With such nicety and exactness, indeed, can an expert joiner or cabinet maker work, that with some woods the joint is only to be recognised by noticing the figure. True, an amateur craftsman can hardly expect to reach this standard, but the novice will know what his aim should be, and by a little attention to the method of working he will be in a better position to make a good joint than the man who goes about it anyhow. Let us take the plain glued joint first of all, and when this is considered go on to the stronger and more serviceable dowelled joint, as well as that formed by ploughing and tongueing.

The plain joint is serviceable enough for thin wood, say for anything under half-inch thick, and in certain situations for material of any substance. When practicable, however—that is, when the wood is thick enough—the novice will find it safer not to depend on plain glued surfaces only. With thin stuff, however, he must do so, as there is no room for dowels.

In any form whatever of "jointing up" the same general principle of working must be observed, so we will begin at the beginning, remembering that the object is to get one wide board formed by connecting several, or it may be only two pieces. Let us suppose the planks are quite in the rough. The first idea that occurs to the tyro will probably be the necessity of smoothing two of the edges so that they may come in close contact with each other.

But here occurs the question—are the edges to be planed, or are the boards to be got nice and smooth first? Assuming my position as instructor for the novice (I hope some of my readers may favour by reversing the position as far as any craft they are connected with is concerned), let me say that this must depend on circumstances. If the boards when joined will be too wide and cumbersome to smooth, then do so before they are joined; but if the width will not be great, say not over two feet, it will be better to plane them when they are together.

Should the boards selected be very rough, they may be gone over beforehand with the "Jack" plane just to get them into fair working order. This, however, is not necessary, and whether to do so or not may safely be left to the discretion of the worker. It will also be seen that widths of over that given will in ordinary cabinet work seldom be required, so it may almost be taken as a definite rule that wood is smoothed over after it has been joined.

The "Jack" plane has been referred to, and I suppose that even but few intending workmen will need to be told that with it the coarser planing is done; but, in any case, we are concerning ourselves with joints, not with planes, so it must be taken for granted that the ordinary forms of this tool are familiar to the worker, if only by name. And here please note that the ordinary "Jack" plane and the trying plane, though very similar in appearance, cannot be used indiscriminately in preparing edges of boards for jointing, nor can the smoothing plane be used so efficiently as the trying plane for the same work. I may almost go the length of saying that a long joint could not be made perfectly with a smoothing plane. This statement ought, perhaps, to be qualified a little, for I am aware that some workmen can joint up with the smoothing plane just as some persons can write with the left hand, but it is not usually done. No; the trying plane is the proper one to use. It cuts finer than the "Jack," and its greater length gives it an advantage over the smoothing plane in planing up a straight edge.

Well, with the long plane known as the trying plane the edges of the board which are to be glued must be got perfectly straight. Get one of them so first, as it will serve as a test for the other. Whether it is perfectly straight or not can easily be ascertained by casting the eye along it, as one does when looking along a gun barrel. Irregularities can easily be detected in the length of the cut, and in reducing any remember that a fine shaving or two will make all the difference. Whether the edge is at right angles with the surfaces of the wood cannot, however, be determined by this means, and it must be tested by the square. For short lengths the ordinary shooting board will be found invaluable, but it cannot be used with long pieces. As long and short are only comparative, I ought, perhaps, to say that anything over three feet may be considered long, but, of course, very much depends on the length of the shooting board. In cabinet work a board six feet in length would be decidedly called a long one, and such only require to be used for sideboard tops, wardrobe ends, etc. etc.

When one piece has been got ready with a perfectly straight edge, the other may be prepared to fit it, and the two should be tried together before gluing them. With short joints both edges should be perfectly straight and level. To try them fix one in the bench screw with the prepared edge uppermost, then take the other and note if it fits closely. If the boards are fairly thick it will not require much experience to know by the feel whether the joint is a good one, or, rather, whether both edges are true. The feel of properly worked edges when rubbed against each other is not easy to explain in words, but it almost may be described as suction. It is almost imperceptible, but is to be distinctly recognised by trained hands. This is alluded to, not so much because the novice can be expected to do such accurate work, as to show those who have no opportunity of seeing good cabinet work in progress what their aims should be. We are almost all more or less familiar with the appearance of things when made up, but comparatively few have an opportunity of seeing work in progress, and I wish to convey to those who have not, as far as may be, some idea of the actual manipulation of material as practised in the workshop. Naturally, it will be a very faint reflex of the actual, but at the same time it will be better than nothing, and if the details seem tedious, remember that in reality the work is much more so. Here, however, I must pause, and leave further remarks on this subject for another paper.

OUR GUIDE TO GOOD THINGS.

60.—The Cartoon Collector's Frame.

It is a relief to turn for a time from the consideration of lathes and appliances of a more solid character to articles that have the charm of absolute novelty, or, at all events, newness of adaptation, such as those which I am now permitted to illustrate and describe, and which are manufactured and supplied by the "Surprise" Box-Table Company, 3, New Inn Yard (186 A), Tottenham Court Road, London, W. Although the first of these is not yet in the market, or, at least, was not in the market when the inventor furnished me with particulars about it, and the second, in its various forms, or, as suited to various purposes, has barely touched it, and is as yet but little known, it is desirable, I think, to call attention to them thus early that retail dealers, many of whom read Work, may seize the opportunity of making arrangements for agencies for their sale, and that, if the inventor grants licences for their manufacture, makers of such goods may hasten to secure the right of manufacture in their respective localities, for, unless I am very much mistaken, both the one and the other will meet with a large and ready sale.

The object of the "Cartoon Collector's Frame," to use the words of the inventor, "is to provide a picture frame with a recess at the back, in which prints, etchings, drawings, etc., may be stored, to enable those who use it to change at pleasure the print on view next the glass, and to store such additions as may be made to the collection from time to time, affording thus a continual variety of pictorial effects in the decoration of a room or other place." This is, of course, from the home or collector's point of view, but professional men, in many cases, can turn the invention to good account, as it would enable a dealer to keep and display some of his stock to the best possible advantage. Again, by its aid, any architect, designer, or artist could collect and place his drawings and sketches, one at a time, under glass for inspection, and an advertiser could make good use of it to secure diversity of treatment and varied exposition for his notices. Moreover, by a simple arrangement of mechanism the frame can be lowered at pleasure from its place on the wall and raised again to it, and even more than this, the frame can be accommodated to the picture by transposing it from a horizontal to a vertical position or *vice versâ* at will.

Thus, in one and the same frame prints may be framed, stored, and changed, and the frame itself may be lowered, raised, and transposed at pleasure, and these various operations can all be carried out quickly and easily. When closed and in position, the frame, whether in a horizontal or vertical position, looks just like any ordinary picture frame, as all means of movement are in no way conspicuous, but, by merely touching a spring under the centre of the frame, it slides downward, stopping in its length. The front of the frame, it will be found, is secured by a button, and when this button is turned the front will open and fall forward in a slanting position, thus affording facility for a change of the picture in front or for adding to the contents. Thus, in Fig. 1, the frame is shown open, but in its proper position, and a stay is shown by which the front is prevented from opening beyond a certain extent. The picture behind the glass may be supposed to have fallen forward on and with the front, and then we see that behind it is another flap, between which and the back pictures may be stored. This is shown more clearly, perhaps, in Fig. 3, in which the flap in the interior is shown open, as well as the front. When the storing, changing, or closing has been effected, the flap and front are closed and the frame pushed upward into its place. Its appearance when reversed or transposed from a horizontal to a vertical position and closed is shown in Fig. 2; Fig. 3, in addition to a complete exposure of the interior, also shows the means of transposition, which is effected by holding the sides or ends of the frame between the hands, and moving them laterally from left to right or right to left, according to the position the picture may require. The picture cord is attached at its ends to a bar, on which are two buttons, on which a piece of semicircular form moves by means of a slot of the same shape cut near its edge. To this is attached another piece on which the frame itself slides. The frames are made in many various sizes, to take pictures from royal quarto ($11\frac{1}{2}$ in. × 9 in.) to atlas (33 in. × $26\frac{1}{2}$ in.), selling respectively at from 7s. 6d. to £1 17s. 6d. when supplied in oak.

61.—The Artist's "Surprise" Box-Table.

This ingenious invention enables what is apparently nothing more than a simple box or case with a handle for transportation from place to place, and a surrounding cincture, to be turned with very little trouble and very quickly into a table displaying every convenience for artists' work, as shown in Fig. 4. The height of the table when opened out for use is 27 in.; its size, when closed up, that is to say, when in its box form as shown at c, in Fig. 4, is $14\frac{3}{4}$ in. × $11\frac{3}{4}$ in. × $4\frac{1}{4}$ in., and its total weight is 8 lbs. The artist's table is supplied at present in two forms —No. 1 and No. 2. The former costs £2 10s., made in oak, walnut, or mahogany, or £2 15s. if polished. The latter is supplied with three trays for pastels, and fold-over flaps for table, and is supplied at £3. Waterproof bags to contain the box-table when in transit are to be purchased at 3s. each. No more complete or portable apparatus can be imagined for the use of artists. It may be bought in other sizes than that given above at proportionate prices, and the principle is applied in the same manner to box-tables for writing, match scoring, chess and other games, luncheon, and for work-box and toilet purposes, storage being provided in every case for all necessary articles in connection with the purpose for which each box-table is made. Supposing the box-table to be closed, as at c, all that is necessary to bring it to table form is to unbuckle the strap, and, holding the box firmly between the feet, to lift the upper portion evenly until the legs of the trellis work shown in Fig. 4, at A and B, are drawn up to the stops. Then, lifting the catch, the cross bars at the bottom must be turned towards the trellis feet till the catch drops in the slot and holds. Lastly, gently press the top down till all the feet are tight up against the bars, when the table will be found perfectly rigid. To close the box, all that is necessary is to release the check at the bottom and press downwards, when the table will shut up and resume its original box-like form. At A, the table, when opened, is seen as from the front, the top being lifted, to form an easel. At B, it is shown as seen from behind. Within the box are the levers by which the parts within are elevated or depressed. These parts come out of the lower case, and consist of an upper portion forming table, material case, and easel, and a tray with divisions for colours, brushes, dippers, etc., and a lower portion forming a tray for the palette and support for brushes, etc., when painting. There is a recess in the lid in which two millboards, each $13\frac{3}{4}$ in. × $10\frac{3}{4}$ in., may be carried, with means to keep them from touching. The lid is adjustable to any angle, and provided with check rests for sketching board. The bottom is furnished with a spike to hold to the ground. When closed, a strap is passed round the centre, or a metal band with lock and key is used to keep all secure. A camp stool may be carried with the box under the strap to complete equipment, and if it be considered desirable to provide means of obtaining shade and shelter as well as rest, an umbrella may be added which may be placed under the strap that surrounds the box and holds the camp stool in durance until released to meet the needs of its owner.

The Editor.

I.—LETTERS FROM CORRESPONDENTS.

Securing a Patent: My Experience.—AJAX writes:—"Having made up my mind to apply for a patent, my first step was to get the Patents, Designs, and Trade Marks Act, so as to get the fullest information. This can be obtained from Eyre and Spottiswoode, price 1s. 10½d. And having learnt that the Patent Office Library (25, Southampton Buildings, W.C.) is open free till ten o'clock each evening, I spent several evenings there, after I had done work, searching the Index Books, to make sure I should not be infringing any existing patent, examining specifications and drawings made out by the various agents, and taking notes to assist me in making out my own. Having procured the necessary form of application for provisional protection, which can be had free, at No. 6 Room Royal Courts of Justice, I filled them up at my leisure, and took them back to the Royal Courts of Justice to get them stamped, the cost of which is £1. This gives protection for nine months. I then deposited them at the Patent Office close by. During the next few weeks I was kept well supplied with circulars from patent agents, offering to get it through for me. But as my funds would not allow of this, I was obliged to dispense with their services. Some I received from America and Canada, which I declined for the same reason. About a fortnight after my application I received a letter from the Patent Office objecting to the title I had given as being of a fancy nature. The letter went on to say, 'If, as appears from the description, the invention is an improved apparatus to facilitate, etc., this should be clearly stated in the title.' I understood by this that if I wanted a fancy title I should have to register it as a trade mark, and that the only title the Patent Office would accept was the one indicated in the letter. I accordingly made the necessary alteration; and shortly afterwards I received a notice to say my application had been accepted. My next step was to hire a small workshop where I could work for an hour or two in the evening. And as my invention was an article complete in itself, I thought I would make several, and advertise them, and as I sold them use the money to increase business. This appeared to be very good in theory, but it was very different in practice. I had some circulars printed giving a full description of the apparatus, and inserted a few advertisements in suitable papers. I received many replies from all parts of the country, asking particulars and name of nearest agent where it might be seen. The only answer I could give was that I had no agent at present near them, but would send article on receipt of cash. This was like buying a pig in a poke, and looked so much like a swindle that it is not surprising that I heard no more from them. Now and then, one more venturesome than the rest would forward the money. But they were too far between to be of much help to me, and I found myself gradually getting into difficulties. Five journals, including *Invention*, kindly gave an article in its praise, and I received several testimonials. This gave me the hope that if I could hold out long enough I might succeed in the end. The months flew by, and it became necessary for me to send in my complete specification. I got the form in the same way as before (unstamped), made out my drawings, and wrote a more detailed account of my invention, clearly stating in what I claimed protection. And as the Patent Office made no objection, I received my patent in due course by post, twelve months after my first application. The stamping of these papers cost £3, making a total cost of £4 for the patent. This was the last straw. I had secured my patent, but I found myself very much in debt. Most working men with a family know what that means. It means a long struggle before you get straight again. I gave up making, and tried to sell the patent. And now for the first time I began to see the advantage of employing a patent agent. Had I been able to do so at first he would have been interested in trying to find a customer for it. I also found that capitalists have very little confidence in a patent that has been secured without the aid of an agent. Of course, if a man in business makes an improvement in an article that he has already before the public, it is all very well. But my advice to any one without capital who has something new is to place it in the hands of an agent to get it provisionally protected, and place it in the market at once, so that the buyer bears the expense of patenting it. But should he prefer to act for himself, there is nothing to prevent him doing so. Of course, being in London, I had a greater advantage than any one would have who lived in the country. But there are many cheap excursions to London which a man might take advantage of; and while his friends were sight-seeing, he could spend the day at the Patent Office, where there is every convenience for writing out specifications. And they could be stamped and deposited at the office the same day." [You have doubtless done the only thing I could advise—namely, to submit your invention to dealers in instruments and persons connected with the musical profession. I myself am not competent to give an opinion on it, for I cannot play any instrument myself, and know nothing about music. Possibly some patent agent might take it in hand even now, on payment of the necessary fees. At present it is, I presume, worth nothing to you, or, rather, bringing in nothing; and if it were possible to do so, I would rather dispose of it for a small sum and recoup even the original cost of the patent than permit it to be utterly unprofitable. I daresay it may be objectionable to you to adopt this course, but after all it is only a common-sense way of looking at and dealing with the matter. I cannot help you to *sell* your patent.—ED.]

In Praise of WORK.—J. P. R. (*Liverpool*) writes:—"I purchased the first copy of WORK as a matter of curiosity, and I was so pleased with the lucid manner in which the various articles were written, that I have continued to take it weekly. Not only so, but I bring the paper under the notice of my friends whenever an opportunity occurs. It is just the kind of paper required by amateurs, for it goes so thoroughly into details that the 'merest tyro' could not fail to understand and work out the instructions set down for his guidance. I wish you particularly to kindly convey my personal thanks to Mr. David Adamson for his very valuable, graphic, and lucid articles published in Nos. 2 and 3 of WORK on artistic furniture—'An Overmantel.' I read the paper with great interest, and was so struck with the simplicity of the work described, that I determined to commence at once and make an overmantel myself from the drawing shown in No. 2 of WORK. In the first place, I may say I am an amateur, pure and simple, never having earned sixpence at joiners' work in my life, with very little spare time, and very few tools; but I find a great amount of work can be got through by an amateur when his heart is in his work. I commenced the overmantel on April 1st, and had it finished and in its place on the mantelshelf on Saturday, May 21st. I have only an hour or two in the evening, and that not every day, and part of Saturday afternoons, in which to do the work. In making the overmantel I have kept to the design, but varied the measurement, so that the work when finished would be the entire length of the mantelshelf; in place of wood panels to the doors I have fitted sheet-glass, with a shelf in each cupboard for books. Fitted in the back are four pieces of plate-glass mirror; the woodwork finished with dead black and gold, and varnished. The entire cost, including timber, plate-glass mirror, glass for doors, ironmongery, paint, gold leaf, and varnish is 35s. For which sum I consider I have a very artistic and handsome piece of furniture—so much admired, that all who have seen it are so struck with the originality of the design that they are anxious to possess one like it. My answer is, 'Subscribe to WORK, and commence to make one yourself.' Not only do I consider it handsome and cheap, but from the very fact of having made it oneself, enhances its value in the eyes of the worker. I shall be very pleased to show the overmantel to any subscribers to WORK that may reside in my neighbourhood, and give any information they may desire, if they will call upon me any evening after seven p.m. I wish you all prosperity with your new undertaking—WORK; and trust it is, and will continue to be, a financial success."

Bronze Blue.—W. B. (*Lenton*) writes:—"I hereby send you a suggestion with reference to your excellent paper WORK, which I hope you will work out. Excuse me for taking the liberty for sending this. But on page 158 in 'Shop' you will find under the heading 'Litho Bronze Blue' what I wish to point out. That answer is only of use to the person who asked for it. Would it not be as well to put the question with all short ones, so that others may understand them, and so that those who are in the same trade might make use of them, and know what they are using them for? Is the question one of the blue sticking on the stone, or what?"—[Your suggestion, which is a useful one, shall be followed as far as possible. All who answer questions are requested to show by their answer what the nature of the question was. If questions were put briefly, and written on a separate piece of paper, each could always be given before or above the answers to it. But not one correspondent in twenty observes this rule, which, if universally adopted, would greatly facilitate matters. The question asked was—"I had a job to work in bronze blue, and it was rather inclined to take the work off the stone, and I should be very much obliged if you could give me any information so as to prevent that occurring again; if so, you would greatly oblige."—ED.]

Sharpening Carving Tools.—D. D. writes:—"Notwithstanding J. W. B.'s remarks in page 172 about sharpening carving tools, the method he advocates is decidedly an amateurish one, and is open to several objections. Instead of fastening the slips in a handscrew, a much better way is to practice the method adopted by most, if not all, good practical carvers, who certainly would not prefer it unless it were better. This is the advice of one who knows."

Lesson for Lesson.—J. H. (*Walthamstow*) writes to the effect that it is easier to learn how to do anything when we are *shown* how to do it, than when we are *told* how to do it. He suggests that one reader of WORK should give a practical lesson, say, in carpentry and joinery, to another reader, in exchange for a practical lesson in some other trade, and would be glad to hear the opinion of fellow-readers. This is the pith of J. H.'s letter, which I am obliged to give in this way in order that all readers of WORK may easily arrive at his meaning.—ED.

Per Contra.—C. G. W. (*Barnsbury*) writes:—"Although 'only a clerk,' with an earnest desire to 'spoil wood,' as described by one of your correspondents in WORK, permit me to congratulate you, despite the criticism which, even if justified, might have been made in a less high-handed and less conceited style than your correspondent has done. Probably if the truth were known he is not in the first rank of his craft, and, perhaps, he will permit me to inform him that the more one knows the less he thinks he knows, and he is the more anxious to learn more. It therefore follows that it is only the ignorant who fancy they know all. I should strongly advise your correspondent to start a paper on the lines he suggests, if, as he contends, he has a better knowledge of the wants of readers than a firm who are one of the largest, if not the largest, publishers in England, may be, in the world, and who annually issue a greatly diversified amount of literature. In conclusion, may I be allowed to make a suggestion that will be of benefit to the amateur and professional alike, and that is, that in the description of the manufacture of an article the approximate price of each part, and of the whole when finished, be given?"

Measuring up Painters' Work.—A. H. (*Edinburgh*) writes:—"As an admirer and anxious reader of your valuable little WORK, I venture to suggest that when the series of papers on house painting come out in your journal, you might see your way to introduce a few practical remarks on measuring. This is a branch of the business that very few painters understand thoroughly. There are books on this subject, but more practical knowledge would be gained from one in the trade. The reason I write this is that the papers on sign writing and lettering are so ably written that this subject, I am sure, would be properly treated; and, speaking as one connected with the trade, I know that the remarks would be appreciated. I wish your grand little paper every success."

Enlargement of WORK.—F. A. C. (*Bradford*) writes:—"I beg to say that I, as one of the readers of WORK since its birth, would very much like the paper to be doubled, or even trebled; and I quite hold with T. J. H. (*Trowbridge*), and I think that there will be a lot of grumbling until it is made into a larger paper (price 3d.). It is nearly impossible to treat all amateur and professional work fairly in the little space you have allotted. I am not grumbling, because I myself have had my share of oats, doing mostly woodwork, fretwork, etc. I wish every prosperity to WORK, and hope that it may be made larger."

About WORK.—G. B. P. (*Birmingham*) writes:—"Allow me to congratulate you and the powerful staff at your command in answering us correspondents in all parts of the provinces, and I must say on the behalf of workmen here and myself, that in bringing out WORK in its present perfection it will do us all good from a practical and monetary point of view, and I for one have no hesitation in saying that WORK is the premier paper for any amateur or professional man to study; but of course you must be tired by this time of having so much praise sent you, but in sending your answers to correspondents I cannot help but praise your inestimable WORK."

About WORK.—ARTISAN writes:—"I have taken in WORK since the beginning, and as a practical man think it likely to prove on the whole a very useful paper for workmen of all kinds. If it has a fault, to my idea, it is amateurish. Probably amateurs bulk largely (more largely, perhaps, than professionals) in your circulation, but still I hold that sound workshop methods of construction would be much more satisfactory all round than some of the makeshifts so largely adopted by amateur tradesmen, and sometimes advocated by contributors to your paper. This, as I have hinted, is the only fault I have to find with WORK, and I have taken the liberty of writing you, not through any carping, fault-finding spirit, but from a sincere desire to assist in making the paper even more useful as a workman's friend. Please do not suppose in what I have said above that I am making any reflections on the ability of the contributors to WORK; on the contrary, I believe them one and all to be thoroughly competent teachers of the various crafts they write about, and that, sir, is just the reason why I feel uneasy when I see talented writers such as they are sometimes advocating methods of construction which they know would not be tolerated in any workshop in the country. Under these circumstances I was very glad to see your remarks in this week's paper in defence of your review of ponderous and expensive tools. I thoroughly agree with you in all you say there, and I say review every new labour-saving tool that comes under your notice, either large or small, or WORK will not be so useful as it might and ought to be to the professional reader. I intend availing myself shortly of the undoubted ability of your staff. Your 'Shop' column is a valuable privilege, which I should be sorry not to take advantage of; meantime I shall not trouble you further than by asking you to review as early as you can the new dovetail cutter produced by the Britannia Company to work on circular saws."—[As soon as I have sufficient information about the dovetail cutter, or, better still, have seen it, I will report on it in "Our Guide to Good Things." I put your letter into type, because it is helpful with other readers. Amateurs, as well as professionals, read WORK, but the latter largely predominate, and it is very largely bought by the rising generation of workmen. It is just because the modes of construction described "would not be tolerated in any workshop in the country" that they are described. A mode of construction that is strong, stable, and serviceable, is not to be ignored or regarded as belonging to, or fit for, the amateur alone, because it is not the stereotyped method adopted in the shops. It is not "scamping," and I am not ashamed to say that I prefer work done fairly, strongly, and well, even by bye paths of construction, to things thrown together in the legitimate way perhaps, but bearing the impress of haste and want of care when you look into them, the looking-in, perhaps, being induced by the evident tendency of the parts to part company, through the article being of rickety constitution. I append these remarks to your letter, not with any idea or wish to deprecate accepted methods of construction, but to point out that there can be no absolute need to proceed on stereotyped lines, if any other method which saves time without lessening strength can be followed. Both modes are good of their kind, and the workman can follow whichever he prefers, or whichever he thinks is best suited for the job in hand without incurring blame.—ED.]

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Material of Kitchen Utensils.—F. C. (*Bedford Row*).—They are made of sheet iron coated with tin. The "block tin" plates, technically termed "doubles," are superior to the commoner kinds, first, because the covering of tin is thicker, and secondly, because they are well hammered upon a polished anvil, the better to consolidate the metal. —J.

Tools for Home Work.—R. R. W. (*Glasgow*).—When you ask me to decide without knowing a great deal more of your aspirations than you tell me, what are the best tools and fewest to buy for home work, such as model engine making, etc., I am puzzled to know how to answer you. That "etc." may include such a lot; then do you want to make your own patterns and castings, or to get the latter and fit them up? I shall presume the latter, in which case you might make shift with two or three files, a drill stock, a die and taps for screws, and one or two other small things, such, for instance, as those recently described in our articles on boring cylinders. A lathe also is a convenience, if not indispensable. It depends really so much on the exact class of work you wish to undertake that it is almost impossible to say more than I have; but if you will write again, and state the sum you contemplate spending on tools, I will make out a list of those which, in my judgment, would be the fewest and best.—D. A.

Art Repoussé.—(*Glasgow*).—See answer to W. E. S. (see page 205) for transferring and address for tools. Hammer and handle together should weigh from 3 to 4½ ounces. Pitch, 11 parts; resin, 7; tallow, 1; and brickdust 5, will make a very good composition; but Gawthorp's special cement can only be obtained of him, at 16, Long Acre. In mixing the above, powder the brick finely, and add, after melting and mixing, the others, stirring all the time. By "tooling over" the raised parts is meant putting in the fine texture of feathers, leaves, cloth, skin, etc., after those parts have been raised from the back, and is done by lightly and skilfully hammering a very fine tool, according to the texture required, over those parts. This is very difficult, and is more easily learnt by practical tuition than by explanation. It greatly enhances the effect of the work.—G.

Broom and Brush Making.—T. M. (*Rochdale*).—The fibre, or bast, a specimen of which you enclose, is made up into small bundles of a size sufficient to enter the holes made in the wood, and then fixed by running melted pitch into each hole. If you are going to try to make brooms and brushes for your own use, be careful with the melted pitch; fill the holes with fibre, one by one, fastening each in succession with the pitch, melting it in a can or tin furnished with a spout or nozzle, and hold the fibre firmly against the bottom of the hole when you are pouring in the pitch.

Paper for Pasted Papier-Mâché.—J. H. S. (*Romsey*).—The paper made specially for pasted papier-mâché is of a grey colour, about the thickness of medium blotting-paper, but rather more close and firm in texture, and unglazed. It is now made to order only, and may be procured through Messrs. McCallum & Hodson, Summer Row, Birmingham, who would doubtless give particulars as to price. There are plenty of papers answering to the above description to be bought at any paper warehouse which would do equally well. The special paper has no especial merits.—S. W.

Scale for Bassoon Stop.—AMATEUR ORGAN BUILDER (*Arundel*).—Your wish for a small scaled "bassoon" stop for your organ can be carried into effect by making the pipes the same diameter at the top as those of the open diapason an octave higher in pitch. Thus, your 8-foot C bassoon would be the same diameter as the 4-foot C open diapason. I presume you know that the bassoon is a reed-stop, and that the wood pipes are conical in shape, with the point at the bottom which fits into the boot containing the reed. If made of wood, these pipes are square on plan; if metal, they are circular. The "gemshorn" is a flue pipe of a conical shape, the point in this case being at the top. At the mouth, where it joins on to the foot, it should be about one scale less than the open diapason for the same note; and at the top it should be one-third of that diameter. Cut up the mouth rather more than a fourth of its diameter, and nick rather finely. You are in error in supposing that this stop is used only for chamber organs; it is used both as an 8-foot and as a 4-foot stop on many large organs, and there is one in the beautiful organ at the Temple Church, London.—M. W.

Soldering Iron.—H. A. (*Chesterfield*).—I wish your queries were of a specific character, because when you ask for "hints" I do not know precisely what kind of hints to give. In reference to soldering, of course you know that the first essential is absolutely clean surfaces, first scraped and then covered with a flux, to prevent the formation of oxides, or to dissolve them as soon as formed. Resin, or spirits of salts killed with zinc, are used. The soldering "iron," more properly the "copper bit," is first heated to a dull red, quickly cleaned with a file, rubbed on a piece of sal-ammoniac, and dipped into solder; being then wiped with tow, it is ready for use. The copper bit being drawn along the edge of the joints in contact, both melts the solder and warms the work. The copper bit must not be overheated, or it will not pick up and distribute the solder.—J.

Guide to Photographing.—P. C. G.—The best thing P. C. G. can do will be to obtain an elementary book on photography, of which several excellent ones are published. Burton's "Modern Photography," or "Photography for Amateurs," by T. C. Hepworth (Cassell & Co.), are thoroughly reliable and easily understood. These columns are scarcely adapted for a course of instruction in any art, the space being limited.—D.

Papier-Mâché Trays for Photographic Purposes.—J. G. B. (*Dudley*).—The black japan varnish with which papier-mâché is covered would resist acids for a long time, but, as any accidental injury to this coat would place the paper at the mercy of the chemicals, J. G. B. is scarcely advised to adopt papier-mâché trays. His other query he will find answered in our reply to J. H. S. (*Romsey*).—S. W.

Wood for Fret Sawing and Carving.—WOOD SPOILER.—I repeat part of my reply to E. G. (*Ipswich*) in No. 8, page. 126. With reference to fretwork, wood may be bought of R. Melhuish and Sons, 85 and 87, Fetter Lane, London, E.C.; Henry Zilles, 24 and 26, Wilton Street, Finsbury, E.C., and Charles Churchill & Co., 21, Cross Street, Finsbury, E.C. To these I may add the names of Messrs. Thomas J. Syer & Co., 45, Wilson Street, Finsbury, E.C., of whom wood for carving may be obtained. In Liverpool wood for fret cutting may be obtained from G. Busschotts, Park Lane; in Bath, of Fritz Collins; in Settle, Yorkshire, of Messrs. Harger Bros.; in East Dereham, Norfolk, of Messrs. J. H. Skinner & Co.,; and in Dublin of Booth Bros. From most, if not all, of these wood may be bought for turning or carving. I shall be glad to be favoured with the names of dealers in wood of all kinds in all large towns and other localities. I should then be able to refer any applicant to the dealer that is nearest to his own place of residence.

Carpenters' Bench, etc.—NAIOS.—You shall have the description of one or two carpenters' benches before long; a strong bench of the ordinary form, and a folding bench for light work to fall back against the wall to which it is attached. It is difficult, as I know from experience, to do without one. A paper for mounting a small grindstone has just been sent in by a valued contributor to WORK, and shall appear as soon as I can find room for it. The boards of a kitchen table may be tongued and grooved, or pointed up by dowels. You can get a patent iron tonguing and grooving plane for about 10s. 6d.

Advertisements in WORK.—AD FINEM.—I am glad to find that you are making progress in carpentry by the aid of WORK. With regard to the advertisements that appear in each number, I can only say that there are many who find them to be useful, and value them accordingly. For my part, I am disposed to think that in time to come they will be considered as constituting one of the most valuable portions of WORK, inasmuch as they will form ultimately a finger-post and directory which will help the workman to many a useful article which he might possibly look for in vain, were it not for the seasonable *vade-mecum* placed at his disposal by the very pages to which you are now pleased to take exception. It must be understood, to avoid useless repetition, that with regard to future letters on this subject I can do no more than refer their writers to this reply.

R. T. (*Bolton*) and A. B. T. (*Wycombe Marsh*) are requested to consider the above as a reply to their letters also.

Tarnished Clock Dial.—S. F. (*Gubal*).—You made a mistake in cleaning it the first time, as, in doing so, you cleaned off the lacquer, the only thing is to thoroughly clean it again with bath brick, and finish off with whiting, then give a coat of lacquer, when it will be good for years. If it gets dull or dirty wipe over with a damp cloth; the circle with the numerals on should be silvered, when it will show up the hands better, as well as the lacquered brass.—A. B. C.

Naming Deal and Pine Woods.—TYRO (*Edinburgh*).—Yellow and white deal are usually known as "deal," although pine may be so called. For instance, you speak of a "deal box;" you mean one made of pine, not of any hard wood. In the trade a "deal" is understood to be a size—*i.e.*, $2\frac{1}{2}\times 9$, 3×9, or 4×9.—A. J. H.

Covers for Bookbinding.—M. W. M. (*East Dulwich*).—C. Hindley & Son, Oxford Street, sell the Japanese leather paper. Liberty's had remnant bundles at 1s. and 1s. 6d. lately. I know no good manual on the subject.—E. B. S.

Books on the Power Loom and Weaving.—D. B. (*Perth*).—A good book on the subject is "Spinning Woollen and Worsted," by W. S. B. McLaren, 4s. 6d., published by Cassell & Co., Ludgate Hill, London, E.C.

Castings for Engine Cylinders.—T. W. (*Gray's Inn*).—Go direct to the founders. There are very few good steel founders in the market. From ample knowledge of their castings during several years past I can recommend Jessop's and Hadfield's, both of Sheffield, but I question if they will care to undertake such small work as you want; neither would the castings be of much use for your purpose; but you may try. You must not use wood for patterns that is liable to warp. Thus, you should not use elm, ash, or unseasoned mahogany or pine, otherwise, almost any wood will do for patterns. The best of all is mahogany. By the way, is not your cylinder of 2 in. bore and 2 in. stroke rather oddly proportioned?—J.

House Painting.—HARLOW.—Our correspondent desires help in estimating for external house painting in a country place about twenty miles from London. Prices of house painting are materially governed by the rate of wages paid in the district in which the work tendered for is situated. For instance, house painters' wages in best part of metropolis is 8½d. per hour, whilst in the outlying districts and suburbs 7d. and 7½d. would be the general rate of payment. In the present instance we assume that the painter's wages in the district indicated is 6d. per hour, and that our inquirer has no personal experience of such work wherewith to gauge the cost of the job. Let him, therefore, in the first place, examine carefully the condition of walls, the putty of window glazings, which frequently requires replacing, and, if necessary, provide for repointing round doors, etc., as well as the first-mentioned plasterers' or masons' work. The cornices, sashes, and doors should then be separately noted, and allowed for at the following prices:—Cornices, if consisting only of plain mouldings and no ornamental casting, and if within reach of a ladder which one man can with safety handle, 6d. to 8d. per yard, lineal or "run," as it is usually termed; if cornice has dentils, or such like enrichment, and requires more labour for ladder, etc., from 10d. to 1s. per yard, lineal, would be a fair charge. Window sashes, frames, sills, etc., if in fair condition, and twice painted, finished in two colours, 2s. 6d. to 3s. 6d. each, according to the size and number of squares of glass in each. If *sashes* are to be grained oak and varnished also, add for these two processes, 1s. 3d. to 1s. 6d. extra to above. Front doors either grained oak and varnished, or plain colours and varnished, are worth the same, since the latter must have more care and preparation to look well than the grained work, where the "figure" takes the attention of the eye, usually requires. The most ordinary front door is worth about 5s., and ranges for a good panelled door and door frame of a large house up to 30s., and higher. For the plain cemented wall-work 6d. per square yard, for two coats "white lead and oil" paint, should pay our correspondent if the house is a fair distance around and within reach of, say, a 40-round ladder. If much of the wall space is above a height of 40 ft., then more strength and time will be necessary to handle ladders with which to execute the work, and 8d. per square yard for two coats must be charged. Four coat work on new cement would be worth about 1s. to 1s. 3d. per yard, according to the convenience, etc., above mentioned. Beyond these prices very little written advice or help can be given, since much still will depend upon the condition of the work, the situation of job, its management and practical supervision, the cost of material differing very considerably between the large employer and a small buyer, and upon which questions the profit or loss depends very materially. Practical experience and observation are the best standards of judging house painting by, and although we, from personal experience and knowledge, can confidently recommend the prices given as being fair pay for fair work, we recommend the inquirer to exercise every care lest he should burn his fingers. After calculating the job on the scale given, it would be a good plan to check it, if possible, by judging the probable cost of time, materials, and incidentals required for its execution: should this leave a margin of about 20 per cent. between the measured estimate and the latter calculation, a fair tender would have been arrived at by that scale. To such as HARLOW we recommend the careful study of our practical treatise on house painting, which will shortly appear in WORK.—F. P.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Small Furnace.—G. T. M. (*Liverpool*) writes:—"Would a reader kindly tell me how to make a small furnace for melting steel, as I am going to make some steel castings, and also what kind of sand to use for moulding?"

Cylinder Marine Engine.—BON FIL asks for "dimensions, etc., for making a working drawing of a two-cylinder marine engine and boiler to be fitted into a boat, 5 ft. long by 9 in. broad, and 7 in. deep, made of sheet iron."

Gear Wheels for Lathe.—C. E. H. (*Warrington*) writes:—"I should be very much obliged if you could inform me where I might obtain two pairs of gear wheels, one pair 2 in. in diameter, the other pair $\frac{1}{2}$ or $\frac{3}{4}$ in. in diameter, to form back gearing for a lathe of $1\frac{1}{2}$ in. centres, which I am making. Please let me know as soon as possible through your 'Shop' column, as I am waiting for them. I am well pleased with your paper."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Polishing Oak Floors.—G. B. P. (*Birmingham*) writes in reply to H. N. (*Bexley Heath*) (see page 174):—"If you cannot get the required polish on your oak floor with beeswax and turpentine, adding plenty of elbow grease, why not varnish it, scrape off your wax, and give three good coats of the following, and you will have a good hard polish that will last for years:—1 lb. shellac, $\frac{1}{2}$ lb. resin, and 1 quart of naphtha; thoroughly shake till dissolved, and apply with a $2\frac{1}{2}$- in. camel-hair brush. If you would rather wax it I will send you instructions and a good recipe with pleasure."

Wood Colouring.—G. B. P. (*Birmingham*) writes in reply to OX GALL (see page 174):—"You want a good old oak stain. Procure a pint of turpentine, and add $\frac{1}{2}$ pint of Brunswick black, and you will have a good and cheap stain for your pine overmantel. You cannot dull polish without a lot of work (not properly), but try three coats of fine spirit varnish; after each coat sandpaper with No. 0 paper, and after last coat of varnish brush well with pumice powder."

Glaze for Finishing French Polishing.—G. B. P. (*Birmingham*) writes in reply to W. H. B. (*Redditch*) (see page 174):—"Glaze used in French polishing is made by dissolving $\frac{1}{2}$ lb. gum benzoin in 1 quart of methylated spirits. Thoroughly pound up the benzoin, then add to the spirit, shaking well every day for a week, then strain, and it is fit for use. Why not finish with pure spirit, as glaze is only fit for common work?"

Sounding Board of Dulcimer.—W. S. M. (*Leeds*) writes in reply to DULCIMER (see page 174):—"I see in your issue of WORK for June 1st, an application for the dimensions of a dulcimer sounding board. Dulcimers are made in several different sizes, according to the pitch of tone required. If your applicant will communicate with me, stating whether he merely wants a dulcimer for home amusement, or suitable for platform, or playing with other instruments, I shall be pleased to forward him the information he requires, or I can supply him with an instrument, if he prefers buying to making one. Last year I was awarded a bronze medal and certificate at the People's Palace, London, for improvements and richness of tone in the manufacture of dulcimers and mandolines."

Pattern of Plane for Casting.—A FOREMAN PATTERN MAKER writes in reply to E. P. W. (see page 172):—"Though there is some advantage in casting a piece across the mouth of the plane, I do not think it at all necessary if soft Scotch iron is used. If inferior hard iron is employed, then it is well to thicken the metal. Actually the metal where the iron has to bed would not come to a keen or 'feather edge' in any case, as that edge would be cut off in the pattern, and in addition there would be the allowance of extra thickness for planing on the bottom—say $\frac{1}{16}$ in. or $\frac{3}{32}$ in. Then there is the strip cast across the inside face, to give the iron a bedding above the bevelled facet, and this keeps the metal rather hotter there than elsewhere, aud so tends to prevent chilling. As a matter of fact, all the outside surfaces of an iron plane are hard when they leave the mould, but such hardness is only skin deep, and is removed by grinding, previous to using the file. I may add also that I speak from experience, but admit, at the same time, that the class of metal used will have a vital influence on results. I particularly mentioned, however, soft eastings in my article, page 50."

Etching on Steel.—G. T. (*Landport*) writes in reply to EXCELSIOR (see page 125):—"The reason for my writing is in consequence of EXCELSIOR asking in 'Shop' for a practical substance for etching on steel. The substance which I have used very successfully for etching names on steel tools is sulphate of copper or common bluestone, which can be obtained from any druggist; a pennyworth will do a good deal of work. The way I use it is this: I take a small crystal of the bluestone, and crush it into powder, and then add to it a very small pinch of salt, and moisten it with a little water; then, having written the name in soap in the ordinary way, I drop the moistened bluestone on to the writing, and after letting it stand for two or three minutes, I wipe it off, and it is marked quite plainly. Of course, the longer it stops on the deeper it goes. This is when I have a few names to mark, but when I have a quantity I make a solution of bluestone; and for etching designs I think this would be by far the better plan. To make the solution I crush some crystals into powder, and put them in a small bottle with a small quantity of common salt, and pour hot water on them, and shake until all is dissolved. It is best to keep adding the powdered crystals until the water will dissolve no more; by this means you will get the strongest possible solution. If kept corked, this will keep its strength for months. In using this for etching designs it would be advisable to make a ridge of soap outside of the design, so as to keep the liquid from running off on to other parts."

IMPORTANT PRIZE COMPETITION.

THE Editor of WORK has the pleasure of informing his readers that Messrs. CASSELL & COMPANY, LIMITED, have placed at his disposal the sum of

THREE GUINEAS,

to be distributed in Prizes for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

which, at the close of the present year, will have attained the aggregate number of TWO HUNDRED AND EIGHT. The books are in themselves of world-wide interest, and may be regarded as forming the front rank of our British classics.

In order to give a fair and proper idea of the space or accommodation that will be required in the Bookcase for the whole of the volumes up to the close of 1889—two hundred and eight in number, as already stated—it is desirable to say that each volume, bound in cloth, is $5\frac{7}{8}$ inches long, 4 inches wide, and about $\frac{1}{2}$ inch thick; or, to be more precise, the linear space filled by thirteen volumes is $6\frac{3}{4}$ inches in length, which admits of the volumes being placed on the shelves without any possibility of being crowded too closely together, to prevent easy withdrawal of any single volume at pleasure. As 13 is the sixteenth of 208, the space required for this number of volumes can be easily calculated.

In order to give satisfaction to as many competitors as possible, the Editor of WORK thinks it desirable to divide the sum offered by Messrs. CASSELL & COMPANY into Three Prizes, as follows:—

FIRST PRIZE ... One Guinea and a Half.
SECOND PRIZE ... One Guinea.
THIRD PRIZE ... Half a Guinea.

Intending Competitors are placed under no restriction as to Form, Arrangement, or Ornamentation, as it is the Company's desire to elicit from the readers of WORK an Original Design for a Repository for the Four Years' Issue of the National Library up to the close of the year 1889 that may be regarded as the most convenient and desirable for the purpose indicated.

Competitors should send in WORKING DRAWINGS to SCALE not later than August 31, 1889, and addressed, carriage paid, to

MESSRS. CASSELL & COMPANY, LIMITED,
LA BELLE SAUVAGE,
LUDGATE HILL,
Prize Competition. LONDON, E.C.
Cassell's National Library.

A motto must be affixed to each set of Drawings, and the name of the sender, etc., enclosed in a sealed envelope bearing *the same motto*, which must be transmitted by post, under cover, to the Editor of WORK.

The Drawings sent in Competition will be submitted for adjudication to Three Competent Practical Men, who will select those that are deemed worthy of prizes.

The Prize Drawings selected will become the property of Messrs. CASSELL & COMPANY, LIMITED, who will return all Designs made by unsuccessful competitors to their respective owners, carriage paid.

