrangement shown in 'Shop,' page 508. By bringing it below the level of the top of the bench the necessity of removing it if the bench is required, say, for planing, is obviated. I should prefer brass or gun-metal bearings for the mandrel. The plummer blocks used for mine are simply of cast iron, and I am hound to say answer very well. Before making any article I generally plan it out on paper, and make careful drawings of the different parts to scale. I attribute a great deal of my success in mechanical work to this habit of drawing; it trains the eye, and is of immense value in teaching to measure and fit accurately. A moment's reflection will prove this; if an attempt is made to draw the parts of which an article is made, they must be carefully thought out, and what is carefully thought out at the beginning of the work has a better chance of being perfect at the finish than it would if done without such a system."—[Send in sketch and description of your lathe when ready if you would like it to appear in "Shop."]



Lathe Attachment.

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

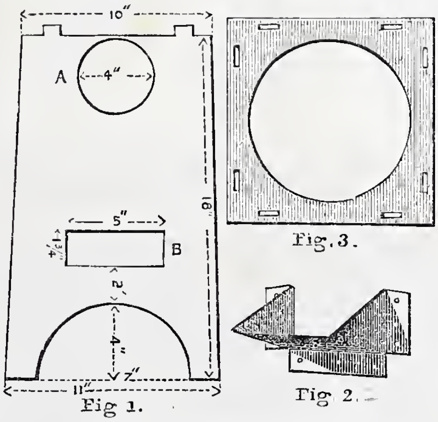
Schanschieff's Battery.—M. F. — The positive element of a Schanschieff's cell is a zinc plate, the negative element is a carbon plate; both immersed in a solution of mercury in a single cell. The E.M.F. is 1·56 volts, and the internal resistance ranges from 0·05 to 0·75 ohm per cell.—G. E. B.

Accumulator and Shocking Coil.—J. A. (*Shaftesbury Park*).—Respecting small accumulator, kindly see reply to D. SCOTT (*Holloway*) in WORK for October 12th. This will tell you how to make the plates. As you do not tell me the voltage and candle power of your lamp, I cannot say how many cells will he required, nor the size of the plates. The cells, to be light, should he of ebonite or vulcanite, and I think you would not be able to make these. Please look up my previous replies to correspondents, respecting Batteries for small Electric Lamps. Also read the articles which will shortly appear on Model Electric Lights. Respecting the shocking coil, one end of the primary wire—that is, the large wire wound around the iron core in the centre of the coil—goes to the foot of the spring of the contact breaker, and is clipped under it by one of the screws. From the foot of the pillar carrying the contact pin, a short thick wire goes to one of the binding screws on the base of the coil, and this is connected to the battery. The other end of the primary wire is connected to the other binding screw, and this to the other pole of the battery when you wish to set the coil in action. The finest wire is from the secondary coil, and this goes to separate binding screws.—G. E. B.

Gassner Battery.—G. W. (*Colchester*).—The Gassner battery is a patented article, therefore it is illegal to make and use it without the consent of the patentee. I do not know the proportions of its contents, so cannot advise you how to charge the battery. Why not make up a Leclanché battery for your bell?—G. E. B.

Electric Time Alarum.—AMATEUR (*Battersea*).—Kindly turn to replies on this subject given to ONE IN NEED (*Coventry*) and IRON TURNER (*Bolton*).—These will give you full information on how to connect the wires. What you suppose to be a lead rod is really a zinc rod, and furnishes the power in a Leclanché battery.—G. E. B.