The Awards, with the names and addresses of the successful competitors, will be announced and engravings of the Prize Bookcases given in No. 30 of WORK, published Oct. 9th.

NOTICE TO CORRESPONDENTS.

*** In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given.

Trade Notes and Memoranda.

A CORRESPONDENT in the *American Machinist* recommends the following for improving burnt steel:—Reheat the steel, and cool in a solution proportioned thus: 1 gall. of whale oil, 2 lbs. of resin, 2 ounces black oxide of manganese, the whole to be hot and well stirred at time of using. The same correspondent recommends using a lead heating bath to prevent the danger of burning small tools.

FILES whose teeth are cut with a gradual increase in pitch, *i.e.*, in degree of coarseness, from the point towards the tang, are largely used in America. They are called "increment cut" files, and are cut by machinery. They work more sweetly than the ordinary files, being less liable to chatter.

UP to the present date, on the Manchester Ship Canal works, about $15\frac{1}{4}$ millions of tons of earth and rock have been excavated, while 28 millions more have to be removed. It is thought that the work will be completed in two years from the 1st of January next. There are on the works 183 pumping engines, 82 steam navvies, 5,000 waggons, 158 locomotives, and 116 steam cranes, and in a few months 15,000 men will be employed.

A COMPANY has been formed to manufacture a new white lead, which is stated to possess certain important advantages over the ordinary compound, such as permanence of colour in a bad atmosphere, and increased covering power for a given weight. Ordinary white lead, as is well known, consists of the carbonate; the new compound is the sulphate. It is prepared directly from galena by roasting in a furnace, and condensing the fumes or vapour of sulphate of lead, which is formed by the oxidation of the sulphide. The sulphate is collected from the condenser, washed with weak acid, and after drying is ready for the market.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Working Men Co-operators:

What they have Done, and What they are Doing.

Being a Handbook giving an account of the Artisans' Co-operative Movement in Great Britain, with Information as to how to Promote it. By ARTHUR H. DYKE ACLAND and BENJAMIN JONES.

"The co-operative movement is one of great social and economic importance, and those who wish to learn what hold the principle has obtained over working men cannot do better than consult the little book prepared by Mr. Acland and Mr. Jones. It furnishes an interesting account of the artisans' co-operative movement in Great Britain, with information how to promote it. It cannot, we imagine, but prove a useful little manual for those for whom it is intended."—*Times.*

SOLDERING:

THE NECESSARY APPLIANCES AND MATERIALS.

BY ROBERT ALEXANDER.

Introductory—Definition of Soldering—Soldering Irons—Their Length, etc.—The Solder Ladle—Making Solder—Test for Solder—Fire or Stove—Fuel—Gas Stove—Home-made Stove—Fluxes for Soldering—Hydrochloric Acid—Rosin or Resin—Other Needful Appliances.

In these and other papers to follow I propose to try to clearly describe and illustrate the methods employed, the patterns and dimensions, and the tools used in the trade of a tin-plate worker, tinsmith, or tinman, who has, perhaps, a greater variety of work to do in the various sheet metals, tin, zinc, iron, copper, and brass, than any other workman, especially in a country shop where he has to take the whole of the work, sometimes in conjunction with a smith, but as often as not by himself.

Of the prospects of the trade, I will only say that a man who can qualify himself to take such a place as I have mentioned can always get a job, and can (in reason) name his own wages. In these articles, though I shall not be able to fully describe every article or process, yet I shall endeavour to make as comprehensive a selection as possible; and my hope is that they may be of use to many.

How I should have welcomed a magazine like Work in my 'prentice days! and I would say to all young men who have started to take it in, stick to it; don't growl because your pet hobbies and ideas do not come out in the first number, or even the first twelvemonth. Make a hobby of something that is appearing, remembering that what you put in your head no one can take away from you. With these few hints, I will commence the first part of my subject, which will treat of soldering, brazing, and tinning.

Soldering.—This may be defined as the art of uniting two metals by means of an alloy termed solder, applied to the work with a tool called a soldering iron, or copper bit as it is sometimes termed, various fluids and substances termed fluxes being used to facilitate the melting and flowing of the solder, and to assist it in adhering to the work. That soldering is not such a simple process as it looks, most people, who remember their first attempts, will readily admit. How the solder positively refused to go where it was wanted, and how resolutely it seemed to stick where it was not wanted; how, when after much patience and waste of solder we managed to do the job we were at, it as often as not fell to pieces with very little provocation. Such reminiscences must be familiar to many who have dabbled in metal work of any kind. But these faults and failures are more from not understanding the fundamental principles of good soldering than from any real technical skill being required; and it is my aim and object, in these instructions, to show clearly how to succeed and the causes of failure. Soldering playing an important part in many things besides sheet metal working is one of the reasons why I take it first in my list of subjects.

Soldering Irons.—I will now proceed to describe the soldering irons. These are of various sizes and shapes, according to the work to be done. Fig. 1 is the ordinary pointed soldering iron used for general work. Fig. 12 is called a bottoming iron, and is used for soldering round the bottoms of such things as saucepans, boilers, etc. Fig. 4 is called a hatchet bit: this is more used by plumbers than by tinsmiths. Fig. 2 is similar to Fig. 1, only bent at the point and lighter.

There are several things to be noted in buying or making soldering irons. There should be from four to five inches of copper, exclusive of that which is riveted in the shank, as with the constant usage, and the filing and drawing out, the length soon diminishes. Then it should not have a long shank, as a long iron fatigues the arm very much, not only by the weight of the iron, but by the cramped position into which it throws the arm.

Generally speaking, the soldering iron should be about 16 inches long from point to extremity of handle. The handle also calls for a few remarks. Most of the copper bits on soldering irons sold in the shops are fitted with common file handles with iron ferrules; the shank is generally drawn to a point and stuck in about two inches; the consequence is that, after using a short time, the handle shrinks, the ferrule slips off, the handle splits, and the iron draws out, causing great annoyance and waste of time. If the handles are made as shown in sketches, they will afford a firmer grasp, balance the iron better, and last as long as the soldering iron itself. They are turned from good sound beech, 5 in. long, and $1\frac{1}{8}$ to $1\frac{1}{4}$ in. diameter. A groove is turned in them to receive a binding of copper wire instead of a ferrule. A hole should be bored about three-parts of the way through the handle, the size of the round shank; the remainder should be burnt through with the pointed part of the shank till the point comes through about $\frac{1}{4}$ in. It can then be either bent and clenched into the end of the handle, or riveted with a small burr or washer. It is worth while to take this trouble with them in order to get them secure. I have more than once seen a heavy iron slip out of its handle while being carried up a ladder, to the great danger of the man's mate standing below.

The next subject to consider is the solder. This is composed of lead and pure block or grain tin, in varying proportions according to the work that it is required for. I do not intend to give ten or twelve recipes for solder, some of them only varying in their melting points a few degrees, but simply three kinds. The first is suitable for rough jobbing and outdoor work, such as zinc roofing, etc. To make 7 lbs. of it, take 4 lbs. of tin and 3 lbs. of lead, melt the lead in a lead pot, and add the tin when melted, stir well with a ladle, and remove the dross which will float on the top, and run out into strips in moulds made by bending some pieces of sheet iron anglewise, and turning the ends so as to prevent the metal running out. These moulds should be about 14 in. long. (Fig. 5.) This solder melts at about 350 deg. Fahr. For a finer solder for all general purposes, new work, etc., take 4 lbs. tin, 2 lbs. lead, or in that proportion, viz., two to one. This is a splendid flowing metal, and is good enough for anything. If blowpipe solder is required, take the same proportions as last mentioned, and add one part bismuth, run out in very fine strips.

The best way to do this is to take a small ladle, and drill a $\frac{1}{8}$-in. hole in it near the top edge. (See Fig. 7.) Dip a ladle full of solder out of the pot, and, holding it over a sheet of iron or cast-iron plate so that the bottom of the ladle just touches the iron, cant the solder towards the hole, at the same time drawing the ladle from left to right; a fine stream of metal flows through the hole in the ladle, which cools as it touches the cold iron plate. A little practice will soon make perfect. Blowpipe solder should be kept in a canister to keep clean.

It is very often required to make solder when no tin is available. In fact, in most ironmongers' shops they seldom use tin for making solder, as they buy up scrap pewter, such as old tea-pots, beer measures, etc. Pewter being an alloy of tin and lead, it is obvious that if it is used to make solder with, a smaller quantity of lead must be used than if tin and lead were being used; it is a difficult matter to give a proportion of lead and pewter to make solder, as some articles are of a better quality than others, that is, they contain more tin. But as a general rule I have found that it is not wise to put a larger proportion of lead than 3 to 10 of pewter.

Test for Solder.—As a guide in cases of doubt, after mixing the metal, run out a stick and watch it cool: should it cool with a bright silvery appearance, it will not be far wrong; should it turn a bluish grey, it shows too much lead; should it turn dull white and pit all over with little dots, too much tin. The remedy is obvious: add whichever metal is wanted, a little at a time, trying it after each addition till you get it right. It is also a common way of trying it by bending a stick; if it emits a slight crackling it is good; should the crackling noise be too pronounced it will bear a little more lead, and in fact a good working hard solder is that which on crackling very slightly has a trifle more lead added. I think this is all I need say on the preparation of solder, except that no zinc must be allowed to get into it, as a very small quantity of that metal will utterly ruin a pot full of solder. Old composition pipe also should be carefully kept out of the solder.

Fire or Stove.—Our next thing to consider is the fire or stove. There are several stoves made specially for soldering. Fig. 3 is a very good form. The top part lifts off; the front and outside grating are in one piece, and also removable to clear out the ashes that drop through from the top part; the whole stands in a cast-iron tray. They cost from 20s. to 25s., and may be procured from Messrs. Rhodes and Sons, Wakefield, a firm whose reputation as makers of tools and machines for tinmen and sheet-metal workers is world wide. To say that a tool or machine is of Rhodes' make, is to say that it is all that can be wished; such, at any rate, is my opinion, and was that of my father before me, and readers of these articles would do well to get their catalogue. There are, of course, other firms of good repute, but of these I cannot speak from experience. To return to the subject of stoves, Fig. 11 is a sheet-iron fire-pot mostly used for outdoor work; most workmen make their own, and I will give particulars of this farther on.

Fuel.—With regard to fuel for these stoves; coke is the best for the indoor stove, and charcoal for the outdoor one. Years ago charcoal was almost universally used for both shop and outdoor work, and it is no doubt the best in many respects, being easily lit and easily kept alight, but coke being much cheaper, has to a great extent displaced it, though some still would not use anything but charcoal. Coal is not a good thing, as unless it is a clear fire it blacks and smokes the irons; but, as the showman says, you can pay your money and take your choice.

Gas Stove.—Gas stoves may also be used for heating the irons, and where gas is cheap, or for amateurs who do not do a great deal of soldering, I am inclined to think that they are a better means of heat than a fire, being clean, always ready for use, easily lit and put out, and the irons are not so liable to be burnt through non-attention.

Home-made Gas Stove.—Mr. Fletcher, of Warrington, makes stoves specially suitable for this purpose, or the workman can make his own for a trifle. Fig. 9 is a stove that I made very recently, which answers the purpose for which it was intended, viz., keeping one iron constantly in readiness, very well. It consists of a frame of stout hoop iron 8 in. by 3 in. and 3 in. deep; the burner is a piece of $\frac{1}{2}$-in. gas pipe, welded up at one end, cut off 7 in. long, with $1\frac{5}{8}$ in. of thread cut on it. A backnut is then screwed on it, and a row of holes $\frac{1}{8}$ in. diameter, or a row of saw cuts, whichever comes easiest, is then made in it, commencing $\frac{3}{4}$ of an in. from the backnut and going to about 1 in. from the other end; ten or twelve holes or cuts will do. A hole is then cut or drilled in one end of the frame, large enough for the pipe to go through and an air bulb is then made as follows: Take a 1-in. to $\frac{1}{2}$-in. diminishing socket and cut a dovetail in it as Fig. 8; then cut a piece of brass the shape of Fig. 6, $\frac{1}{8}$ in thick, and wide enough at the ends to fit the dovetails; in the centre drill and tap a $\frac{3}{8}$-in. hole, rivet the piece of brass in the socket, cut a thread on a piece of $\frac{3}{8}$-in. brass tube 3 in. long, fix a No. 2 or 3 gas-burner in it, and screw it in the cross-piece of the air chamber; pass the piece of pipe through the hole in the frame, screw on the air chamber or socket, and then drill four holes in the frame and run $2\frac{1}{4}$-in. rods across to rest the irons on; support the cover Fig. 10, and the stove is complete; connect to gas pipe or bracket by means of flexible tubes. If wanted for two irons make frame 2 in. wider and insert another burner.

Fluxes for Soldering.—Having considered

he soldering irons, the solder, and the fire-
ots and fuel, we will now turn our atten-
ion to the various fluxes required for sol-
tering.

I. *Hydrochloric Acid.*—This is also known s muriatic acid, or more commonly termed pirits of salts; it is a corrosive poison, and hould be kept in a stoppered bottle. In its aw state as purchased it is used for solder- ng zinc and galvanised iron, and for pickling ınd scouring purposes previous to tinning; t is not fit for soldering tinwork till it has een what we term "killed" and diluted, which operation is performed as follows:—Into a quart jam or salt jar pour a pint of aw spirits. (N.B.—This operation must be lone in the open air.) Into the spirits drop handful of zinc cuttings a few at a time: this will cause the fluid to boil and give off offensive fumes, which you must be careful not to inhale. When the boiling has ceased to some extent, add some more cuttings and let it stand for an hour; then put a bit or two more of zinc, and if no action takes place it is "killed" sufficiently. Pour the clear liquid into a bottle, and add nearly an equal quantity of water; cork up and put by for use. Some use it without the addition of water, but it is not a good plan.

The spirits thus prepared are termed killed spirits, and are used for tinwork, wrought iron, brass, and copper.

II. *Baker's fluid for tinning and soldering.*—This is a specially prepared article sold in bottles. It is supposed to answer for all the purposes of spirits, and it is a good thing to use for new work, as it is not so corrosive as spirits; but it is not so good for zinc, especially if the zinc is a bit dirty, as the fluid does not seem to possess that cleansing power that the raw spirits have.

III. *Rosin or Resin.*—This was at one time the chief, and, indeed, I might say the only, flux used for soldering; it is used a good deal now in many places for new bought tinwork, especially any that is likely to be in stock a long while. For tinwork it is used pounded fine, and mixed with oil to the consistency of paint, and applied with a brush; it should be wiped off whilst warm. It is also used for soldering lead pipes, making joints in electrical wire, etc., being entirely non-corrosive; in fact, rather preservative. There are two kinds, the black and the white (so-called); the white is the dearest, but it is no better for our use than the black. These are the principal fluxes used.

Other Needful Appliances.—A few other tools and appliances are required in soldering, viz., a jar to hold the spirits, a lump of sal-ammoniac, a file or two, a scraping knife, and one or two brushes for the spirits. I make mine by turning a tin tube on a bit of quarter rod, cutting a knot of hair out of a broom, slipping it into the tube, and flattening it with a blow of the hammer.

Tinning Iron.—Having got all these in readiness, before anything can be soldered the soldering iron must be tinned. Heat it in the fire to a blood-red, then grip it in a vice if you have one, and file the four faces quite bright; dip the iron in the jar, in which you have previously poured about a gill of killed spirits, then rub it on the piece of sal-ammoniac, holding a stick of solder to the point of the iron and melting a little on to the lump of sal-ammoniac, rubbing and turning the iron at the same time. If it is hot enough the solder will flow and coat the face of the iron. This is called tinning the iron. Dip again in the spirits, and the operation is complete; and it should be the aim of the workman so to use his irons that they shall not require tinning oftener than is necessary. I have used, and seen other workmen use, a pair of irons for a day's work, and, by judicious management, leave them in nearly as good condition at the end of the day as they were at the beginning, without filing them at all; and, on the other hand, I have known some who seemed to have the unhappy knack of constantly burning their irons, as it is called when left in the fire too long, so that they get red-hot and the tin burns off. The degree of heat required varies, of course, with the job to be done, but, as a kind of guide to general use, it should, when taken from the fire and held about an inch or so from the cheek, give off a hot (not warm) glow, and a peculiar sharp hissing sound when dipped in the spirit pot, which should always be done before commencing to solder anything. Some workmen have a jar of sal-ammoniac water to dip the iron in, to save dirtying the spirits. It is a very good plan, but as far as my knowledge goes it is not much practised.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

(*Continued from page* 198.)

SUBDIVISIONS OF SMALL LETTERS OF ALPHABET—ITALICS—SPACING—ROMAN CAPITALS.

HAVING shown in the last chapter that all letters are formed of straight lines and curves, either singly or combined—not that they could be very well formed by any other means—the student who has never given much thought to what he might consider so small a matter, should now be better able to grasp and understand the individual construction and character of all the letters in our alphabet. But, before leaving this subject entirely, it is necessary to again subdivide the alphabet as regards small letters, technically called by the printing profession "lower case," and also "script," or handwriting letters; in the latter case both capitals and small letters being so divided. We will thus divide them into four classes, viz.: short, ascending, descending, and "kerned" letters. The short letters are A, C, E, I, M, N, O, R, S, U, V, W, X; ascending letters consist of B, D, F, H, K, L; and descending letters are G, J, P, Q, Y, Z. Again, "kerned" letters are those which have part of their face hanging over either one or both sides of their shank. In the Roman F and J are the only "kerned" letters, but in Italic (which I do not illustrate at present) they are B, D, F, G, H, J, K, L, P, Y. The reader may ask whether it is absolutely necessary to go into this minute definition or analysis of the alphabet, so I will now show that it is, and, moreover, that all good sign writers ought to possess such knowledge. In the first place, most of the different styles of letters used by the sign writers are facsimiles, or, at least, very close copies of the ordinary printing type letter.* This is caused in a great measure, I believe, by the sign writer originally learning his letter-forming by taking as examples the specimen sheets of letters found in the "Book of Alphabets" sold by decorating firms and publishers, and which are frequently printed from ordinary type to save the expense of engraving specially designed blocks suitable to the purpose. A good many professionals are also very fond of making complete sets of ornamental letters from any printed example which may take their eye, but which, I am sorry to say, is not always so pleasing to other people, especially to those with an advanced artistic taste.

Now, in type founding it is usual for "kerned" letters to have part of their face overhanging the body of the type, and the type is cast in this way in order to economise room and prevent an ungainly appearance, which would be caused if the face were wholly on the body, since a blank would intervene in the midst of a word almost equivalent to a space, *i.e.*, a blank lead inserted to divide words. This is done by the type founders because the compositor is unable to have any share in the proper spacing of letters; but with the sign writer it is different, as he has unrestricted freedom in the spacing of his letters and displaying his words, and it is to this point which I have been working up to. I would therefore point out to the novice that, in cases where he is using such letters as have just been described, he must give the utmost care and attention to their spacing, otherwise his work when completed will have a most ungainly and awkward appearance. To make this fact the more apparent, let us suppose he is called upon to write in Italic letters the word

S w a f f h a m

and executed his work as shown in the word; it would, of course, look most unsatisfactory—in fact, divided in the middle, or consisting of two words. This is caused solely by bad spacing. Now, let us try again and see how the word appears when it has been judiciously spaced, such as this specimen—

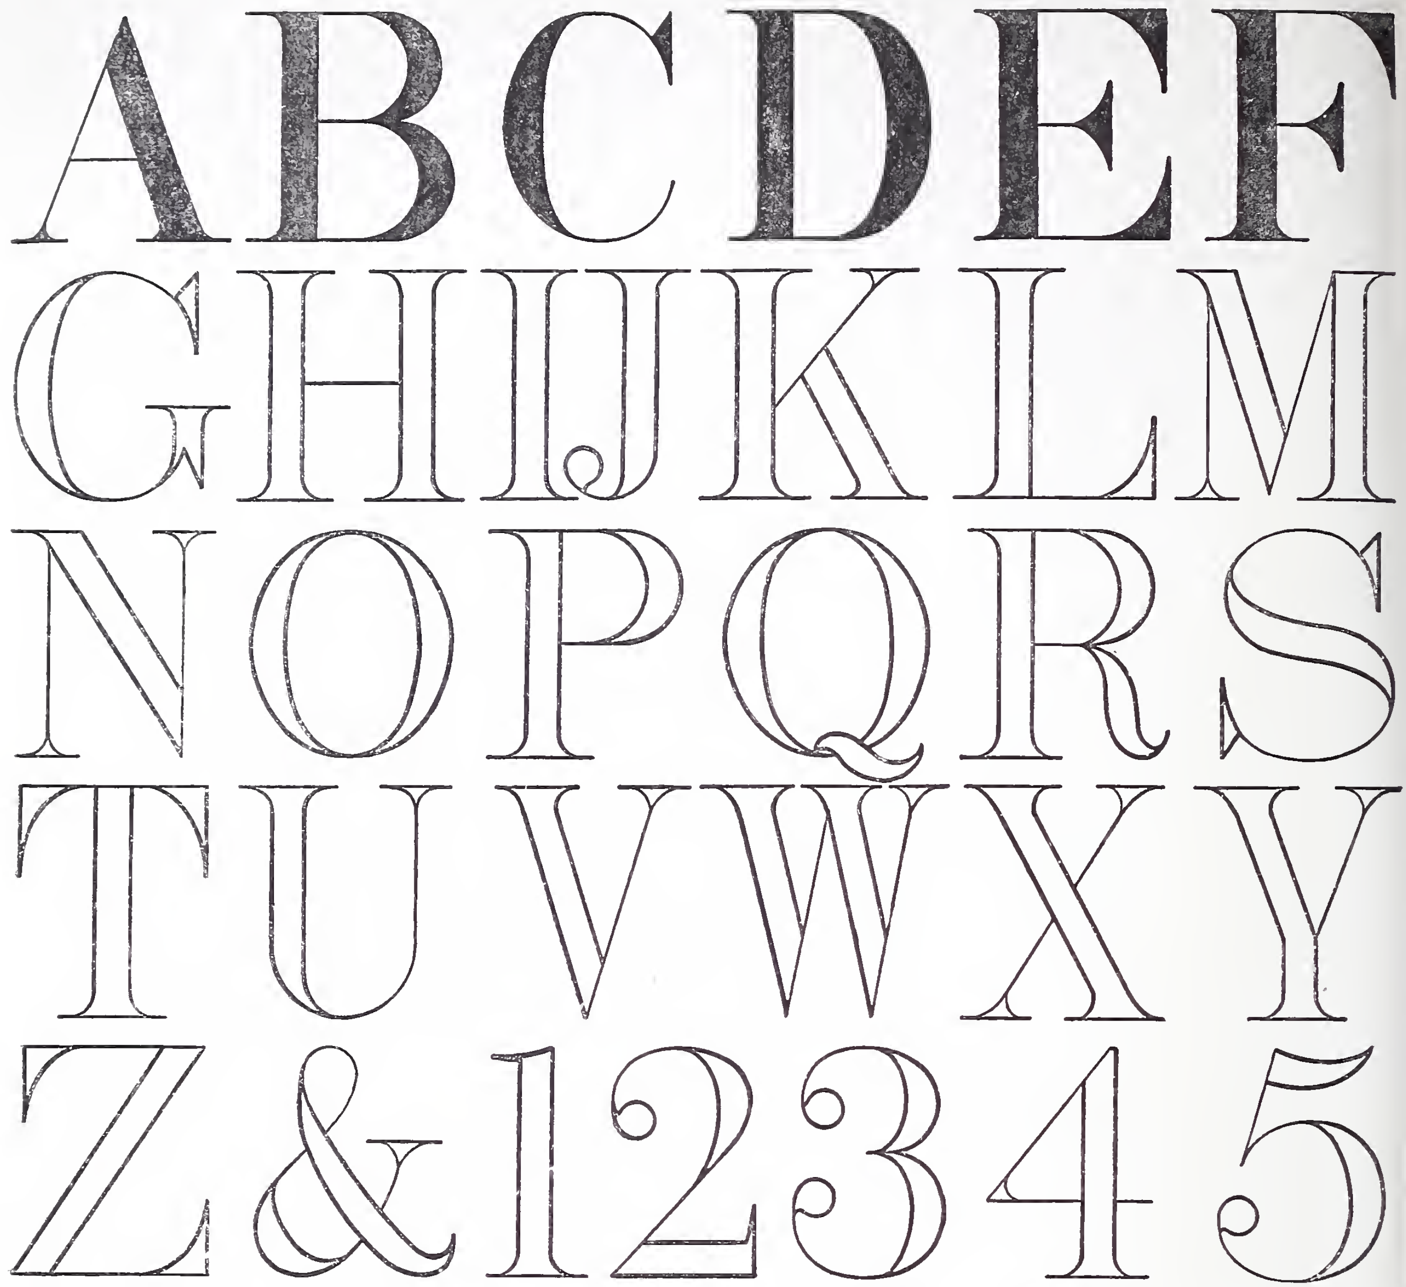
Swaffham

Now the word has a symmetrical appearance. The defect in the first example lies in the fact that the "kerned" letters take up more space in width than the others, so to have each letter regularly spaced in this identical word it is necessary to have the short letters a little wider apart than would otherwise be the case if no "kerned" letters were used. Difficult words, such as this, require much forethought, but I shall speak more fully on the subject of "spacing" in a subsequent chapter, having said enough for the present to show how essential it is for the student to consider the alphabet in all its forms and phases, and more important still—what a help such knowledge will be to him in his after-work.

Presuming that the student has by this time made a fair advance in drawing letters of the sans-seriff order, I must now direct his attention to more difficult work in the shape of alphabets of Roman capitals, Fig. 33. The small letters I leave for the next chapter. With the exception of the first six letters, I have drawn the capitals in the style known as "Open Roman." They will, of course, require more practice to form correctly than their more simple predecessors, but as the Roman is one of the most commonly used styles, they must not be left till perfection has been attained. The small letters should be in due proportion to the capitals—that is, the former should be one-half as high as the latter.

Hitherto the student has practised drawing his letters in outline only; he may now go a step further and commence to fill them in from A to Z, as shown from A to F in

*As I do my own printing I am in a better position to know this, perhaps, than the ordinary sign writer, who very often is unaware of the fact.—H. L. B.



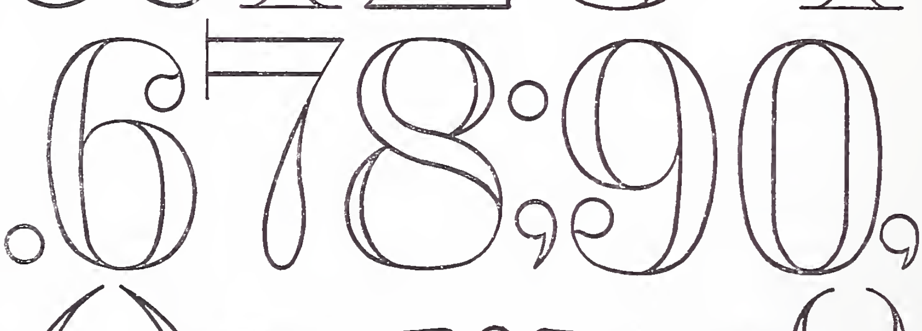


Fig. 33.—Solid and Open Roman Capital Letters and Numerals, Brackets, Dashes or Rules, and Stops.

Fig. 33. He will do this with the camel-hair pencil and paint, having first gone over the outline in the same way. This outline, be it said, should be drawn first of all, not with chalk, but very softly with a piece of Brodie & Middleton's sign-writer's pipe clay, which only costs about 3d. per dozen sticks, and will last at least a year. In filling in his letters there is one thing the novice will quickly discover, and that is that they (the letters) show up their defects more plainly when filled in than they did when only in outline, but to counterbalance this, he will also find that it is possible very often to perfect the shape of letters in the act of filling in, but this discovery should not in any way encourage him in making a careless drawing of the outline of the letters at the outset.

Having made satisfactory progress so far we must next pay attention to the numerals 1 to 0, and the stops, commas, brackets, dashes, and braces, as shown in Fig. 33. Their proper use will be described in the chapter devoted to spacing and display, so that it is sufficient for the present to learn how to make them. This, like the rest, comes with repeated practice.

LATHES FOR EVERYBODY.

BY SELF-HELPER.

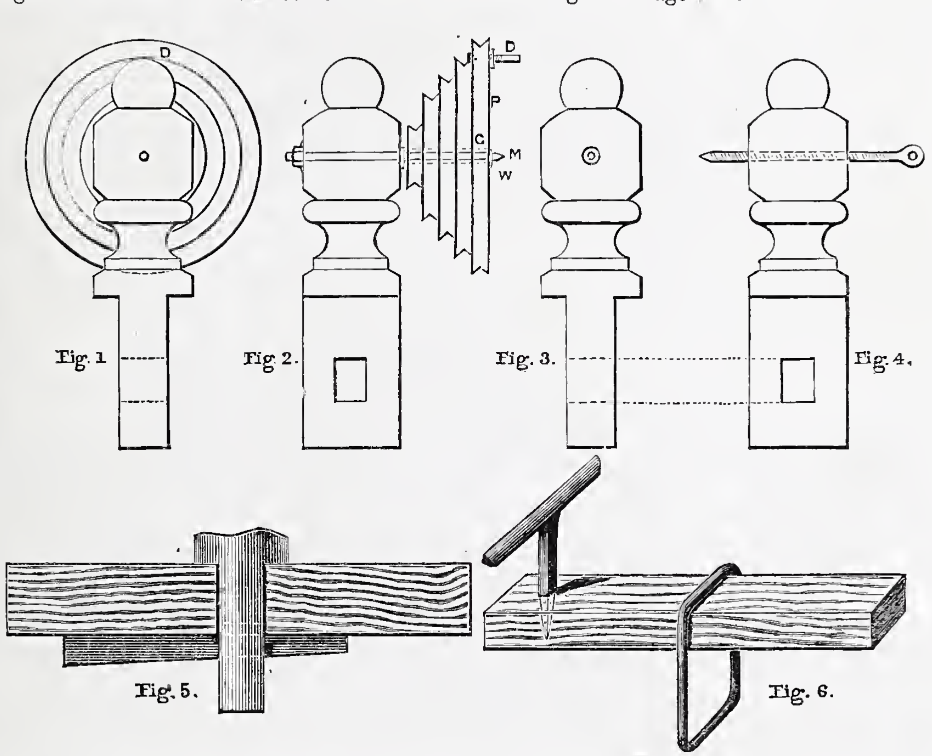
You must not imagine, reader, from the title of this article that I am the chosen advertising agent of some enterprising firm of lathe manufacturers who sell lathes from sixpence to five thousand pounds, to suit every pocket. No; I would be the worst person in the world for that task, as my passion would be sure to assert itself in the end, and that is a passion for lathe making.

Like most amateurs who have any pretensions to skill, I have had a great number of pupils in mechanics, men who would come to see my workshops, and, attracted by the beauty of the work which can be there done, would request that, if they were not in the way, they might come now and again and watch the various processes and learn as much as they could from them.

Such were usually welcome. I have had village tradesmen, and those very worthy individuals who are sometimes called handy men, sometimes Jacks of all trades, as well as amateurs in the strict sense of the word, among my pupils.

Them, as soon as I saw that their love for mechanics was really sincere, I almost invariably recommended to make a lathe. "Make a lathe!" many of them would repeat with astonishment, glancing at my highly polished and japanned machines which cost me months of patient labour.

"No, my dear friend," I would reply; "not one like that, at least not just yet, but one that will do, and do well, all that you require to do at present."



Figs. 1, 2.—End and Side Elevation of Fixed Headstock, showing (P) Pulley, (M) Mandrel, (D) Driving Pin, (G) Gun-barrel Bush, (W) Wire Knotted to prevent Pulley running off, Mortise for holding down Wedge (Scale, $1\frac{1}{2}$ in. = 1 foot, or one-eighth size). Figs. 3, 4.—End and Side Views of Poppet for Simple Wooden Lathe. Fig. 5.—Mode of Fastening Poppet to Bench with Wedge. Fig. 6.—Hand Rest with Stirrup of Half-round Iron, which passes through Bed and is fastened with Wedges.

And so I have been the father of many and many a lathe. Now, when I look back upon my pupils, I feel that my life has not been all in vain. Some of them are doing remarkably well. One, who pooh-poohed the idea of his having or using a lathe, is making a large amount of money by it, and he is an amateur. Another, a tradesman, is taking all the work from his fellow-tradesmen because he can beautify his dressers and tables with sundry turned legs and knobs, which they vainly try to imitate by hexagonal and other angular productions; while a few potter about their workshops like myself and derive nothing from their hobby but the unalloyed pleasure which it gives them.

Stay, though, is that true? Not it! Are there not sundry little tables and stools and boxes and candlesticks about the house which found their birthplace in these workshops? Yes, verily. Are there not many jobs brought there which otherwise would find their way to the village tradesmen, and have to be paid for in shillings and pounds?

Certainly there are. I am convinced that I must qualify the expression that I derive nothing from my workshop but pleasure. If it does not bring money in, it prevents it from going out, and that amounts to about the same thing.

Now a lathe was my first start as an amateur, and a lathe I made myself. Since then I have accumulated other lathes, and tools of sundry and divers descriptions about it, but the lathe was the start.

The readers of Work may be divided into two classes, amateurs and professionals. The amateurs may begin with a lathe, and build up their knowledge, with that as a basis, as I did. The professional will use his lathe as a means of increasing his income. There can be no doubt that the intelligent village carpenter or joiner would increase his income considerably by having and using a lathe. Many jobs which have to be sent to the city or the nearest turner could be done at home; for instance, rollers for mangles, spindles for washing machines, rolling pins, wooden platters, table legs, finials, knobs, and a thousand other things which are sure to turn up. These are usually paid for at a high rate considering the time spent on them, and this money the tradesman could put into his own pocket. Add to this that pieces of rustic furniture, which are now usually finished with either square or octagon legs, could have them nicely turned at the same price, while knobs which cost 3d. or 4d. could be made for nothing, and turned pillars and ornamentation could be added *ad libitum.*

The country people are vastly taken with anything that appears grand, and I am sure the village carpenter who supplied his furniture, for instance, tastefully finished with plenty of turning about it, would soon rival all his compeers, and be a rich and prosperous man.

We often see very taking advertisements in the newspapers telling us how to add £2 a week easily and honestly to our earnings. If I was asked how to do this, I would say "Buy Work, and do what it tells you. It will recommend the best plans for doing everything, and, by following its directions, you will work intelligently, and not do a thing simply because you were told to do it so."

To return to the lathes. I lately designed a lathe for a very beginner at the work, which will serve to show how an efficient tool, for it is efficient, can be made out of the very simplest materials.

My enthusiastic young friend has a good grindstone, about two feet in diameter, mounted on a low stand, and driven by a treadle. This I pitched upon as a fly wheel. He was about to make a bench. I asked, as a special favour, that the two 9-in. planks which formed the top should be left a couple of inches apart. The space could be filled up with a slip of thin wood when the lathe is not in use. I give diagrams of the heads. They are of oak, 4 in. square, and about a foot and a half long. Of course, any hard wood would do as well; beech would, perhaps, be better. I beautified them a bit by turning a knob on top, and also the space between the centres and bench, but this may be neglected by a man who has not a lathe; who, if he is æsthetic, may stop-chamfer them instead, and, if he is not æsthetic, may leave them rough as they come from the hatchet or saw. The height of centres I made was 6 in., and the tenon shown at the lower end of the heads was 2 in. wide to fit nicely between the planks which formed the top of the bench.

The position of the mortise depends on the thickness of the top of bench. In my case, it was $2\frac{3}{4}$ in. from shoulder, and was 2 in. deep and $1\frac{1}{2}$ in. wide. Fig. 5 shows how a long tapered key of hard wood fastens these heads to the bench. In Fig 2, which I will call the fixed headstock, there is a mandrel of Bessemer steel, fastened by a shoulder in front and a nut and washer behind. It extends four inches forward from the head, and has its end pointed to an angle of 60 degrees.

I turned this in the lathe; but, if any one of my readers has a difficulty in doing this, he may well be content with a piece of Bessemer steel 8 in. long and $\frac{3}{4}$ or $\frac{7}{8}$ in. in diameter. One end could be filed to a fairly true cone, and the other driven tightly into a hole bored in the headstock. I had a piece of gun barrel $\frac{3}{4}$ in. in diameter, which I made the mandrel to fit, and then I drove the barrel into a piece of wood which was to serve as pulley. This was of peculiar construction. It consisted of three pieces of oak one inch thick, and screwed and glued together with the grain crossed.

I mounted this on a face-plate, and turned a hole for the gun barrel or bush, and also the various speeds. The largest of these is 10 in. in diameter, and the smallest about 2 in. A very good job could be made of the pulley, without the aid of a lathe, by first boring the hole for the bush, and then, with a compass and chisel, making the pulley as round aud true as possible. When mounted on its own mandrel it would be turned quite true by fitting up a temporary band and changing it from speed to speed.

The pulley is kept from running off by cutting a groove round the mandrel before it, and tying a piece of stout wire in the groove in such a way that half its thickness projects over the surface of the mandrel.

With regard to the gun barrel, I am sorry that I cannot offer my readers a piece from my stock, but I just used the last bit of a long musket barrel in making a lathe similar to that I am describing. Steel tube can be got now from most large ironmongers, and if there is any difficulty about it, ordinary drawn brass tubing would do very well.

Messrs. R. Lloyd & Co., Steelhouse Lane, Birmingham, would, I am sure, supply tubing and Bessemer steel to suit for a few pence.

The other headstock or poppet has a screw 8 in. long and $\frac{3}{4}$ in. diameter to take the place of a mandrel. My friend has to revolve this with the help of a "tommy" until he gets braius and skill enough to fix a hand wheel on the end. A long, stout bolt or bed screw is a fair substitute for this screw, which, to some, would be troublesome to make.

The hand rest is somewhat original. It consists of a baseboard of oak $1\frac{1}{4}$ in. thick, 2 in. wide, and a foot long; into one end is stuck the T, and it remains there permanently.

A stirrup of $\frac{1}{2}$ in. round iron passes through the slot in bench; the baseboard is slipped through it on top, and a wedge, somewhat similar to those used for fastening the heads, slips through it under the bench top. Things are arranged, however, so that the baseboard can be raised about a quarter of an inch from the top of the bench when the stirrup and wedge are in position, and a second long thiu wedge is slipped between the top of bench and the bottom of rest, and thus clamps it firmly in any position. The plan looks crude, but works admirably.

A driving pin is fastened to the pulley. It is a $\frac{3}{8}$-in. round bolt with the head cut off and fitted with two nuts, one inside and the other outside of the largest speed. The inside nut I had to sink somewhat into the wood so that it would not strike the band when revolving. When the pulley revolves, it brings the driving pin into contact with a carrier fastened to the end of a piece of wood, and thus revolves the latter also.

I think I have now shown how a lathe can be made from materials that are found in most workshops, and a lathe which will do an immense amount of good honest work.

If a fly wheel were used instead of a grindstone it would be sometimes preferable. If the latter is used, it should be a kind which will admit of the trough being lowered out of the way to facilitate the shipping of the band.

I had intended to give a few hints on the construction of a still simpler lathe, but I will now bring this short paper to a close, hoping that it will prove useful to some.

I do not know whether I have made it sufficiently clear that when the lathe is required to work, the heads and hand rest are slipped between the two planks which form the top of the bench, and keyed there with the wedges. The grindstone is shunted underneath the bench, and a band passed between it and the pulley through holes bored in bench top for the purpose, and the lathe goes "merrily as a marriage bell."

PIN-HOLE PHOTOGRAPHY.

BY L. IVOR POOLE.

The idea of taking photographs without a lens seems, at first sight, so preposterous that readers who have not heard of it may almost be excused if, on being told that this article is written to inform them of its practicability, they are inclined to fancy that an attempt is being made to impose on their credulity. It is almost needless to assure them that there is no such intention, the desire being merely to direct attention to the possibility of taking a photograph with the very simplest apparatus, no lens at all, and no camera to speak of: nothing but a light tight box, and some contrivance to hold the plate. I do not, however, propose to write any instructions about these, but merely to make a few remarks ou pin-hole photography for readers who wish to try it.

Most of us, wheu we were boys, either in our scientific amusements or in perfunctory lessons on optics, no doubt became acquainted with the fact that if a very small hole were bored in the window shutter of an otherwise darkened room, an inverted image of the view outside would be cast ou the wall behind. I suppose very few of us ever satisfied ourselves by actual experiment; I know I never did. The conditions were altogether too irksome, and it was one of the assertions to be received on trust. No doubt it is correct, but an ordinary photographic camera is far preferable, and any one who will take the trouble to replace the lens with a piece of cardboard, through which a small hole has been bored with a pin, will find the image thrown on the focussing screen; not so vividly as when a lens is used, the amount of light which enters the camera being much less, but still, all there and quite perceptible.

Now, it stands to reason that if a sensitised plate is exposed, the image will be imprinted, the quality of the resulting negative depending on the same conditions as if a lens had been used. Of course, I am not for a moment implying that lenses are useless, or that they can be superseded by a piece of pricked cardboard, for I don't think it can be disputed that with a lens, better negatives are to be produced than without. There are, however, a few points about pinhole photography which render it something more than a mere scientific curiosity. Apart from the extreme simplicity of the necessary apparatus, which, alone, would hardly recommend it to serious consideration, there is the strange fact that it is always in focus. The size of the image varies according to the distance between the pin-hole and the plate, but near and distant objects are equally iu focus. It is therefore quite possible to make use of any small box as a substitute for the ordinary camera. Some day I may describe the arrangement of an ordinary plate box for taking several small negatives on the same plate, but, in the meantime, it will be sufficient to suggest a few ideas in connection with the photographs themselves.

It is important that the hole should be perfectly even, without any burr on the edges to interfere with the light. With a roughly-made hole it is impossible to take a pin-hole photo. to the greatest advantage. Scarcely less important is the size of the hole. This should be as small as it can well be made, sharpness of the image being greatly diminished as the hole increases in size. The merest prick through is sufficient. Instead of attempting to make a suitable hole in a piece of thick coarse cardboard or wood, it is better to make it in a thin fine piece, such as an ordinary visiting card, and stick this over a larger aperture in the box or camera, the inside of which, of course, must be black. Such an improvised pinhole lens, if it may be called so, can easily be stuck on with some of the gummed paper surrounding sheets of postage stamps.

The time of exposure, of course, is considerably longer than when a lens is used. Some idea of this may be given by saying that on an ordinary bright day with good light a photograph may be taken on a slow Ilford, with au exposure of 20 to 30 seconds. It will thus be seen that the time required hardly puts the pin-hole beyond use, even for portraiture. Instantaneous views are, however, out of the question with it, as any one who has the slightest acquaintance with photography will at once perceive. Personally, I have never been able to get a picture as sharp as if the negative had been takeu with a lens of good quality, but it must be a poor specimen which is not very superior to those taken with the cheap toy cameras, as fitted with a double convex lens. Not that a good photograph taken with a pin-hole is so blurred as to be useless, for at their best they rather resemble those taken with a lens slightly, and only very slightly, out of focus. They may almost be classed as photographs of the "impressionist" school, so that it is quite possible some may admire the slight indistinctness. There is certainly an absence of harsh outline which is sometimes rather pleasing than otherwise, or is it perhaps perverted taste which renders them not distasteful?

The evils of distortion with any but the best lenses are too well known to require attention to be called to them. With a common lens it is impossible to take a photograph of a building without the lines nearest the edges of the plate being curved. In pin-hole photography they are, however, perfectly straight and true, and to me, this seems one of its chief advantages in practical use, not the slightest distortion being observable. Enough, however, has doubtless been said on what many practical photographers, with command of the best apparatus, will perhaps regard as a somewhat trivial branch of the art, to show that is not only interesting, but at times may be useful in enabling a photograph to be taken with an extemporised camera.

BACKING ELECTROS—BALANCES.

BY GEORGE EDWINSON BONNEY.

Backing Electros.—When an engraved surface, or a medal, or a medallion, or a set-up forme of type is copied in copper by the electrotype process, the copy is named an "electro" in the workshop. A mere thin shell of copper, of about the thickness of a visiting card, is deposited in the mould, and this shell must be carefully removed from the mould to receive a backing of some stouter material before it can be used in the printing press or mounted in a cabinet. If a wax mould is employed, the removal of the copper shell is quite an easy matter, for the operator has only to pour a stream of hot water over the back of the mould to cause the wax to melt off from the shell. Any persistently adherent wax can be got off by immersing the shell in a solution of hot caustic alkali. The shell must be got off without buckling it or wrinkling its surface, and it is then ready to be backed. If a small shell, such as a copy of a coin, a medal, or a medallion, place it face downward on a heated iron plate, and brush over the back a little "killed spirits of salts," such as plumbers and tinmen use. Next coat the back to the required thickness with common tinmens' or plumbers' solder. Larger electros are placed on an iron backing plate or tray furnished with handles, and the tray with its electro is floated on a bath of stereotype metal until hot enough to melt solder. The back, having been previously prepared by brushing the ordinary soldering liquid over it, is now coated with solder much the same as copper bits are "tinned" with solder, that is to say, enough solder is melted ou to ensure a bright coat all over the back. The hot tray is next removed to a level surface, and enough backing metal is poured on the electro to make the back $\frac{1}{8}$ in. in thickness. The following formula is given by Mr. A. Watt as a good one for the composition of backing metal:—Tin, 4 parts; antimony, 5 parts; lead, 91 parts. Full information on this subject is given in "Electrotyping," by J. W. Urquhart, pp. 212—222.

Balances.—The balances or scales required by an electro-plater will vary with the class of work on which he is engaged. For the ordinary work of weighing the goods before and after plating, to determine how much metal has been deposited, a pair of scales with a stout steel or brass beam will be required. For weighing gold and gilded articles a lighter pair, indicating a turn on one grain at least, should be provided; these will also serve for weighing out the ingredients used in making up solutions. For rough assays and estimations a small cheap balance indicating a turn of $\frac{1}{10}$ grain will serve the purpose; the cost of this, together with weights from 500 grs. down to $\frac{1}{10}$ grain, will be about £1 10s. A still more elaborate and correct balance will be required for assays, analysis, and calibrations; such as an Oertling assay balance fitted with agate bearings and indicating a turn with at least $\frac{1}{100}$th of a grain. Such a balance with a full set of weights will cost from £5 to £10.

In some plating establishments the weight of deposited metal is determined during the operation of plating by means of a plating balance. This is merely a pair of large scales furnished with a scale-pan at one end of the beam and a metal frame suspended over the bath at the other end. The goods to be plated are slung to the metal frame, and the whole is balanced by weights placed in the scale pan. The pillar of the beam is connected to the negative pole of the machine or battery. As the metal goes on the goods to be plated, the beam is thrown out of balance, and the exact weight deposited can be ascertained at any time by additional weights placed in the scale pan. A full illustrated description of this balance, and the mode of working it in French plating establishments, is giveu in A. Roseleur's *Guide pratique du Doreur, de l'Argenteur et du Galvanoplaste.* An account of the same is also given in "Electro-deposition," by A. Watt.

AN ORNAMENTAL CLOCK CASE AND BRACKET.

BY J. H. MOODY.

(*Continued from page* 242.)

Fashioning of Spindles—Jointing of Pillars—Bracket-Pieces—Steps—Cornice—Canopy Roof—Scroll—Door—Fixing of Dial and Door — Treatment — Bracket — Finishing Bracket.

If my small contribution upon the subject of home embellishment be attended by no better effect than that of demonstrating to home-workers how easily an article, till now commonplace, may be made important, it will not have been written in vain; but I venture to predict that it will not be so lightly dismissed. And when the possessor of a clock like the one I altered reads how cheaply the alteration was effected, he will be impelled to undertake the same amount of transformation.

Tho pillars were each one made in three parts—a procedure which was necessary, as I did not possess a lathe; and it will not be *infra dig.* to confess that I ventured to fashion the turned portions without one, and although many difficulties would have been smoothed over by the employment of such an accessory, yet I succeeded in making very presentable spindles by using only files of various shapes and a dovetail saw. The other portions of the pillars were the top part which carried the pierced brackets and formed the capital, and the lower part which with plinth formed the shaft and base. I left a short plug at either end of the spindles, and I bored sockets in the top and bottom pieces; and when the three parts were joined together by means of these dowel-like plugs and sockets, the pillars looked quite as perfect as though they were made from one piece of wood.

My auxiliaries in carving the stages and sunk panels in the plinth and shaft were a couple of keen chisels; and glass-paper, of course, contributed its quota toward the success of the work; and for material I used $\frac{3}{4}$-in. mahogany for all the parts of the pillars, which when they were finished were fastened to the case by means of screws driven home in deep counter-sinkings. The screws were then concealed respectively by the brackets and by the plinth (Fig. 2).

The eight bracket-pieces which enriched the capital were cut from thin mahogany with a fret saw, and pierced with a brace and $\frac{3}{16}$-in. bit. They were connected in pairs, by pieces of wood of sufficient thickness to keep the individuals of each pair at a due distance apart; and each pair of brackets were then attached to the pillars by glue at the proper places, which will be seen from the drawing.

I next arranged the two steps. One I had already obtained by cutting down the plinth of the original case, and I now finished it by giving it a tread of thin mahogany. The lower step I made from $\frac{3}{4}$-in. mahogany, and also provided it with a tread, and fixed it in position, tightly jammed between the two pillars; therefore glue was sufficient to hold it firmly.

The cornice (Fig. 3) now claimed attention, and the easiest way to make it was a matter for consideration. At last I decided that my best plan would be to make it in two parts—the first part being two beads, with a depression between them. This was done with a bead plane on a piece of wood of suitable thickness. By working first one side and then the other, the two beads and depression were produced. The second part was a slip of wood to earry the carving.

Perhaps the best way to obtain this carving will be to take a cylinder of wood of suitable diameter, and cut and file the pattern right round it. This, when split or divided in its length, will give a better result than if the pattern had been cut on the edge of a slip of wood. The slips of carving being fastened upon the pieces of wood provided as their foundations, the two parts comprising the cornice were glued and pinned together. When the glue was dry, the moulding was cut and mitred to go on the top of the clock at the front and sides only, and fixed on to the piece of wood that formed the roof proper. The edge of this roof-piece became then the third part in the moulding.

The gablet or canopy surmounting the roof was built up of three pieces of $\frac{3}{4}$-in. mahogany, which were cut decreasing in size, and roughly shaped, so that when their surfaces were placed together the whole very nearly assumed the form that I intended to give to the canopy; and to obviate the objectionable weight of solid wood, I hollowed out the first and middle piece, leaving them simple frames each about $\frac{3}{8}$ in. in width. The three pieces being glued together, and dry, were finished with proper tools. A piece of mahogany pinned in to the top formed a ridge. (See Fig. 2, clock case in section.)

The scroll was made of wire, worked with the round-nose pliers and soldered; and the heads of fancy nails supplied me with flowers for it.

The door was made from $\frac{1}{4}$-in. mahogany, and cut to proper dimensions for fitting between the styles; and the panels were carved in it, but were endowed with a degree of importance which the panels upon the pillars did not possess. A piece of thin wood of suitable size and shape was glued on to the face of each panel, thereby advancing it beyond the level of the surface of the door. A circular aperture was also cut in this door for the dial.

The old dial was useless to me, and I procured another bearing ordinary numerals, and painted on delf; but there was no provision for fixing this in position until I glued thin pieces of wood at the back of the door, and just peeping over the edge of the aperture. This prevented the dial falling through to the back; but something was also needed to prevent it from falling forward, and to keep the hour of noon from displacement. To that end I filed nicks in the edge of the dial, and, placing the 12 in its proper place, drove headed pins past those nicks and through into the wooden stops which were glued on at the back of the door. I then procured a brass rim with glass, costing eightpence, from Messrs. Smith, of St. John's Square, E.C. The door was kept in position by a rebate formed by gluing slips of wood at the back of the styles, and by buttons fixed at the front. I cut an opening in the back, so that the pendulum could be readily got at for purposes of regulation, etc.

There is little to be remarked in regard to the moulded stand, save that it were best cut out of the solid plank; but if the tools are not equal to the job, do as I did, and build up and mitre it in the same way as the cornice was procured.

A clock altered in this way when finished, as far as the woodwork is concerned, may be submitted to either of two kinds of treatment: it may either receive polish by a coat of varnish or other means, or it may be covered with enamel paint—a plan that will admit of a wide range of selection, as there are so many useful tints to choose from. Light blue, light green, cream, or even white, would look equally well; and at this point I must say a word or two regarding the bits of ornament occurring in various parts of the design. These may be incised work and gold paint, if the operator feel equal to the task; but if not, the brush may be employed to do the work upon the surface. I got my clock up in black enamel and gold paint, using the latter method, and was well satisfied with the result.

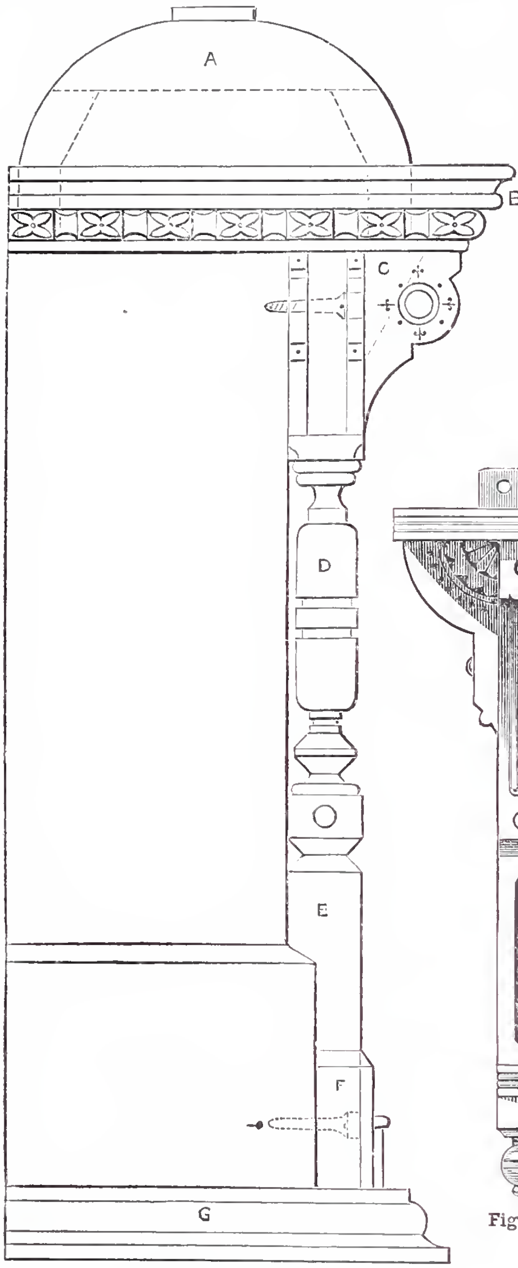


Fig. 2.—Clock Case in Section.

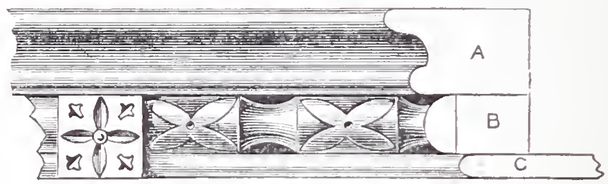

Fig. 3.—Detail of Cornice.

A, Portion made with Bead Plane. B, Portion bearing Slip of Carving. C, Top Piece of Clock.

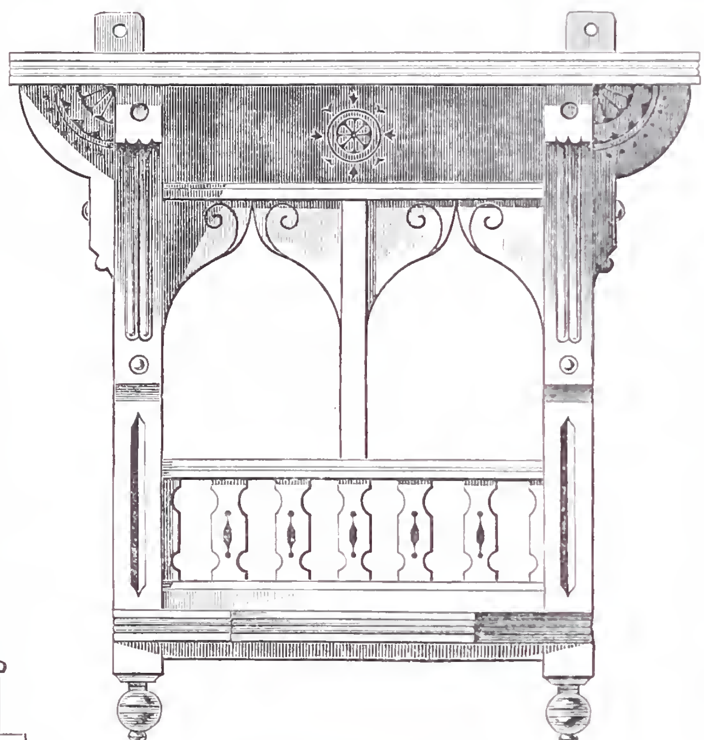

Fig. 4.—Bracket suitable for Clock (one-third full size).

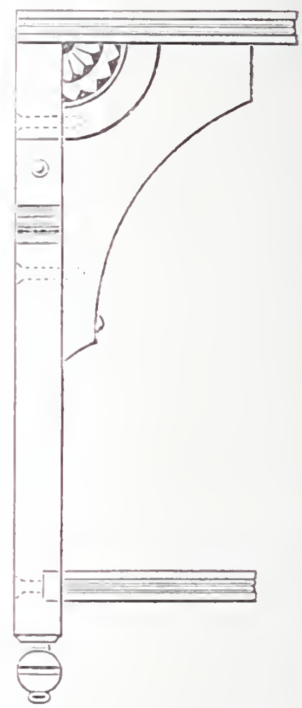

Fig. 5.—Bracket in Section.

I rather anticipate that this clock will be thought unsuitable for the mantel, because of height and narrowness; but want of width and loftiness may recommend it, especially if the other ornaments are tall or numerous. I would, however, suggest that it is particularly suited for placing upon a bracket; therefore I have ventured to append a design for a bracket suitable for this purpose or for use independently; and as the ornament it bears will be in the shadow of the shelf it will not detract from the importance of the clock above it. This bracket (Fig. 4) may be made of $\frac{3}{4}$-in. stuff, and the back framed by mortise and tenon, leaving the styles longer at the bottom for the attachment of terminals. It will not be necessary to carry the tenons right through; but great attention must be paid to the close fitting of the joints, and the square cutting of the shoulders of the tenons.

The bracket-pieces must be cut out with a turning-saw; and when the front ones are reeded, and the side ones are dressed smooth, they may then be attached in their places on the styles in manner as follows—the side brackets by dowels, and the front brackets by means of screws from the back. (Fig. 5.)

Before gluing up the framed back, it must be rebated, by the best means at command, to receive the fretwork; and the ornamental furrow, as shown in sketch, must be cut upon the styles. The handrail of the balustrade is mortised into the styles; and the short upright bar in the centre, from which the small arches spring, is let into the top bar of the frame, and into the handrail; and as these two help to support the fretwork, they also must be rebated.

The pieces for the arches and the rails being cut may be placed in the rebates, and secured by slips of beading at the back. But if, instead of being left open, it is intended to fill the spaces with mirror glass, backing boards must be used, and the whole secured by brads after the manner of a picture frame.

The top shelf is cut from $\frac{1}{2}$-in. wood reeded on three edges, and then fastened at the top of all by screws; and, being sustained by the front brackets, it is quite adequate to carry the weight which the clock represents. The lower shelf is of $\frac{1}{2}$-in. wood reeded on the appearing edges, and, not being intended to bear a greater burthen than a small vase, it is simply let into a channel in the lower bar of the framed back. It is cut away to enable it to pass the styles, and screws from the back are sufficient to hold it securely.

I would further call attention to the fact that the lower shelf is not allowed to retain full width throughout, but has its carrying capacity very much reduced by reason of its corners being cut off, thus leaving 3 in. in the centre to boast of only sufficient width to hold a small article. The turned knobs may be of a piece with the styles, or may be turned separately and joined to the styles by means of plug and socket.

Suspension of the bracket is effected by a pair of plates screwed on at the back, and by nails driven into the wall through holes in these plates.

We must, of course, put the same style of finish upon the bracket as the clock received, and then our labours will be concluded. But whether our completed work receive commendation, or whether it deserve condemnation, is largely dependent upon the attention and care that even insignificant details received at our hands whilst the construction progressed. With due care in this respect neither clock nor bracket will fail, I think, to give satisfaction.

PAPIER-MÂCHÉ.

How to Mould It, and how to Ornament It.

BY SYLVANUS WARD.

(*Continued from page 186.*)

DECORATION (*Continued*) — BRIGHT GILDING SILVERING—ARABESQUES—EMBOSSING.

Bright Gilding.—This differs from dead gilding in being done on a polished instead of on a dull ground, besides which the method of procedure is widely different. In dead gilding, the design is carefully pencilled in size, and the gold is only attached in those places where it is intended to remain. In bright gilding, on the contrary, the whole space over which any part of the design may extend is sized and gilt, all superfluous gilding being afterwards removed. The more perfect the polish of the surface on which the work is done the more brilliant will be the gilding.

As in dead gilding, if both deep and pale gold are used they must be put on separately, and the deep is generally applied first, since, being richer in appearance, it will occupy the more important parts of the design.

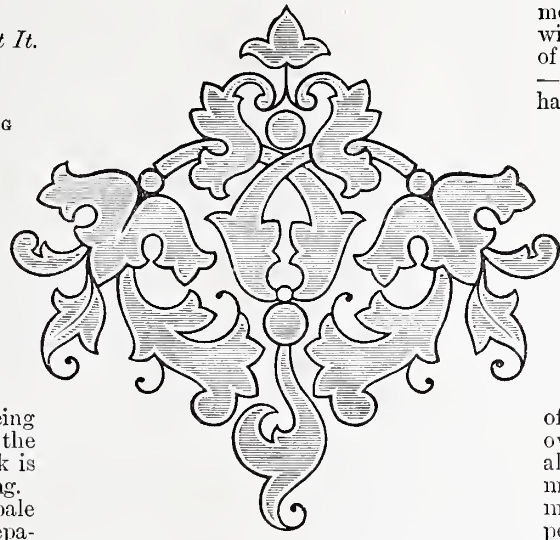

Fig. 32.—Arabesque Ornament in Bright Gold.

As a preliminary operation, the surface should be breathed upon and carefully wiped with a *silk* handkerchief; for it must be freed from even the slightest suspicion of grease. Even that left by the touch of a finger will prevent the size now to be used from lying evenly.

This size is a weak solution of isinglass—say, as much as will lie on a sixpence dissolved in a half-pint saucepan of water. The worker has to estimate the space over which his design will extend, to spread the size over it with a flat brush or with a little ball of cotton wool, and to lay on the gold at once. The design Fig. 33 is for bright gilding, the shaded portions being in deep, and the remainder in pale, gold. It is intended for the border of a blotting case or any similar purpose. As it is about an inch wide, a strip of somewhat more than an inch in width round the article will have to be sized, and to cover it a book of leaf gold may be cut through the middle—that is to say, into strips of an inch and a half.

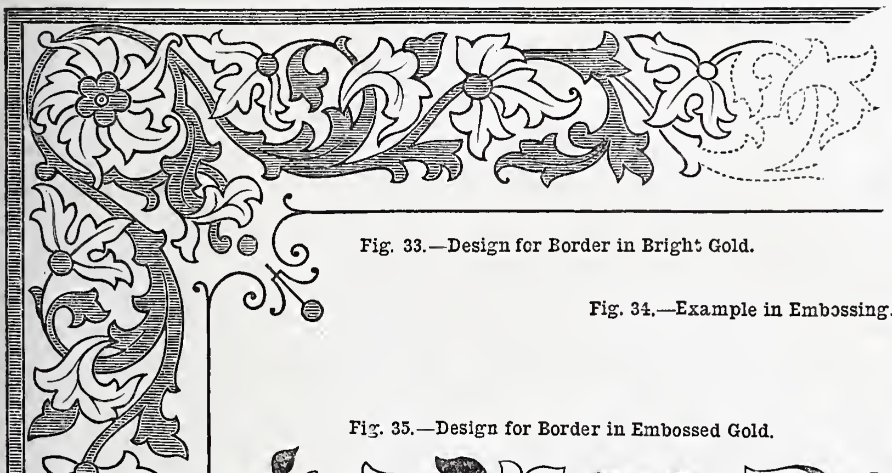

Fig. 33.—Design for Border in Bright Gold.

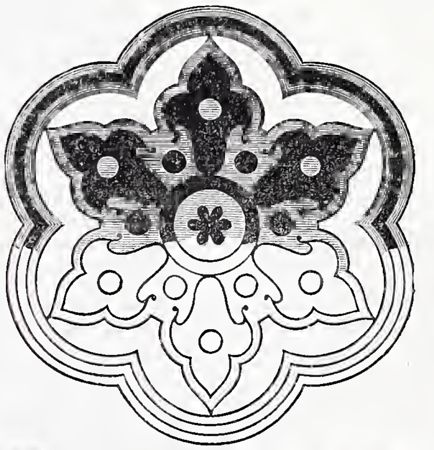

Fig. 34.—Example in Embossing.

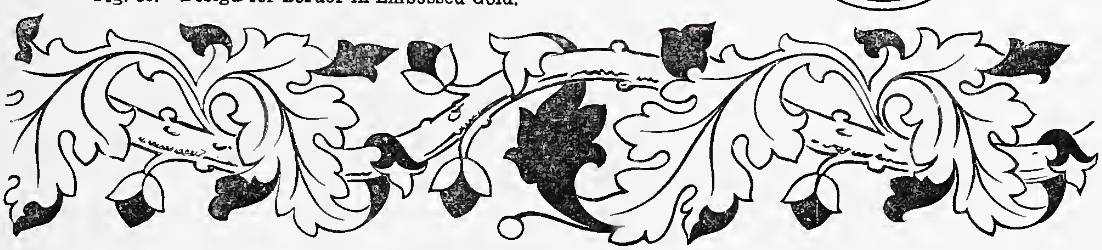

Fig. 35.—Design for Border in Embossed Gold.

In bright gilding the gold needs to be laid on with great care. If a leaf is found to be crumpled it is better not to use it, but to lay it by for future dead gilding. Different men have different methods, but the writer would not recommend the use of the tip for the work now under hand. In bright gilding it is desirable that all parts of the leaf should touch the size at once, or a crack will result; and he prefers to lay it on with the paper of the book, using *both* hands. The edge of each piece as it is laid should slightly overlap that of the preceding one. When all the space is covered, any cracks that may appear should be mended with fragments of leaf applied with the point of a penknife; and if the size should be too dry to hold the scrap of gold, it should first be breathed upon. Sometimes whilst the gilding is going on some part of the size may get too dry, and need sizing over again; if so, care should be taken not to let the size used flow over gold already laid on, or it will injure its colour.

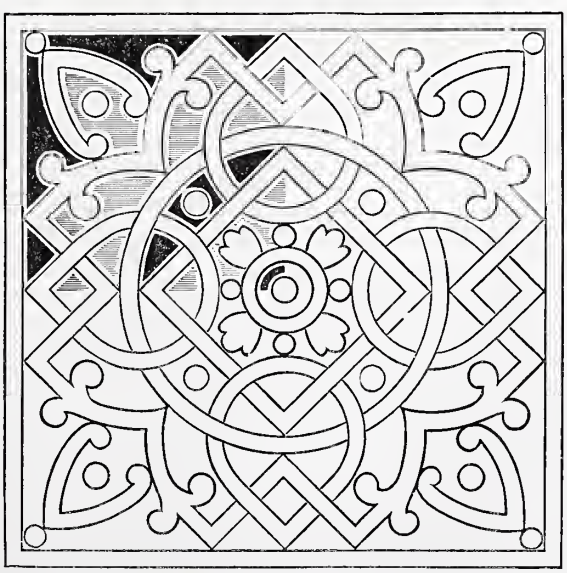

Fig. 36.—Bright and Dead Gold in Combination.

The work will at first appear dead, but as it dries it will gradually brighten. Drying may be hastened, if desired, by holding the article moderately near to the fire. When the work is thoroughly dry and the article cool, breathe on the gilding, and with a ball of cotton wool press down the gold firmly but lightly. The pressure must be applied directly downwards, not obliquely, or there will be danger of disturbing the leaf. Then hold the work to the fire for a moment, warming also a fresh ball of cotton wool, and with the latter rub off all the little wrinkles, etc., which appear. By this the brilliancy will be greatly increased.

The pattern has now to be pounced

upon the gilded surface, after which (to protect so much of the gold as is intended to remain) the design has to be painted on it in asphaltum or brunswick black. This will need drying for half an hour in a tolerably warm stove, and then all unprotected gold may be wiped off with a piece of wet cotton wool. The design—that is to say, so much of it as is in deep gold—now appears as brown ornament on a black ground.

The work is now ready to receive the pale gold. If this occurs freely in all parts of the pattern, as it does in the example before us (Fig. 33) we must gild the whole—in this case our inch strip—over again; had it, however, been in isolated parts only, it would have been sufficient to have gilded patches covering those parts. All the gilding, pouncing, protecting with asphaltum, and cleaning away of superfluous gold have to be gone through as with the deep gold; and that done, we shall have our whole design, both in deep and pale gold, on the papier-mâché, but alike hidden under a brown covering.

To remove this coat of asphaltum is a simple matter. The article having first been slightly warmed, to soften the asphaltum, a ball of cotton wool has to be dipped in turpentine, and wiped lightly and carefully over the work. This will first result in a smudge merely, but a second wiping with *clean* wool and *clean* turps will have a more satisfactory effect. When first cleaned the gold will have a somewhat yellow look, from the turpentine; but a light rubbing with finely powdered whiting will remove the discoloration and bring out the full brilliancy of the gilding. In finishing a design like the present, it is usual, where forms in deep and pale gold cross each other, to separate them by black lines. The veins may be either in black or white. The shading may be in wash black; this looks better than burnt sienna, which is often used for the purpose. The thin line which bounds the inner side of the border should be either in colour or in dead gold.

The design might have contained other ornaments in dead gold, and these could well have been introduced after the bright gilding had been rubbed with whiting as above described. The whiting, by removing all grease, would have prepared the ground for them. The required ornaments would have had to be pencilled in with japanners' gold size, as directed under *Dead Gilding*. The introduction of dead gold in this manner often gives a pleasing variety. Fig. 36 is a design in which the two kinds of gilding are shown in combination. In this the plain, outlined ornaments are in deep bright gold, the shaded parts in pale dead gold, and the black parts in deep dead gold. It should be noticed that a narrow space is left all round the dead gilt parts, of which the result will be a black line (the original ground) separating the different parts.

Note.—If it should be desirable to tint either bright or dead gold at the extremities of a leaf or ornament, it will best be done by sizing the gold over for a distance with copal varnish, to which a spot or two of oil has been added; and when this is a little dry, by taking dust colour of the kind desired, and with a dry camel-hair brush dusting it on to the varnish and letting the colour die away. Of the process of "dusting" more will be said by-and-by. Also, if bright gold be used in combination with pearl, it is better that they should not actually touch; neither should bright gold be laid over pearl anywhere, as the pearl asserts itself through the thin leaf metal, producing a disagreeable and nondescript effect.

Silvering.—Silver leaf if applied as bright silvering is apt to have a "tinny" and cheap effect in papier-mâché work where it can only be used in small quantities; it is, therefore, more commonly applied as dead silvering. The process is much the same as that of dead gilding, except that, owing to its greater thickness and weight, silver leaf has to be laid on whilst the gold size is slightly more moist.

Leaf silver, like leaf gold, is bought in books, but these contain twice as many leaves and are larger—$4\frac{1}{2}$ in. square. A book of silver costs 9d. or 10d. In addition to the ordinary silver an iridescent leaf has recently been introduced, which has a rich effect of colour, and is worthy the attention of papier-mâché decorators.

A valuable use of silvering is to give brilliancy to transparent colours laid upon it, as for lighting up the stained-glass windows in interior views of churches, for imitating the lustrous eyes in peacocks' feathers, etc. Also for a class of illuminations known among japanners as "arabesques," in which the ornament is outlined in bright gold and filled in with patches of brilliant colour; and wherever a body colour sufficiently brilliant is not to hand, the method is to lay in with silver leaf, and to cover it with a transparent colour.

Arabesques.—Fig. 36 may to some extent serve to illustrate the arrangement of arabesque ornament. The black and tinted portions of this design may be supposed to represent the coloured spaces, some slight interval being left between the gold bands and the filling. Usually, however, japanners' arabesques are combinations of the kind of ornament seen in this design and that seen in Fig. 32. In this latter diagram, the black lines indicate outlines in bright gold, whilst the tinted spaces within represent the bright patches of colour, either opaque or silver leaf stained.

The colours used for staining the silver leaf are usually—carmine and crimson lake for red, prussian blue and ultramarine for blue, verdigris or a mixture of Italian yellow (sometimes called Italian pink) and Prussian blue for green (with verdigris a little Italian yellow is generally used to warm it), and for purple a mixture of carmine and ultramarine. It will be noted that the colouring is always kept a little within the gold outline, so as to leave a line of black between colour and gold. White is sparingly used in this kind of work; so also is yellow, which too nearly approaches the colour of gold, whilst emerald green is used freely.

In Fig. 36 the brilliant colouring is confined to the ground, but in Fig. 32 it will be seen that the ornament itself, though bounded by a *strong* outline in bright gold, is the portion silvered and coloured. The ground in this case may either be left plain black, or it may be picked in with dead gold, or with some colour which does not appear in the ornament.

These papier-mâché arabesques have little in common with what might more properly be called arabesque decoration, except brilliancy of colour and formality of design, and were probably suggested in the first instance by Cloisonnée enamels.

An additional use of silver leaf, often seen in very old work, was that of serving as an imitation of gold when washed over with Italian yellow.

It is not possible to beat out silver to so extreme a degree of thinness as gold; hence the greater thickness and weight of silver leaf; hence also its comparatively high price when the relative value of the two metals is taken into consideration. It would seem probable that in the old days when silver with a wash of yellow was made to do duty as a cheap substitute for gold, that gold leaf must have been very much thicker and therefore more costly than it has been in recent years.

The practice preferred by the writer with silver as with gold, is to lay the leaf on the sized surface with the paper of the book in which it is bought; some, however, may like better to apply both in the manner considered by gilders to be more orthodox, namely, with the tip. For the benefit of such persons it ought, perhaps, to be said that the tip is an instrument which the gilder commonly makes for himself. He doubles a waste playing card, and between its two thicknesses glues a thin layer of camel's hair, so as to make a kind of attenuated brush. This he uses by first drawing it over his hair, whence it gets a faint suspicion of grease, but just enough to cause the leaf to adhere to it and allow itself to be taken up, and so slight as at once to permit the leaf to leave it on coming in contact with the more sticky gold size. In gilding an uneven surface, the value of the tip in bringing the gold leaf equally in contact with the various parts will be obvious.

Embossing.—This, as practised by japanners in the palmy days of papier-mâché, was a method of producing the effect of dead gold slightly embossed or raised upon bright gold by one operation of gilding only. The parts intended to be in dead gold were first pencilled in with gold size on the bright surface of the papier-mâché, and when nearly dry were rubbed over with a "bob" dipped in bronze powder (usually pale bronze), and this resulted in the ornaments appearing in solid bronze. At this stage the work was dried in the stove, so as to render the ornamentation hard. Afterwards it was water sized and leaf gold laid over every part, and burnished in the manner before described, where the decoration was wanted. Sometimes the whole ground of the article was bright gold, on which lay the embossed gold ornament; at other times the bright was merely a bordering to the ornamental dead gold work.

The result of this process was that, where the gold leaf was laid upon the bronze, it appeared dead and slightly raised. Fig. 34 is intended to illustrate embossing. Black represents the portions pencilled in with bronze. In this case it is supposed that a bordering of bright gold only surrounds the embossed ornament. This is represented by the tinted parts. The method of forming such a border was by pencilling over the gilding with copal varnish. So far as it extended, the varnish protected the leaf beneath it, and the superfluous gold could then be wiped from the remainder of the surface with wet cotton wool.

It is sometimes desirable, especially in borders, to represent leaves in bright gold, with fibring and turnovers in dead gold as in the design, Fig. 35. The process is exactly that last described. With some designs pouncing has to be employed first for the embossing, and again, after gilding, for the copal-varnish pencilling. The reason for using varnish and not asphaltum, as in ordinary bright gilding, is that the turpentine necessary to remove the asphaltum would be liable to disturb the embossing. In Fig. 35, the black portions, including the fibres of the leaves, will show as dead gold, and in finishing the work the interlacing portions are carefully divided by a line of black.

OUR GUIDE TO GOOD THINGS.

62.—MESSRS. HARGER BROTHERS' SPECIALITIES.

I HAVE received very recently the latest edition of the catalogue and price list of fretwork materials and appliances of various kinds used in making and fitting up ornamental work, issued by Messrs. Harger Brothers, of Settle, Yorkshire, and sent, I may say, to any applicant, post free, for 6d. Messrs. Harger Brothers' establishment in Settle may be regarded as the chief emporium in the northern counties for the supply of these articles, and as such is well worthy the attention of all retail dealers in such goods, as well as of all professional and amateur workmen who make them—the one, possibly for profit; and the other, certainly for the honour to be gained for successful achievement.

It will be useful to give an extract from a letter recently received from Messrs. Harger Brothers, as it shows what they can do and will do far more effectually than anything I might be led to say on this point. They write:—"We may say that we usually send goods the same day as order is received. Our patterns (that is to say, for fretwork, etc.) include many not in miniature, and our stock includes some hundreds of thousands for the wholesale and retail trade. We have noticed inquiries for timber for fretwork in WORK: this we cut and plane on the premises by machinery, and can make any special moulds or turning which amateurs require. We also hold enormous stocks of veneers and all fancy woods for carving or turning, and can cut to any special sizes. We also make a speciality of hinges, fasteners and fittings, locks, etc., for small boxes, cabinets, etc., and are large importers of the best American fretwork machines. Carving tools we supply all shapes."

Catalogue and Price List.—I will now proceed to notice such articles as have been sent me by Messrs. Harger Brothers as specimens of their specialities, and may well begin with a few words with regard to their price list, sent, as I have already said, post free for 6d. It is a large quarto pamphlet of 64 pages, and contains illustrations of most of the tools and appliances comprised in their stock with prices, etc. On the second page of wrapper useful instructions and recipes for various kinds of work are given, and on the fourth page an ample index to its various contents. Pages 1 and 2 are devoted to remarks on patterns, woods, machines, terms, etc., and testimonials from home and abroad. Then follows description, prices, and illustrations of fretwork goods and articles kept in stock, conspicuous among which is the page devoted to carving tools, in which is shown not only the shape of each tool, but its full-size form at the cutting edge, or, in other words, the shape of the incision that may be made by pressing the edge against a piece of wood. To enter into a specification, even of the classes of goods described and figured, is simply impossible, and it will suffice now to call attention to Harger's "Patent Adjustable Bench Stop," a useful and time-saving adjunct to the carpenter's bench. Fittings of every kind for cabinet work, fretwork, etc., hinges of all kinds, draw-pulls and handles, are abundantly illustrated; and the last 22 pages of the price list are filled with miniature reproductions of most of their fretwork designs, which is of the utmost utility in enabling any would-be purchaser to form some idea of the character of the design, before sending for the actual design itself for pasting on the wood. Those who send for the catalogue will find, I fear, that my brief *résumé* of its contents falls very short of the mark.

Designs for Fretwork, Carving, Inlaying, etc.—That the taste and liking for fret sawing has been greatly on the increase of late years is amply evinced by some of the recent designs of Messrs. Harger Brothers, which, when cut and finished, work up into large and elaborate pieces of furniture, many of them bearing the mark of having been produced by skilled designers. No. 675 is a handsome hall ornament, consisting of a bracket, with mirror at the back rising above it, contained in an elaborate frame, flanked by equally elaborate wings or side pieces. No. 679 is a quaint emblematic design for a calendar, in which are figured the signs of the zodiac, and which, by means of index hands, shows the month, the day of the month, and the week. No. 673 is a sideboard, the patterns of which extend over five large sheets, containing many parts and panels which might be utilised in a variety of ways. Bold, venturesome, and persevering must be the man who attempts to cut it. No. 676 is a work-box of Indian design, to be cut in ebony backed with white holly. No. 606, a clever design for an overmantel; and No. 609, a design for a newspaper rack or waste-paper basket. The only thing that is lacking in some of these is a representation of the article itself when made up, which Messrs. Harger Brothers will, doubtless, supply in future reprints. The patterns for inlaid work are well conceived, particularly No. 654—a round table top, ornamented with shells, birds, and foliage, and buds and blossoms of the passion flower. No. 648—two paper knives for inlay—is also good. Of the carving patterns, the most noteworthy is No. 580, a bold and well-executed wall bracket, which would present an effective appearance on completion.

Hinges and Cabinet Fittings.—Messrs. Harger Brothers also send many good samples of strong hinges of polished brass for fretwork fittings of various sizes, ranging from 1½d. to 1s. 9d. per pair, according to size, stoutness, and pattern. These are what may be termed fancy hinges; but brass or nickel-plated hinges of the ordinary form, from ½ in. to 1¼ in. in length, may be had from 1d. to 3d. each, according to size. In addition to these are some good gilt or nickel-plated fasteners for boxes or cabinets, from 4d. to 6d. each. Knobs for drawers and feet for box or tea caddy are also supplied at cheap rates, the former, in bone, ¼ in. in diameter, being 1d. each, or 8d. per dozen; and ½ in., 1½d. each, or 1s. per dozen. These fittings will be found illustrated in pages 8, 9, 10 of the catalogue.

Samples of Fretwood.—Lastly, I will call attention to the fretwood that is stocked by Messrs. Harger Brothers, solid, in boards of various widths, according to the wood, and of thicknesses ranging from ⅛ in. to ⅜ in. Samples of almost all the different kinds of wood kept in stock have been sent to me, and all seem to be well seasoned and of the best quality. Many of the woods are supplied in the form known as "three-ply wood," which consists of three thicknesses of wood glued together, the grain of the intermediate layer being transversely to the grain of the exterior pieces. I need scarcely say that any thickness of wood prepared in this way is far less liable to fracture than solid wood of the same thickness, and should be used in all cases when the design is intricate and extends over a large area. Samples of various kinds of fretwood about 2 in. square, numbering about twenty kinds, are sent out, post free, for 2s. The possession of a set of samples enables the fret sawyer to decide more readily on the kind of wood he will use for his work.

63.—MESSRS. GIBBONS & CO.'S SPECIALITIES.

I have received from Messrs. C. Gibbons and Company, 2, Avenell Road, Highbury, London, N., some specimens of the specialities in which they deal, and which they make themselves. I will notice these presently, but before coming to this part of the subject, let me say that I am more especially pleased to be asked to speak about Messrs. Gibbons and Company's goods, because they are the first working dealers, if I may be permitted to put it so, who have come forward to ask for a notice in WORK. Now WORK is essentially a working-man's paper, and I see no reason why the productions of working men should not be mentioned and described as well as the more elaborate and costly goods of the manufacturer on a large scale. I mention this here with some degree of emphasis because some persons seem to labour under the idea that WORK is an advertising paper, which means, when translated into plain and unmistakable language, that notices in "Our Guide to Good Things" are paid for. A greater mistake was never made. Everything that is noticed is noticed on its merits, and on its merits alone. Only such things as are sent for notice are reviewed in "Our Guide to Good Things," and to me there is as much pleasure in mentioning a tool, appliance, or article for sale made by the humblest workman, as in calling attention to costly machinery from the factories of the first makers in the land.

Scratch or Bead Router.—Messrs. Gibbons and Company send a very nicely made scratch or bead router with four cutters, being led to do so by the article on this subject by Mr. David Denning, which appeared in No. 7. Of this they say:—"The article on the bead router was just what was wanted. We make and have sold many of them, and I beg to hand you one for your inspection. We supply the scratch stock and four cutters for 2s., and extra cutters at 2d. and 3d. The stock, which is 8 in. long, 1½ in. broad in the widest part, and ⅜ in. in thickness from side to side, has a nicely shaped handle, and is well finished. The carrier for the cutter is clamped by three brass screws, having heads pierced with a hole to admit of their being turned by a lever in the form of a short piece of stiff wire." So handy do I find this scratch, and so little time have I for making such appliances for my own use, that I retain it in my possession, sending Messrs. Gibbons & Co. its value in stamps, for as they sell these things, the money value is as good to them as the scratch itself.

Small Mouldings.—Of these Messrs. Gibbons and Company write:—"We also send you samples of small mouldings. It is at very few places that these can be got so small in size, and we have much pleasure in drawing your attention to our samples; we have them in stock from 1d. per foot." Of these mouldings fourteen patterns have been sent neatly glued on a board. They range in width from $\frac{3}{16}$ in. to ¾ in., and are sold at prices ranging from 4d. to 1½d. per linear foot. They appear to be made with the scratch and cutters used with it, and will be found useful, I think, by many who require this sort of thing for small work, but cannot find time to make mouldings for themselves.

Violin Clamp.—Another speciality of Messrs. Gibbons and Company are violin clamps, of which a specimen is sent that is supplied at 8d. The parts of the clamp, which are ⅝-in. square, are firmly connected by mortise and tenon, and in the lower arm is a screw, by which the clamp is tightened or loosened as may be required.

Samples of Fretwork.—Messrs. Gibbons and Company are also fret cutters, and in submitting some specimens of their work, they say:—"We send you samples of our fretwork to show you we are practical men at this sort of thing, and we shall be most happy to help any reader of WORK who may want help in this sort of work. We feel competent to give advice from the long experience we have had, Mr. Gibbons, senior, being one of the first, if not the first, of the earliest workers in fretwork who used to do the work for Moseley and Simpson." The fretwork consists of four panels, well and carefully cut.

64.—FALLOWFIELD'S PHOTOGRAPHIC ANNUAL, 1889.

This well-printed volume of 336 pages constitutes for the present year the "Photographic Annual and Comprehensive Catalogue of Photographic Materials, Chemicals, and Apparatus," together with "Complete Working Formulæ for most of the Photographic Processes." This is issued by Mr. Jonathan Fallowfield, South London Photographic Stores, 35 and 36, Lower Marsh, and 86 Oakley Street, Lambeth, S.E., and will be sent by him post free to any applicant on receipt of 1s. It has all the appearance of being a sufficient directory to everything that a photographer ought to know or ought to require in the way of apparatus and appliances for the prosecution of the art of photography. To attempt even to summarise the contents of this volume is simply impossible, and it is enough to say that no photographer, whether professional or amateur, should omit to find a place for it on his shelves. The value of the book is enhanced by a good index; and another noteworthy feature is a list of agents at the end, in which a great number of towns, chiefly English, are arranged alphabetically, and under each the name given of one or more agents resident therein, who supply Fallowfield's photographic goods.

THE EDITOR.

A Corner for Those who Want to Talk It.

. *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Cabinet in Fretwork.—Electro writes:—"I have very great satisfaction in endorsing to the utmost the opinion of the many correspondents who have testified to the value of Work. From the first number I have looked forward to its appearance every week with much pleasure. I have begun and nearly finished the cabinet in fretwork from Mr. White's designs. It has occupied nearly all my spare time, but I am more than repaid for the trouble I have taken, although, probably, a practical cabinet maker would shudder at the result; but I have got on with it much better than I could have expected considering my lack of experience."