Sheet Iron Stove.—DUTCHMAN (*Bristol*).—I do not remember ever seeing a plumber's stove made of sheet iron. It seems to me that it would wear out too quickly with the heat that it would get if in use constantly. I have made sheet iron firepots for my own and other people's use, for burning charcoal, but where coal or coke is the fuel I prefer cast iron stoves. There are some good stoves made specially for the purpose you require. Messrs. Rhodes & Sons, tool makers, Wakefield, supply a good strong one at 27s. 6d., and Messrs. Fletcher and Co., Warrington, make one in which gas is the heating power, the price of which is 15s. I can confidently recommend either of them, hut as it is probable that you may be already aware of this, and still wish to make one yourself, I will endeavour to help you all I can. You must make it out of stout plate, say, 16 in. gauge; use charcoal iron, or the mild steel which is fast superseding charcoal iron; its better quality will repay you for the slightly higher cost over common iron; cut out two pieces as shown in Fig. 1. In one piece cut out the circular hole, A, 4 in. diameter, or a little less, letting the edge of the hole he ¾ in. away from the edge at the top. This is for the back of the stove. The other piece will, of course, not have the circular hole, A, but cut in that the oblong hole, B, 5 in. by 1¾ in. The tenon pieces at the top are to rivet on the top with; instead of these, if preferred, you could rivet angle pieces ¾ in. by ¼ in., and drill and tap them, and screw the top on with stove screws. Punch a row of holes ($\frac{3}{16}$ in. or ¼ in.) down each side, about 1¼ in. apart, and ⅜ in. from the edge of the plate; mark down each side a line 1 in. from the edges, fix in a pair of clams in a vice, and hend at right angles. Now cut two pieces same shape and depth as Fig. 1, but 2 in. less in width, as they have not to he bent; these are the sides, and the front and back pieces have to he riveted to them, marking the holes from the pieces just punched. Next turn four angle pieces of ¾ in. by ¼ in., and rivet two on each side to support the hottom—the bottom should come an inch below the hole, B. Next make the apron piece, Fig. 2, and rivet it on the front of the body, to support the irons, etc. Then make a short piece of 4 in. pipe, and throw off a flange on it, and rivet on the hack, for the smoke pipe to fix on; cut out the top ½ in. larger all round than the body, and in it cut a hole 6½ in. or 7 in. diameter; carefully make the holes for the tenon pieces, and after placing the grating for the hottom in its place, rivet on the top by means of the tenons, unless you decide to use the angle pieces and stove screw, which, I think, is the best way if you have the tools, as the top could he easily removed if wanted. The next thing is the cover. I should, for this, turn a ring of ½ in.



Sheet Iron Stove Pieces.

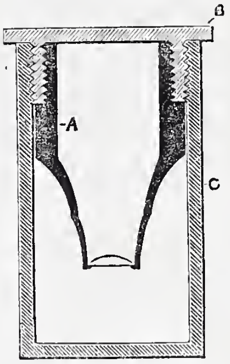
square iron that would just fit in the hole in the top, and rivet it to a round plate cut a little larger than the hole; rivet an eye or something to lift the cover for putting on fuel, and the stove will be complete, and although not perhaps so satisfactory as a proper cast iron one, I think it will answer your purpose. The dimensions I have given you can vary to suit your own convenience, and hope you will succeed in making it.—R. A.

Chemical Action in Gassner Battery.—H. H. L. (*Chester*).—I am not myself certain respecting the reaction which takes place in a Gassner battery when the circuit is closed. The constituents are (I am informed):—$Zn + Zn\ Cl + Ca\ SO_4 + Zn\ O + H_2\ O + C$, but I do not know in what proportions they are present, as I have not analysed the contents of a Gassner cell. Zinc chloride is a far more deliquescent salt than ammonium chloride, hence its superiority in a so-called dry battery, since it absorbs and retains the moisture necessary to keep the battery in working order.—G. E. B.

Switch for Bell.—IRON TURNER (*Bolton*).—As your question respecting the construction of the switch and its connections is fully answered in my reply to ONE IN NEED (*Coventry*), I must respectfully refer you to that reply. The switch could be used as you suggest instead of an ordinary push to keep a bell ringing for a long time. All letters received by me receive prompt attention, and are registered, so cannot he forgotten. But there is such a crowd waiting at the printing office! All cannot be served at once, and each are admitted in turn.—G. E. B.

Book on Masts.—J. W. (*Plymouth*).—The following book may answer your purpose:—"Masting, Mast-making, and Rigging of Ships," by Ripping, 2s. 6d., Lockwood & Co.—F. J. C.

Microscope Object-Glasses.—OLD SCOTCH AMATEUR writes a very encouraging letter to the effect that, from the drawings and description given in WORK, he has made a microscope, and that it is a very handsome instrument. He calls himself an old smith, and says that during the last six months he has made a lathe, and that with the aid of this he has made his microscope. Such a letter as the OLD SCOTCH AMATEUR writes is encouraging, not only for those who desire to work, but also to those who, from time to time, endeavour to assist them to do so. In reply to his questions in reference to the cell for object-glass, I will say that each object-glass is fitted into its own cell; so that if he has, say, a 2-in., 1-in., and ½-in. power, they must be mounted in separate cells to fit into K, Fig. 1, No. 22. I would suggest to O. S. A. that he make a brass hox to receive each of the cells; thus, procure a piece of hrass tubing, of a size that when an internal thread is cut in it, it will allow the cell to screw into it. Cut off ½ in. in the lathe, and to the end that has not the thread solder a stout piece of brass, a little larger than the ring. Place it on a chuck and turn down the disc, and finish hy milling the edge. On the outside of the ring cut another thread: this is to screw like a lid into a box. Take 2 in. of tubing, of a size to take the lid when a thread is chased on it. The other end is closed with a disc. When the object-glass is not in use, screw it into the lid and the lid into the hox. It will thus be safe against dust and bad usage. The above sketch will make this matter quite clear. A is the cell of object-glass screwed into B; C is the cover of hox. The sketch is not drawn to scale.—O.B.



Object-Glass.

P.S.—Will O. S. A. explain what he means by a "small pair of chops, which he finds the handiest tool helonging to the lathe?" Personally, I should be glad to know; perhaps others, also, would be henefited by the information.

Coil with Three Powers.—ELECTRIC LUBRICATOR (*Manchester*).—As you know how to make induction coils, I can soon tell you how to arrange the three powers. When winding on the secondary, wind on enough for the first power, then bring the finish end of this out to a stud on the hase board. To this same stud connect the starting end of the second power, wind it on the coil, and bring its finish end out to another stud on the base board. Start from this stud to wind on the wire for the third power, and carry its finish end to a third stud. These studs may be separate binding posts, or simply large round-headed brass studs, arranged in part of the radius of a circle within reach of the arm of a switch. Connect the handles of the shocking coil to the binding post at the commencement of the first power and to the pivot pillar of the switch arm. When the arm rests on the stud of the first power, the shock will be mild, when it is moved to the second stud the shock will be medium, and when moved to the third stud it will be strong, because then the effects of the whole three powers will he combined in one. A sketch will not be needed, and we cannot spare space for unnecessary engravings.—G. E. B.

Electrical Lantern.—A. O. A. (*Plaistow*).—I am now writing a series of articles on Model Electric Lights. When these appear you will see that it is impracticahle to do as you suggest. The generator itself for an electric lamp could not he put "in a hand lantern to he carried about," whilst the sloppy, dirty battery, would, in any size or weight, be an intolerable nuisance. The light from such small electric lamps would be useless in a lantern, as it would not be equal to that of a rushlight.—G. E. B.

Circular Louvre Lights.—DIDO (*Buckland*).—I fail to glean from your short note what it is you exactly require. Are the louvres to be glass, wood, or glazed? Do you wish them to he movable? Are they to be circular on plan or elevation? What purpose are they for? Have you any particular stipulations in the way of construction, etc.? If you will send a sketch (no matter how rough) with approximate sizes, you will prevent me giving a description which might be a very long way from meeting your requirements.—E. D.

Battery for Alarums.—J. C. (*Coatbridge*).—You should have had three cells at least, arranged in series, to work six alarums through 100 feet of wire. You do not say how long it is since you set up the first cell, but it is clear to me that the cause of failure lies in the resistance offered by the first partly worn-out cell. When you added another cell, you supplied enough pushing power to overcome the resistance of the first cell, but now this second cell has lost its youthful vigour, and adds its resistance or dead weight to the circuit. I advise you to discard both old cells, and set up three new ones, to make a creditable job. You do not say what kind or size of wire you have used inside. If No. 18 or 20 copper wire properly insulated with double cotton covering and properly stapled, it will do. The underground wires should have been run through a gas pipe, or else covered with tarred tape to protect the gutta-percha covering. Always provide more than enough battery power, as this is the truest economy. I shall be pleased to advise you at any time.—G. E. B.

Photographing on Wood.—WOOD ENGRAVER (*Birmingham*).—I would point out that the description you give of the process is evidently far from correct, nor have I any idea as to what is intended, unless it be the dusting-on process. It, however, appears to me that the method is a more lengthy one than that described in my article on photographing on wood, which you consider would take up too much time to be of financial value. If WOOD ENGRAVER wants a cheap process, he cannot do better than coat his blocks over with salts of iron as used for blue printing (already described in WORK) and for copying plans, etc. The block, after being exposed under the negative, is sponged with water, and a blue picture appears. I remember my father making all the illustrations for "Science at Home," of which he was the author, by this means.—W. E. W.

Model Slot Machine.—CLAUDIAN (*Nottingham*).—(1) You require no power to drive the machine, the weight of the penny does all the driving that is necessary, unless your machine is to do some kind of work of which you do not inform me. In the chocolate and similar machines, the dropping of the coin releases a catch, and the weight of the material above does the rest of the work. If you will send particulars of the purpose to which you propose to apply the machine, I will give you full information as to its construction. (2) In French polishing you do not need to soak the surface to be polished; let it be made perfectly smooth with the finest glass-paper, then dust off with a linen duster, and leave the work in a room where no dust will settle on it. Then brush it over with a weak solution of white shellac in spirits of wine, being careful that no damp strikes it. When dry pass over a linen pad moistened with pure olive oil; then polish with French polish on a pad of linen over chamois leather, working only about one square inch at a time, and finish off with a fine silk rubber. Some of the old-fashioned French polishers used the ball of the thumb to finish.—F. C.