Copying Fretwork Designs.—Electro writes:—"Possibly some of your readers—beginners like myself—do not know an easy way of taking copies from fretwork. Here is a little 'wrinkle' I learnt the other day. Hold a piece of thin white paper firmly over the design to be copied, then rub it all over with a piece of common shoemakers' heelball; the design will come out black, and will be an exact copy of the fretwork underneath. Of course I am speaking of the actual fretwork, and not the paper patterns."

Sounding Board for Dulcimer.—T. C. B. (*Birmingham*) writes:—"I quite agree with Dulcimer when he says the proper dimensions of a sounding-board for a dulcimer would be welcomed by many subscribers. It is what I have been waiting for. I have made two attempts at the same thing, and done fairly well, but I have had to guess the angle by seeing them in the shop windows. The body I construct according to my own idea; the only trouble I have is to get the proper length of the strings or the proper angle (as Dulcimer speaks of); this is all that is wanted, I think, by an amateur. And this, I think, could be given by a piano maker, as they are constructed on the same principle as a piano. I have seen it announced that articles will appear on piano making, which I have been waiting to see, so that I could glean what I wanted from them. Now that the subject is started I hope some professional dulcimer maker or piano maker will hurry up, and let us amateurs know what we want to know."

Sharpening Carving Tools.—H. C. (*Lincoln*) writes:—"I notice in Work No. 11, a suggestion that the slips for sharpening carving tools be held in the hand screw. Allow me to present another way. The appliance is made out of any hard wood in a few minutes; the sketch shown in Fig. 1 explains itself. It is not usual, I believe, to have a bench vice on a carver's bench, so the appliance for holding slips may be quickly held by the modification of bench screw known as 'hookey,' which I suppose is known to all carvers. I am pleased to

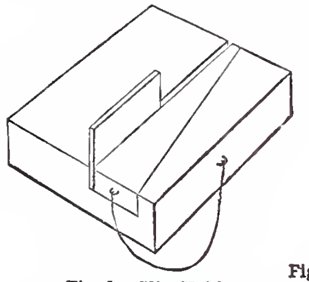

Fig. 1.—Slip Holder.

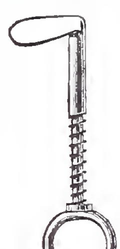

Fig. 2.—Carver's Holdfast.

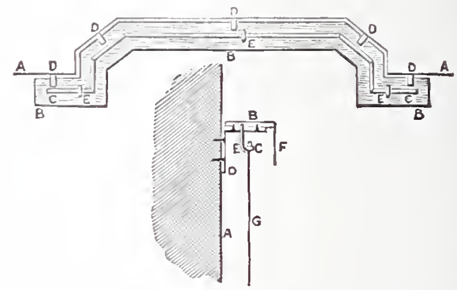
see the wide scope of Work. As an amateur in many branches besides carving, I welcome the paper as supplying a want I had felt for many years. I have seen it in many working men's houses, yet often alas, torn! I trust we shall be taught how to bind it ourselves. To return to the subject of carving, I look forward to seeing some good designs in Work. A mantelpiece with side panels in good Italian Renaissance work, not tool complex, or a Gothic sideboard with tracery panes at the back and a canopy, would be delightful! I do not mean detailed instructions, but a full-page design, with or without a little letterpress. In conclusion, let me wish a long and prosperous life to Work."

Papier-Mâché.—Disappointed (*Soton*) writes:—"I feel rather disappointed that the articles on papier-mâché have been discontinued for several weeks; have they come to an end?"—[Disappointed will see ere the publication of this that the papers have been resumed.]

About Work.—S. F. (*Gulval*) writes:—"For many weeks past (in fact, ever since I received the first number of Work) I have intended to offer my humble congratulations on your having brought out such a valuable magazine as Work. I have watched with interest from week to week the many expressions of praise bestowed on it, coupled with suggestions of improvement by my fellow-readers, but after having seen a paragraph in 'A Corner for Those who want to Talk it,' by T. J. H., which finished by asking his fellow-readers' opinion on it, I felt I could no longer refrain from sending my views respecting Work and T. J. H.'s views. He says the most tantalising of your publications is Work. Now, sir, it appears to me that some of the readers of weekly and other papers seem to think that every week there must of necessity be an article published to suit their respective requirements, according to their calling or occupation; and should one of these articles be too long for insertion in one number, it must be continued in the next issue. This I do not agree with; for instance, take the article by Mr. Adamson on 'The Screen Secretaire,' or 'Some Lessons from an Old Bureau.' Supposing, in consequence of other articles in other branches being published, neither could be continued for two or three weeks, was there not enough contained in the first part of either sufficient to impart knowledge to any reader intending during spare hours to make one to go on with until the article should be concluded in a subsequent issue? Certainly. T. J. H. says your present method is 'like feeding a lot of donkeys with one oat at a time, each donkey waiting his turn to get his oat.' Is it not much better to take a little good food at a meal, than to overload one's stomach with a large quantity which would produce indigestion? For my own part, I think that to find fault with the method now carried out by you is utter selfishness; indeed, what paper is there, whose custom it is to publish, say, a serial story, would for a moment (to gratify the wishes of a few readers) think of filling two or three issues following with it, and then for a week or two go on with general news? The success of that paper would be doomed, as would Work, if it should adopt that policy. Then respecting his suggestion to enlarge Work, and, consequently, its price, I say adhere to its present size and the penny. I once took a weekly journal which, when it first came out, was one penny, but after two years it was enlarged by the addition of tinted covers and a couple of extra leaves, and double the price. This, in my case, as I believe in many others, led me to discontinue my subscription. I believe your motive is to give knowledge to those who require it, and there is no better way in doing so than publishing a cheap weekly journal such as Work. Then, again, T. J. H. mentioned about Work, with others, being thrown out of a train on a dirty platform. Well, has this every-day occurrence in any way injured the copy of Work that he happened to buy? If it has his, I have found all mine to be as clean as when they left the publisher's office, although I happen to live near to the last country town in England. Whenever I have seen newspapers thrown on to a platform, I have seen that they have been bound with brown or other paper. I don't know that newspapers require to be very carefully packed, and labelled, 'This side up, with care,' and I doubt if T. J. H. can give an instance when he has seen newspapers in any way injured by delivery from the train. Well, sir, being a mechanic, and having charge of engines, I am glad your 'Corner' is open to questions, etc., in my calling, and that at any time I can get information from you, and some of my clever fellow-readers. I consider Work as it is just the paper that is supplying a long-felt want among artisans and amateurs generally. I wish you and Work the greatest prosperity."

About Work.—T. O. P. writes, in reply to J. P. A., page 188:—"With your permission I would like to say a few words in reply to J. P. A., in issue of June 8. He says, in reference to Work, 'I find it almost useless to practical men.' J. P. A. must be a most unusually practical and know-everything kind of man when he finds the combined knowledge of so many other practical men as subscribe to Work almost useless; and would it not look better in J. P. A. if he would help brother-readers to a little of his superior practical knowledge instead of wasting three-fourths of a column of what is 'valuable' space to others, whatever it may be to him; or was it all a preliminary blow-off to partly obscure a free advertisement at the end of his epistle? But not content with that, he must tantalise us by leading us to expect valuable information of how to make up a superior saw bench to any in the market, made up of odds and ends and anything that comes handiest, and winds up with 'it is about to be patented,' and cannot be described till that operation is performed (another prospective advertisement, I presume). But why does he say that iron planes, for instance, can be 'bought cheaper than made' (when the writer of those valued articles informs us they can be made for about one-fifth or one-sixth the outlay), and yet evidently thinks that one of the merits of his saw bench is its home-made nature out of odds and ends lying about (as of course it is)? I have a smoothing plane (iron) which cost 25s., but I have no doubt I could make one for 5s. outlay, thanks to the esteemed information in those articles; and not only that, but special work requires special tools, which are not to be bought, but can only be made to order at prices at which J. P. A. may or may not know something about; whereas a worker may make use of his 'odds and ends' of both materials and times, get his castings at a nominal cost, and again fit up at spare moments to his own satisfaction, and which he may even still have to do after paying a toolmaker a lot of money for his idea of what the requirements may be. But with those instructions on the standard articles he can easily alter to his own requirements; and, unfortunately, we have not all had the vast practical experience in every branch of work that J. P. A. has had the advantage of (has he had two or three lives to acquire his great practical experience in?). If J. P. A. wants more of Dr. Dresser's, why not go to the great Doctor himself? Some of us at least would rather be excused more of his outlandish teapots and candlesticks, or building construction. Surely there are plenty of periodicals devoted to that branch for J. P. A.'s requirements without his wanting to carry off 'our' paper as well; or 'for good old or new furniture' why cannot he be content with his *Cabinet Maker?* But I presume J. P. A. would have a paper more of a general character made to suit his own special requirements, at the same time to be vastly superior to all the specialists. He says the '*Cabinet Maker*, though cheaper, has much more information.' How cheaper, when it costs 1½d. to 2d. per month more than Work? Now, Mr. Editor, I have some fifty monthly numbers of that work since its commencement, and had the reading of many of the others; also a big pile of the other trade organ; but I find Work gives more information than either, if not both the others, to workers, though perhaps not to window dressers and counter jumpers and masters, and consequently am giving up both the others in preference for Work; and therefore hope you will not make such sweeping changes as J. P. A. would have, even if we have to lose the support of all such practical men of his type. I must apologise for this long letter, but I would like you to have a little encouragement from the other side than that of carpers and grumblers, who are never pleased with anything outside themselves."

An Amateur's Cornice.—W. B. B. writes:—"Observing in your issue for 27th April a description of a cornice (see page 83), I venture to send a plan which I adopted last year, and found to answer perfectly what I wanted. It is, I think, very much simpler to put up, and to some tastes would be as effective as the design of your contributor, Olla Podrida. At all events, any one who can handle a screwdriver, and a hammer and tin tacks, can try it at a very trifling outlay. The first requisite is an iron curtain rod with holes at each end. These can be purchased at any ironmonger's for a few pence, of such length as may be requisite. The rod should be suspended by iron hooks screwed into a ½-in. board, and the board must be fixed over



the window on iron brackets screwed into the wall. The board holds the rod, and the rod will allow the curtain rings free play. In front, and at the sides, tack a piece of tapestry, which may be purchased at the draper's, to harmonise with the curtains, to conceal the rod, and the matter is complete. Where the window is flat the matter is perfectly simple; and in the case of a bow window, a little more ingenuity is requisite, but no more than any intelligent man can overcome. The principal difficulty in the latter case is to procure a bent rod of the requisite size, and to cut the boarding to the proper shape. Any ironmonger will procure the bent rod, but the measurements require to be carefully taken. I add a couple of sketches to explain what I mean. The same plan would, of course, answer for a curtain over a door. In conclusion, I beg to offer my compliments on the work you are bringing out. Personally, I should be glad to see some wood carving designs, especially in Renaissance work, but recognise that you cannot do everything at once."

Building Construction.—C. M. (*Leicester*) writes:—"In answer to your request for the readers of Work to express an opinion on the subject of building, I think the way you suggest will be the best—in beginning from small houses. Hoping that you will be able to give early attention to it, I trust that your paper will be a success, as it has supplied a long-felt want."

Ammonio-Citrate of Iron.—P. W. S. (*Poplar*) writes:—"In an early number of Work I note 'ammonia, citrate of iron,' or something similar, which had misled a correspondent, and had been corrected by omitting the comma. But I submit the form is still incorrect, though I know often used. 'Ammonia-citrate' is as incorrect, in my view, as 'Russia-Turkish war' would be, the true phrase being 'ammonio-citrate,' not forgetting the hyphen."

An Opinion on Work.—W. V. C. (*Dublin*) writes:—"As a reader from the first number, I think I may venture to write with the object of giving my opinion on your paper. In the first place, the greatest fault (if it is a fault) your paper has, in my eyes, is that most of the articles are far above my head, and are apparently intended for skilled artisans. I think there ought to be a medium between this and the opposite extreme of presupposing your readers knew nothing whatever, and giving a definition of a hammer as an instrument for driving nails, etc. Possibly your paper is not intended for amateurs; in fact, your first number, which of any paper is usually taken as a forecast of its future line, contained as its leading article 'A Cabinet in Fretwork for Skilled Workmen.' In every other important particular I consider your paper admirable, the supplements and illustrations being particularly good. I will certainly continue to subscribe to Work, in the hope that I may advance in knowledge, and that it may come down to my level. While I think advertisements of tools, etc., not uninteresting, I do not think they ought to encroach on the pages of the paper, but should be on a separate cover, as in *Tit-Bits*, etc. I hope, too, that at some future time you will see your way to have the paper cut and stitched. I have induced a good many of my friends to take in Work, but some have dropped off for the first objection I have made. I trust, however, that I may soon have reason to ask them to rejoin. I would suggest your sending specimen copies to the reading room, Mechanics' Institute, here, and also to the workmen's clubs at Wellington Quay and at York Street, and to the Corporation Library; at all these places they would come under the notice of the class of people most interested. The addresses given will find them."

II.—Questions Answered by Editor and Staff.

Sheffield Steel and Wire Gauge.—J. H. (*Sheffield*).—I am not aware that there is any gauge known specifically and authoritatively as the "Sheffield." But I suppose that Stubs's gauge is meant, termed also the "Warrington" and the "Lancashire," this being largely used in Sheffield. In any case, the origin of all the old gauges is a matter of surmise only. No one can say with certainty how any of them originated, but a great deal of research and discussion have been expended over the question. The Committee of the Society of Telegraph Engineers, which was appointed to report on the Birmingham wire gauge, concluded—and they based their conclusion on the opinion of specialists—that the Birmingham wire gauge, in common with others, originated as follows:—Beginning with No. 1 wire, which is the largest, each successive size corresponds with a single draw of the wire through the plate, so that No. 10 wire, for instance, would have passed ten times through the draw-plate. Practical, and not mathematical, considerations, therefore, determined the sizes of the early gauges. The manufacturers would naturally draw down as small as possible at one operation in order to save labour; but they would be limited by the strength of men, and by the machinery in use in the last century, and by the cohesive strength of wire. As bearing out this theory, it is found, on investigating the series of sizes, that nearly a constant relation exists between the breaking strength of each wire and the resistance opposed by the draw-plate in drawing it down from its original diameter. Stubs's gauge, in common, probably, with all the older gauges, originated in this way. In 1843 Mr. Charles Holtzapffel, in conjunction with Mr. Peter Stubs, of Warrington, accurately determined the sizes of the best gauges in Mr. Stubs's possession, and formed a table of them. Mr. Stubs adhered to these averaged and determinate sizes, and it is from these that the tool makers of Lancashire and Sheffield have extensively copied. It is only during the last few years that Sir Joseph Whitworth, Messrs. Mallock and Preece, Latimer Clark, Robert Briggs, Mr. Hughes, and others, have proposed, or made, gauges based on strict mathematical principles, and in which either weight, or area, and diameter follow in a simple series of gradations. The outcome of these efforts is seen in one direction in the legalisation of the new standard wire gauge. As to the second portion of your query, it seems to me simply a question of mensuration. Knowing the weight of a square foot of steel sheet of definite gauge, which is supplied in tables, you can easily see how many times that is contained in a sheet of given length and breadth. Something more would be allowed for shearing off the edges: how much would depend on the practice of the rolling mills.—J.

New Adjustable Callipers.—D. R. M. (*Dundee*).—I do not happen to know the name of the maker of these useful callipers, but in reply to your inquiry as to where they may be got, I may say that they are sold by Messrs. R. Melhuish and Sons, 85 and 87, Fetter Lane, London, E.C. I think if you were to bring the notice under the attention of any enterprising tool and hardware merchant in Dundee, he would soon find out by whom they are made, and add them to his stock.

Cutting Edges and Bookbinding.—C. E. (*Hepburn-on-Tyne*).—I presume our friend, C. E., wants to cut the edges of his periodicals; if so there are three methods open to him. If he can get access to one or other of the first two methods to be named he will have his periodicals exactly as he wants them—viz., "to resemble work from a binder's hands." First, cut them with the cutting machine used by binders. Second, cut them with a binder's plough. To do this, the books will have to be screwed up tightly in a press called by binders the "lying press." The third method is a makeshift. Get a piece of deal board a little longer than the book to be cut, and about the breadth of ordinary flooring; plane one edge perfectly straight to serve the purpose of a straightedge or "cut against;" a few heavy weights, and a shoemaker's knife sharpened at the point. Make the book perfectly straight (which by this time must have been sewn) by knocking the back on a flat table. Having decided how much is to be taken off the edges, lay the board on the book in a position to guide the knife and place the weights upon it; take the knife in the right hand and cut close to the board. It will be well to keep the left hand on the board while cutting. Care will have to be taken to cut straight down—the knife will be liable to cut in. Book edges are not polished; they are burnished; and as this operation requires costly apparatus, I would advise C. E. not to attempt it. The edges can be sprinkled with Venetian red mixed with water, to which a little flour paste has been added. If C. E. succeeds in cutting his edges, the sprinkling will be an easy matter, and they will look as well unburnished as otherwise.—G. C.

Old Gold and Frames.—A. F. F. (*Leigh*).—As old frames require a deal of work and variety of treatment, I would suggest your waiting until this subject can be treated in the pages of Work.—G. R.

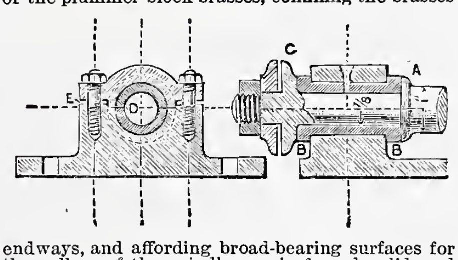
Handrailing.—Tancred.—My writer on handrailing is a working man, and one of the cleverest workmen I know in carpentry, joinery, and cabinet making. Like most of his trade he must make hay while the sun shines, or, in other words, work when and where he is wanted, so just at present his papers do not progress at the rate I should like. Even the practical work that I want him to do for me must wait, for the bigger builders' jobs must of necessity be done first. So I must ask you to be patient and abide his time, as I do, and I can assure you that when the papers appear, the simplicity of his system will amply reward you for waiting.

Bricklaying, etc.—A. S. (*Battersea*).—Bricklaying and house joinery will be fully and comprehensively treated in Work, but it is not possible for me to tell you "where you could get a thorough practical knowledge of bricklaying and house joinery at a small outlay, and the time required to obtain such knowledge." Practical knowledge can be acquired only by practice and by actually engaging in the work. You can learn the theory of bricklaying from books and articles, and how to distinguish between English bond and Flemish bond, etc. etc., but proficiency in actual work you can only attain by doing the work itself. With regard to house joinery, see papers on the "Joinery of the Workshop," which are about to appear.

Back Numbers of Work.—W. B. (*Enfield*).—Back numbers of Work are, and will be, always kept in stock, and you have only to order No. 6, or any number that you require, through the newsagent from whom you usually buy your newspapers and serial publications. I am glad you can say:—"I had the first number of Work placed in my hand by chance. Being pleased with it I have continued taking it in, and my pleasure in it has greatly increased, and I think it will in time surpass any other paper of the kind—in fact I think it does so now." (So do I! Ed.). "I forgot to buy one number—No. 6, I think—and should like to know if I can obtain back numbers, and from whence."

Quarter-Plate Camera.—Camera (*Charlton*).—An exhaustive article on the subject is now in course of preparation; the camera will be the first appliance treated upon. The idea will be to select the most simple and useful types of all appliances at present in use, accompanied by working drawings.—E. D.

Spindle for Circular Saw.—Mona.—The two figures annexed give a detail of the bearings of the saw spindle on page 141. Replying to your specific queries, A is a collar forged solid on the spindle, there being one against each inner bearing face to prevent endlong movement. B B are the flanges of the plummer block brasses, confining the brasses



endways, and affording broad-bearing surfaces for the collars of the spindle. C is forged solid and turned with the spindle. Wear is taken up by filing a little from the joints, D, of the brasses, as much as happens to be required, and screwing down the cap of the plummer block, which is made open at E for the purpose. The surfaces of the pulleys in the figure on page 141 are made round in order to prevent the strap from slipping off, because a belt must run to the largest diameter, and will only leave it when the stress of the work put upon it overcomes its power. That which you take to be a collar behind the flanged pulley is the boss on the back of the pulley, cast with it, and standing out a little beyond its back face. The drawings are to scale.—J.

Where to Buy Gold Leaf, etc.—W. S. W. (*Hummingley*).—Books of gold leaf and also of imitation gold or "Dutch metal" may be obtained at any oilman's or shop where painters' requisites are sold.—Opifex.

Wire Thread Fret Saws.—W. B. (*Enfield*).—On inquiry I find that these saws are not yet in the market: as soon as they are I will mention prices, sizes, etc.

Hand Saw.—H. A. G. (*Rugby*).—You ask, "What is the use of the little knob at the end of a hand saw, which projects above the blade at the end of it?" It is of no use whatever; it is merely ornamental, and is introduced, I take it, merely as affording less abruptness in the transition from the broader to the narrower part of the blade. The decrease in width from heel to end of the saw blade tends to lighten the weight and render the saw more manageable, if I may so speak.

Boat Building.—G. H. (*Cork*).—This subject will be taken in hand at an early date, or rather when summer has given place to autumn. Probably the canoe will be the first boat described, but in due time all kinds of boats for rowing and sailing will be described, and the mode of building them.

Model Sailing Vessel.—W. R. (*Wigston*).—Kindly see preceding reply relative to boats and canoes for fresh and salt water. You wish for a model. Will you write again and give some idea of the size and state the rig you desire? There will be no difficulty in getting papers on the subject; but the writer would naturally like to know the taste he has to suit.

Cement for Repoussé Work.—S. H. E. (*Plymouth*).—Mr. Gawthorp's paper on "Repoussé Work," in No. 7 of Work, is in no way intended as an exhaustive description of the process. It was merely an accompaniment to the pattern sheet given with No. 7, and to serve to show the reader roughly and briefly the broad outlines of treatment. Mr. Gawthorp will go into details in papers that he has undertaken to supply on this beautiful and attractive art. He will readily supply you or any other workman, professional or amateur, with everything necessary for doing the work, and will tell you how to make the cement. I append the recipe you kindly send, and which, you think, has never been published. It is:—"9 lbs. of emery or fine brickdust, and emery in equal parts; 2 lbs. of pitch, 1 lb. of resin, 1 candle, or its equivalent in tallow."

Broken Film in Developing Plate.—A Novice (*Norwich*).—Procure a tube of neutral grey, moist water colour, and then with a fine sable pencil carefully stipple over the defect until by *transmitted* light the patch is the same apparent density as the surrounding parts. It will be as well to varnish the negative first, then if the stipple has to be removed, it can be without further damaging the film. An experienced retoucher would do it before varnishing; it is a mere matter of practice to judiciously match up with the image. Novice had better try repeatedly until he succeeds. It is always best to stipple it too thinly than too much. A light patch in most photographs is more conspicuous than a dark one in the resulting print.—E. D.

Maple Varnish.—H. W. G. (*Stourbridge*).—I have never heard of this varnish being of a rich crimson colour. Maple varnish is of a pale colour, so that yours has either been reddened or is incorrectly described. In either case I should hardly advise you to shake up the sediment, though if this is "sugary" I cannot speak positively. I fancy, however, you must be mistaken about its saccharine qualities, as I do not remember any varnish of which sugar is usually an ingredient.—D. A.

Simple Measurement of Timber.—C. F. (*Bradford*).—The simplest method of measuring round timber is by the "Quarter-girt" system. Required the cubic contents of a tree 30 ft. long and 96 in. in circumference.

Circumference 96 in. Quarter-girt=24 in.
Quarter-girt 24×24=576
30 ft. long

Quarter-girt divisor 113)17280(152 cubic ft.
113
598
565
330
226
104

Answer, 9 ft. short of 153 cub. ft.;
or, according to "Hopper's Measurer,"
Quarter-girt 24×24 in. =576
30 ft. long
divisor of 12×12=144
144)17280(120
144
288
288
0

A difference of about 22 per cent.—A. G. H.

Wood Stains.—French Polisher (*Maida Vale*).—There is no book which I could unhesitatingly recommend, but the "Practical Guide to French Polishing," published by Wyman & Sons, is, perhaps, the best. The subject will be fully treated in Work as soon as possible; meanwhile the following suggestions will be of use to you:—Yellow—Methylated spirits, 1 pint, turmeric, 4 oz.; or water, 1 qt.; picric acid, 1 oz.; ammonia, 1 oz. Blue—

Solution of indigo in sulphuric acid diluted to shade. Greens of various tones by mixing blue and yellow in different proportions. Red—Decoctions of alkanet root, logwood, and kindred dye stuffs. You will find it far better to buy your stains ready made. A large variety of stains may be made from the aniline dyes which you can buy either dissolved or dry. W. R. Roberts & Co., Earle Road, Liverpool, manufacture some excellent wood stains in all colours.—D. A.

Books of Japanese Fret Designs.—P. E. (*Ebbw Vale*).—I was very interested in your letter, but to comply with your request is not possible, for, alas! I know of no real books of Japanese fret and carved designs. I own some hundred native books, and the few motives for such patterns therein are already reproduced in WORK. I have designed many which I fondly hope are not those mongrel ones you have obtained at emporiums. I have seen such, that made one blush for the artistic depravity of their draughtsmen. You have had a chequered career, and should be a master of all trades and Jack of none—some day. May you reach 6 ft.—J. G. G.-W.

Removal of Paint from Plaster Cast.—A WHITESMITH (*Norwich*).—Should the removal of the black paint at present on the cast be absolutely necessary, a strong solution of American potash may be made and some sawdust wetted with it. If the sawdust thus moistened is left lying like a poultice over the cast all night, the paint may be washed away next morning with cold water. But it appears to us that the trouble and risk of this might be avoided by painting over the old colour—by giving it two coats of new paint, mixed with oil in the usual way, and a third of flat colour—*i.e.*, colour with very little oil and a good deal of turpentine. Painted casts look better dead than shining. Terracotta colour would be very suitable. Tube colour, bought at the artists'-colourman's, is the best, but it is the most expensive. Common tinned paint, to be bought at any oilman's or ironmonger's, would be quite sufficient for the two coats, tube colour being used with the turps for the flatting.—S. W.

Hardening Cold and Wood Chisels.—C. W. (*Kilburn*).—You have described the process of hardening and tempering correctly, and therefore the only thing to advise is to practise, varying the shades of colour until you get the right one. Let down and quench at a plum colour, and if that does not succeed, try shades between it and a straw. All steel is not alike, but qualities vary widely. Do not get it too hot either in the first place, or you will burn it so that it will not take a temper. There is no advantage in using oil for chisels; water will answer as well.—J.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Drilling Square Holes.—A READER writes:—"I noticed in a paper, I think the *Railway Herald*, that the scientific method of drilling square holes has been found out, and patented in Austro-Hungary. Do any of your readers know of the same, and could explain it?"

Sharpening Carving Tools.—AMATEUR (*Stockport*) writes in reply to J. W. B. (see page 172):—"Will J. W. B. kindly tell me how tools should be ground, and oblige?"

Child's Wooden Toys.—W. A. (*Hanley*) writes:—"Can any correspondent inform me where I could purchase the above wholesale, or is there a book to be purchased on the manufacture of the above, if so, where and price?"

Ivory Walking Stick.—W. A. (*Hanley*) writes:—"Can any brother reader kindly suggest the best cement that will join broken ivory walking stick?"

Soap.—G. H. (*Manchester*) writes:—"In what manner is paraffin wax used with soap for washing, and what is the benefit?"

Joiners' Composition.—J. R. (*Oldham*) asks:—"Can any of your correspondents in 'Shop' tell me how to make a composition for filling up joints and crevices in wood?"

Convertible Furniture.—W. W. W. (*Nottingham*) writes:—"Will some experienced readers of WORK give me their modes (with sketch and few dimensions) for a suitable and convenient arrangement of constructing a neat and artistic convertible chair, which, when turned, can be made into library steps?"

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Pronged Rings.—Syer & Co. (75, *Chiswell Street*) write in reply to E. C. (*Battlemore*) (see page 190):—"Replying to your correspondent's inquiry *re* above, we should be glad to undertake the making of these for him."

Machine for Current of Air.—P. P. (*Withington*) writes in answer to BELLOWS (see page 190):—"He had better get two pairs of house bellows, and having screwed fast the handles to a large board (which will serve as a bell-plate or stand), connect the hinged handles to a double crank shaft, in such a manner that the bellows will alternately rise and fall, and thus if the nozzles are connected a continuous flow of air will be the result. I have the above arrangement under my bench (but without the shafting), and I work them with my feet direct. I use the wind for blowpipe work, and the result is a fairly steady blast. If BELLOWS wishes it for a forge, my advice is get a rotary blower; they are cheaper than smiths' bellows, in first cost, and last much longer. If he is an amateur, and has a small portable or other hearth, the above arrangement will act admirably."

Fretwork Patterns.—F. S. (*Dorchester*) writes:—"I am a constant and very grateful reader of WORK, and being anxious to 'do unto others as I should wish to be done unto' (in this case the helping out of a difficulty), if W. E. M. (who is making inquiries for a book of fretwork patterns) will send his address to me, also rough sketch of frame, I will send him the covers of a book I have by me, and address where to send for it. By description of frame, etc., I fancy I have the identical book."—[I insert your reply to W. E. M., but it will be unnecessary for him to avail himself of your kind offer owing to replies on this subject from other writers.—ED.]

French Polishing.—C. S. (*Radford*) writes in reply to T. A. (*Belfast*) (see page 174):—"I think the reason why your polishing goes dull after a time is that you use too much oil. I only use just enough oil to prevent the polish from sticking to the wood by applying a little on my finger to the pad. If you try that you will find a difference."

French Polishing.—R. H. (*Lewisham*) writes in reply to T. A. (*Belfast*) (see page 174):—"As regards French polishing fretwork, perhaps the following hints may prevent the excess of oil from spoiling his work in the future. After dipping the wad of wool, with its covering of rag, into the oil, apply a little French polish, and rub well in, but do not attempt to polish. After applying what you consider sufficient, put the work aside in a warm room for a few days. When you begin to polish use white polish at first; no oil at all if the wood appears greasy; change the rag each time fresh polish is put on to the wad of wool; when a fair polish appears then use French polish; when the polish is perfect, finish off with fresh wad of wool and rag, and a small quantity of spirits of wine, rubbing lightly. This will clear off all oil, and leave a first-rate surface, if only small drops of oil have been used during the polishing process. Always polish in a warm room, one with a good fire in it, and thoroughly dry and air the linen rags; put small quantities of polish on the wads of wool, very little oil, and make the circular strokes cover a fair space each time, rubbing the way of the grain only at the finish each time. If you carefully follow this advice I think you will be as successful as myself, since I had them given to me."

Wood Colouring.—W. G. (*Southport*) writes in reply to OX GALL (see page 174):—"That he will find the following answer his purpose for staining deal a dark oak colour: Two pennyworth of vandyke in oil, one-eighth of a pint of terebine, ditto of turpentine, and one fourth of a pint of kerosine or paraffin oil. Mix well, and try on a piece of planed deal, first laying it on thinly with a piece of sponge or old felt. If too dark, add more paraffin, again experimenting until the desired colour is obtained. After staining the overmantel, rub well with a piece of old woollen cloth or felt, then give a coat of French polish, using a wadding rubber. Finish with beeswax and turpentine, well rubbed with a soft, dry cloth. This will simulate the colour and dull polish desired, with as little labour as any process that I know of. Permit me to add, for the information of other readers of WORK, that this stain may be brightened by using more or less of raw sienna, also ground in oil, instead of all vandyke, thinning as required with paraffin oil. I use it largely for trade purposes, being cheap, easily and quickly applied, has a nice appearance, and leaves the work with a smooth surface ready for polishing or varnishing. And speaking of varnishing here is another wrinkle from my own practice. Before varnishing plain wood, either stained or unstained, the article must be well sized, or the varnish will sink in. Ordinarily glue or gelatine size is used. My plan is to give two thin coats of French polish laid on with a brush; when dry rub down with fine, worn glass paper, finishing with a coat of good oak varnish. This beats anything I have yet seen used."

Elizabethan Twist in Lathe.—W. P. W. (*Newport, Mon.*) writes in reply to C. C. E. (see page 109):—"I am not quite clear as to the word 'Elizabethan,' but if C. C. E. means any spiral having a convex contour—a piece of rope for instance—he is quite mistaken, it can easily be done in the lathe. I have a 4½-in. screw-cutting lathe of ordinary type, in which I have done several pieces of spiral work, and could do it in any such lathe with overhead gear, without the aid of rasp or file. If C. C. E. would wish I will send him a specimen finished by cutter only."

Refrigerator.—C. H. W. (*Hampstead*) writes in reply to URGENT (see page 174):—"A refrigerator is constructed as follows: First an inside case of ½-in. or ¾-in. deal lined with not less than No. 12 zinc; this case is covered outside with felt; a space is left between this and the outside case that can be made of inch stuff, usually with two lids or doors of cabinet pattern. On the inside lid the zinc is raised, and the space thus formed is filled with cork dust. Ventilation is made through inside case near the top, to carry off warm air that would condense and drop on contents of cupboards. I have made several, and the last one something of the pattern URGENT wants. It was used as a counter, etc., in the ice cream trade, and pronounced by Gatti's men the best on their round to keep ice. The place to store the ice was at the top, and water from same trickled down sides of cupboards in centre, into a sort of trough, and through pipe in floor, to drain. There is a lot of work in making one, and they would come expensive. I will send plans with Editor's permission."—[By all means send plans.]

Trade Notes and Memoranda.

MR. FRANKS, of the British Museum, recently secured from the gravemounds and dolmens of Japan a splendid collection of old pottery, iron weapons, and copper ornaments. The pottery is very curious, and the collection, as a whole, is unique.

A MR. ANDERSON, of Leeds, has invented a system of ventilation for the underground railways, which is, at least, ingenious. He proposes to discharge the noxious fumes from the locomotives into a long exhausting flue placed between the rails. A long sliding box underneath the locomotive receives the vapours from the smoke box, and transmits them to the flue. The sliding box travels over the flue fitted with suitable valves, which are opened by the sliding box in its passage, the valves being of such a length that a second valve is covered by the sliding box before it has quite passed over the previous one. The flue is exhausted by fans stationed at intervals along the line, and driven by stationary engines. The fan being set to work, and the train started, as the engine passes over the valves in succession, the steam and products of combustion are sucked from the engine through the valves in the exhausting flue, and are drawn from it and discharged through suitable shafts into the atmosphere. The difficulties which we should apprehend here would, however, be of a mechanical nature, due to the great difficulty of making the apparatus sufficiently free from leakage.

A RELIC of the iron age has been found at Nötterö, on the Christiania Fjord, in Norway. It consists of an iron pot with handles, a sword 2 ft. 6 in. long, an anvil, and a pair of smith's tongs, together with some bones. The mound in which it was discovered is now 300 yards inland, and was believed at one time to be close to the sea.

A SAN FRANCISCO journal contains an account of the discovery of a new method of preserving ironwork from rust. It consists in brushing it over with a thin wash of turpentine and white lead, a thin compound which will penetrate into the very interstices of the metal, which the thicker oil paint is unable to do. No corrosive action or scaling can then take place. Mr. Heald, the discoverer, is said to have been led to this result by observing that some old gasholder plates which were badly corroded still retained the "shipping marks" in a state of perfect preservation.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price 3s. 6d., or securely packed by Parcel Post, 4s.

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albumenised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price 7s. 6d. Securely packed, post free, 8s. 6d. If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.

Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

Catalogue of Machines, Designs, Wood, Tools, &c., with several Hundred Illustrations, and full Instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. Good Fret Saws, 1s. 6d. per gross; best ditto, 2s. per gross.

Eclipse Design, No. 102.

Wall Bracket. Price 5d.

PRINTED AND PUBLISHED BY CASSELL & COMPANY, LIMITED, LA BELLE SAUVAGE, LONDON, E.C.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

VOL. I.—No. 18.] SATURDAY, JULY 20, 1889. [PRICE ONE PENNY.

A MITRE BLOCK AND HOW TO MAKE IT.

BY DAVID DENNING.

INDIFFERENTLY known as the mitre trap or mitre block, the useful appliance which forms the subject of the present article is just one of those things which may be made by the user quite as well as by a specialist in tools, if indeed it can be called a tool, for it is rather an aid to the successful use of those things which come under the comprehensive name of tools than one itself. I daresay mitre blocks are to be bought in the ordinary way of trade, but they frequently, I may say generally, are made by those who use them. This is not surprising, as any cabinet maker or joiner can make one if he possesses sufficient ability to work accurately in the way of squaring up, etc., and unless he is able to do this he would be a very poor craftsman indeed. Nor will the advanced amateur experience any great difficulty in constructing a mitre trap when it is described to him. He has not the same opportunity of knowing how to make it as his professional *confrère*, for the latter is sure to have at least some shopmate who can lend him one to copy from, or improve on according to his own ideas. The amateur, however, working mostly alone, is to a great extent dependent on other sources for his information, and I don't think it would be too much to say that a large proportion of amateur wood-workers have never seen or heard of a mitre block. Anyway, its usefulness is so great to any one who has occasion to form mitres, that no apology is necessary for its mention in these pages. It may be an old-fashioned contrivance, but old or new, anything which can in any way facilitate operations is deserving of attention.

With regard to home-made articles, it will generally be found in every appliance, made by a worker for his own use, that there is some character about it—the maker knows what he wants, and has his own ideas about its construction. One man thinks one way best, another fancies that some little alteration will render the thing more convenient or serviceable. Hence, in these appliances which are made with a full comprehension of what is wanted, and an equal amount of facility in manipulating the materials of which they are formed, one finds that they are stamped with an individuality which is not, indeed, cannot be, seen in ordinary purchasable tools. Now, I don't wish you, for whom I specially write, to try and find out some feature in the block described, simply with the intention of impressing your own individuality on it, but if you think you can improve on it in any little detail, and so render it more serviceable for your own special class of work, by all means embody your ideas when making up the block. I tell you how you may make a good useful one of suitable size for ordinary purposes, but do not suppose that any departure from dimensions or even mode of construction will necessarily be a fault. If you are in doubt, or don't know anything about a mitre block, follow the directions as closely as desired, but, of course, incorporate any improvements which may suggest themselves, and if you hit on a good practical idea, pass it on for the benefit of both amateurs and professionals.

As the construction of the mitre block is under consideration at present, its use need only be incidentally alluded to, as those who know what a mitred joint is will require few directions how to use the block when they have made one. Its adaptability for its work will be evident, but in addition to the aid it affords in cutting mitres, or rather in finishing them, it may be said that if made as directed, it will afford a ready means of squaring off ends of pieces, such as door rails and styles. Indeed, to give the thing its full title, one would be justified in describing it as a mitreing and squaring block. The illustrations, Figs. 1, 2, and 3, show the block. Fig. 1 represents it in front elevation, or by merely imagining the ends reversed, as the back, and Figs. 2 and 3 the ends. A and B are two blocks, both precisely alike in size and shape. The one at the left-hand end is fixed to the frame, D, to which the other is so secured, that it can be

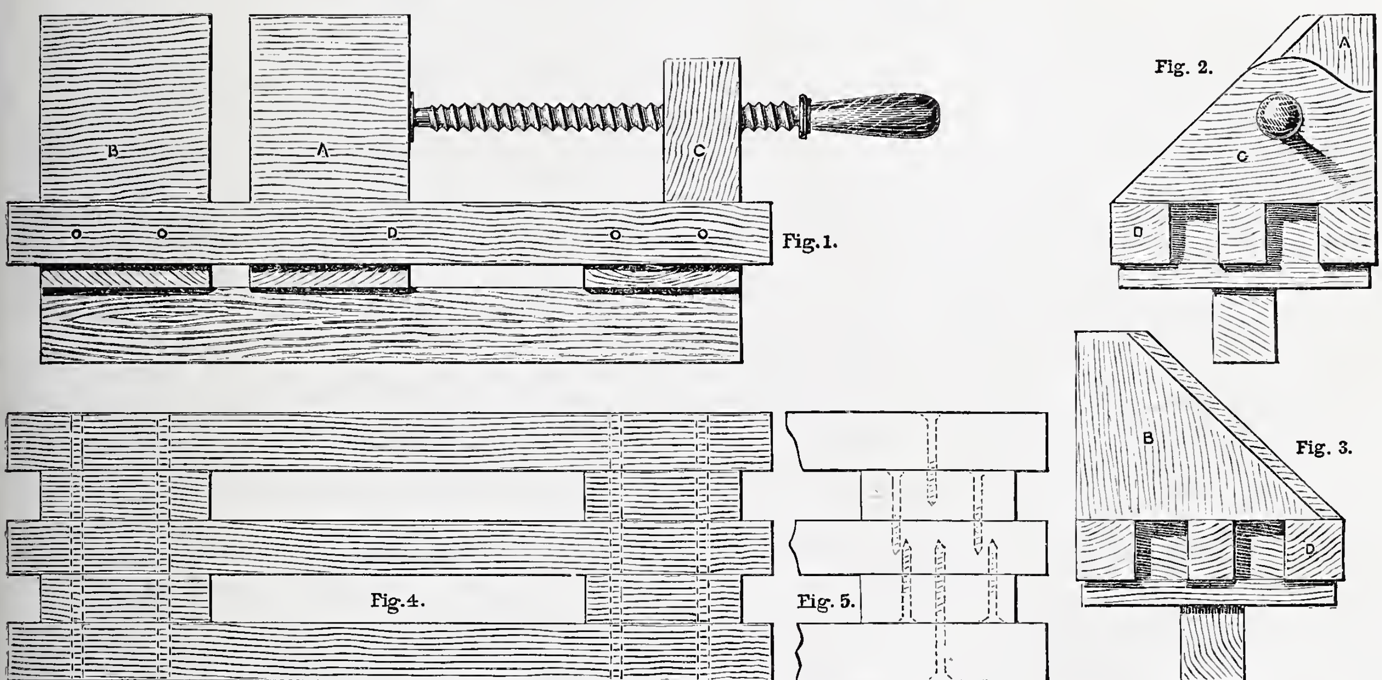

Fig. 1.—Front Elevation of Mitre Block, showing Hand Screw. Fig. 2.—Elevation of Right-hand End. Fig. 3.—Elevation of Left-hand End. Fig. 4.—Plan of Frame. Fig. 5.—Alternative Mode of Fastening Parts of Frame together by Screw Nails.

moved by the screw working in c. As will be seen from Figs. 2 and 3, one face, *i.e.*, the front of A and B, slopes at an angle of 45 degrees from the top of D, forming the guide for mitreing, while the back is perpendicular to the top of D, or rather to the triplicate bed of which D is a member.

Having said this much on the outline of a mitre block, let us now consider its construction in detail. In describing this, I take the various parts in the order in which I fancy work may be most readily intelligible, for it can easily be understood that in making the block it is of small consequence which part is made first. Before going any further, let it be said that of whatever kind of wood or woods the thing is made, the material must be perfectly dry, so that there may be no subsequent twisting or casting. If the trap is to be of any use it must be accurately made; something near exactitude will not do, so that it is necessary not only to make and fit it correctly, but to use no wood which will not remain true. If there is the slightest suspicion of the wood being damp, place it in some warm place, and let it remain till all moisture has been got rid of, or to borrow a very expressive word from the workshop, till it is almost "baked," before attempting to finish any of the pieces.

Suppose we start with the frame. I should say perhaps that the measurements and other details are described from a block which lies on the table before me. They may therefore be taken as accurate, but minute fractions are not noted. The frame, or bed, is 16 in. long by $5\frac{1}{4}$ in. wide, and is formed as shown in Fig. 4. It is of birch, but any hard wood will do. The two outside pieces are $1\frac{1}{4}$ in. square, the centre piece $1\frac{1}{4}$ in. by 1 in.; the three of them being connected by four other pieces $1\frac{1}{4}$ in. deep by 1 in. thick, and $3\frac{1}{2}$ in. long. It is most essential that the open spaces which form the guides for the movable block, A, should be perfectly true. It would never do to have them wider at one end than the other, or in any way irregular, and, of course, accuracy will depend on both sides of the centre piece being parallel with each other and the inner edges of the outer rails. If these points are attended to, and the pairs of connecting blocks are equally correct, the result must be satisfactory. These parts may be fastened together by glue, and by wooden pegs running through all of them, as shown by the dotted lines on Fig. 4. If this mode be adopted, it will be more convenient to bore the holes in each piece separately before gluing up, their positions being accurately marked. For the pegs, ordinary dowel stuff will do very well. If on fastening the pieces together it should be found that the top and bottom surfaces are not quite level through the holes not being accurately bored, the inequalities may be reduced by planing.