Plate Shelf. — SIGNALMAN (*Bebington*). — An article describing the construction of plate shelves is in the Editor's hands, and is awaiting its turn for publication. Your former question was received and answered in due course, but it is quite impossible for replies to appear immediately they are written, for all must take their turn. You may be sure that all inquirers are answered as soon as practicable. Pray do not think you are "too young a subscriber" to receive attention, for we want to encourage all workers, whether young or old. Pleased to hear of your increasing interest in WORK.—D. A.

Harp, Design for.—AMATEUR.—This cannot be treated in "Shop." The harp proper is far too complicated an instrument to be dealt with in a brief paragraph. Perhaps some reader will describe, and give a sketch of, a Welsh harp.

Model for Papier-Mâché.—H. G. N. (*Islington*) requires an egg-shaped core, 3 ft. in length, on which to paste papier-mâché. Models for pasting used in the trade are commonly of American ash, but any wood which will stand well will answer the purpose. H. G. N. can either make his core, or have it made, by gluing pieces of wood roughly to the shape and then using the lathe; or, more easily and cheaply, he can turn it from a solid block of beech-wood. The objection to this would be its weight; but it might be made in two or three pieces, turned hollow, and then glued together. The turners of wooden bowls at Berkhampstead and Chesham would readily make him a core in this way. They make their beech-wood stand by boiling it.—S. W.

Tin Pattern Covers. — G. B. (*Manchester*).—Personally I do not know the articles you speak of as bevel wheel guards, and cannot find them in any book. Could you give fuller descriptions of them, with dimensions and a sketch showing them both flat and made up? I might then be able to tell you the best way to get the patterns.—R. A.

Self-acting Blowpipes, etc. — W. F. (*Woolwich*).—The lamp, Fig. 14, is sold by Rhodes & Sons, Wakefield, and, writing from memory, the price is, I believe, 10s. 6d. The Paquelin lamp is 12s. There is no book that gives the prices for doing such jobs as you speak of, and it would hardly be right for me to lay down a standard of prices in WORK; but if you let the Editor have your address, I will write you out a list of prices for a number of simple jobs, what I consider a fair price, and forward it to you, with the Editor's permission.—R. A.

Working Models.—J. H. P. (*Dewsbury*).—I do not know of any catalogue of working models being issued.—F. C.

Audiophone.—DAKER (*Camberwell*).—This instrument is a very simple affair, and is, I believe, the invention of an American called Rhodes, who is, or was, himself deaf. About seven or eight years ago it was introduced to this country through the agency of a Glasgow merchant (whose address unfortunately I am not able to give). The American audiophone consists of a thin elastic sheet or plate of vulcanite, provided with a handle about the size and shape of a Japanese or palm leaf fan. To the upper edge a series of strings is fastened, and these are brought down to the handle, where they are held by a small clamp. These strings bend the plate into a semi-circular form. When the instrument is thus strained into shape it is pressed tightly against the upper front teeth by the deaf person, who holds the instrument in its position by the handle, the rounded side of course being turned outwards. The sounds received upon it cause it to vibrate after the manner of the face of a violin, or the sounding-board of a piano, and these vibrations are thus conveyed through the teeth and bones of the skull to the auditory nerves. Fig. 1 shows the instrument in section, and the method of holding it against the teeth. Fig. 2 is an inside view. The strings are shown unstrained, and the position of the strings are not of importance, provided they give the proper degree of curvature to the plate. So much for the American instrument. It was very costly, owing to the material of which it was made. After its invention it was greatly experimented upon, with a view to find out some material to substitute for the costly vulcanite—sheet metal, wood veneer, cardboard, even paper, all of which produced most wonderful results, some of them producing results far superior to the original material. Indeed, anything of a vibrating nature, providing the form of it has sufficient surface

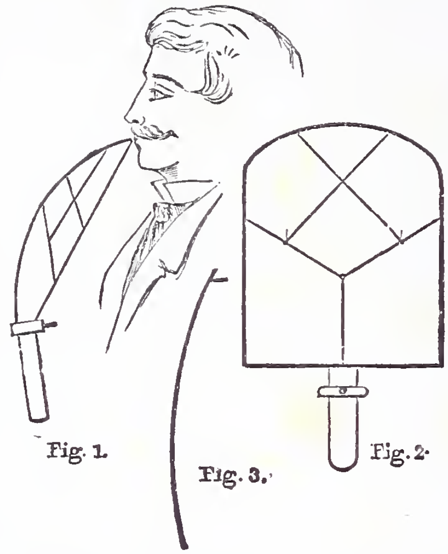


Fig. 1.—The Audiophone: section. Fig. 2.—Inside View. Fig. 3.—Fletcher's Audiophone in Section.

exposed to the source of sound, seems to answer the purpose. This I have found out by actual experiment. I will not occupy space here by giving details of the various contrivances I have made use of. Although the experiments always seemed satisfactory to myself (being possessed of a normal sense of hearing), they might not seem quite so much so to a partly-deaf person. I cannot do better, however, than describe the audiophone made by Thos. Fletcher, of Warrington. It consists of a piece of birch-wood veneer cut oval 12 in. by $8\frac{1}{2}$ in. bent like Fig. 3. The bending is accomplished by steaming it and tacking it down upon a curved board, and keeping it in this position until it is perfectly set. It should then be varnished with shellac varnish, to which a little ivory black has been added, or it may be decorated to suit the fancy of the person who uses it. This being very light it can be held between the teeth without any effort. If the querist makes this, which will cost only a few pence, he will find it to answer much better than the American instrument already described, and he will, therefore, not require the address of the Audiophone Company, which I am sorry I cannot give.—W. D.

Bent Iron Designs. — TIM BOBBIN. — Try B. Bradley, 180, Fulham Road, West Brompton. You can get iron there, and probably designs; if not the latter, I will, with Editor's permission, send an article, with illustrated designs, to WORK.—J.

Iron Strips.—J. P. S. (*Hertford*). — You will probably get these of B. Bradley, 180, Fulham Road, West Brompton.

Wooden Printing Press.—FAUST (*Liverpool*).—I have in my hands a paper on the mode of making a wooden printing press, which will appear shortly.

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—DOUBT (*Glasgow*); E. W. (*Hurstpierpont*); R. T. (*Edinburgh*); F. H. H. (*Wednesbury*); S. B. (*Exmouth*); T. B. (*Sunderland*); M R. (*Burnley*); CLERICUS SECUNDUS; A. R. (*Scorrier Saw Mills*); J. K. (*Nottingham*); J. W. H. (*Holywood*); KEYNSHAM; W. K. (*New Wortley*); W. B. (*Glasgow*); R. W. (*Newcastle*); G. L. (*Liverpool*); F. T. B. (*Slade*); C. H. (*Bloomsbury*); NO NAME (*Reading*); STICKPHASTE; A. F. (*Hamilton*); A. F. (*Bath*); F. N. K.; W. J. (*Belfast*); R. O. B. (*Edinburgh*); G. F. H. (*South Lambeth*); FAIR PLAY; W. P. (*Blackburn*); G. S. (*Fulham*); C. H. C. (*Cheltenham*); A. J. B. (*Peckham*); LITTLE SCOT; T. B. (*Swanley*); J. S. W. (*Glasgow*); CINQUE PORT; A. H. (*Arlington Square*); A. H. W. (*Newcastle-on-Tyne*); D. W. T. (*Sydenham, S.E.*); A. H. (*London, N.W.*); H. M. B. (*Wakefield*); H. S. (*Clapham Junction*); R. W. B. (*Poplar*); ONE IN THE DARK; J. H. (*Heaton*); ALIQUANDO; T. K. (*Glasgow*); J. C. (*Newcastle-on-Tyne*); J. H. S. (*Wigan*); and H. G. (*Liverpool*).

Trade Notes and Memoranda.

ROBERT H. SMITH, Professor of Mechanics in Mason College, Birmingham, England, has made a series of mechanical tests relative to the durability, friction, and temperature of bearings made of magnolia anti-friction metal when running in bearings on journals of different diameters and lengths. In all, between three and four thousand tests were made, in which the temperature of the bearings and the friction were actually determined. In his conclusion he states the metal to be superior either to Babbit or gun-metal for bearings. The results of the experiments show that the temperature of the bearing and friction was less, and durability of the material considerably greater, than the other materials tried.

FOR the cementing of iron railing tops, iron gratings to stoves, etc., the following mixture is recommended—in fact, with such effect has it been used as to resist the blows of a sledge hammer. This mixture is composed of equal parts of sulphur and white lead, with about one-sixth proportion of borax, the three being incorporated together so as to form one homogeneous mass. When the application is to be made of this composition it is wet with strong sulphuric acid, and a thin layer of it is placed between the two pieces of iron, these being at once pressed together. The *Scientific American* says, "In five days it will be perfectly dry, all traces of the cement having vanished, and the work having every appearance of welding."