A somewhat easier and simpler method of joining the pieces together, and one which will probably find more favour with most readers, is simply to screw the pieces together as suggested in Fig. 5. The short pieces are first screwed to the centre rail, and then the outer rails to them. The heads of the nails should be well sunk, especially those into the middle piece, in order that they may not interfere with the glue acting properly. Glue alone might do, but I am inclined to think dependence on it would hardly be advisable, especially as the use of a few screws does not entail much trouble. The frame is further braced with two pieces of $\frac{3}{4}$ stuff fastened on underneath. The width of these is the same as the block, B, which, of course, must be screwed down before the piece at the bottom can be fixed as it is with screws.

The same may be said of the other end piece, but before considering it further, it will be convenient to describe the blocks, A and B. They are of mahogany, faced up on the sloping side with $\frac{1}{2}$-in. rosewood, which is glued to them. If the work of facing should be objected to, it may be dispensed with, though it is advisable to face with some hard wood, if not absolutely necessary. However, whether faced up with another wood or not, too much care cannot be exercised in making the work true as already stated. The fittings of the sliding block, A, are as follows: Two pieces of equal width and thickness with those connecting the main portion of the frame are screwed to the bottom of A, and work within the open spaces of the frame without either stiffness or side play. They must, of course, be so fixed that the sloping face of A is perfectly level with that of B, for if not, the intention of the mitre block will be frustrated. Another piece of rosewood, the same size as the others, must also be screwed under A, but this time instead of fastening it to the frame, it is fastened to the movable block by screws driven into the sliding pieces. By this arrangement, A is free to move backwards and forwards along the frame, but in no other direction.

We may now proceed to consider the screw and block, C, which, however, hardly call for any special remark. The face of C must be on the same slope as those of the other two blocks, to allow of the plane being used, and, of course, the back must be square. The shape of the top of the screw block is merely rounded off as shown, for the sake of appearance. It may be suggested that so long as hand screws are to be obtained as cheaply as now, there is small reason for incurring the expense of having a special screw and block prepared. That, however, is merely a detail which has not been enlarged on, as the great thing is to have a screw with tapped block. Screwing up will force the block, A, towards B, but unless some arrangement be made it will not draw it back. The simplest and most natural way of causing the screw to pull as well as push, is to have a small plate of metal with a hole in it for an ordinary screw nail to revolve freely in it. The nail is driven into the end of the wooden screw, just as if the plate were being fixed to it, but not tightening it up so much that the plate cannot revolve. This plate is then further screwed to A, as indicated in Fig. 1, when, according to the direction in which the wooden screw is turned, the sliding block is either pushed forward to or drawn away from B, so that anything placed between can be gripped as in a vice.

It will now be seen that on a piece of wood being laid on the upper surface of the bed and held fast between the two blocks, the end can either be trimmed off to form a perfect mitred joint, or squared up as the case may be. It will be understood that the block is merely used for the finishing of the surfaces, as it is not a mitre cutter. Consequently, when using the plane, care must be taken not to injure the block itself by taking any shavings from it. The remaining piece of wood at the bottom, which has not yet been mentioned, is merely for the purpose of allowing the trap to be held by the bench screw when mitres are being worked, and for fastening to the top of the bench by hand screws when the trap is wanted for squaring purposes. Though simple in construction, few who have much occasion to use one would care to be without it. If properly made on the lines laid down, and properly used, such a mitre trap as described should last a lifetime, though it may be necessary to true the surfaces now and again.

PRACTICAL HINTS ON MOUNTING OBJECTS FOR THE MICROSCOPE.

BY A. T. SMITH.

THE microscope has of late years rendered such signal help to the cause of science, and the secrets wrested from nature by its aid are so many, varied, and of such vast importance, that almost every scientific worker finds it necessary at some time or other to turn to it for assistance; but apart from those who make use of the microscope simply as a means to an end, there are a large number of workers who make the microscope and microscopic research their special study.

The members of this fraternity are aptly named "microscopists," and the family may be readily divided into two well-marked varieties, easily distinguishable by their special peculiarities.

The first variety, comprising all those who devote their energies to the study of the microscope as a work of art, and confining their attention almost entirely to the invention and perfection of apparatus, with very little regard to the wonders revealed by their favourite instrument, may be briefly described as the "brass and glass" variety.

The second, including those who spend their time roaming the country exploring fields, hedgerows, sandhills, ponds, ditches, etc., etc., in search of fresh objects of interest for examination and preservation, may be briefly described as the "bug and slug" variety.

Though both varieties are necessary to ensure the due perpetuation of the species—the former being more ornamental than the latter, which is, perhaps, the most useful—we will for the present confine our attention to the wants of the B. and S. variety, which also, perhaps, boasts of the largest number of disciples.

The acquisition of the technical knowledge and practical skill required to successfully prepare and mount an object for examination under the microscope, is one of the great desiderata aimed at by every microscopist; and it is my desire to give as clearly as possible a few practical hints gathered from my own experience as to the best methods of preparing and mounting objects for the microscope. I don't pretend to say that all that follows will be absolutely new; on the contrary, I expect that most of what I have to say will probably be old news to expert microscopists, but I live in the hope that what I am writing will at the least repay perusal by novices.

Microscopic objects may be divided into three classes, according to the method of lighting employed in their examinations:

1. Opaque objects, which require to be examined by direct or reflected light.

2. Transparent objects, which are best seen by transmitted light; and,

3. Semi-opaque objects, which may be examined either by transmitted light alone or in conjunction with reflected or direct light.

Examples of these three classes will readily present themselves to the reader.

It may be well to premise for th

information of absolute tyros, that nearly all microscopic objects are now prepared on slips of glass measuring 3 in. × 1 in., which slips, with the edges ground, may be obtained from most opticians at prices varying from 4d. to 1s. 6d. the dozen, according to thickness and quality. The cheaper slips are cut from pretty thick glass of a coarser quality than the dearer kinds, and they are apt to contain air bubbles or streaks on the surface or in the interior at inconvenient places; however, they answer quite well enough for mounting dry objects.

The edges of the slips are prepared in two ways, ground either perfectly flat or rounded. Those prepared in the latter way are most generally used, but some prefer the former, because having a comparatively sharp upper edge, they are more readily picked up from a flat surface than the rounded ones, and not so liable to accidentally slip out of the fingers and get broken. Covers of exceedingly thin glass, which may also be obtained from the opticians, of different sizes, and either round, square, or oblong, from 1s. 6d. per half-ounce, are used to preserve the objects from contact with the air and from dust.

No workman can work without tools, but in this, as in most other things, the fewer and simpler the tools used, the better the result will be. Everything necessary for present purposes, in addition to slips and cover glasses named above, is comprised in the following list, and of those named very few items need be bought, as will be readily seen:—

Two or three dissecting needles; a small camel's-hair pencil; a pair of tweezers, curved preferably; a few vulcanite or glass rings; a turn-table; a small pair of scissors; a small bottle of japanners' gold size (to be obtained from the oilman); one or two bottles of various coloured varnishes made in accordance with instructions following; a bottle of dull black varnish, and a little marine glue.

The dissecting needles may be made out of wooden pen-holders, as follows: After removing the barrel, wrap tightly round the end a few turns of strong thread or thin bouquet wire to keep the wood from splitting; then take a common sewing needle and push the point into the end as far as it will go, taking care not to split the holder; now pull it out, reverse it, and push the head into the hole just made, and the dissecting needle is completed.

It is well to have the needle pushed in a good way, as it is not advisable for it to have too much spring, and it is also useful, instead of having all your needles perfectly straight, to bend the end of one to a right angle, and of another to an angle of about 45°. This is best done by heating the end red hot, bending it to the required angle, heating it again, and cooling suddenly by plunging in cold water or tallow. This latter operation restores the steel to nearly its original hardness.

The camel's-hair pencil needs no description.

The tweezers and vulcanite rings (cells) should be obtained from the opticians.

A small pair of ordinary scissors will answer present purposes, but if small dissecting scissors are bought, care should be taken in choosing them that they will cut right up to the extreme point, otherwise they will be almost useless for our purpose.

All the remaining articles tabulated can be obtained from the opticians, but if it is preferred to make the varnishes at home, here are the recipes for them.

Sealing-Wax Varnish.—Made by dissolving as much sealing wax (any colour) in methylated spirits as the spirit will take up. If a few shreds of gelatine are put in the bottle as well, it will have the effect of absorbing any water with which the spirit may be adulterated, and will cause the varnish to dry with a good bright surface.

Zinc White Cement.—Dissolve half an ounce of gum damar in one ounce of benzine, and add white oxide of zinc until the mixture is quite opaque.

Japanners' Gold Size.—This may be used either by itself or mixed with various coloured pigments according to taste.

Brunswick Black.—Ordinary Brunswick black makes a very good varnish for finishing slides.

Dull Black Varnish.—Made by mixing lampblack with turpentine. This varnish, if properly mixed, should dry with a perfectly opaque, dull black surface.

The zinc white and gold size varnishes are the most reliable, as the sealing-wax varnish is apt to shell off when it becomes very dry and old, being too brittle, but it looks very nice when newly put on.

The turn-table is used for causing the slide to revolve, and so facilitate the application of the varnish to the edge of the cover glass, and in choosing it you should see that the slide holder runs true and revolves freely. A turn-table will cost from 5s. to 21s., but you cannot very well get on without one, unless you are content to allow your work to look "botchy." Those having an automatic arrangement for centreing the slide are the most convenient.

Having procured the few necessaries mentioned above, let us proceed to work, and as opaque objects are the most easily mounted, and require the least preparation, we will commence with them and suppose we have to mount the wing of a small butterfly or moth.

Opaque objects are, as a rule, best examined in their natural state, and without any preparation except removal of all moisture; and as they are usually of some perceptible thickness, to avoid pressure they nearly always require to be mounted in a raised cell.

To make a cell, choose a ring of vulcanite or glass sufficiently large to enclose the object and of the requisite thickness; after carefully cleaning a 3-in. × 1-in. slip, cement the ring to it at the centre with marine glue, and when the cement has dried make the inside of the cell black by applying to the surface of the glass and the edges of the cell a thin coating of dull black varnish. When this is dry apply evenly to the top edges of the cell a thin coating of japanners' gold size.

The slide should now be put on one side for a few hours, under a glass shade or in a place free from dust, in order to allow the gold size to become "tacky," and when it has reached this stage the cell is ready for the reception of the object.

If the object, which I repeat should be thoroughly dry, is just large enough to touch the edges of the cell and the under side of the cover, well and good, place it carefully in the cell; but if the object is slightly small, the least sensation of gold size, between the object and the bottom of the cell, will have the effect of keeping the former from slipping about and so getting injured after the mount is completed. If gold size has to be applied in this way, it is as well to let it get nearly dry before completing the mount.

When all these instructions have been carried out, select a cover glass sufficiently large to extend about halfway between the inside and outside walls of the cell, and clean it carefully with a fine cambric handkerchief. I say cambric, because if a silk handkerchief or chamois leather is used, electricity is set up on the surface of the glass, and particles of dust are attracted, which is not desirable.

The cover glass, when cleaned, should be taken in the tweezers, warmed, and carefully placed on the top of the cell, care being taken that the edges adhere all round.

The slide should now be placed on the turntable, and a thin coating of gold size applied to the edges of the cover glass, and the whole should be allowed to dry. When dry, another coating may be applied, sufficiently thick to fill up the angle between the edges of the cover glass and the top of the cell walls, and this again may be nicely finished off with coatings of various coloured varnishes, sealing wax, or other fit substance.

All slides should be carefully labelled as soon as mounted, but it is often inconvenient to do this at once on account of the varnish not being dry. A good plan is to write the name of the object in ink on the back of the slide. This can be cleaned off after the varnish is dry, and a neat label affixed at one end to the face of the slide. The label should state the name of the object, where the object was obtained, date of mounting, method of preparation, and name of mounter.

Various modifications of the above method, to suit different objects, will at once suggest themselves to the careful observer; for instance, the object may be too large for any of the cells you have in stock. This difficulty may be met by cutting a cell of a suitable size out of a piece of cardboard of the requisite thickness, and using a square or oblong cover glass, instead of a circular one. Again, the object may be of such a nature that you may wish to have both sides of it displayed. In this case you will, of course, proceed as above, but omit to blacken the interior of the cell, but you must be careful to choose a cell of the exact size required, as you will not be able to use gold size to keep it in its place if it does not fit.

Sometimes the object is so thin that all your rings will be too thick; this difficulty may be met by cutting a cell out of paper with the help of gun wad punches; or a circle of gold size of the requisite width may be described on the surface of a glass slip with the help of the turn-table, and the object mounted in the cell thus formed. In this case, all that is necessary after placing the object in position is to gently warm the cover glass, which will at once adhere, then finish off in usual way.

If you have many objects to mount, the best plan is to prepare a number of slides by cementing cells to them beforehand; but great care should be taken that when the cement is dry the rings adhere at every point, so that there may not be the slightest chance of air penetrating to the interior of the cell.

You can always ensure the success of a dry mount by taking care that everything inside the cell is dry before the cover glass is put on, and making sure that when the slide is finished it is hermetically sealed. If these two rules are carefully adhered to, you need have no fear of mould appearing to spoil your work.

As mounting for the microscope requires great nicety of manipulation, it may be found difficult at first, but this will soon disappear by practice.

AN IRON REBATE PLANE.

BY A FOREMAN PATTERN MAKER.

Purpose of Rebate Plane—Why Skew-mouthed—Effect of Skew-mouth—Pattern for Rebate Plane—Core Box—Prints—Mouth—Filling in Blocks—Dimensions—Special Rebate Planes.

Hitherto I have treated only of those planes which are used for working over broad surfaces, the planes being traversed sideways at will to operate on any portions of these surfaces. In another and larger class of planes the action is entirely localised in the direction of the breadth, so that they remove a narrow zone of material only. These embrace the rebates, rounds, and hollows, fillisters, ploughs, beading, and other planes. They constitute by far the largest portion of the kit of a joiner and cabinet maker, and are mostly made in wood. The simplest of all is the rebate, because it operates only on flat surfaces, the irons of the other planes, the plough excepted, being mostly of various sectional forms. In few of these is the cutting action so good as in the common bench planes; first, because they have single irons only, and second, because in many cases, as for example in the moulding planes, the proper cutting action degenerates into scraping at certain sections towards the sides of the planes, where the angle which the iron makes in relation to the sole, and which should properly be normal at every portion of the curve, cannot be maintained. Moreover, all these irons are very slight in themselves, and apt to chatter on their seats.

It is to obviate somewhat the tendency of the rebate plane to chatter that it is usually made skew-mouthed. The skewing is not great, but it has the effect of causing the iron to sever the grain fibres in detail, in the same way as a chisel when directed obliquely cuts more sweetly than when it is thrust straightforward through the stuff. Making the body of the plane of metal instead of wood extra weight is obtained, and the best results possible from the rebate plane are secured.

A common iron plane is shown in section in Fig. 1, the pattern in Figs. 4 and 5, and the core box in Figs. 2 and 3. In Figs. 4 and 5, the print, A, of the pattern is of the same thickness as the width between the inside faces of the casting. This print is planed to gauged thickness first of all, and upon it the pieces, B, which are of the same thickness as the sides of the castings, are nailed. The thickness of these sides when finished should be $\frac{1}{8}$ in. In the pattern they may be $\frac{3}{16}$ in., or a trifle more if it is intended to plane the sides in preference to filing them.

Before being fastened on, the holes through which the shavings have to escape are cut out, and usually the top edges are shaped to an ornamental outline, somewhat as shown in the figure. Note the great breadth of the print, which is quite double that of the pattern itself, in order to enable it to balance the core properly, the pattern moulding upon its side. Being so shallow it is not necessary to make any taper in the sides of either pattern or print. If made dead square, the rapping will cause it to deliver freely. This is a case where coring out is quite necessary, because the deep and narrow body of sand between the sides would not deliver from a pattern made just like its casting, except by imparting an extravagant amount of taper thereto.

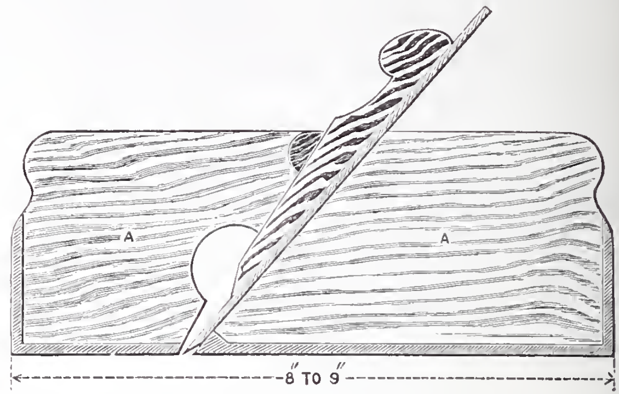

Fig. 1.—Section through Rebate Plane.

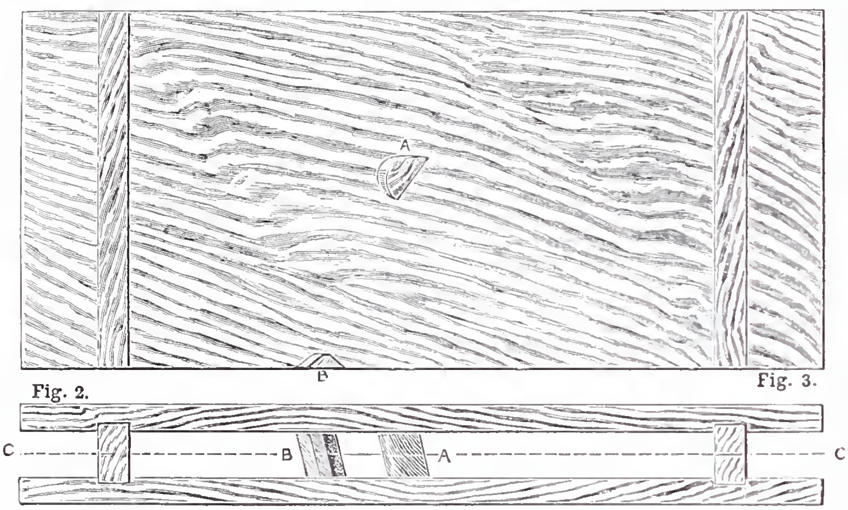

Fig. 2.—Core Box for Rebate Plane: Plan. Fig. 3.—Ditto: Section.

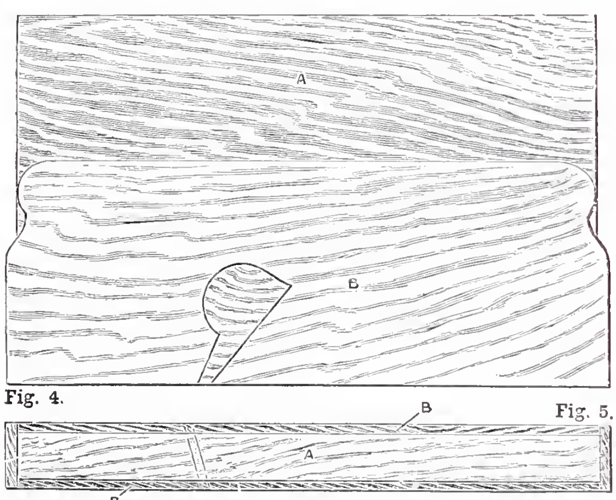

Fig. 4.—Pattern of Iron Rebate Plane: Elevation.
Fig. 5.—Ditto: Plan.

The actual mouth for the iron cannot be cut in the pattern, because it would not mould properly. This must be cut through in the casting, either with a slitting file, or with a hack saw, and finished by filing to the size required.

The core box (Fig. 2) is simply a rectangular open framed box having its ends grooved into the sides in the usual way, and having a piece, A, bridging across it to act as a stop for the wedge, and also a triangular bit, B, forming a bedding for the lower end of the iron which comes just above the bevelled facet.

The filling in blocks shown at A A (Fig. 1), made of any suitable hard wood, are fitted carefully in place, using red lead to test the accuracy, or otherwise, of their contact. Before fitting them, it will be necessary to rough file the inside faces of the casting, and to check their parallelism with internal callipers, to be sure that the width at the upper portion is not less, but of the two slightly greater than the width lower down. As in the previous examples, see that the fit is perfect everywhere, and also that the bedding of the iron on its seat, and of the wedge on its iron, are perfect, in order to diminish risk of choking and chattering. The section (Fig. 1) shows the relative arrangements of blocks, iron, and wedge so clearly that further explanatory remarks are unnecessary.

I have not given many dimensions in this instance, because the drawings are proportional, and all measurements can be scaled. An ordinary rebate plane is about 9 in or $9\frac{1}{2}$ in. long. The width for an iron plane may range from 1 in. to $1\frac{1}{2}$ in.

It is not advisable to exceed $1\frac{1}{2}$ in., nor is it well to go below 1 in. in an iron plane; though in wood we may go to $\frac{1}{2}$ in. and $\frac{3}{8}$ in.

In rebates, as in smoothing planes, it is often convenient to bring the iron close to the front, for the purpose of working right up to a shouldered end. This cannot be done in a plane made of wood, because of the weakness of the short grain. But such a plane is easily made in metal. The one here figured might be modified in such a way, but usually the tool is made altogether smaller. One of this special type will be described in a future paper.

It has been advanced that no one who can buy a tool will make one; but this is by no means the case, as many a professional workman will be found who will not only make, but even contrive special tools for special purposes. Moreover, the methods of making tools described in this and other papers on the subject are useful as forming a stepping-stone to the art of pattern making, which will eventually be treated in a more comprehensive manner.

SOME LESSONS FROM AN OLD BUREAU.

BY DAVID ADAMSON.

(*Continued from page* 246.)

Preparation of Drawers—Fitting Drawer Fronts—Treatment of Wood—Dovetailing of Parts—Lap Dovetail—Reasons Why—Improvements in Wood Working—Fastening Drawer Bottoms—Plain Bottoms—Munted Drawer Bottoms—Why Drawer Backs are Narrower than Fronts—Cock Bead—Stops—Fitting Locks—Keyholes—Plate Escutcheons—Plinth—Connection of End Pieces—Cleats for Plinth—Mouldings—Blocks.

The work, so far as it has gone, may be glued and fitted up now; indeed, it will be better that it should be before preparing the drawers. These will require some degree of expertness, though what may be lacking in this respect may, to a great extent, be made up by carefulness in every detail. Anyhow, a drawer is not the easiest thing to make if it is to work well and satisfactorily; and though it may seem such a simple piece of work, the man who can construct one perfectly may, without vanity, consider himself a skilled mechanic. Let the drawer fronts be fitted very tightly to their places before making the drawers, and in particular see that they are a little too full in width, if there is the smallest doubt about the wood being perfectly well seasoned, for if wood is cut exactly to width, and afterwards shrinks, the drawers will not fit well.

It is by no means a bad plan, in order not to run any risk, to let the wood stand for a day or two in some warm place before it is fitted. I would say that it should be placed near a fire, were it not that other risks are incurred by so doing, unless care be taken, and judgment used in turning the boards about, so that all parts are equally and gradually warmed. If this is not done, the boards, through drying more in one part than another, will probably twist and bend. If carefully watched this should not occur, and, in case of bending, it will be well to know that the hollow will be on the side nearest the fire. This arises from the wood nearest the heat shrinking most, so that the bend, if taken in time, may be counteracted by merely reversing the sides. The sides of the drawers may also be submitted to the same treatment; but whether they are or not they must be cut to fit very tightly; a rub with the glass paper will soon ease them sufficiently afterwards, if they don't run easily enough.

The front, ends, and back of each drawer are dovetailed to each other, in the way that may best be explained by reference to any ordinary drawer. In fitting the sides to the front, what is known as the "lap" dovetail is used. With it the ends are sunk in the drawer front, so that looking at this from the front no joint is perceptible. The back is fitted with the ordinary dovetails into the sides. The question may occur to the mind of the novice in drawer making, whether the pins (the dovetails) are to be formed on the ends, or on the back and front, or even whether it matters which. In this, as in most other construction, there is a right and a wrong way, and we can easily judge for ourselves which is the proper method in the present instance. Of course, the object of the dovetailing is to keep the parts together in the best possible way. The question then is in which direction, or where is the greatest strain on a drawer. The answer can only be that it is on the front, for on opening, it is that which is pulled. If it were loose it would come apart from the remainder. The same applies, though in a less degree, to the back. We therefore discover from theory, why it is that experience has shown the best way to fit a drawer together is by dovetailing the parts so that a backwards and forwards pull will not separate them. A lateral pull on the two sides would soon do so, for there is no resistance offered in this direction, except that caused by glue; but then, again, no great strength is required, for the strain cannot be so great as on the back and front.

Never thought of that! No, perhaps not, for we do so many things correctly by force of habit, that one is apt to lose sight of the fact that some one in far-off times perhaps must have pondered even on the right and the wrong way of making such a matter-of-fact article as a drawer. Did the man who first promulgated the now accepted method of fastening a drawer together meet with opposition from his fellow-workers? Did they look upon him as a dangerous character, who, instead of being content to follow his forefathers, was always bothering after some new-fangled idea? Did the antiquarian of his time think he was not a true "art worker," because he actually had the audacity to fancy that he could improve on old forms? I wonder. Probably he met with much the same kind of reception that one does now from a certain class of patrons, as they like to consider themselves, of art, when one advocates new and modern improvements.

Even in such a venerable handicraft as that of the wood worker, suggestions for improvements may be listened to with respect, unless experience shows them to be faulty in themselves; for though they are not very common, improvements are sometimes made. I saw one the other day in a piece of furniture on which it might fairly have been supposed ingenuity had exhausted itself long ago. No, it is not a patent, and I may tell you some day what it was, but as it has nothing to do with the bureau, it does not concern us at present; not, at least, further than gently reducing the shock it may be to some, when I tell them that the style of fitting the drawer bottoms in the old bureau will not be recommended for the present day workers. In it the drawer bottoms are fastened underneath the sides and back, and against the front. The grain, moreover, runs from back to front. The consequence is, that in several places the bottoms have split, although—think of it, unreasoning admirers of the antiquated—in the "good old times" workmen never—no, never—used anything but seasoned stuff. Nowadays it is considered best to let the grain run from side to side, and to make due allowance for any possible shrinkage. So that if the bottom does contract, it shall do so without detriment to the efficacy of the drawer.

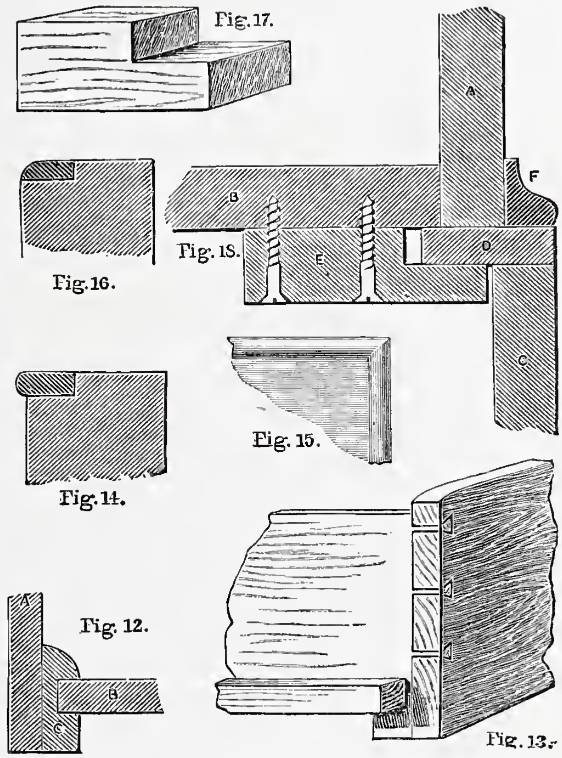

Fig. 12.—Fitting of Drawer Bottom. Fig. 13.—Back of Drawer. Figs. 14, 15, 16.—Beadings for Drawer Fronts. Fig. 17.—Cleat. Fig. 18.—Section of Plinth Fastening.

This may easily be managed by fitting the drawer bottom into grooves in the sides, similar to Figs. 10 and 11, but as the groove to a certain extent weakens the drawer side, as well as for other minor considerations, another plan is preferable and commonly adopted. In it the groove is run in a separate piece of wood, which is afterwards glued to the drawer sides, and the drawer bottom subsequently pushed in. Fig. 12 explains this more fully. As in the preceding illustration, A and B represent the side and bottom, while C shows the grooved slip. This may be about 1 in. wide, ½-in. stuff. The edge within the drawer is usually rounded off for the sake of neatness, and the lower edge is level with the bottom of the drawer side. This grooved slip runs the whole length of the end or side. It is a good plan to cut a groove also in the drawer front, into which the front edge of the bottom may be pushed, as otherwise the least contraction will leave an open space between the bottom and the front. Another hint that may be useful in connection with drawer bottoms is this:—Do not cut them off too bare at the back; let them project a little, and don't put any nails through them into the back, at any rate for a time; or if they fit so loosely in the grooves that they must be fastened to the back someway or other, let it be with screws, which can easily be withdrawn, and not with brads hammered in. If this precaution is taken, the groove along the front may be omitted, though it is never objectionable, and may often be serviceable.

Plain bottoms, such as have been described, do very well for short drawers, but when these are of any considerable length, such as the long drawers in the bureau, it is better to have a "muntin," as it is called. I am not sure about the orthography of this word, as it is not a common one in literature, and I have failed to find it in any dictionary, of which I have looked into several for the purpose. It is, however, given phonetically as used in ordinary workshop parlance, and as spelled by cabinet makers when writing for their craft, so that it will be well understood by those who are familiar with the construction it indicates.

A munted drawer bottom consists of three parts, the muntin itself and two others. The muntin is merely a piece of wood acting as a stay for these, and extending from the front of the drawer, where it is fastened, to beyond the back, underneath which it is secured. Its width may be from 3 in. to 4 in., and its thickness ½ in. Along each side edge a groove of the same width as that in which the drawer slips is to be ploughed. A recess is cut at the bottom of the drawer back, equidistant from each end, for the muntin to lie in, so that the grooves shall be in the same plane with those in the slips and front; or, instead of cutting a space in the drawer back for the muntin, this is cut down or rebated as far as the top of the groove, and then secured underneath the back. Each method has advantages peculiar to it, but the latter is the one generally adopted. The other pieces of wood are of the usual thickness of drawer bottom stuff, and it will be unnecessary to do more than state they are pushed into the grooves as if there had been no muntin.

The reason why the drawer backs (Nos. 34 and 35) are stated in the list to be narrower than the fronts (Nos. 6 and 9), will now be apparent, for the bottoms are fitted under them. Fig. 13 shows a corner of a drawer seen from behind. It will be noticed that the top of the back piece is shown lower than the sides. This generally is so, but it is not of importance that it should be, unless, perhaps, a trifle, just to be sure that it is not above the level of the sides. These, it will also be noticed, are slightly rounded at the top corners for the purpose of giving the drawers an easy entrance. The bottom corners and outside edges may also be rounded for the same reason, though it is not necessary if the upper ones are done. It will, however, be well to rub the upright angle down a little with glass paper, not too much, but just enough to allow the drawer to enter easily. The drawers as described are perfectly plain, without even a pretence at ornamentation, although Fig. 1 indicates a bead round each. This bead is represented on a larger scale in Fig. 14, which shows it to project a little in front. It is known as the "cock" bead, and though rather out of date, there is no reason, except on fashionable grounds, why it should not be as popular as ever it was. It is, indeed, one of those details of finish which, though temporarily neglected, never seem altogether discarded. To make it, a shallow rebate is cut all round the drawer front, usually as far back as the dovetails, on the ends and thickness of the front on top and bottom. In this rebate, and filling it, the piece forming the bead is glued or fastened with glue and a brad or two. The front edge is rounded, as it may easily be with ordinary appliances, for, though there is a specially constructed tool for the purpose it will not be worth any one's while to get it, unless he wants to make a great number of "cock beaded" drawers in the shortest time. The corners of the beads are mitred (see Fig. 15). Another bead, and one perhaps slightly easier to form, equally suitable as the other, though not so often made use of for oak drawers, is shown in Fig. 16. The principal diffe ence is that it does not project beyond the drawer front, and consequently only one edge is rounded. Neither of these beads should be too thick; ⅛ in. is quite enough. There is, of course, no necessity why the beads should be used, their only object being to relieve the drawers from absolute plainness, and, after all, it may be open to question whether they are worth the labour involved by them. Now, to prevent the drawers being pushed too far in, for I assume that they do not extend quite to the back of the bureau, and when quite in they should be level with the rails between them, or the merest trifle within them, unless beaded as in Fig. 16, when they should project a little, just the extent of the rounded wedge, some kind of stop will be wanted. These can easily be made of a thin piece of wood bradded to the rails, so that the fronts of the drawers catch against them. Usually a couple of stops are placed for a drawer—one near each end, and, of course, clear of the drawer sides. Their exact position can easily be ascertained by measurement and experiment. Thus, if the drawer front is exactly 1 in. thick, and it is, when in, to be quite flush with the rail, the front edge of the stops must be just 1 in. back on the bearer.

Locks may be fitted to the drawers any time after the stops have been placed, or, indeed, locks may be fitted as soon as the drawers have been made, only the holes for the bolts cannot be accurately cut till the exact position of the drawers when shut is known. These holes, of course, are cut into the under sides of the bearers; but, perhaps, before mentioning them, I should have said something about fitting the locks. These must be sunk so that their backs and tops are level with the wood to which they are attached. Nothing looks worse than a lock too deeply sunk, especially on the top of the drawer front, and it is a fault that is easily avoided by a little care. If too much wood has been cut away, the lock may easily be got to a proper level by packing with a thin slip glued. Be careful not to make the opening too wide for the lock, though, for this is a mistake not so easily remedied. The best way to do so will be to cut the space out clean, fill with a block glued in, and fit the lock afresh. Now a place for the bolt will have to be cut in the bearer above each lock. Its exact position may be ascertained by measurement, but a simpler plan will be to blacken the top of the bolt with a little gas black and glue say, then, when the drawer is in place, shoot the bolt, of which an imprint will be left where the hole is to be made. Of course, the blacking, or whatever it is, must be wet, or no imprint will be left on the bearer. The hole may be cut with a small chisel of the ordinary shape, though there is a contrivance, a kind of bent chisel, made especially for cutting holes in similar positions. It is, however, not often seen. Perhaps I ought to have mentioned something about cutting the keyholes, though really the only thing to be said about these is that they should be neatly formed if the ordinary thread escutcheons are to be sunk in them. In case, however, this is beyond the skill of the maker, he may be pleased to know that he can hide any unshapely keyholes by plate escutcheons, which are pieces of brass made to screw on to the drawer front, and having an opening to pass the key. The bulk of the bureau is now done, and those who have managed thus far will find the rest comparatively simple, though, in point of time, it may take as long. There still remain the plinth, the writing lid, the small fittings inside, and the back to be attended to. It is immaterial in what order they are done, but perhaps that just given will be as convenient as any.

The plinth may, therefore, be described first. This should be of 1-in. stuff for the ends and front, which may be either shaped, as shown on Fig. 1, or left plain. The advantage of the shaping out is that the feet of the writer do not knock against and bruise the front of the plinth, as they are apt to if it is left solid, and perhaps it is more pleasing to the eye. In length the plinth should measure about 1½ in. more than the extreme length of the bureau above it, and ¾ in. more than the width of the ends; in other words, it will extend ¾ in. beyond the upper portion of the bureau, in front and at each end, the ends of the side pieces being flush with the rest of the job behind. The front and ends may be dovetailed together, the pins being cut in the front pieces. A very much neater way, however, will be to mitre the corners, and fasten them together with the mitre dovetail. This joint, however, as already intimated, may not be convenient, and a plain mitre, though sightly, would not afford the necessary strength. This may, however, be gained without any dovetailing, by simply gluing a block on the inside of the angle. All that is required is that the block should be rectangular on two of its sides, and that these should be glued one to an end, and the other to the front piece of the plinth. The block may be one to two inches wide on each face, and if made triangular in section it will be an easy matter to further strengthen the joint with one or two screw nails driven through it into the plinth. The length of the block, of course, cannot be more than the width of the plinth pieces, and it should not be much shorter.

Somewhere near the back connect the two end pieces by another of the same width. Pine will do very well. It must be slightly shorter, as it is to be dovetailed in the same manner as the drawer bearers were—*i.e.*, a groove shaped to fit it must be cut across the end pieces of the plinth, or it may simply be attached by glued blocks such as those mentioned for the front corners. The result will be a frame, some 4 in. deep, say, with the back three or four inches within the ends. The remainder of the bureau will stand on this, but no provision has been made for fastening the two parts together. There are at least two ways by which this may be done in a thoroughly workmanlike manner, and a good many more, which, though in practice may be found sufficiently efficacious in the hands of skilled workmen, cannot be recommended to the amateur. In one of the two methods which he should adopt if he wishes to avoid all risk of something "going," pieces of oak, or whatever the bureau is of, are laid on the frame of the plinth. The thickness of these does not matter, though they should hardly be less than ¾ in., still if this is not convenient ½ in. will do very well. They should not be less than 2 in. wide, and each piece should be as long as that on which it is placed. The outer edges should be level with the outside of the plinth, so that they hang over on the inside 1 in. or so. The ends should be mitred to fit each other, and when this is done these pieces should be fastened by glue and screws to the other part of the plinth. There is now a rail through which screws may be put into the bottom of the bureau; but remembering what has been said about the undesirability of rigidly binding cross grains together, it will be seen that screws (or screws and glue) can only be used in front, as if the ends of the plinth were to be fixed to the bottom in the same way, this latter would have no freedom in case of shrinkage. Still it is necessary that the ends should be fastened, and it may very simply be managed by a couple of cleats to each, one near the back rail, and the other midway between the front and it. The exact size of these cleats (Fig. 17), or blocks, is not important, but as some idea 4 in. long × 2 in. wide may be stated. The depth of the piece cut out should be the same as the thickness of the top rails of the plinth, so that when the cleats are screwed to the bottom of the bureau they will hold the plinth to it.

This being done, the moulding also mitred may be laid on and glued to it. In addition the front moulding may be glued to the pine bottom, the edge of which it should cover and hide the joint with the oak bearer above it. Be careful not to glue the end mouldings except to the plinth, and if there is any fear of them being knocked off, or the glue giving way, a screw or two driven in on the slant from below will prevent any injury of this kind. The section of the completed plinth, with its attachment, is shown by Fig. 18; A and B are the end and bottom of the bureau; C, the lower part of plinth; D, the upper part hanging over underneath the bottom, to which it is held by the cleat, E; and F is the moulding planted on to the plinth outside. If desired, a piece similar to D may be fastened on the back rail of the plinth, and if the bureau is made much larger, perhaps it will be as well to do so, securing it to the bottom by cleats, which should allow it, or rather the part above, sufficient play. In a bureau of moderate size, however, such as the present, this extra labour need not be incurred. In the other method alluded to, the pieces, D, may be omitted, and their purpose served by blocks glued inside the plinth, and fastening it to the bottom. Those in front may be glued, but those along the ends should be fastened by the cleats. No object could be served at present by giving other methods, as the latter is as simple as possible, though not quite so good in all respects as the former; it has some advantages to recommend it, and with fair workmanship and sound, dry wood it is reliable enough for ordinary purposes.

BURGLAR ALARUMS:

How to Make, Work, and Maintain.

BY GEORGE EDWINSON BONNEY.

(*Continued from page 180.*)

THE YOKE—THE BOBBINS—THE COILS—THE ARMATURE—THE ARMATURE SPRING—THE CONTACT PILLAR AND SCREW—THE HAMMER—THE GONG AND ITS PILLAR—THE RELAY.

The Yoke.—The yoke of the magnet is the piece of metal to which the cores or legs of the magnet are attached. This should be either made of iron entirely and the legs fixed to it, or the two legs must be connected by a strip of soft iron. A short piece of angle iron of the right dimensions to suit the size of bobbin to be mounted on the legs will make a good yoke, since it will serve as a bracket as well. On reference to Figs. 4 and 5 (page 179), it will be seen that the yoke is attached to the metal frame, and is made to fulfil a double purpose. It forms an angle, one side of which serves the purpose of a yoke, whilst the other forms a lug to which the armature spring is attached. Some magnetic advantages are secured by this arrangement.

The Bobbins.—The bobbins for the cores of electric bell magnets are usually turned out of boxwood or ebonite. They are made as thin as the strength of the material will bear, and special attention is paid to the thinness of the body, the best effects being obtained in an electro-magnet when the insulated coil of wire is as close to the core as it can be brought. This consideration will also determine that the bobbins should fit the cores in every part. Should the workman make a slip and the bobbins go loosely on the cores, the space must be filled with a slip of thin paper wound on the cores and the bobbins fitted on this.

The Coils.—The wire for the coils of an electro-magnet should be of pure soft copper perfectly insulated with a silk coating. The wires generally in use for electric bell magnets are coated with green silk, and thus have an attractive appearance. The silk coating must be without a break in any part, that is, we must not be able to see the copper wire beneath. Should a bare place be seen whilst winding the wire on the bobbin, stop winding, and cover the bare spot with a thread of silk wound around the wire. If this is neglected, and two such bare spots on two different layers come together, the coil will be short circuited, and a portion of the magnetic effect of the current be lost. The bobbins may be wound with wire in a small lathe, but a little experience will be needed before a strange hand can wind the wire on regularly.

If, however, the bobbin, reel, or spool of wire is placed on a piece of iron wire where it is free to run around, and held in one hand at a distance of about a foot from the bobbin to be filled, the wire will go on in coils side by side and almost guide the hand, if this is allowed to follow its course. A fold of white tissue paper between each layer of wire enables the winder to guide the wire with exactitude. The bottom end of the wire placed on each bobbin must first be brought out through a small hole bored in the end of the bobbin, or laid in a small nick made in the edge of the end, and some 8 inches of it coiled around a small rod to form a helix. This will serve as an elastic connection between the two bobbins, or to connect the coils with any other part. The bobbins should be quite filled with wire, and the top ends secured by a string of silk to keep the wire from unwinding, or the ends passed once or twice around the last fold and then drawn tight. The top ends should also be coiled on a rod to form a helix. When this is done, the bobbins may be slipped on tight on the cores, and the two bottom ends of the wires connected together. To do this, lay bare the copper by stripping off half an inch of the silk insulation, clean the bare copper with a bit of emery cloth, and twist the two ends tightly together. These may be soldered to ensure good contact, but this is not always done.

The Armature.—This must be made of a strip of soft iron, as soft and as well annealed as the iron in the cores of the magnet. The size of this strip must be proportioned to the diameter of the magnet coils and their distance apart. It should be long enough to come to the edges of the coils, and wide enough to cover the cores, whilst it should be thick enough to hold the hammer shaft inserted in one end. A good size for a 4-in. bell is 2 in. × $\frac{5}{8}$ in. × $\frac{3}{16}$ in. This piece of iron must be filed up smooth and true. In one end drill a small hole and tap it to take the screwed end of the hammer shaft; at the other end, in the positions shown A, B, in Fig. 16, drill and tap two small holes to receive two small iron set screws. These last are intended to hold the armature spring shown at Fig. 19.

The Armature Spring.—This may be made of spring brass, German silver, or steel. Its length and width are determined by the dimensions of the armature, but it must be long enough to extend from the lug, S, Figs. 2, 3, 4, and 5 (page 180), to the contact or break pillar at P. It should be just stiff enough to bring back the armature to the contact screw sharply after the bell has been struck, but not so stiff as to require a lot of extra battery power to work it. Two holes must be drilled at A, B, to receive screw studs for holding it to the lug, S, and two holes at C, D, to receive screw studs to attach it to the armature. At E, another small hole should be bored to receive the tip of a bit of No. 20 B. W. G. platinum wire to form (when riveted to the spring) the contact speck of the spring. If the armature is intended to be used with the form of relay trigger shown at Fig. 21, two small holes must be drilled and tapped on its upper edge to receive a couple of screw studs to hold the bent strip of brass shown at Fig. 20. In the form of relay trigger shown at Fig. 25, this is not required, since the hammer shaft is made to carry the catch for the trigger of the relay. Neither is it required where the bell is to be used with an indicator relay.

The Contact Pillar and Screw.—This, with its accessories, is shown at Figs. 22, 23, 26, and 27. The pillar should be turned down out of $\frac{1}{2}$-in. brass rod, the top part above the foot should be $\frac{3}{8}$ in., and the lower part $\frac{1}{4}$ in. The lower part, or tang, of the pillar must be screwed to receive the hexagon nut (Fig. 26), or to be screwed into the wood base. Both methods are adopted by makers, but I give the preference to that wherein the pillar is secured to the frame by a nut beneath the base, as this prevents shifting of the pillar. When thus formed, a recess for the nut is cut with a brace bit beneath the base, the connecting wire is carried into this recess through a small hole, and the end secured to the tang of the pillar between the nut (Fig. 26) and the thin brass collar (Fig. 27). As the tang of this pillar will pass through the hole, P, in the metal frame, and the pillar must be insulated from the frame, we must turn a collar to the shape of Fig. 22, out of boxwood or ebonite, and fit this to the tang under the foot of the collar, as shown by the dotted lines at Fig. 23. The upper part of the pillar carries a contact screw to connect the pillar with the armature spring. This screw is made of brass; diameter of screw $\frac{1}{8}$ in., length $\frac{3}{4}$ in., furnished with a milled head. A small hole should be bored in the tip of this screw, into which a platinum wire must be fitted to form contact with the platinum speck on the armature spring. Platinum is used because the electric spark which passes at this point when the bell is ringing has very little effect on this metal, whilst it will corrode or burn away most other metals. A hole must next be bored through the pillar, about $\frac{3}{8}$ in. from the top, and tapped to receive the contact screw. The top of the pillar down to this hole should then be slit with a thin circular saw, a fret saw, or a hack saw. Across this slit, transverse to the contact screw, near the top of the pillar, bore a small hole, and tap it to receive a small steel screw. I will now explain the object of all this. The contact screw must be nicely adjusted to ensure the best ringing action of the armature on the bell. When the exact position of this screw has been obtained by practice, we must secure it there. This may be, and is often, done by using lock nuts on the screw, but as even these shake loose under the intense vibratory action of the armature, it is found best to tighten the screw by clipping it in the slit by means of a transverse screw. By this means, also, the wear of the threads may be taken up.

The Hammer.—The hammer of an electric bell is merely a small disc of brass, or ball of brass, secured to a shank or shaft made of hard iron or brass wire. The disc shape of hammer is shown at Fig. 17, but there are several other forms, including one in the shape of a small brass marble. A small hole is drilled in the hammer head and tapped to receive the screwed end of the shank, then screwed on tight. It is well to secure the head in its right position with a drop of solder in addition to the screw, to prevent the head shaking loose (as it sometimes does), and so getting this part out of its proper position. The shank is secured to the armature in the same way as it is to the hammer head. Wire of No. 11 or 12 B. W. G. may be used for the shaft. The exact length cannot be given, but must be found by measurement to ensure the head striking the bell in the most advantageous manner.

The Gong and its Pillar.—The bell itself is generally distinguished by the name of gong. Electric bell gongs are now a speciality, and are sold for this purpose nicely polished and plated with nickel, at prices ranging from 1s. 6d. to 7s. each, according to size. The pillar to support the bell may be made out of a $2\frac{1}{2}$ to 3 in. length of $\frac{3}{8}$ iron rod, turned at the ends, and screwed as shown at Fig. 18. If made thus, the bottom part may be screwed into the base and metal frame, or secured by a nut beneath the base as the contact pillar is fastened. The top part passes through a hole in the centre of the gong, and is then secured to it by an ornamental brass nut or head (Fig. 24).

The Relay.—This is an important part of a burglar alarum system, since it prevents the intended burglar from stopping the ringing of the bell by cutting the line wire or quickly closing the door. Without a relay the bell might be stopped, but when a relay is in circuit the bell will go on ringing, although all the main line wires are cut, until the local battery is switched off from the bell, and this can only be done close up to the bell itself. Several forms of relays are in use, some attached to the bell base itself and named automatic relays, others on separate bases apart from the bell. Fig. 21 shows a form of trigger employed on a relay attached to the bell base. It is made of brass, exact size and shape of sketch. A hole is drilled at A, and countersunk on both sides. This receives a cord to pull the trigger with when about to set it. Another hole is drilled at B to receive the set screw which attaches the trigger to its pillar, shown full size at Fig. 11. At C a small hole is drilled and countersunk on both sides, to hold the end of the spiral spring which pulls the trigger back when it is released from the catch on the armature. At D another small hole is drilled, and into this is fitted a bit of platinum wire to form contact with another piece of platinum on a contact pillar. I have not sketched this pillar, as it is similar in form to that shown at Fig. 23, only much shorter ($\frac{5}{8}$ in. from top to base), whilst the collars and nuts are also the same. Fig. 25 shows another form of trigger to be used on the base of a bell as a relay. Further details of this will be given in another paper, together with a sketch explaining its action. It is made of brass, shape and size of sketch, and is fitted at the small end with a steel pin, which engages with a catch soldered to the hammer shaft of the bell.

In my next paper I hope to show how to put the various parts together to form a bell, and also explain the action of the automatic relay employed on this class of electric bells.

A FOLDING SCREEN IN EGYPTIAN TRELLIS WORK.

BY C. H. OZANNE.

Though the screen illustrated is scarcely adapted for the usual purpose, that is, to shelter a portion of the room from draughts or observation, it forms a very striking piece of furniture in a drawing-room. To get the full benefit of it, it should be stretched across a large window, so that the light behind it shows up the pattern effectively. If it is desired, a very little trouble will make it useful as a screen. Serge or any other material desired can be lightly tacked on one side, the colour in harmony with the rest of the furniture of the room.

The workmanship is simple and bold. As is seen in the sketch, it consists of three folds hinged together. Each fold is like the others, with the exception of the centre, which has a recess. This recess generally holds a water-bottle of porous clay, which, by the constant evaporation that goes on upon its surface, keeps the water within cool. As in England thirst is not the continual misery that it is in Oriental climes, a vase would naturally replace the water-jar.

The screen measures 5 ft. 4½ in. in height, and each fold 2 ft. 2 in. in width. I do not think it is necessary to give the dimensions of each panel, as they can be taken off the sketch, Fig. 5; and there is no necessity to keep to any special measurements, as the joinery of the screen is very elementary. Each fold consists of a framework 1¾ in. wide, and a little over 1 in. in thickness. The inner edges have a simple moulding run on them. Within these are the panels shown, made of frames mitred at the corners, and moulded slightly by way of ornament. A brace runs across the fold to strengthen it; it is of the same pattern as the frame of the panels. The general body of the screen is filled up with trellis work shown in Fig. 3, that is, the upper half; the lower half is of a rather coarser pattern, like Fig. 1, only that the intervals between the beads are plain cylindrical strips. The detail of the trellis work in the panels is shown in Fig. 6, in

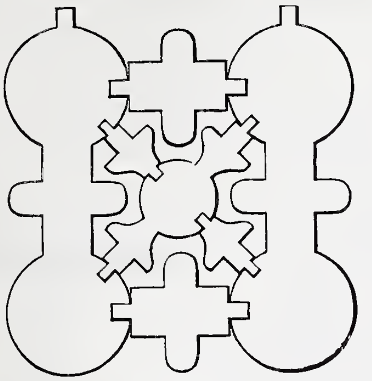

Fig. 1.

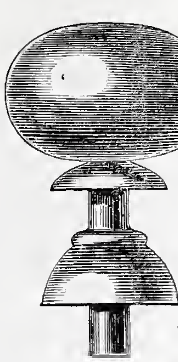

Fig. 2.

Fig. 3.

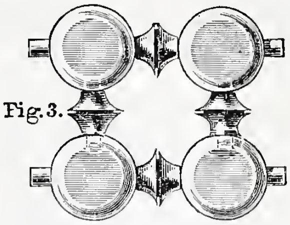

Fig. 4.

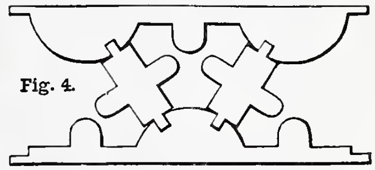

Fig. 1.—Details of Work in Lower Half of Body of Screen (half size). Fig. 2.—Knobs at Angles of Recess. Fig. 3.—Details of Work in Upper Half of Body of Screen (half size). Fig. 4.—Small Panels in Back of Recess.

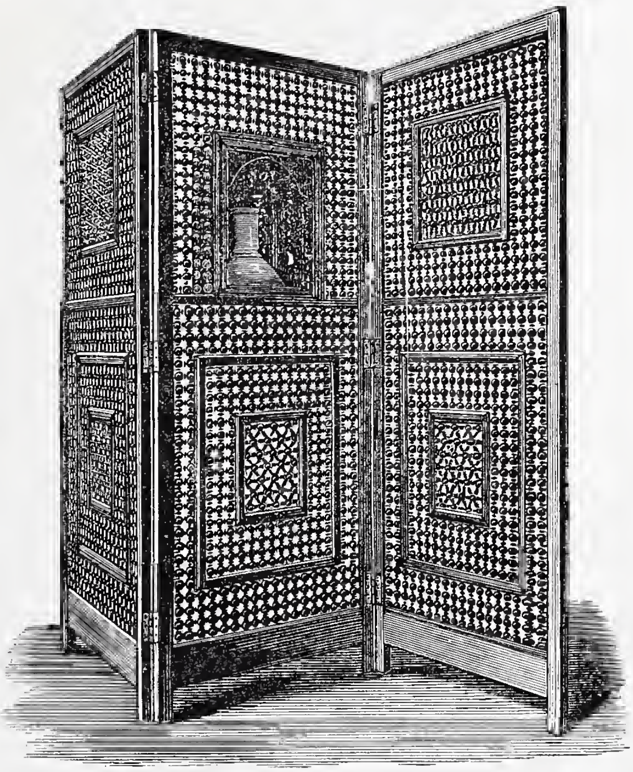

Fig. 5.—Perspective View of Folding Screen in Egyptian Trellis Work.

which is given the mode of joining it together. The solid bars on which the beads are turned can run horizontally or vertically across the pattern — the effect is different — and thus give variety to the completed screen. In putting together the trellis work, care should be taken to make the solid bars run the shortest way across any space, so as to give the greatest rigidity to the whole. The trellis is turned out of wood about ½ in. thick, so that the beads have flattened tops as shown in the sketch. It would be far too heavy if the beads were complete globes of the size given.

The panels are held in position simply by the solid bars of the trellis work inserted in the edges of the frames, and running to the framework of the screen in which the other end is inserted.

Before turning a bar into a strip of beads and intervals it should be marked off accurately, so that there may be the required number of beads and intervals. It is not necessary for the ends to be complete beads. Naturally all the bars must be alike.

The folds would each, of course, have to be built up from the centre, beginning with the panels, and finally framing all up in the outside framework, which is mortised together.

The small recess is formed of two pieces as in Fig. 7, which act as top and bottom. On this are fastened strips to form the sides. The length of these sides depends upon the size of the opening which forms the mouth of the recess. Each side is cut out, and panels are let in. In Fig. 1 is shown some of the trellis,

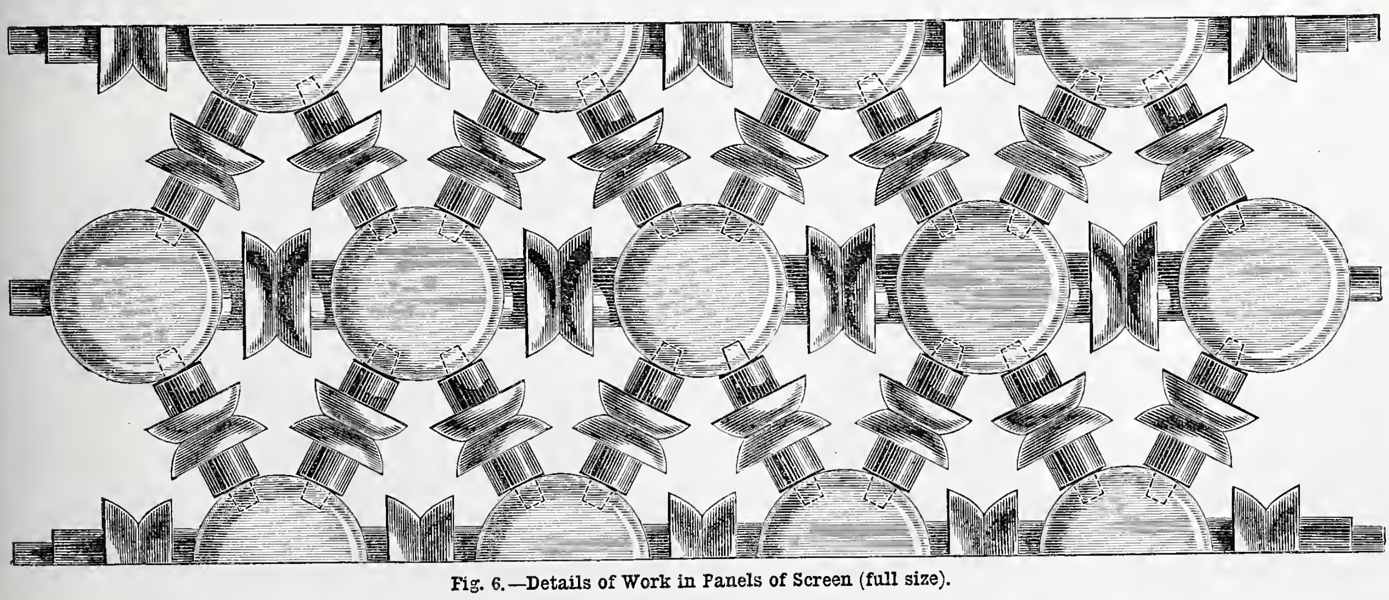

Fig. 6.—Details of Work in Panels of Screen (full size).

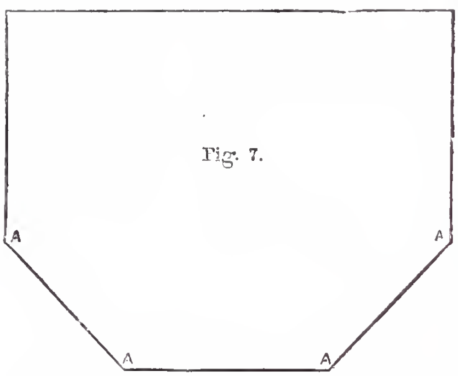
which fills in the centre part of the side; above and below are little panels filled in with Fig. 4. The rough sketch in Fig. 8 will explain.

This little cupboard is hung on at the back of the opening by hooks, as it must come off when the screen is folded. In front, the top is ornamented with a piece of wood cut into a dome shape, and on each side is a little turned pillar, and a third at the bottom. The top of the cupboard, as well as the bottom, is finished off by little knobs (Fig. 2) inserted at each angle.

The pattern of trellis work described is of the simplest. It can, of course, be made more ornamental, and more intricate, but in so large a piece of furniture any delicate work would be out of place, and, in the constant moving that it is necessarily subjected to, it would get chipped and shabby.

As for material, stained beech is generally used for the bead work and pine for the



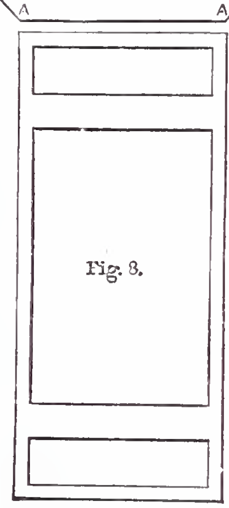


Fig. 7.—Plan of Top and Bottom of Recess in Central Fold (one-fourth size).

Fig. 8.—Elevation showing Panels at the Back of Recess (one-fourth size).

frames. Walnut would, of course, be more expensive, but would make a handsomer article.

It will be found necessary to dust the screen frequently, and, as the domestic duster will not reach the interstices of the trellis work, a tooth brush will be found convenient. If walnut is used, it can be polished with a paste of beeswax and turpentine, and can be kept bright with a stiff brush and the addition of a little of the paste occasionally.

This screen is much admired, and fills up the room conveniently, for it can be fitted into any unoccupied part, and when necessary folded up out of the way. It hides any great expanse of bare wall, without appearing to do so, for you can see through it; but, as a matter of fact, the eye is arrested by the pattern, and does not travel beyond the screen. It is not so high as to hide pictures hung at the ordinary height.

HINTS ON HOLLOW WORK IN SHEET METAL.

BY OPIFEX.

The making of cups and other vessels, and the forming of hollow work of any kind, is a most useful and interesting branch of sheet metal working; the silversmith and the plumber are equally interested in it, and the irrepressible amateur, who is anxious and ready to attempt anything and everything, should know how it is done.

Suppose it is required to form a cup- or saucer-shaped article, *e.g.*, such a thing as the copper cup in an ordinary pair of scales, or the hemispheres which, joined together, form the ball of a cistern cock, there are three methods to choose from. 1st, the article may be stamped "at one fell swoop" by machinery, involving considerable power, and, therefore, much expense; 2nd, it may be "spun" in a lathe; and 3rd, you may do what you want with a hammer.

I take it for granted that the reader will elect the third and simplest method, which is also the most artistic.

The tools and appliances required are a hammer, a vice, and a round surfaced anvil, with shank; the hammer should be rather heavy, but at the same time small on the face, so that it will be capable of inflicting a "dead blow" of considerable force, which shall not, however, affect too much of the surface of the metal; a piece of round or octagonal $\frac{3}{4}$-in. steel about $2\frac{1}{2}$ in. long, made into a hammer by having the centre slightly flattened and bored for a light, strong handle, will be found to suit this work admirably (Fig. 1); or in the absence of a special tool, an upholsterer's hammer will be effective.

The round anvil belongs to a class of tool sometimes called "stakes," which are of various shapes and sizes according to the work for which they are intended.

Fig. 2 shows a mushroom-shaped tool, with nicks or grooves in the shank, by which the height of the tool may be regulated in the vice.

There are various other tools of the same character used by sheet metal workers, but this one will be sufficient for our present purpose, which is to show how a hemisphere of copper or brass may be formed by means of the hammer.

But, first, it may be well to add a word which may encourage some reader who may not be able to procure this "mushroom" stake by pointing out that it is not absolutely necessary, and at the risk of being the innocent cause of "raising a row" in some peaceful household, I would whisper in the ears of such a one, that a poker which possesses a fairly round, smooth, polished knob makes a capital substitute.

First cut out a disc of sheet copper, say five inches in diameter, and with the compass describe several concentric circles, marking the metal very slightly, as these circles are merely meant as guides in the process of hammering; now holding the disc in the left hand, and laying the centre of it upon the centre of the "stake," proceed to hammer it firmly and evenly in a circle round the centre, gradually working in larger circles in such a manner that every part of the metal is subjected to the action of the hammer.

The worker must bear in mind that he is not to endeavour to make the metal take the shape of the rounded tool which underlies his work, but that it only serves to resist the hammer blow at the point immediately beneath, or opposite to where the blow falls, the effect of which is to strike another blow, as it were, upon the other side, and thus cause the metal to stretch, or expand, at that point.

Thus working gradually outwards from the centre the metal will be found to assume a convex form upon the hammered surface, and the hammering being continued in the

Fig. 1.—Anvil.

same way to the circumference, the result should be that the metal disc is transformed into a saucer shape nearly an inch deep at the centre; and if the direction, that the hammering be carried out in perfect circles from the centre, has been attended to, and if the force of the hammer blows has been fairly equal throughout, the work will be uniform in curve.

During the process of hammering the metal will have become hard, and, in order to restore its ductility, it should now be annealed. This is done in the case of brass or copper by heating the metal to a dull red over a clear fire, or with a blowpipe, etc., and then plunging in cold water.

The operation of hammering in circles from the centre is now repeated several times until the metal assumes the required shape; but the reader must not be disappointed if absolute success does not attend his first attempt. With a little practice, however, the work will be found comparatively easy, and most effectual in the forming of innumerable articles both useful and ornamental.

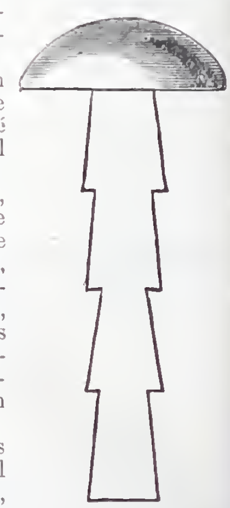

Fig. 2. — Mushroom Stake.

Surfaces raised in this way may be worked in repoussé and chased, the metal being first annealed.

Sheet brass, copper, etc., of considerable thickness may be worked by this method, and by employing anvils of different shapes, coupled with judicious hammering, it is surprising what the practised workman can produce.

The bowls and bases of goblets, ornamental cups, teapots, kettles, lamps, candlesticks, etc., etc., etc., are wrought in this way in the first instance, being afterwards chased and otherwise ornamented.

I have pointed out that there are other means of forming hollow work in sheet metal—namely, stamping and metal spinning in the lathe. I am in no way alluding to the manufacture of hollow balls in one piece, which are formed by the action of machinery, to be described at no distant time by another writer.

OUR GUIDE TO GOOD THINGS.

65.—Macnaughton's New Spring Ferret Muzzle.

The readers of Work, I am pleased to know, are to be found in all classes and grades of society, and the workmen who take "ours" may be somewhat surprised to learn that a great many country gentlemen, who naturally take considerable interest in field sports and outdoor amusements, are to be found among them. Even if direct and personal evidence in support of this were wanting, which it is not, there is yet indirect testimony to the fact in much that appears in the pages of the Magazine itself. Some little time ago, for example, our friend Opifex, who clearly indulges at times in a little congenial rabbiting, and perhaps ratting, mentioned in his "Tips for Tyros" (see page 90) a muzzle for ferrets which he had found to be very useful in the field. This catches the eye of Fal, another valued contributor and reader, who gives us his ideas and experience on the subject in page 189. And this metaphorically brings Mr. Macnaughton, gunmaker, Edinburgh, to his feet, and he sends me specimens of his New Spring Ferret Muzzle (Registered, No. 24326), which is made in four sizes, numbered 1, 2, 3, and 4, sold at a uniform price of 1s. each. Thus it is plainly shown how action and reaction, with regard to any particular subject, takes place; and how the thoughts and words of one elicit the views and opinions of another, confirming a remarkable assertion in Holy Writ: "Iron sharpeneth iron; so a man sharpeneth the countenance of his friend." Even in this way may we long continue to sharpen the countenances of one another by that which is set forth in the pages of Work.

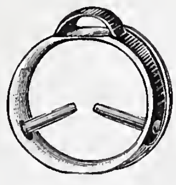

Fig. 1.—Form of Ferret Muzzle.

Fig. 2.—Muzzle Placed on Ferret.

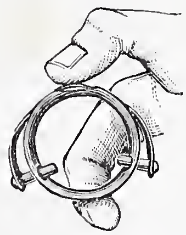

Fig. 3.—Muzzle with Spikes Withdrawn.

The value of the ferret muzzles to which reference is made may be ascertained from the illustrations afforded of it in Figs. 1, 2, 3, in the first of which the muzzle itself is shown. This consists of a brass ring, concave in form on the outer side, and carrying in its concavity a spring bowed at the top, and carrying at each end a short iron spike, which enters through the brass in holes specially contrived to take them. In Fig. 3 is shown the method of pressing the spring and withdrawing the spikes when it is desired to pass the ring over the muzzle of a ferret; and in Fig 3, the muzzle when placed over the ferret's mouth. "To fix the muzzle," says the inventor, "hold the ferret round the shoulders with the left hand, compress the arch of the spring with the thumb of the right, slip the muzzle on wide side first, to suit the taper of the ferret's jaw; the muzzle should fit just over the tusks; when there, ease the spring and the pins will slide in behind the tusks. The spring muzzle cannot fall off if the suitable size be used, and the ferret's tusks are all right. A ferret unaccustomed to a metal muzzle, should have this put on once or twice for a short time before being hunted. A ferret, when systematically muzzled, will hunt a whole day; as without a muzzle, he spends his strength in worrying at sulky rabbits; with a muzzle he soon learns to bolt those rabbits that will bolt, and to leave the sulky ones, as he cannot lay hold."

66.—The Lingham Sash Fastener.

This excellent sash fastener is manufactured and supplied by its inventors, Messrs. Lingham Brothers, locksmiths, makers of fireproof safes, brass-founders, etc., 22, Great Hampton Street, Birmingham, its price being 12s. 9d. per dozen, net. It serves two purposes, for it not only affords a simple mechanical arrangement of easy action for fastening window sashes with perfect security, but it also prevents any unpleasant rattling of the sashes, which often occurs in stormy weather. On the outer sash is screwed the socket piece, shown in the upper part of Fig. 4, lettered A; and on the inner sash is attached the catch piece of the fastener, marked B. From the upper side of A rises a square socket, in which is inserted the square end of the barrel, also marked A in the illustration. The connection between barrel and socket is made by an iron pin, which passes through socket and end piece from side to side, and is securely riveted. This pin is not shown, as it should have been in the engraving. In the barrel is a helical spring of considerable strength, which acts on a disc formed on the inner end of a small spindle, square in form, which projects from the end of the barrel, and carries a winged finger-piece which abuts on a knob forming a termination to the spindle. From the plate on the inner sash rises a double catch, B, and when it is desired to secure the fastener, the object is attained by pressing the finger-piece down over the inclined surfaces of the catch. This causes the spring in the barrel to be compressed, and the square portion of the finger-piece slips under the notched portion of the catch, where it is securely held by the pressure of the helical spring against the disc of the finger-piece. The release of the fastener is accomplished in a moment, whenever necessary, by placing two fingers against the curved ends of the finger-piece and drawing it towards the operator, so as to compress the helical spring to a greater extent, the compression affecting the release. Below the square end-piece of the barrel is a movable plate, which is pressed upwards by a spring fastened to the inner surface of the socket-piece, A. This spring is necessarily hidden, and is not shown in Fig. 4, by reason of its position. This plate serves to retain the movable part of the fastener in a vertical position when thrown back. The Lingham Sash Fastener is well made in brass, with the exception of the pin, spindle, plate, and spring. It has a much better appearance than the ordinary sash fastener when placed in position on the sash, and as I have been enabled to test it practically by placing a specimen on one of my own windows, I can bear testimony to its utility and manifest superiority to the old-fashioned regulation spring catch which has held its own for many years.

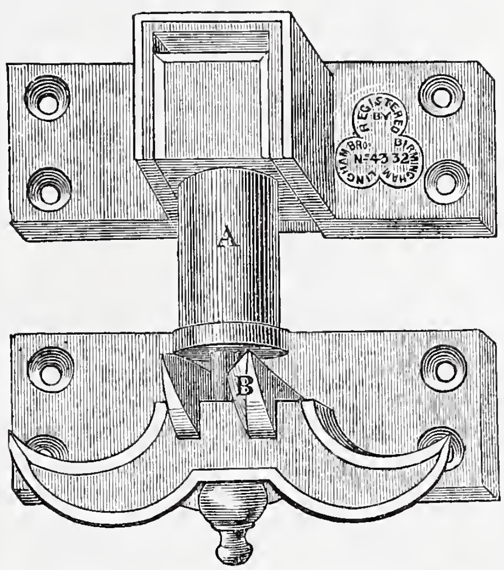

Fig. 4.—The Lingham Sash Fastener.

67.—Broadway's Patent "Eccentric" Casement or Fanlight Stay.

These casement or fanlight stays are also manufactured by Messrs. Lingham Brothers, Birmingham, and are supplied in two patterns, namely, that which is shown in Fig. 4; and another, in which at the end of the stay, a stud or button is substituted for the turned end which appears in the illustration. All the stays are 12 in. in length, without reckoning the knob at the end. Those with the knob are sold in brass, polished, at 27s. per dozen, net; and in brass, sanded, at 25s. 6d. per dozen. Those with the button are of iron bronzed, with brass fittings, and are sold at 13s. 6d. per dozen, or 9s., according to quality. All prices quoted are net. They can be made in any length. The stay itself is similar in form and arrangement to ordinary casement stays, with this difference, that the patent stay is solid throughout, while the ordinary stay is pierced with holes, to be passed over a peg rising from the plate, over which the stay is caused to move. Thus, it can only be secured at certain points in its length; but the "Eccentric" Stay can be secured at any point throughout its length, as it runs in a socket rising from the plate which carries the locking arrangement, and by which it can be fastened at any point at which it may be desired

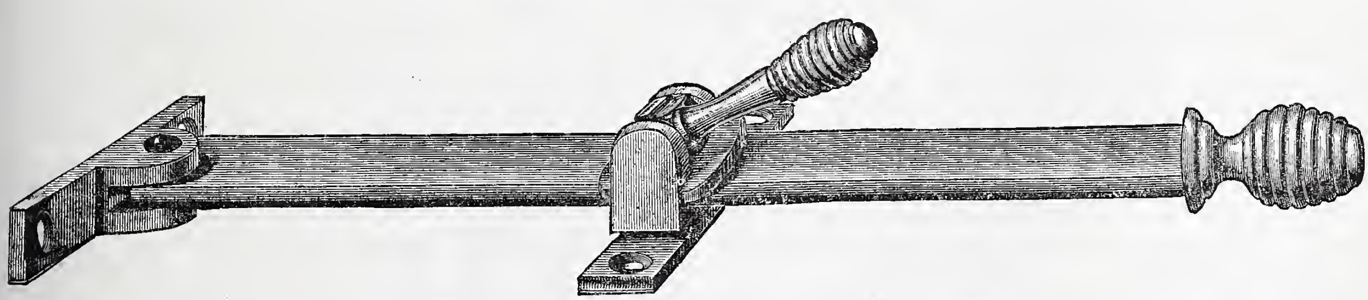

Fig. 5.—Broadway's Patent "Eccentric" Casement or Fanlight Stay.

to do so. The principle of the locking arrangement, shown in the centre of Fig. 5, is simply that of an eccentric or cam, actuated by the short handle that proceeds from it. Thus, supposing the stay to be fastened, it is only necessary to raise the handle, which liberates the plate resting on the stay, and sets free the stay itself. Again, to fasten the stay it is only necessary to press down the handle as shown in the illustration. This immediately locks the stay, making it quite secure. At the same time the eccentric acts as a fastener when the casement is closed, making it impossible to open it from the outside. Moreover, being perfectly tight all rattling of the casement is prevented, which occurs, more or less, with all stays in which pegs, screws, or springs form part of the construction. The advantages to be derived from the use of the Broadway's Patent "Eccentric" Stay are perfect security, extreme simplicity of action, and rapidity of adjustment. THE EDITOR.

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** *All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

Circular Saw Rigs.—G. E. writes:—"In No. 11 (see page 172) I regret to see FOREMAN PATTERN MAKER'S failure to understand me, but will try to be more explicit. Respecting Fig. 1, very few amateurs are capable of making it as drawn, because it requires to be centred and boxed up in a collar plate, tapped between centres, faced, and the recess turned out to clear thread—therefore, superfluous work with small results. I must always take exception to cutting a thread in a saw spindle, because (according to the law of mechanics applied) the action (if possible) should always be between centres, and certainly possesses the advantage of being the simplest form. Again, if the spindle be made from cast brass to pattern, it will be too soft to be of much practical use. Bessemer steel is best. The fitting of chucks to a lathe is different in every respect (without exception); to cut and fit a chuck is one thing, but to screw a 6-inch brass spindle is another; and if you expect the same results, I am afraid you will be very disappointed. Wood turners mostly use wood, where possible, in all appliances for their lathe; but I must say (after thirty years' experience) I never knew of a piece of wood (hard or soft) that kept true for several years. Then what about the saw? The mandrel nose terminates at the face of collar fitting. Yes; then the amount of steadiness given to chuck depends on whether the face is true and ground flat, and how the mandrel fits in the collar. The table in T-rest socket is preferable because simple, easily fitted with angle metal fence, and fixed with bolt, nut, and slot; therefore adapted equally to amateur and professional. I must object to complicated appliances for amateurs, as productive of unfavourable impressions, rather than an incentive to work."

Small Cabinet Fittings.—C. C. (*Chippenham*) writes:—"On going for my magazines last month I chanced to see Part 1 of WORK, which I purchased, and was fairly astonished at the contents; it is, indeed, a splendid work, just what was wanted. That overmantel, by David Adamson, is a capital thing for amateurs, and those who couldn't see how to do it after reading the description should never touch a tool again, as they would never make much use of it. Could you inform me, through the medium of 'Shop,' the cheapest place to get small cabinet fittings? They must be produced very cheap somewhere. I have a list of Mr. Zilles, but if the makers of the small articles you see in fancy shops gave the price for their fittings that he charges, that alone would be more money than the article is sold at. As I think the greater part of amateurs are wood workers, I think a fair proportion of the contents should be devoted to that trade."—[For small cabinet fittings you may apply to Harger Bros., Settle, Yorkshire; Skinner & Co., East Dereham, Norfolk; G. Busschots, Park Lane, Liverpool; Fritz Collins, Bath; and others, who deal in these articles. R. Melhuish and Sons, Fetter Lane, London, E.C., have some, without doubt, although the fittings principally kept there are for full size furniture. The hinges and connecting hooks, etc., used by "the makers of the small articles you see in fancy shops," are the cheapest possible, and of necessity must be. They are sold in large quantities—at per gross, very likely. They would not suit you, and I strongly recommend you to use such fittings as are supplied by Mr. Zilles, for your own work, which I have no doubt as much surpasses the cheap wares of the shops as the fittings sold by Mr. Zilles excels the fittings that are put on them. There is a passion for cheapness in the air at the present day, I know, but there is something too often bracketed with cheapness which always hangs about very cheap goods, and of which they can never be purged.—ED.]

About WORK.—PRO BONO PUBLICO writes:—"Allow me a short space in what I am pleased to call 'ours,' to add my testimony to what I consider the value of such a well got-up paper for such a nominal sum, although the high compliments paid to you and your organised staff by previous correspondents leaves but little to be said by me. My opinion is this, were I to write a volume in praise of WORK it would not express my satisfaction with which I read each number. (1) Pray keep from technical terms, or, if used, use them sparingly and with an elucidation, as this is, in my opinion (and I speak from practical experience), a shoal whereon amateurs get metaphorically shipwrecked. (2) I would also, wherever practicable, like to see working drawings, when reduced, given as $\frac{1}{4}$ in. to the foot, leaving other fractional scales till an amateur has gained some experience with the rule, bevel square, etc. (3) I would, as an amateur worker having a number of hours each day at my disposal, and sitting amongst a multitude of different articles of my own make, like to give a little of my own experiences to others, whereby home may be made attractive and the pot-house kept in the distance (I am not teetotal), and if acceptable, a few designs of artistic articles, and also as many difficulties surmounted as you advise this week. Buy tools wherever you see them cheap. This course I have adopted for some years, and I am convinced the pawnbrokers' shops have a good stock, where, if an amateur is short of cash at the time, an article can be secured for a deposit, and got at some more convenient time. (4) Surely each amateur has amongst his acquaintances a friendly joiner or one meeting his requirements according to his hobby, and to him I would go for a few practical lessons, getting to know, above all, something of the fundamental principles of geometry, a few problems only being worth a gold-mine to an amateur."—[(1) WORK is for professionals as well as amateurs, and technical terms cannot be excluded. But why object to technical terms at all? After all they are the right terms, and terms that are recognised by the trades. Any term you do not understand can be explained to you in "Shop," if you will ask the question. (2) No object can be gained by bringing all working drawings to a scale of $\frac{1}{4}$ in. to a foot. There is nothing, or ought to be nothing, puzzling in the proportions for working drawings, but if you cannot understand them a paper shall be given in explanation. (3) You are always at liberty to communicate the results of your experience with designs, working drawings, etc., and papers on any subjects on approval. (4) By all means go to the "friendly joiner" for practical lessons in carpentry, but the "fundamental principles of geometry" will be best gathered from a text book, such as the "Lessons in Geometry" in the "Popular Educator."—ED.]

Overmantel with Cupboards.—KILDONAN writes:—"Having procured the glass and some narrow moulding, I found myself face to face with a difficulty—namely, how was I to secure the three glasses at the bottom, so that when the overmantel was lifted they would not slip out between the back and the moulding, and come to grief? This required a smoke. I offer my plan for what it is worth to any novice in a similar quandary. Ferreting out some pieces of sheet brass and an old file, I proceeded to shape six strips, each $1\frac{1}{4}$ in. by $\frac{1}{2}$ in., and then to bend them at right angles $\frac{1}{2}$ in. from the end, as in Fig. 1. The dimensions are probably

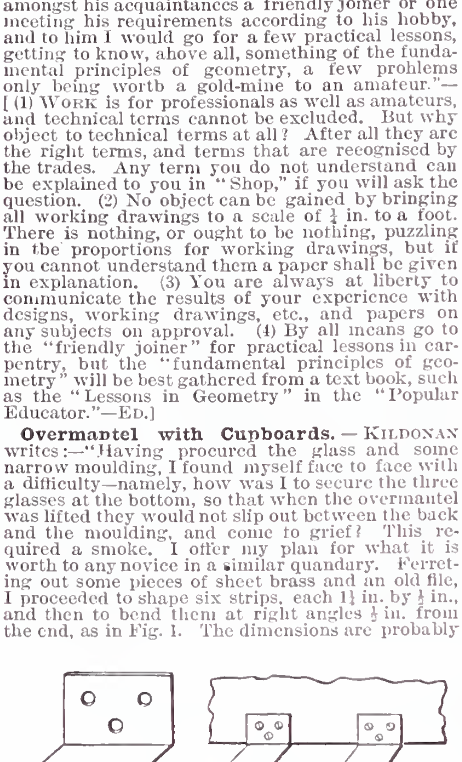

Fig. 1.—Glass Support. Fig 2.—Method of Securing Glass Supports to Back.

a little larger. As they are not seen I was not particular about their appearance. Using two of these brackets to each sheet of glass, I screwed them to the inside of the bottom of the back, as in Fig. 2, with the sole projecting under the edge of the bottom moulding, in which I cut shallow grooves, so that the whole would be flush throughout its entire length, and thus allow the article to stand straight, and not on tiptoe. I borrowed a brace and countersinker to make the holes. I may say that I have as yet completely failed to gild the panels according to OPIFEX'S directions, and have consequently handed the panels over to a painter friend."

Weight of Fly-Wheel.—MR. F. CAMPIN writes:—"The formula from Molesworth for above $W = \frac{\cdot 6366\ F\ S\ C}{D}\left(\frac{N}{60}\right)$ is wrong (you quote it page 189). The weight varies *inversely*, as N, as shown in the remark—'A slow-running engine will require a greater reserve of energy than a fast-running one.' The fallacy of the above formula has previously been exposed in the *English Mechanic* and elsewhere. The theory of the fly-wheel is perfectly clear, and leads to the expression—

$W = \frac{10648\ E}{V\ d^2\ N^2}$—where W = weight of fly-wheel in cwts.

d = mean diameter of rim in feet.
N = number of revolutions per minute.
V = total variation in per cent. of mean speed.

As my name is on my article, I am sorry this error occurs over initials the same as mine—F. C.—as it might naturally be attributed to me."—[The initials F. C. were appended in error. The reply in question should have been signed J.—ED.]

Metal Ball Making.—B. W. R. (*Walkley*) writes:—"The balls mentioned by your correspondent, on page 172 of WORK, are not made as you suggest, by soldering two halves together, but in this wise: A piece of metal is cut round and put under a press called a 'fly,' and in the bottom is a hollow cup; in the fly nose is a punch. The metal is put over the cup or hollow, and forced down by the top punch, not all at once, as a set of dies or cup are used to bring it down gradually so as not to crack the metal. When got to semi-spherical shape, they are put in a furnace until red hot, or, as it is called, 'annealed.' When cold they are put into the cups, round parts uppermost, and instead of round punches cup punches are used, with small hole in centre to allow of air escaping, so as not to burst them, granitoid punches being used in doing them; they must be annealed two or three times, or cracked balls are usual. I make mine by using a machine with graduated grooves in its top and bottom table, allowing them to work in quite opposite directions by cross bands working from pulley on main shaft, the balls being half cupped first in the hand fly. Plenty of oil must be used in the machine so as to keep balls cool, or they would clog. If you would like one ball I will forward you a specimen, or you can see them in any silver plate show rooms as feet for frames, etc. They are made plain, fluted, and with a ridge round them, so that a bead can be turned on them, and in all sizes, from $\frac{1}{16}$ of an inch to 3 in. diameter."

A Rejoinder about WORK.—PHAETON (*Ipswich*) writes:—"In respect to the strictures so thoughtlessly (I had almost said ignorantly) expressed by J. P. A. on the various and most useful articles treated so ably in your, or, rather, our, valuable and most interesting weekly magazine, WORK, I am surprised to find a man so thoroughly practical as he represents himself to be calling a space devoted to so important a subject as 'Hinges, and how to Fix Them,' 'wasted.' Is it possible that any man practical at anything can be so shortsighted as to call those valuable hints and suggestions on that subject 'wasted'? Truly, I can scarcely credit it. I, sir, am engaged in carriage building, and have had considerable and long practised experience in the different forms and methods of fixing hinges; and yet I feel bound to offer my most grateful thanks to Mr. David Adamson for valuable information I have imbibed from his able pen; and I would ask, does J. P. A. really understand the full meaning of the word 'trifles'? I cannot think he does, or he would not so distort the real name that belongs to any act that has for its object the benefit, improvement, or pleasure of his fellow-men; and judging him by the 'spirit' of his remarks, am inclined to consider him one of those individuals whom we are told 'rush in where angels fear to tread.' Although a coachmaker, and in respect to which trade I have not yet seen any reference (excepting Mr. Adamson's too brief notices in his article on hinges), I am bound to say that I not only feel some impatience for the appearance of WORK from week to week, but I read and thoroughly enjoy every article treated therein, and then take a good look through the advertisements, as a likely means of 'dropping' upon something, either necessary or desirable of possession. If J. P. A. possesses a sawing machine of such unrivalled merits, surely he could tell us about it without this tirade of objections; and his wonderful saw must lack lustre indeed, if to make it shine visible at all necessitates the total extinguishing of every other object of note or importance. It is just possible, sir, that if you could arrange the sale of a few of J. P. A.'s Elizabethan twists for him, it might tend to remove somewhat of the jaundice with which he seems to view the wants and necessities of his more grateful and appreciative fellows; and in respect of the prophesied exodus of practical men as subscribers, I cannot help thinking that it is only such as J. P. A. who would be 'missed,' but not 'wanted.' Personally I am delighted with WORK, of which I take and dispose of a dozen or so every week; and I offer my humble, but warm, thanks to all concerned; and if I can at any time be useful in 'Shop' to any brother in want, kindly do me the favour to apply to me."

Screen Secretary.—C. H. O. (*Alderney*) writes:—"You remark upon the resemblance between Mr. Adamson's screen secretary and Mr. Gleeson-White's cheval screen escritoire. I was also struck by it, as not a fortnight ago I had just finished a secretary similar to Mr. Gleeson-White's. Yesterday I met a friend, and he told me he had also just designed something similar, when No. 13 of WORK was issued. In all these cases the idea seems to have occurred simultaneously to different people. My secretary is of a portable character, and not of the ornamental style of Mr. Gleeson-White's handsome design. That gentleman says he is doubtful whether the projections in Fig. 3 would not be needful. I took off mine, which are almost exactly the same as his, and are fastened on by a keyhole and screw arrangement, and I found that the secretary rocked very much. My base is 1 foot deep without the projections. I have the projections only under the writing flap, and about 3 in. on the other side. This is sufficient. The height of mine is 4 ft. 5 in., and it is 2 ft. 6 in. across."

Boot and Shoe Making.—BOOTS AND SHOES (*Farnworth*) writes:—"I would be pleased to know if you intend to give papers in WORK on boot and shoe making and repairing, with all particulars as to the tools required, etc., with drawings, as I am sure many fathers with large families would gladly welcome such a subject. In the meantime will you please give me the names of the tools required for finishing a pair of old boots, after being resoled, so as to make them look well? I have a little knowledge how to repair, but that's all. I may state I am very well pleased with WORK, as it is just the thing I've wanted a long time, and I hope you will have great success with it."—[At present I cannot promise the papers you ask for, because there is so much in hand which must be dealt with first. I have given publicity to your question about repairing by inserting your letter, and possibly some reader of WORK will reply to it.

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Particulars for Intending Frame Makers.—W. L. (*Wigan*).—(1) Best shops for tools that I know of, and are generally acknowledged for good tools, are—Buck's, Whitechapel; Tyzack's, next Shoreditch Station, L. and N. W. Railway. (2) We do not in trade use any cramp; we use cutting blocks, stinting block and plane, and vice and hammer. (3) No books that I have heard of give any practical hints or information of any value to trade. (4) There was a trade paper recently started. I do not know if it is now in vogue, but it gave no simple information, as it was a trade paper, and naturally assumed its position amongst practical men who had served their apprenticeship.—G. R.

Spiral Springs.—VULCAN (*Wakefield*).—Here is one method. Mix of sperm oil, 1 gill.; melted suet, 1 lb.; neatsfoot oil, 1 gill; resin, ¼ lb., and smear the spring all over. Place the spring—if a long one —on a mandrel and hold it inside a red-hot pipe until the composition burns uniformly all over and with a blaze, when it must be quenched in oil. An even blue temper is required. If any part blazes before another, it must be cooled with grease and blazed afresh. Thick springs require repeated applications and blazing. A few trials will give the necessary confidence.—OLLA PODRIDA.

Annealing Cast Steel.—B. P.—Heat the steel to a low red heat and bury in quicklime until cool. Another method is to pack the steel in an iron box filled with lime or whiting and covered tightly with clay; then heat the whole to a red heat and allow it and the fire to die out until cool. By either method the steel should be soft enough for any purpose.—OLLA PODRIDA.

Small Fan.—DA CAPO (*Grosvenor Park*).—One about 3 in. in diameter would suit you, running at about 1,000 revolutions per minute. Any handy tinman could make you one. The body of fan should consist of a disc of tin with four blades or vanes soldered on each side, the whole soldered to a brass spindle and cased in a tin box, the bearings for spindle soldered to sides of case. Spindle to carry a small grooved pulley at one end for gut or leather band. If you require a sketch, please say so, and I will try and furnish you. It will save talk, and I am rather overweighted with work at present.—OLLA PODRIDA.

Circular Saws.—A READER.—I gave the power with working margin for hard wood and heavy work. This would be the practical way to meet light work of any description under. I regret that I have no data by me with which I can meet the theoretical expenditure of power, and I doubt very much if such can be obtained in reliable form dealing with different gauges.—OLLA PODRIDA.

Injector for Small Engine.—P. A. (*Girvan*).—To make a small injector of the size you want is not so difficult as the getting of it to work satisfactorily is. The writer regrets that pressure has prevented him replying earlier, and also getting a design prepared to meet your case, but hopes to forward a sketch in a few days.—OLLA PODRIDA.

Fret Saw for Small Lathe.—E. A. P. (*Co. Carlow*).—Your idea for fret saw is all right, except that the motion slot should be in *lower* arm, so that the saw blade may be held in tension both ways. As made by you, the saws have no chance but to break directly a cut is made. Raise the table and shift the driving point, and the saws will stand with fair play.—OLLA PODRIDA.

Valve Gear.—E. C. M. (*Ipswich*).—Your drawings duly to hand, but I have not seen the copy of *English Mechanic* referred to, and this is necessary for complete reference. The design is very ingenious; but there are several gears in the field already so closely resembling yours. In the face of this, therefore, I would not advise you to risk money upon it. When I see the *English Mechanic* I may be able to give you further opinion.—OLLA PODRIDA.

Lettering Watch Dials. — W. F. B. (*New Wandsworth*).—I am sorry to say I know nothing of the subject, and cannot refer you to any one, unless the editor of the *Horological Journal*, Northampton Square, Clerkenwell; he could, perhaps, through his paper. I will send the query to him if you like; but that is a monthly, and published on the first, so I should have to wait a month. —A. B. C.

Lithographic. — P. BROUGH (*Glasgow*). — The paper for lithographic writing is a good printing paper—not too stout—brushed over with a preparation which may vary with the fancy or requirement of the operator; ordinary flour paste, or even starch, tinted with dark chrome, may be mentioned as simple formulæ; and there are more complicated recipes, numbering isinglass and plaster of Paris among their ingredients. The coated paper is then finished by rolling between metal plates or by being pulled through the litho press over a clean and dry stone to obtain a smooth surface. I would scarcely advise you, however, to take all this trouble. The paper may be obtained ready prepared of any lithographic sundriesman. Cornelissen, 22, Great Queen Street, London, W.C., or Winstone, Shoe Lane, London, E.C., would doubtless supply you. The price is about from 3s. per quire demy. Writing on stone for printing purposes is, of course, done backwards; an exceedingly minute sable brush is the tool employed, and a large amount of practice is necessary before the tyro can command this tool sufficiently to produce legible work; but application and perseverance in this process, as in all others, will work wonders.—J. H. M.

Advertisement Pages in WORK.—R. T. (*Bolton*).—You should write to the publishers, and not to the editor, of a magazine with respect to wrappers for weekly numbers, the numbering of advertisement pages, etc. The editor's business does not include any of these matters. It is no use writing to the captain of a ship about the manner in which she is fitted up and the provisions that are put on board for the crew and passengers; but if you have any cause of complaint, you must write to the owners. Nor is it a step in the right direction to take the driver of a coach to task if you do not exactly approve of the team he drives. Men think differently about different things, and an article which one does not like may be highly approved of by another. I can assure you that advertisements are not put in for the sake of filling up the paper; their mission is a far higher one than this. It is true that this is an advertising age, or, as you aptly put it, "the public can get such information by the ton." True, the public could, if it bought serial publications by the ton. It does do so, in point of fact, collectively, but as the public is an aggregation of units, each unit gets just a small share of information about the things that are selling and offered for sale from year to year and all the year round, by the two or three serials and papers, more or less, that he may happen to purchase; and so individually the public only gets such information by the ounce. You continue—"Excuse me, I have no intention of hurting your feelings, though I have seen it doubted whether editors had any." It is very good of you to say this; but say what you will, you will never hurt *my* feelings, for, editorially speaking, I have not got any. Ah! you wind up your letter by saying—"Believe me a hearty well-wisher for the success of your paper." Well, that is just the termination I like to find to all letters—a burst of sunshine after a little wind and storm. *Pax vobiscum.*

Buckram for Bookbinding.—J. H. B. (*Pendleton*).—The buckram enclosed is quite a distinct material. When I tell you I had to tear one slip of white cardboard to find out if it were buckram, you will understand what it should be in appearance—fine, thick, and white, pasting perfectly. The parchment is rather thin, and not so glossy and ivory-like on surface as it should be. The covers should certainly be folded before the material is pasted on, and the pasting done in the final position they are to occupy, even if they are opened flat to press afterwards.—E. B. S.

Wood Colouring.—OX GALL.—One of the simplest methods of staining deal and obtaining the dull polish seen on very dark oak is to stain it first, and then varnish with flatting varnish. The way to proceed is as follows:—First see that your work is entirely free from glue, grease, or rough places, and then twice stain with dark oak stain (Stephens', for instance), softening the work down between each coat with a soft brush, called a badger, before the stain dries, which will take out all marks, etc., left by brush in staining, particular notice being taken that this is done very thoroughly and expeditiously, as any touching up is almost sure to show. When the stain is properly dry, rub it down with a piece of canvas, not glass-paper, as the latter is very liable to leave white marks, and the canvas can be got more easily into the members of columns, mouldings, etc. (The less glass-paper is used in all stained work, even in preparing, the better, and in no case paper across the grain, as it is sure to show.) Then twice size with best clear size, rubbing down between each coat as explained for staining. If the work is now varnished with good flatting varnish, and when hard rubbed with a soft rag or piece of silk, it will be found that the surface has a nice dull gloss. A cheap substitute for dark oak stain can be obtained by thinning down good Brunswick black to the shade required with turpentine; but unless one thoroughly knows the nature of these materials, this plan had better not be adopted.—E. D.

Stretching and Priming Canvas.—WAITING.—Canvas, like other fabrics, is best stretched by first tacking loosely all round the stretcher, then tacking firmly at one corner, tightening across (diagonally) to the opposite corner, and then treating the two other corners in the same way; lastly, by pulling level and tacking the intermediate spaces. A pair of pincers with flat tips 2 or 3 in. broad is used for stretching canvas. A bought canvas will show how the wedges are adjusted at the corners of the stretcher for further tightening after tacking down. Calico for tempera or other rough painting may be strained by tacking laths to its top and bottom, hanging it against a wall, sizing it, and, whilst it is wet, by hanging weights to the bottom lath. This will pull the cloth taut, and the size will keep it so. Bought canvas appears to be sized and heavily coated with paint, which is scraped smoothly off by some apparatus which, acting like a huge palette knife, sweeps its entire width. This could scarcely be imitated at home. WAITING is advised, after sizing, to give his canvas a not very free coat of paint, to level this with a broad, flat camel-hair varnishing brush. When dry, to give a second coat of white paint warmed with a tint of burnt sienna or light red, and smooth as before. Then after laying in his sky (from his remarks it is concluded that he paints landscape), to stipple it with a badger-hair brush. Indeed, the granulated surface produced by this latter process is always pleasant for painting upon; the better canvas that one buys has a tooth given to it by mixing finely ground rottenstone or Bath brick in the priming colour.—S. W.

Fret-cutting Machine.—A READER.—A capable and competent writer on the staff of WORK has been commissioned to write on this subject.

Lathes and Turning Appliances.—A READER (*Huddersfield*).—You will have noticed that this subject has been brought to a close. You must remember, however, that although "lathe work is the first thing an apprentice is put to in the engineering line," he is certainly not put to it first, if at all, in other trades, to which the majority of the readers of WORK belong. Plans and specifications will appear in due time.

Mists in Painting.—The art of painting mists is by what artists call "scumbling"—that is, taking a brush filled with colour, and rubbing thinly over any part that has been distinctly painted up, which must partially appear through. It can be done with any colour mixed with white according to the local colour of the mists.—J. A. F.

Preparing and Mounting Photographic Views.—G. A. C. (*Nunhead.*)—It is imperative that a lantern transparency should possess qualities that are peculiar to itself, and unnecessary in any other kind of transparency. They must have absolutely clear glass in the high lights, be thin, and have a good colour. In your case, the prints had better be placed in optical contact with glass. This is done in the following manner:—A piece of thin patent plate glass, rather larger than the print, and free from defects—scratches, stria, etc.—is selected. The print is placed in clean cold water for a few minutes; the glass is also put in the water, the print being adjusted face down on the glass, the glass and one edge of the print being grasped; both are slowly lifted out of the water together; this is in order to avoid air bubbles, which would produce imperfections on the transparency, being imprisoned between the glass and print. A squeegee is then lightly passed over the back to get rid of much of the moisture, and to press the print into close contact with the glass. Now carefully examine it, and if there are any air-bubbles not easily pressed out, repeat the process until the print shows a perfectly bright and even surface. Now place three or four folds of white paper, also wet, at the back of the print, and, with another piece of glass of the same size laid over, press together, and carefully wipe the front glass dry and clean; the advantage of this proceeding is that the print is kept uniformly moist during the time occupied in copying, and can be easily removed and dried afterwards. Now set the prepared print as sandwiched between the glasses upright against a board, to which it can be attached by a tack or two to keep it from falling forward, and photograph it in a strong side light, taking care there are no reflections to interfere with the definition. The exposure must be carefully timed, rather under than over, and the development conducted as much in the dark as possible. The high light must be perfectly clean glass; any deposit on them will spoil it for lantern work. A development made with one of the fixed alkalies is preferable to ammonia; the following is a very good one:—Solution A—pyrogallic acid, 3 gr.; sulphate of soda, 12 gr.; bromide of potassium, 6 gr.; water, 1 oz. Solution B—carbonate of potash, 20 gr.; water, 1 oz. Use equal parts of the two solutions, and fix in a bath of hypo, one to five, freshly made, to which about 10 per cent. of sulphate of iron has been added. Wash well, and then place the transparency in a bath of alum and citric acid. Wash again well for a few hours, and dry; the slide is now ready for mounting. A number of masks of different shapes being at hand, choose the most suitable, lay it on the transparency film side, and cover with a piece of thin clear glass; bind them together with gummed paper. Write on the title, and place two white spots on the top front edge as a guide to placing it in the lantern for exhibition, and the slide is complete. After development we have a negative from which any number of lantern slides may be made. To do so, we carefully place the negative in contact with a sensitive plate (plates are specially made for this purpose), in an ordinary pressure frame, and expose to weak diffused daylight, or a gas burner, according to the sensitiveness of the plate used, and which vary greatly. A slow plate is to be preferred, giving a finer image than a rapid one. The size of the slide must not exceed 3¼ in. square. Masks and gummed paper may be purchased at photographic warehouses.—D.

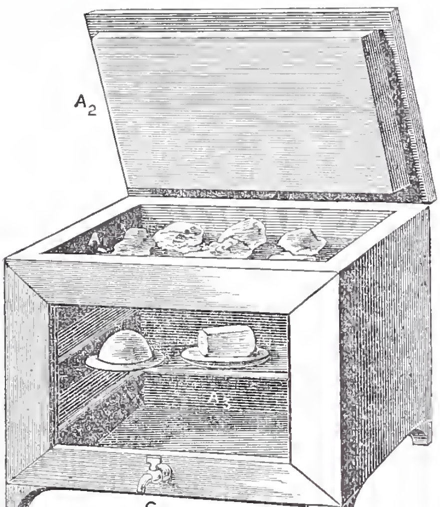
Erratum.—MR. G. E. BONNEY wishes to call attention to an error in page 70, col. 1, in which read "mindererus" for "minderus."

IV.—Questions Answered by Correspondents.

Joiners' Composition.—W. M. (*Market Drayton*) writes in reply to F. B. (*Guernsey*) (see page 158):—"The composition is made of beeswax and resin mixed with colour to match whatever your work may be; it can be melted in an iron spoon, and poured into the defects while hot; it sets directly, and when sandpapered down could not be detected. I have enclosed you a specimen. This is mixed with venetian red; it is a little darker than the wood, so that you might see the way it is done."

Making a Xylophone.—Electron writes in answer to Correspondent (see page 206, No. 13):—"The xylophone is made of pieces of wood about 1 in. square, the upper side of which is rounded; a hole is bored near each end, through which cords are passed, and knots made to keep the pieces apart—pine may be used, but rosewood is considered better; when played they are laid on two straw ropes and struck with small wood hammers; the compass is from twenty-eight to thirty-six notes; the length may be from 1 foot; they are tuned by cutting the pieces shorter."

Refrigerator.—J. M. (*Newhaven*) writes in reply to Urgent (see page 174):—"As you wish to know how to make a refrigerator, I send a sketch of an American one. The drawing is as plain as I am able to make it, as I never learnt that art. A_1 is a zinc tray to hold the lumps of ice; A_2, lid, is zinc lined; A_3, interior lined entirely with zinc, with small pipe at back from tray above, to let the water trickle down the back and run out by the tap. The door when put on also lined with zinc. The top tray slightly deepening to the back, and bottom one deepening to front to the tap. The dimensions as regards width, depth, and length can be of any size, according to the wants of Urgent."



Blue Prints.—W. J. R. (*St. Germans*) writes:—"May I be allowed to supplement Mr. Poole's excellent article on 'Cyanotypes' (see page 194), which appeared in No. 13, by stating one or two simple methods of improving the colour of these blue prints? To produce a green tone, immerse in sulphuric acid, 1 dram, water, 16 oz. Brown tones may be obtained by immersing the prints in water, in which about 10 gr. to the ounce of caustic soda or potash has been dissolved, then washed and transferred to a 6-gr. solution of tannin. A sepia tone may be produced by taking the print, when arrived at the stage last indicated, and immersing in a bath of plain soda and water, taking care not to let it act too long. The original blue colour may be intensified by immersing in sulphuric acid, 1 oz.; saturated solution of protosulphate of iron, 1 oz.; water, 1 oz."

Saws Running out of Truth.—Alpha (*Grangemouth*) writes in reply to A. R. (*Scorrier*) (see page 204):—"I have read A. R.'s (*Scorrier*) remarks in your issue of date about saws running out of truth, and hope to derive some benefit from same. Would he kindly say the gauge of a swedge saw at centre and point he would consider most suitable to cut three boards ⅝ in., and one board ⅞ in. out of a 7×3 deal. The boards to stand that thickness after being dressed into lining."

Joiners' Composition, or Beaumontague.—H. M. B. (*Edinburgh*) writes in reply to F. B. (*Guernsey*) (see page 158):—"Required beeswax, resin, colour. For mahogany, mix yellow ochre and Spanish brown; for ash and light oak, ochre and chalk; for walnut and dark oak, brown umber and chalk. Rub the colours very fine, and use common sense in mixing them and the various materials together. Melt the wax in a large spoon, add the colour till pretty thick, add a small quantity of ground resin, just enough to harden the wax. When partly cold roll it between the palms so as to form a stick handy for the pocket. To use it light a match, or heat a small poker, and melt it, dropping some on the defect, then with wet finger point press it home, and in a minute or so the surplus will sandpaper off."

IMPORTANT PRIZE COMPETITION.

The Editor of Work has the pleasure of informing his readers that Messrs. Cassell & Company, Limited, have placed at his disposal the sum of

THREE GUINEAS,

to be distributed in Prizes for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

which, at the close of the present year, will have attained the aggregate number of Two Hundred and Eight. The books are in themselves of world-wide interest, and may be regarded as forming the front rank of our British classics.

In order to give a fair and proper idea of the space or accommodation that will be required in the Bookcase for the whole of the volumes up to the close of 1889—two hundred and eight in number, as already stated—it is desirable to say that each volume, bound in cloth, is 5⅞ inches long, 4 inches wide, and about ½ inch thick; or, to be more precise, the linear space filled by thirteen volumes is 6¾ inches in length, which admits of the volumes being placed on the shelves without any possibility of being crowded too closely together, to prevent easy withdrawal of any single volume at pleasure. As 13 is the sixteenth of 208, the space required for this number of volumes can be easily calculated.

In order to give satisfaction to as many competitors as possible, the Editor of Work thinks it desirable to divide the sum offered by Messrs. Cassell & Company into Three Prizes, as follows:—

First Prize ...	One Guinea and a Half.
Second Prize ...	One Guinea.
Third Prize ...	Half a Guinea.

Intending Competitors are placed under no restriction as to Form, Arrangement, or Ornamentation, as it is the Company's desire to elicit from the readers of Work an Original Design for a Repository for the Four Years' Issue of the National Library up to the close of the year 1889 that may be regarded as the most convenient and desirable for the purpose indicated.

Competitors should send in Working Drawings to Scale not later than August 31, 1889, and addressed, carriage paid, to

Messrs. CASSELL & COMPANY, Limited,
La Belle Sauvage,
Ludgate Hill,
Prize Competition. London, E.C.
Cassell's National Library.

A motto must be affixed to each set of Drawings, and the name of the sender, etc., enclosed in a sealed envelope bearing *the same motto*, which must be transmitted by post, under cover, to the Editor of Work.

The Drawings sent in Competition will be submitted for adjudication to Three Competent Practical Men, who will select those that are deemed worthy of prizes.

The Prize Drawings selected will become the property of Messrs. Cassell & Company, Limited, who will return all Designs made by unsuccessful competitors to their respective owners, carriage paid.

The Awards, with the names and addresses of the successful competitors, will be announced and engravings of the Prize Bookcases given in No. 30 of Work, published Oct. 9th.

NOTICE TO CORRESPONDENTS.

*** In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given.

Trade Notes and Memoranda.

Messrs. Crossley Brothers have just completed two pairs of double cylinder gas engines for a paper works at Godalming, which are the largest yet constructed. Each pair is of 100 h.p. Dowson gas is to be used, and the consumption is guaranteed not to exceed 1½ lb. per h.p. per hour.

Recently, an examination of plumbers for registration was held at the Guilds' Institute, the examination embracing joint making, lead laying, etc., and various questions relating to the trade. Applicants came from London, Kent, Hants, and Devon, and rather over three-fourths of the number failed to pass. The examiners were Messrs. Charles Hudson, W. H. Webb, G. Taylor, H. B. Lobb, C. T. Millis, and R. J. Lyne.

Two instances of rapid work in marine engineering have just been recorded. The ss. *Khio* was launched from the ship-building yard of Messrs. E. Withy & Co. on Friday the 5th at 5 p.m., and went into the Victoria Dock that evening to receive her engines, by Messrs. Richardson & Sons, Hartlepool. The work was begun on Monday morning, and the engines were tested under steam on the Thursday following at 11 a.m. The engines (triple expansion) had cylinders of 22 in., 37 in., and 61 in. diameter respectively. The other case is that of a crank shaft of steel, having a double throw, which was commenced on a Monday, forged from the ingot, finished, keyways cut, and despatched on the forenoon of the following Thursday.

The late Mr. Warren de la Rue was a splendid illustration of the fact that a commercial career by no means unfits a man for original scientific research. He did not retire from business until 1880, and the bulk of his scientific work was also accomplished, and his reputation made previous to that date. It is quite impossible to enumerate the work of his life. He held office in many societies, was a corresponding member of the principal foreign academies and societies, was a voluminous contributor to the transactions of many learned bodies, and was an accurate experimentalist, astronomer, photographer, chemist, electrician, and physicist.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

3 months, free by post	1s. 8d.
6 months, "	3s. 3d.
12 months, "	6s. 6d.

Postal Orders or Post Office Orders payable at the General Post Office, London, to Cassell and Company, Limited.

Terms for the Insertion of Advertisements in each Weekly Issue.

	£	s.	d.
One Page	12	0	0
Half Page	6	10	0
Quarter Page	3	12	6
Eighth of a Page	1	17	6
One-Sixteenth of a Page	1	0	0

MELLIN'S FOOD
For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

It is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

FRETWORK & CARVING.
Highest Award—Gold Medal for Tools and Patterns.

MACHINES, DESIGNS, TOOLS, WOOD, MIRRORS, HINGES and FITTINGS, VARNISH, &c.

Fret-saw Outfit on card, with Instructions, 2s. 6d., free.
Set of 12 best Carving Tools, with boxwood handles, ready for use, price 9s., free.
If you want good Designs, and are competing for exhibition, try ours, for which we receive testimonials daily.
☞ See our complete Catalogue, 64 pages, quarto, containing the best variety of designs published, free for 6 stamps. [22

LENSES, SHUTTERS, TRIPODS, &c.
HUMPHRIES' CAMERAS, 1889.
THE DRAYTON.—Most compact. Every movement best workmanship. Highly finished; low price. Illustrated Lists free.—W. H. HUMPHRIES, Photographic Apparatus Manufacturer, 116, Highbury Hill, London, N. Factory, 70, Elfort Road, Drayton Park, N.

NOTICE.

CASSELL'S CLASSIFIED CATALOGUE, containing particulars of upwards of **One Thousand Volumes** published by Messrs. CASSELL AND COMPANY, ranging in price from

THREEPENCE to TWENTY-FIVE GUINEAS,

will be sent on request *post free to any address.*

NEW AND ENLARGED EDITION. Price **1s.**; or in cloth, **1s. 6d.**

Photography for Amateurs:
A Non-Technical Manual for the Use of All.

By T. C. HEPWORTH.

WITH ILLUSTRATIONS.

"One of the most thorough and efficient manuals for the non-professional photographer has been written by Mr. T. C. Hepworth. It deals with everything which an amateur should know, not from a hazy, semi-scientific point of view, but from a really practical standpoint. All the many difficulties which amateurs are likely to encounter, and the many errors into which they are almost certain to fall, are foreseen and provided against, while numerous ingenious hints are given so as to make the amateur's labours as easy as possible. Mr. Hepworth has an intimate knowledge of photographic science, and his book will be welcomed by all amateurs."—*Graphic.*

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

VOL. I.—No. 19.] SATURDAY, JULY 27, 1889. [PRICE ONE PENNY.

SWORDS: THEIR MAKE, WEAR, AND CAUSES OF FAILURE.

BY JOHN C. KING.

WE must first ask and answer the question —What is a sword? A steel weapon to cut, pierce, and parry. This triple action requires exceptional potency in the form and the temper of the blade, so that it is to these two last-named material conditions of a sword we must look for efficiency, or the cause is failure. The best of swords will yield to excessive strain; but if they fail upon slight impact with any substance they should cleave or pierce, they may be regarded as weapons made to look like swords: for sale, etc. etc.

A sword we select for consideration is the ordinary cavalry sabre of the British service. Besides the blade, we shall have to consider the form and materials of handle, guard, and scabbard.

The Blade.—The main consideration is the blade, its length, shape, sectional form, and temper. As any sharp weapon will pierce, but without proper sectional form it will not cut effectively, and cutting being the prime factor in sword effect, we make the sectional form the first matter to investigate.

The accompanying illustrations of cross sections of sword blades show the best, the indifferent, and the worst forms for cutting;

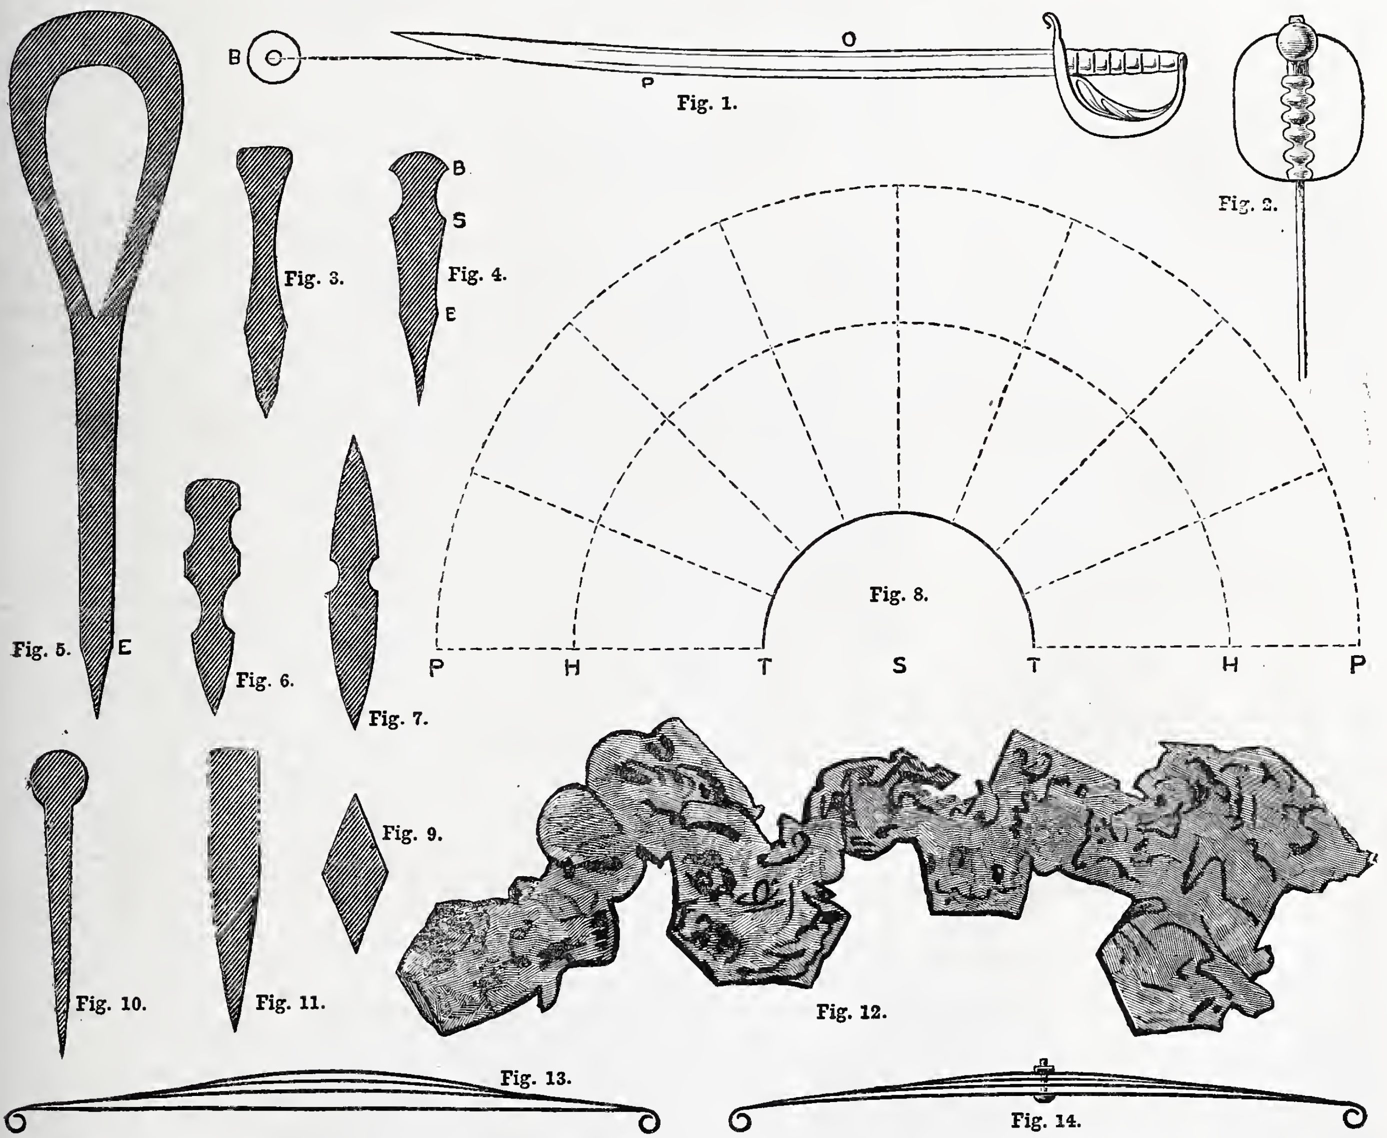

Fig. 1.—Form of Sword generally used by Cavalry. Fig. 2.—Hilt of Oliver Cromwell's Sword. Fig. 3.—Section of Cavalry Sabre in Use in the British Army. Fig. 4.—Cavalry Sabre best adapted for work. Fig. 5.—Section of English Woodman's Axe. Fig. 6.—Infantry Officer's Sword. Fig. 7.—Presentation Sword. Fig. 8.—Radiating Power of Sabre from Horseback. Fig. 9.—Toledo Rapier of Sixteenth Century. Fig. 10.—Sword or Cutlass often seen in Armouries. Fig. 11.—Blade, heavy but devoid of strength. Fig. 12.—Piece of Machine-made Steel magnified at its fracture 550 times. Fig. 13.—Main and Second Plates of Elliptic Spring before bolting. Fig. 14.—Ditto, when bolted together.

which will be explained in detail. The cuts effected by a sword on any yielding substance are either chopping or drawing cuts. As we are now considering straight blades with points only curved about the width of the blade, we may compare the force of the blows of an axe with that of a sword; the one, expending a thousand or more blows on a massive tree butt, without needing to be freshly ground, and rarely failing in the true temper and keenness of its edge; and the other, having to give a few desultory blows, mostly upon a yielding body, and too often failing. A sword may be regarded as an elongated axe, as an axe may be viewed as a section of a sword blade, with the addition of an "eye" for the handle fixing.

The section of an English woodman's axe (Fig. 5) shows a form for effective work on hard wood. This illustration of an axe is described in "Technics of Forestry" in the "Journal of Forestry," by the present writer. It will be noticed that the sharpness of this axe, shown by the part ground to an edge, to the angle E, is keener than four of the six sword edges shown by the illustrated cross sections of swords. The sharpening shows the hollow formed by the grindstone to E, producing a faint angle; this is technically known by woodmen as the "eth" of an axe; this is left prominent for a special purpose, causing the chips to flick out of the cleft of the tree being felled.

The blacksmith who "lays an axe," as steeling it is termed, mostly has a technical mastery of his craft; he does not blame the steel or the coal if failure sometimes results, but adapts his coal, and works his steel to suit his purpose. Why, we may ask, are not swords as reliable as axes?

The use of a sword is more exigent. Much may depend upon a sword parrying without bending or breaking; for a thrust to pierce, or a stroke to cut; life, command, even a nation's destiny may be involved by failure. We have dwelt on this comparison as our experience extends to the making and using of both tool and weapon, and it enables us to point out explicitly that the sectional shape of many sword blades do not fulfil the purpose of this weapon in warfare.

Of the many varieties of sword blades in use, we select for illustration seven of the leading types of swords, to indicate their value for cutting and resistance to strain by drawings of sections at the middles of the blades.

No. 3 is the cavalry sabre in general use in the British army. The "fullers" to lighten and strengthen the sword are worked by "swages," or "top and bottom tools," at the anvil, and by being generally too wide and too deep leave only a thin shell of steel between them. This destroys the rigidity and mars the stability of the blade, causing the sword to yield to a curve at a hard thrust, and breakage to follow; for it must not be lost sight of that this bending easily is insipient breakage, more surely so in a hard tempered blade than a soft blade. This will be made obvious to the reader when tempering is referred to.

The inclination of the bevels of the cutting edge is less acute than the woodman's axe, and would not cut through the collar of a coat or the head piece of a bridle. In fact, the edge is thicker than a new plough "coulter," which has to cleave through stony ground in the front of the ploughshare.

No. 6 is an officer's sword (infantry). The two fullers, narrow and deep, with a ridge between on each side, make a rigid blade, but worse for cutting than No. 3.

"It would be ground sharp before going into action," is said in answer to the objection to the obtuse edge, which would make a soft sword that would bend if much of the surface steel were ground away. This will be demonstrated when tempering is explained.

No. 7 is a section of a blade which may be seen used for presentation swords, but mostly without the middle fullers, so that the writing and devices may more easily be displayed on the blade. It is not suited for actual warfare; very few presentation swords are.

No. 10, with a beaded back, is met with in armouries, and, with two fullers at the back of the blade instead of the beaded back, is the sort of hanger or cutlass used by seamen in the old wars of this century. There has been nothing better devised for the navy.

No. 11 is a section of a blade sometimes seen in use where price determines form and finish. It is heavy, and not so strong as if it were to be properly fullered. Its obtuse edge would have little penetration in cutting. No. 9 is a sectional view of a sixteenth century Toledo rapier. It is introduced here, as reference will be made to it under the head of tempering.

No. 4 shows section of a cavalry sabre best adapted for work. From the edge to the "eth" E is more acute than any except the cutlass, No. 10; from E to S, forming about three-eighths of the total width, is only slightly hollow; the "fullers" are narrow from S to B. This is a reliable form for rigidity for piercing and strength for cutting penetration, with least risk of breaking or bending.

Fullering.—It seems paradoxical to lessen the bulk of a thing, making it lighter, yet making it stronger. But it becomes plain upon reflection that it is the surface form which decides the strength. A form which presents portions of its surface edgeways has edgeway strength. A gun barrel will serve for illustration. Regard the inside of this as two deep fullers as of a sword blade, joined, making a circle, the strength of surface shape becomes obvious. Compare the strength of a gun barrel with the strength of the same weight of a rod of solid iron; thus it will be understood that narrow channels fullered into the blade at the back edge of the blade are the best. Old Scotch claymores sometimes show four or five narrow fullers in the strong or wide part of the blade. The fullering of most blades extends only for three-fourths of their length, the back of the blades being sharpened the other fourth of the length.

The Springing of a Sword Blade.—The springing of a blade and its resilience is a merit to a limited extent only. The less a sword yields from straight to curve under strain, the better for the user of the sword. It must be obvious that a blade which bends to slight pressure, however perfect its resilience, is a defective form of blade for a cavalry sabre. A pliant blade, if struck on a hard substance, with its surface nearly in the same plane as the orbit of the stroke, would glance from it, and in the attempt to pierce a moderately hard or tough substance, the pliant blade would bend instead of piercing. The blade shown in section No. 4 best fulfils all the requirements for piercing, cutting, and parrying.

The Shape and Length of a Sword Blade.—We assumed at starting that a straight blade is best suited for modern requirements for cavalry; the length should be proportioned to the stature of the soldier, and the height of the horse on which he is mounted. The service patterns for cavalry are too short to reach a crouching foe a yard away from the course of the horse on the near side. For cavalry a sword half a foot longer would make a more effective weapon. Its power is augmented in the charge and need not be diminished in defence, at which the better soldier would not long accommodate an antagonist by parries. Fig. 1 shows the form of sword now generally used by cavalry; it will be seen that it is not quite straight along the back to the point, which is a defect, more especially for a long sword. The diagrams of the relative circles formed by the turning the wrist in presenting the back of the sword to guard a cut will show that the adverse cut has no axial leverage offered to its force in a straight sword; but on the curved blade the user offers a leverage out of the straight line at the point just as much as the circle, B, shows is the curve deviation of this sword. The wrist has to sustain this strain in guarding a cut on the blade near the point. It has been urged that a slightly curved blade produces an oblique entering cut into any object, but angles of cuts are always determined by the angle of surface presented to the sword.

The business part of a sword may be reckoned from the point to P, the centre of percussion, both for cuts and thrusts. If the point in cutting meets an unyielding substance, the breaking strain is thrown on the cutting edge at P, and by gradations of points of concussion back to P, the strain on the edge is thrown on the blade back to O; but the concussions of edge of blade, back from P to O, create a cantaliver strain along the back of the blade from P to O, due to the momentum of the weight of the blade from those contact points. Now, breakage, apart from faults in tempering, results from the sudden inertia after sudden motion; that inertia is increased by the edge *not being able to cleave through the objects it strikes*, hence the necessity of a keenness of edge to diminish risk of breaking. For thrusting, a curved blade springs under the impact more than a straight one, and lessens the force of penetration. The diagram (Fig. 8) illustrates the radiating power of the sabre from horseback. S is the saddle centre from which the stirrups should hang vertical, as the cavalry man works standing, his seat being only a contingent support. This steady level foot-bearing on stirrups is best attained by the stirrup being hung to the saddle by V-shaped stirrup-leathers from pommel and cantle. As the neutral axis of the animal's movements is nearly central between the fore and hind legs at junction of the body, the soldier is less affected by the horse's motions than if the stirrups are hung forwarder on the saddle. From S to T may be viewed as the extent of body, arms, and legs to be guarded; from T to H, the range of arm and reach of body, also the orbit of guards and parries; H to P, the sword from hilt to point in its sweep at cuts and effective thrusts. A weapon six inches shorter diminishes the radiating power and range of cuts and thrusts and far-reaching parries. Every horse soldier knows that a cut or thrust short of the mark is perilous in combat.

Steel of which Swords are Made.—We have not yet spoken of the sort of steel of which swords should be made, assuming that good steel would be used in the manufacture of sword blades; nor is it of so much consideration to a sword-smith, as is the shape, section, and length of blade, properly tempered, to the soldier. We therefore combine the matter of consideration of steel and tempering, in the hands of a skilful smith, under one heading. Here arises the talent of the forger, who can make and temper the blade which will either cleave iron or silken floss; for this, the man who forges the blade should temper the blade to ensure success. If ignorant of steel working and tempering, a smith may make a good weapon to look at of the best shear steel, yet it might not be so serviceable a weapon as a better smith would forge out of old iron barrel hoops, that process being simply making your steel out of iron, welding, hardening, and tempering. As this is a matter of the technology of iron working, we may treat of it some future time; it would take up too much time to detail its processes in this essay. A volume might be written on steel for swords; after all, it would be what sort of steel the smith converts it into—good or bad; for every heat he takes, every blow he strikes, every chill he gives, modifies the molecular structure of the metal, making it better or worse than when he began the job. We must not forget that smiths of old had to make their steel out of iron during the process of making the weapon. How few smiths—especially where machinery supplements labour—forge and temper a weapon throughout; the division of labour is too often the blight of earnest skill and the bane of enterprising talent. The contractor, perhaps technically ignorant of the proper manufacture of a sword, and assuredly practically incompetent to know what it should be for efficiency as a soldier's weapon, does not simply want to grind his workmen's "bones to make his bread," but perils the nation's welfare by producing worthless weapons, and, forsooth, something worse sometimes — a parliamentary committee which manages to screen the culprits and start the grinding game afresh. Wrong begets other evils; the wasteful process of bad sword making finds its way into the "dunces' dustholes," as the Encyclopedias are not inaptly termed, when they assume to describe the humble technics of toil. For instance, they say swords are forged, tempered, set true, ground, etc. Contractors' swords may, and no doubt are, ground after they are tempered—it comes cheap; but a sword-smith who knows his work would grind his sword before he attempted to temper it, and so ensure the temper being secure from injury by grinding.

Forging Sword Blades.—This may be well done by smiths without any other adventitious aids than the common forge and a suitable muffle for beating, for getting perfect granulation and fibre into the texture of the steel. A hollow fire is made, which is a culvert of banked-up small coal and ashes, at right angles to the nozzle of the "tew iron." This is mostly done over pieces of wood which form the core; these, when burned out, leave the culvert for the steel, called a "hollow fire."

"Drawing down" the Steel.—This is a very elementary matter for a smith who has worked in steel. The proper heats, and the rapid, regular blows of the hammers and sledge, start the jobs; then avoid any hammering while the steel is only black hot, except light taps that do not jar the grain of the steel violently. This is well understood by steel-smiths. For straight blades, the bending of the steel to a concave curve on the cutting edge is necessary, to counteract the action of thinning the cutting edge, and swageing the "fullers," which bring the blade straight; all is the plainest of work, yet requiring experience and judgment. It is while doing this that the smith learns what sort of steel he is working, and how its tempering should be modified. Here we can appreciate the critical mental power of the worker, which is lacking in the action of machinery which aids his work, and too often is made to do imperfectly, though cheaply, what hand labour can do better. The illustration of a piece of machine-worked steel, Fig. 12, magnified at its fracture, shows a grain quite unfit for sword blades, yet it is good steel spoilt by bad working, and is made into blades for swords, hence their defectiveness in too many instances.

Tempering Sword Blades.—We may here at once demonstrate that two distinct principles of tempering have to be adopted with steel tools or weapons to adapt them to the requisite power for resistance to strain required of them. For some purposes, the outside of the steel tool or implement consists of a tough layer protecting a more brittle-grained core. "Springs" for road and railway carriages, for instance, have the brittle resilient steel protected by a sheath of tough steel, which does not impair the resiliency desired in such springs. This is done by tempering. Railway "springs" are about semicircular in shape before the weight of the carriage is put on them, when they are made to yield to a faint curve, nearly straight. Compare the work done by each of these many plates to a "spring," with the idle existence of a flashing sabre—

> "That sometimes plays at havoc with the work of God
> To drink the stain called Glory!"

By detailing the simple process of hardening and tempering of "springs" of the sort made up of leaves of steel for ordinary carriages, it will explain what was advanced of two principles of hardening and tempering steel, and further elucidate some features of sword-blade tempering which may be new to the sword-smith as well as the general reader, and interesting to the swordsman. Carriage spring plates are drawn out as thin as a knife blade at their extreme ends, and they are fitted together so that each successive shorter plate in the series of layers is more curved than the next longer one it fits against, as will be seen by the sketch of a bow, or half of an ellipting spring, before it is bolted in the middle to close the plates to a dead fit one against the other. Fig. 13 shows the long main plate, which is about $1\frac{1}{2}$ in. fainter curve than the second plate; this again is 1 in. less curve than the next, and so on to the shortest plate, which is only about half an inch more curve than its longer fellow plate. These diminishing gradations of spaces between plates increase resiliency. Fig. 14 shows the "spring" when bolted together. Here we have a tension on each plate permanently as long as the spring lasts, and when in use it is often bent to a reverse curve, and yet it springs back to its true shape. Plenty of such springs have been in regular wear on vehicles for more than fifty years, and are still good. This success is attained by first hardening the curved plates, separately, by plunging them, when cherry-red hot, into water till cool, then passing each plate into a "hollow fire," so that the plate becomes black hot, and yields the following tests: either to flare grease if rubbed on it, or to make a piece of dry, soft wood give out sparks when rubbed hard against the edge of the heated plate, which is then allowed to cool. This process sheaths the diamond grain of the plate in an envelope of tougher steel, which prevents fracture of the plate, even under excessive strain and concussion over rough roadways. With sword blades, the reverse principle of hardening and tempering is necessary; for though a sword may spring, that action is only incidental to occasional strain; the less a sword yields to a curve the more efficient it is both for cutting and thrusting, as has been previously explained. Here it is necessary to get the diamond grain steel on the outside of the blade.

Hardening and Tempering Sword Blades.—There are other ways of forging sword blades besides drawing them out of steel bars; as a bar of iron for the core, and two thin bars of steel for the cutting edge and surfaces welded together, was a common plan of old. In the United Service Museum, Whitehall, London, is the sword used by Oliver Cromwell (Fig. 2) at the siege of Drogheda. It has the marks on it as if it had been struck by bullets in two places, fracturing the shell of outside steel and dinting the softer iron core under it, which is seen where the outer steel surface is broken away; this makes it appear as if thus made. The perfection to which steel is wrought ready for working into sword blades dispenses with this form of making a tough blade, and the process of tempering is as simple as can be, bearing in mind that steel needs the thoughtful study of how to prevent sudden atmospheric action on its constituent fibres from injuring them during the cooling processes, after making and while tempering. Such highly wrought matter as heated steel requires adequate time for the expansion and compacting of its fibres. We know sudden chill will make it brittle as glass; slow cooling soft as iron; so proportional heat or cold will modify its texture, and throwing a hot sword blade to cool on the floor will do harm to the steel by producing unequal tension of fibre in the sides of the blade. A forged blade should, as soon as done, be thrust into charcoal dust or dry sawdust, or the ashes on the forge, to get cool gradually, by which its fibrous grain obtains better form throughout; grinding should follow. In preparing for tempering, two baths may be used for cooling, or only one. We will describe both plans. One is a brine bath, 1lb. of salt to a gallon of water, with three or four inches of oil on the top—linseed oil is suitable—and the brine water should be at 100° temperature. The blade, with others, is put into a "muffle" or pipe packed with charcoal, so that they do not touch each other; six blades, or eight at most, is enough in the muffle, and this is put in a furnace and heated slowly till the blades are a bright cherry-red colour; one at a time the blades are immediately drawn out of the muffle, and plunged straight down through the oil into the brine bath, and held immovable till the tremor of the bubbling of the water almost ceases. This is known by the tremor of the blade ceasing to be felt by the hand that holds the tongs. The blade has been in a sheath of vapour, and the oxygen of the water, it is assumed, has been drawn to the steel, or the carbon on the steel, and has crystallised the grain, making it very hard; the sword blade is drawn slowly out of its bath and laid horizontally in the oil on the top of the water, resting there till quite cool; when seemingly cool it must not be thrown in a very cold place, but should for some little time longer be kept at the same temperature in charcoal, sawdust, or ashes. This is hardening a sword blade. The final tempering is done by heating to 560° Fahr., which produces a blue colour, and cooling the blade in water. This heating should be in a lead bath, so that the thin parts of the blade are not made hotter than the thick parts. The other plan of hardening is to have two baths, one of brine water, the other of liquid resin and oil, three gallons of lard oil to one of liquid resin, well mixed. The blade is operated the same way; first, straight down into the brine water bath till the tremor imparted by its sheath of vapour has nearly ceased, and then drawn out and plunged straight down into the oil and resin bath till cool. Then heated in the lead bath as before described till surfaced with dark blue colouring, then cooling in water, then packed in charcoal or dry sawdust. The smith who has made the blade can tell if the hardening should be at dark or bright cherry-red, and the tempering light blue, or dark, or purple, according to the nature of the steel. Referring to the Toledo rapier (Fig. 9), quite three centuries old, a perfect weapon, the owner desired it to be made six inches shorter, without drawing down and re-tempering; the writer of this essay warned him that it would produce a soft steel point, as it would bring the core of the blade to the point by the process of grinding. It did so, and the weapon was soft pointed, though the grinding was done slowly in very cold water.

The Sword Handle.—It may be a tang, or a flat haft, to have the handle riveted on to it. The tang admits of a better formed handle for grip and plug in the hand. The regulation pattern handle is bad in form and in roughing of the hand-piece, which roughness is not perceptible through the leather glove. We again have to turn to Oliver Cromwell's sword; the handle and guard, or hilt, are unique. The sketch (Fig. 2) shows the handle and outline of hilt. The power to grip this sort of handle is manifest; the ball end ensures the hold of the sword at a swinging cut. The hilt shows the same common-sense application of a light impenetrable metal cover for the hand, the basket part being pierced with small oblong oval holes, smaller than a grain of corn. It looks more serviceable than ornamental, but a soldier's weapon withal.

The Sheath.—The steel scabbard is an absurdity for real service by its weight, trouble of keeping bright, and annoyance in striking the next horseman when flying about like the sweeps of a mill. It is a minor matter, but experience has shown the great service of leather metalled at the mouth; the sling-rings and points to take the wear of the spur and the ground. The soldier with this sheath is not so distressed by the weight of his sword.

Sword Belts.—The present double strings are a makeshift, and a bad one; a belt-frog, eight inches long, with a metal loop to take a spring clip at the back edge of the scabbard near the mouth, answers admirably. When dismounted, the spring clip is fastened on to a loop of the waist-belt to admit walking without clanking the scabbard. Shorter swords for cavalry, fastened to the saddle, are spoken of. The carbine is now fastened to the saddle, so that in a skirmish a dismounted rider has perhaps a broken sword and his ammunition only. A soldier should carry his tools with him, as his horse carries him. With good belts they would ride easy, and be with him on or off his horse.

The sword is a weapon that is attracting considerable attention at the present time, and it is hoped that the above remarks on the sword itself and its appurtenances will not be found uninteresting or devoid of value.

HOW I MADE A DRILL CHUCK.

BY ELECTRON.

SOON after I became the possessor of a lathe, I found a want of an appliance for drilling holes above $\frac{1}{4}$ in. in diameter. I had a few drills with square shanks, which had been made for use with a brace, but I had no brace, and the lathe had no drill chuck, nor had I in my possession any taps, or

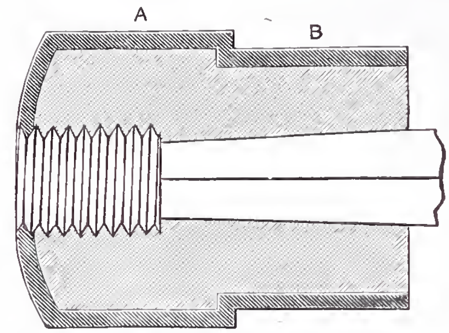

Fig. 1.—Section of Chuck.

chasers wherewith to make a screw to fit the nose of mandrel.

I began to consider how I could overcome this difficulty, and in looking round, I found a brass cup, about 2 in. diameter, with a small hole in the end; this was carefully enlarged till it would just fit on the nose of mandrel, but when pushed up to the end it was only $\frac{1}{2}$ in. in front of the end of mandrel. I then got a piece of brass tube, that fitted inside the cup, and cut a piece off, about $1\frac{1}{2}$ in. long; the headstock was then taken off, and set on its end, with the nose of mandrel upwards, and the cup and tube fixed on; one of the drills was then driven into a piece of wood which was fixed on two supports, so that the end of drill rested on the end of mandrel, and was fixed as nearly in line with the mandrel as it could be; the shanks of drill and mandrel were covered with grease, and the tube and cup filled with melted lead. Fig. 1 is the representation of a section of chuck, A being the brass cup, and B the tube.

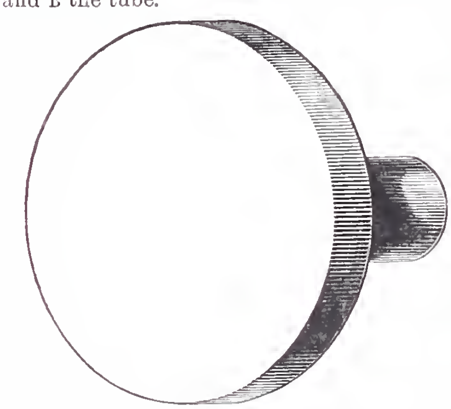

Fig. 2.—Face Plate for Drilling in Lathe.

On fixing the headstock, and revolving the drill, I found it a little out of truth, but by taking a little off one side, and punching the lead on the opposite side, I got it as true as such a drill could be got. I have drilled holes in steel, cast and wrought iron, and brass, and although it has been in use for a long time, it is very little worse. Of course, I don't recommend such a drill chuck where a proper one can be got, as for good work good tools are required; but there may be many a beginner, who may be in the same position as I was, to whom the hint may be useful.

An improvement in making a chuck of this kind would be to have the shanks of drills turned, and drill a hole in the lead when fixed in position. This would ensure it being central; and a set screw put through one side, and bearing on a flat, filed on one side of drill shank, would hold the drill fast.

A cup for holding the lead might be made as follows:—Get a brass tube about 2 in. diameter and 3 in. long, turn the ends true on a wood mandrel, then make a circular plate of brass, with a hole in centre to pass over screw of mandrel; tin the edge of plate and inside of one end of tube with a soldering bit, making the plate a tight fit in the end of tube, and drive it in till level, then solder round the outside of joint, and clean off with a file.

If the tube can be got $\frac{1}{4}$ in. thick, it will prevent the set screw in side of chuck wearing the lead. In drilling with the lathe, a face plate should be made to fix on the end of the screw of loose headstock, to keep the work square. Fig. 2 shows this face plate; it should be covered with wood, to prevent damaging the points of drills.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

(*Continued from page 260.*)

ROMAN SMALL LETTERS—OLD ENGLISH CAPITALS AND SMALL LETTERS—SCRIPT CAPITALS AND SMALL LETTERS.

I PROMISED in my last paper to give a set of Roman small letters or lower case, as a necessary pendant to the complete alphabet of Roman capitals. These will be found in Fig. 34. Any special comment on them seems to be unnecessary.

The student should, as soon as possible, commence working on the Old English letters, proceeding in the same way as before, viz., outlining the letters first and afterwards filling them in. He should first of all take up the capitals only, Fig. 35, and when fairly successful turning his attention to the small letters, Fig. 36. Of course he will find these the most difficult work of all he has yet attempted, but he need only practise their formation in leisure moments, and not force his hand or his patience. It will not do to neglect these Old English characters altogether though, as once they can be drawn with precision, it is a comparatively easy task to learn how to form any of the ornamental and fancy alphabets and church text letters which he will eventually be called upon to paint.

These lessons on forming the alphabet may appropriately conclude with a few remarks on "script," or hand-writing letters, which are illustrated in Figs. 37 and 38. This is the ordinary writing we are all taught when at school, and is known in the copy books as "round-hand." It is much harder, however, to execute this writing with the camel-hair pencil than it is with the pen, but it must, nevertheless, be thoroughly practised, as it is in great demand in the sign-writing business, and must be done well or not attempted at all. It is best to use a sable writer for practising "script" writing, and no previous outline should be allowed, excepting a straight line to work upon. The wrist must also rest comfortably on the mahl-stick, and the work done in a quick, bold, unhesitating manner. I should mention that Old English and "script" letters may for some considerable time be practised with much advantage in pen and ink on some good glazed writing paper, and afterwards on an a b c d e f g h i j k l m n o

p q r s t u v w x y z

enlarged scale on Whatman's or Rowney's hot pressed drawing paper. Of course in cases where this has been previously learnt at school, such a preliminary canter is not requisite.

The hardest part of the work, as far as the writer is concerned, is now over. Specimens of five different forms of letters (those most commonly in use) have been given with the accompanying instructions. They are, so to speak, the root and foundation of all other styles and varieties (German text possibly excepted) in use at the present day, and once let the student become complete master of them, together with the freehand drawing lessons given at first, and he may at once style himself a sign writer. He has nothing more to learn beyond what experience will dictate to him, such as spacing his letters and the proper display of his words. This I will, however, endeavour to assist him in, and also in succeeding chapters point out the necessary tools for a complete outfit, their treatment and care, the colours, with hints on using them, together with directions for painting coats of arms and a pictorial sign; also give a few

illustrations of specimen signboards and alphabets of ornamental letters and church texts, and concluding with some dodges and receipts of English, Continental, and American origin. There is nothing, therefore, in what has to follow, but pleasnrable and interesting reading for the aspirant to sign-writing honours, and in perusing which he will be adding to his knowledge without any apparent effort on his own part. And, moreover, he will always have in these latter chapters a handy book of reference, which he may fly to in any moment of uncertainty or doubt. Every nerve has been strained to exert and encourage the learner and keep him up to his task, and this branch of the painting art has been placed before him in as popnlar light as it could be, and it now rests with him and his indomitable pluck and energy whether he fails in his attempt, or blossoms forth into a respectable member of the sign-writing profession, and pocketing, as his weekly and easily earned salary, a £10 note.

SMITHS' WORK.

BY J. H.

(*Continued from page 226.*)

THE "PIG-BOILING" PROCESS—DRY PUDDLING PROCESS—MR. HALL'S EXPERIMENTS—BESSEMER'S PROCESS—MUSHET'S BATH OF DECARBONISED PIG—SIEMENS AND SIEMENS-MARTIN OPEN HEARTH PROCESSES—PRESENT DEMAND FOR STEEL.

IN my last, I intended to commence an account in this third article of the work of the mediæval smiths. My readers will permit me to postpone the commencement of this subject nntil the fourth article, in order that I may make a few remarks on certain processes for the mannfacture of iron and steel, which were briefly touched on in my first paper.

Since that was printed, I have received, through the Editor, a communication from a gentleman relating to the "pig-boiling" process, a process to which I made a passing allusion in the first article. It appears to me desirable to notice this commnnication somewhat fully, in order to give publicity to a chapter in the history of iron making which is not generally known, and at the same time I will point out a few of the essential differences in the wrought iron and mild steels made at the present time. In taking this course, I shall not lay myself open to the charge of digressing from the snbject of smiths' work, since most readers will probably like to know what constitutes the essential differences between the iron and steel in their various grades which they use in daily work.

The commnnication referred to is as follows:—The writer has received a small volume* from Mr. William Hall, of 14, Broad Street Corner, Birmingham, who claims for his late father the merit of having invented the "pig-boiling" process and the patent cinder, or "bull dog," a refractory oxide, by which the increased temperature required in the "boiling" process was successfnlly resisted; and as this is a fact not generally known, a brief account of the history of this process may be of interest. Since it is probable that some of the readers of WORK who may be interested in these articles of mine do not know the essential method of operation of the process termed "pig boiling," I will first very briefly note the difference between it and the original puddling process.

In the original, or dry puddling process, grey pig iron is first refined on the hearth of a rectangular fnruace, or "refinery." Coke or charcoal is the fuel nsed. By means of oxidising agents, as basic slags, cinders, and hammer scale, and a strong blast of air directed down npon the hearth from inclined twyeres, the metal is decarbonised, and white iron, in which the carbon is in the combined condition, results. The refined iron is then puddled on the hearth of a reverberatory fnrnace, whose bottom is lined with oxide of iron. The metal being white, does not mclt, but becomes pasty, and when in this condition it is rabbled over the hearth in order to mix it with the oxide of iron, and also with the hammer scale which is added to the charge, both basic materials, by means of which, and by the aetion of the atmosphere, the impurities are oxidised out from the metal. Finally it is worked np into balls, and hammered or squeezed, in readiness for rolling into bars and rods. In the later, or "pig-boiling" process, the preliminary aud costly refining into white iron is not necessary; grey pig iron, or a mixture of grey with white, being used. The furnace lining consists of broken slags, tap cinder, hammer scale, and old hearth bottoms broken up; while the fettling consists of "puddlers' mine," which is a pure red hæmatite, and of roasted tap cinder, or "bull dog." In these substances when fused, all rich in oxygen, the grey pig is immersed, and the carbon is thereby oxidised out, the period of the boil coinciding with the complete oxidation of the carbon to carbonic oxide, and with the oxidation of the sulphur, phosphorus, and other ingredients. Soon after, the metal drops quietly upon the hearth, and it is then "balled up" in readiness for the hammer.

This is a very brief account of the process, and many details are omitted, but it will suffice to furnish a comparative idea of the two methods.

Somewhere about the year 1820, Mr. Hall's father was engaged in an iron-works, in which, according to the universal practice up to that period, the older dry puddling process was carried on. At about that time, or a little earlier, about 1816, iron bottoms for puddling furnaces, eoated with oxide of iron, or cinder, were substituted for those of sand, originally used by Cort. Now Mr. Hall had beeu in the habit of saving and puddling up odds and ends of scrap metal, apparently as a perquisite, making use of the ordinary furnaces with cinder bottoms for the purpose. When he first charged a puddling furnace of the new type, the scrap mixed with the bosh slag produced in the cinder bottom a surprising result. The contents of the furnace literally boiled over, running over the fire and flue bridges, through the stopper hole, and down upon the plate where the puddler stands. The experimenter was alarmed at first, and resolved to abandon the work. But this resolution was quickly changed, when on the following week the quality of the bloom of iron thus produced was found to be superior to any made by the intermediate refinery methods. The question naturally arose in Mr. Hall's mind, "If such a fine specimen of iron can be produced from the refuse of the puddlers' boshes, what will not good pig iron yield, with equally good fluxes?"

Three years of experiments followed, with the ultimate result that any grade of iron could be produced either from the bosh slag or from pig iron direct. Then follows an account of the difficulties met with by Mr. Hall in the search for materials of a sufficiently refractory character to withstand the corroding effect of the flux. Finally after thirty years of search, cast-iron plates backed with air spaces, with burnt tap cinder or bull dog for a lining, were employed, and a patent was taken out for the latter in 1839. During the whole period of Mr. Hall's connection with the trade, "bnll dog" only was used for "fettling," and at Bloomfield I believe it is still continued. Mr. Hall's experiments cost him not less than three thousand pounds. The roasting of tap cinder to make "bull dog" was patented by Mr. Hall, who, from various reasons (foreign to the object of this paper), did not follow up the legal advantages that he had in this respect.

It is satisfactory to know that Dr. Percy, the ablest and most scientific and accurate writer on the metallurgy of iron and steel, accords Mr. Hall credit for his invention. He says, "The merit of introdueing 'wet' puddling or 'pig boiling' is ascribed, and, as I believe, with reason, to the late Mr. Joseph Hall, of the Bloomfield Iron Works, Tipton, Staffordshire; but that merit has been disputed, and in this respect Mr. Hall has only met with the fate which seems especially to have befallen the authors of every other improvement of importance in the smelting and manufacture of iron. Mr. Hall, whom I knew personally, was, undoubtedly, one of the most experienced and skilful producers of wrought iron in South Staffordshire, and no firm in that county has enjoyed a higher reputation for the quality of its manufactured iron, for example, boiler plates and horsc-nail iron, than Bradley, Barrows, and Hall. As far as I have been able to ascertain the truth, I believe that Mr. Hall was fairly entitled to much of the credit which he claimed for himsclf."—"Iron and Steel," p. 670.

A tone of evident disappointment pervades Mr. Hall's book.* He smarts uuder a sense of unrequited merit. We can well understand this when he says, that "the pig-boiling principle, with its furnace, had they been patented, would have realised by this time perhaps a million of money, and the trade has received the full benefit of them without any remuneration to the inventor."

Self-made men are apt to be somewhat egotistic. A successful business permitted him to be independent of the necessity of realising on his own inventions, but he. nevertheless, had a pardonable desire to see his endeavours recognised. They were to some extent acknowledged by one or two.

Mr. Hall's account was written at the period when Bessemer's process was nnder a cloud, and his early failures afforded a ground at that time for Mr. Hall's unfavourable comparisons of the pneumatic with the pig-boiling process. Mr. Bessemer met with ill-success during three years, aud spent thousands of pounds before he could perfect his converters, or produce sound steel. And even then, justice compels us to acknowledge that but for another inventor, David Mushet, whose lack of means alone prevented him from deriving benefit from his discovery, Mr. Bessemer's process could never have been a success. Mr. Mushet had patented the addition of spiegeleisen or ferro-manganese to decarbonised iron, and it is this which has reudered the Bessemer and open hearth processes practicable. Mushet allowed his patent to lapse for want of funds, and others reaped the advantage of it.

*"The Iron Question," by Joseph Hall. Hamilton, Adams, & Co., 1857.

* See *ante*.

To those not acquainted with the practical difficulties of steel making, it may seem the simplest thing in the world to decarbonise a bath of pig iron to that precise stage required for mild steel. But it is not so in fact; and more than that, the iron becomes rotten and "cold short," and worthless in the process. Hence, in the manufacture of all mild steels, the process invariably is, to first burn out *all* the carbon, and then to *add* the measured quantity required in the form of "spiegel" or "ferro." Besides, it so happens that manganese is as essential to the production of mild steel as it is to that of crucible steel. Steel, which before the addition of manganese would be absolutely rotten, is rendered malleable by such addition. It is not that all the manganese remains in the metal, but that it reduces the oxide which is the cause of rottenness. But for the addition of carbon and manganese, therefore, in the form of "spiegel" or "ferro" to the bath of decarbonised pig as originally patented by Mushet, Mr. Bessemer's invention might have been unknown except to students. Mr. Nasmyth's invention, for example (patent No. 1001, May 4th, 1854), was in its essential method very similar thereto, consisting of discharging a current of steam from a nozzle bent downwards to the bottom of a bath of molten metal. For a discussion on the claims of Mr. Mushet, see several letters in *Engineering*, 1884, vol. 37.

It follows as a necessary consequence of the method of dry puddling, that iron so produced cannot be homogeneous, but that it will consist of iron with scale and cinder mechanically intermixed therewith. The processes of piling, squeezing, tilting, hammering, and rolling, expel the major portion, but not all of the scale and cinder. The larger the number of reheatings to which the iron is subjected, and the greater the amount of work done upon it, the more free, other things being equal, will it be from these impurities which are mechanically intermixed. B B B iron has more work done upon it than B B, and this again than B, or merchant iron. But the best iron cannot be wholly freed from scale, and every reheating costs more money for fuel and labour. Herein consists the superiority of mild steel that it is *fused*, and, therefore, freed from scale.

Another point is, that it is more difficult to obtain large masses of iron sound than masses of smaller size, because the amount of scale present is a cumulative quantity, and the difficulty of sound welding increases. No such difficulty exists in steel, ingots of which can be made of 100 tons weight.

The Siemens and Siemens-Martin open hearth processes are growing in public favour more rapidly than the Bessemer. The reason is this, that immediately the Bessemer blow is finished and the spiegeleisen has united with the decarbonised metal, the product must be emptied at once into the ladles for casting. But the metal may be allowed to lie in a molten condition for an indefinite period on the open hearth. The Bessemer process is completed in about twenty minutes, and must not exceed that period; the open hearth process is not completed for seven or eight hours, and may be allowed to continue longer. If on testing, therefore, the chemical and mechanical properties of the metal are not precisely what are required, there is time in the latter case for making such modifications as are deemed desirable. Besides this very valuable power of control over the ultimate product, it is considered better to deoxidise the metal by means of metallic oxide, as is done on the open hearth, than by means of atmospheric air as in the Bessemer process. Bessemer steel is more agitated, and occludes bubbles of gas much more readily than the Siemens open hearth and the crucible processes. Still, there are many things for which the Bessemer process will always hold its own, as tyres, rails, and heavy forgings for cranks and shafts.

In the early days of Bessemer steel making, many manufacturers abandoned its use after trial, as being untrustworthy and treacherous. The fault lay partly in the material, largely, however, in the method of treatment adopted, because the treatment that secures good results in the working of iron does not invariably answer with steel. Iron plates fail, and have failed over and over again. Yet such was the suspicion with which, until very recently, steel was regarded, that the fracture of a single steel plate was invested with far greater importance than that of many plates of iron. So great has been this prejudice that steel has been sold under disguised names—as homogeneous iron or homogeneous metal, and thus found a market, where, as steel simply, it might have failed to do so.

Every branch of manufacture demands its own special grade of steel, and the readiness with which steel of any required grade can be manufactured is one of the chief reasons why its use has become so general. The grade of steel suitable for ship plates and bridges will not serve for ships' boilers, nor for cannon, nor shells, nor for rails, nor tyres, nor tools.

It does not follow, however, that because steel is so widely used for purposes to which wrought iron was formerly applied that there is no longer any demand for the latter. It was only in May that Sir James Kitson told the members of the Iron and Steel Institute, that with the enormous expansion of the purposes to which steel is applied, there has followed a multiplication of the many special purposes for which iron is needed. Iron will never replace steel for rails and tyres, hardly for ship plates or for bridges, or for guns; but for chains, cranks, boilers, and for the innumerable purposes of the smith, in the form of rods and bars, it will hold its own for an indefinite period.

THE "BATTLESDEN" CART.

BY OPIFEX.

Good Qualities of "Battlesden" Cart—Body—Sides and Front Board—Floor—Alternative Method of Fixing Floor—"Fixing up" Body—Stays—Materials for Floor and Sheckle Stays—Painting and Jointing—Pieces to Extend Seatage—Angle Pieces—Supplementary Sides—Falling Footboard—Method of Fastening Board—Shafts—Cross Bar or Transom—Fixing of Shafts—Sockets—Springs—Iron Sheckles—Springs—Axle—Wheels—Wings—Fixing Wings—Dashboard—Mountings—Lamps—Painting—Varnishing—Treatment of Wheels—Treatment of Ironwork—Painting Inside of Body—Upholstering Back Rest—Cushions—Holes in Floor—Perforated Rubber Mat—Linoleum on Inside of Falling Footboard.

For a good, useful, commodious, and light-running trap, I know no better than the "Battlesden" cart; the family to which it belongs came first from Croydon, from which town they took their name. But the old "Croydons" multiplied so fast that many of their descendants changed their patronymic, and during the process of evolution they have in a great measure altered their appearance also, the "Battlesden" amongst the number.

The construction of this trap is simple, and well within the reach of any fairly skilful amateur, while in the hands of a good workman every item will be "plain-sailing."

The writer has built many vehicles which, upon inspection by his friends, have drawn forth such questions as "Did you really build it yourself?" "Did you make the wheels?" "How did you make these springs?" etc. etc.; and when the reply was "No, I made none of these things," it is to be feared that in some cases he fell considerably in the estimation of the questioner in his character of coach-builder.

But no builder ever does make all these, or turn out a vehicle all of which has been his own unaided work.

In the professionals' manufactory there are many hands employed in the construction of the simplest form of vehicle.

The "body maker" is distinct from the "wheeler," the smith quite a different individual from the painter, the painter from the "trimmer," and so on through the long list of hands.

But we are going to do the work of most of these men ourselves. We shall buy our wheels and springs ready made, and, having procured these, hope to have to call in the aid of the local blacksmith only in the case of a part of our ironwork, and some workers may even dispense with his assistance.

To my mind coach-building possesses a peculiar charm for this very reason: that there is so much variety, and one has to fill so many *rôles*, being, alternately, carpenter, smith, painter, upholsterer, and saddler.

But we must get to work without further delay, and the character we shall first assume is that of "body maker."

The sketch is perspective. Fig. 4 gives the reader a fair idea of what we are about to construct.

It represents the body proper, and consists of two sides (Fig. 9), front board (Fig. 11), and flooring.

To save space, we shall assume that the worker is supplied with the necessary materials, merely describing them in the directions for building.

The two sides and front board are of elm or walnut, and the shape and dimensions are indicated in the drawings, these, of course, referring to finished work, so that allowance must be made accordingly when selecting the timber and sawing it out. If the wood is of even thickness it should be chosen about $1\frac{1}{8}$ in. thick, which, when cleaned up, will be of the right substance.

The upper and lower edges of the sides are bevelled to suit the angle at which the sides are pitched, so that when in position they may be horizontal.

The front board (Fig. 11) is of the same scantling as the sides, and is secured to them by four long screws at each end, the screwheads being countersunk below the surface, the countersinkings to be afterwards filled with putty coloured to suit shade of wood.

The floor is fixed to the sides by means of screws inserted at the proper angle, at least four to each board and heads countersunk, an overlength of about half an inch being allowed at each end to form a small bead along the edge of the bottom and front board of the trap.

An alternative method of fixing the floor consists of placing a "slip" in the internal angle, to which the boards of the floor are screwed; for detail, see Fig. 19.

If this mode be adopted the floor of the cart will be flush with the lower edge of the sides; thus the body will lose a little more than an inch in depth. It will also lack the finish furnished by the bead before mentioned; this might, however, be regarded by some as an improvement.

In "fixing up" the body in the first instance great care will be called for in order to pitch the sides at the proper angle with the floor, and also that the boards of the latter may be quite square to the sides.

To ensure success in this matter it will be well to "tack" the several portions together by means of temporary stays, or light battens across the top and bottom, or by having the body stay, Fig. 14, first made; this is of best quality, half-round iron, $1\frac{1}{4}$ in. wide, $\frac{1}{2}$ in. thick, and of the shape indicated at Figs. 14 and 4, the former showing the dimensions and angles, the latter indicating the position; this stay is secured to the body by three bolts through each side, and by five bolts through the floor, two of which serve also to secure the hind step, and two the block and back spring. See Fig. 1.

The first, third, and last board in the floor, counting from the front, should be of sound ash, the sheckle stays, etc., being bolted through those portions; the other boards should be of well-seasoned red deal; and all, with one exception, being 1 in. thick, finished work; the exception referred to is in the case of the board at the extreme back, to which the hind step, stay, spring, etc., are secured; this should be of ash $1\frac{1}{4}$ in. thick finished work.

Now, an important part of our labour is before us. Great attention must be paid to painting, jointing, etc., as so much depends upon following them, especially at this point in our work.

The next items are the pieces which give additional width to the "seatage" of the trap, and to which the supplementary sides across the 3-in. pieces, and down the sides about 6 in.; these are to be fixed with stout inch screws (see sketch and Fig. 18).

The supplementary sides, Fig. 12, are of $\frac{3}{4}$-in. walnut, etc., slightly tapered toward the curved and upper portion, and are made to assume the slight outward bend by means of four stays (Fig. 13) which are of half-round iron, 1 in. wide, $\frac{3}{8}$ in. thick, and tapered in width and thickness towards the upper ends; these are secured to the horizontal 3-in. piece at points about 9 in. from back and front by two small bolts, and to the supplementary sides by four stout inch screws through each stay—heads countersunk—which, upon being screwed home, will cause the wood to assume the required outward bend.

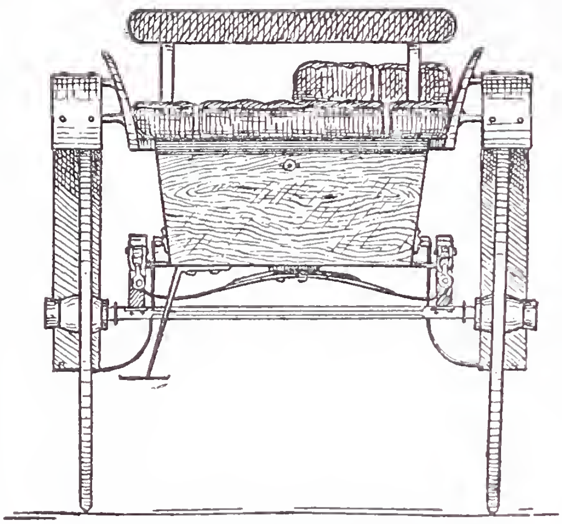

Fig. 1.—Back Elevation of "Battlesden" Cart.

The supplementary sides are also secured to the 3-in. pieces along their lower edges by $1\frac{1}{2}$-in. screws about 6 in. apart; the edges to be flush with the under surface of the floor, and bevelled to suit the angle; the upper edge should coincide with the upper edge of the 3-in. pieces.

The spring hooks used in fastening this board are to be attached to the inside of body at points about 2 in. from the top of the sides. "How," the reader may ask, "is this to be done?" This falling board is attached to the body by a pair of strong "butt" hinges, and when open is secured in position by chains, which may be covered with leather. It is fastened by spring hooks, which are attached to the body on the inside of the sides, and which pass through square mortise holes in the falling board; but there are various methods employed, among which we leave the reader to choose.

Having completed the body we next turn our attention to the shafts, which may be of lancewood, hickory, American elm, or ash. They are obtained from the timber merchant ready bent, and are usually 12 ft. long; and as in this instance there is no plate or other strengthening resorted to, they should be selected free from knots or shakes of any kind.

For this cart the extreme length of the shafts is 11 ft., 6 ft. from the point to the cross-bar or "transom," and from the point to the end socket 5 ft.

The transom consists of a piece of sound ash about 2 in. square, which extends from shaft to shaft, and is a most important item, as it supports the whole vehicle in front, serves to connect the shafts, and to it also the steps are attached. Figs. 10, 15, and 22 explain the method by which the transom, shafts, and steps are secured, and also the arrangement by which the body is hung. Fig. 22 represents the step. Fig. 15 the under plate, with bolt and nut arrangement at one end, and sheckle socket underneath.

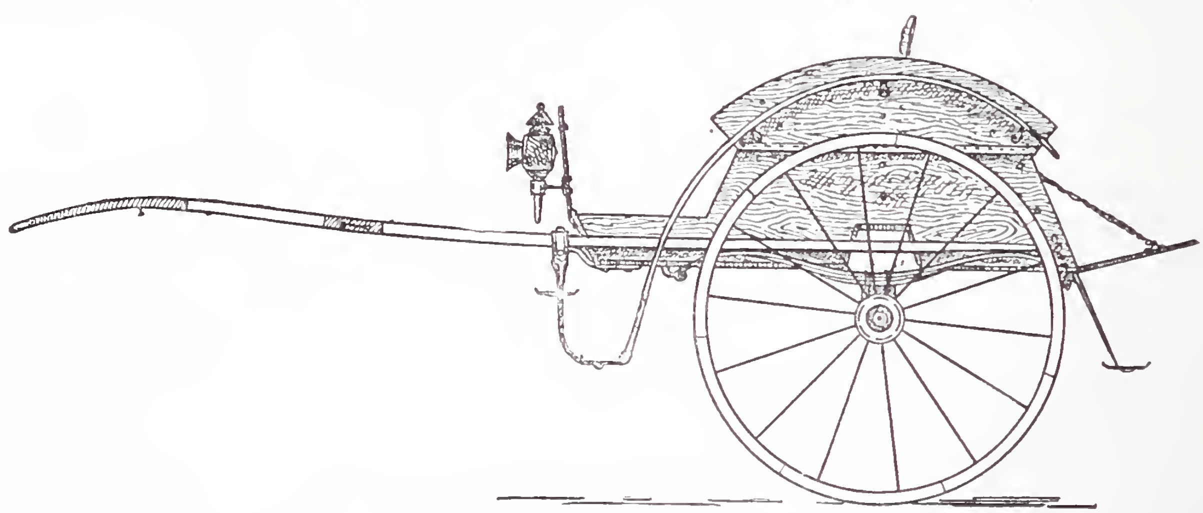

Fig. 2.—The "Battlesden" Cart: Side Elevation.

(Fig. 12) are fixed. These are of ash; the dimensions are indicated at Fig. 17, and the shape, position, and method of securing are represented in detail at Fig. 23. They are secured to the body by strong $2\frac{1}{2}$-in. screws, well countersunk in the sides, and placed about 6 in. apart.

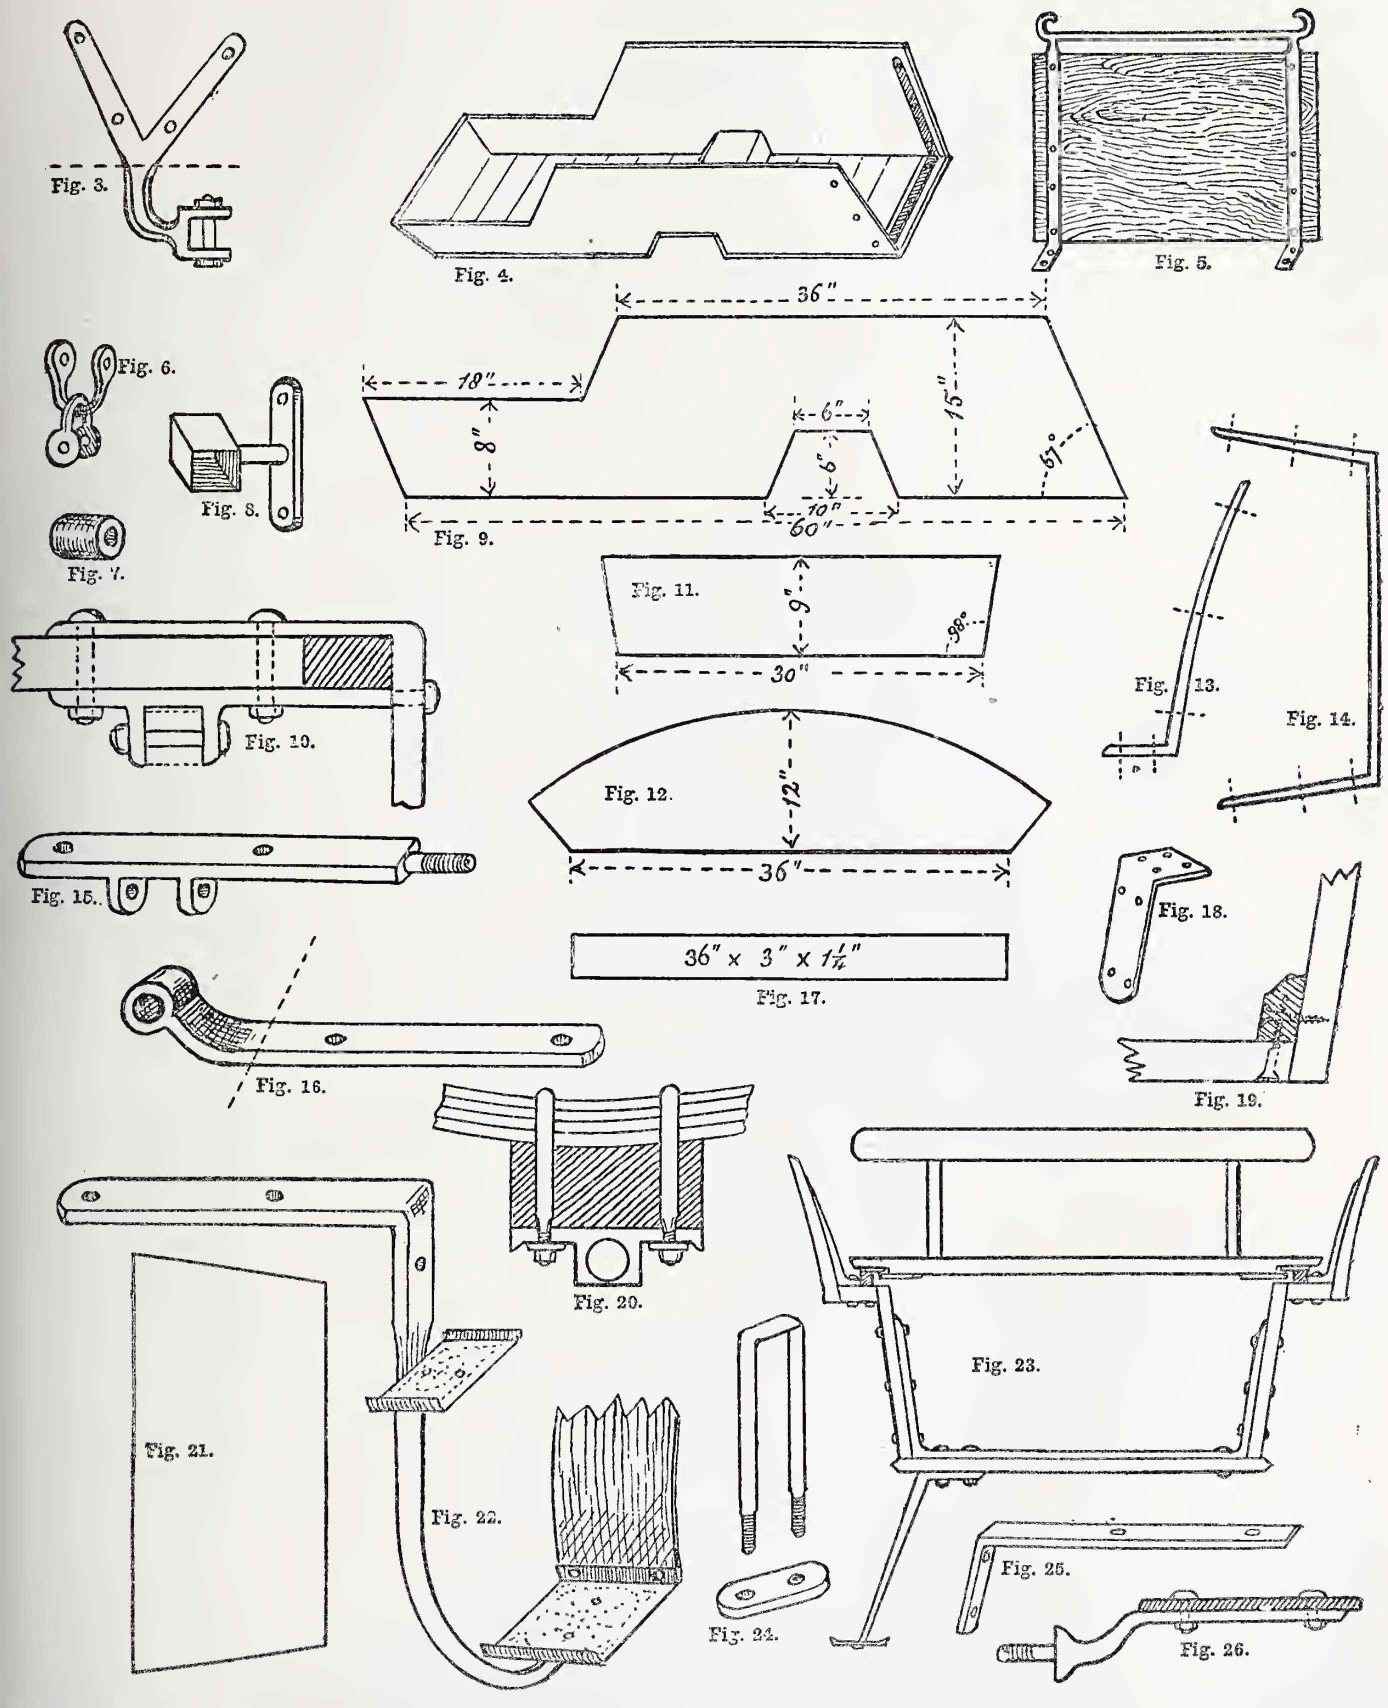
To further strengthen the attachment of these pieces to the body, it will be necessary to place small angle plates of iron, 3 in. wide by $\frac{1}{8}$ in. thick, at points about 6 in. from each end, and which shall extend heads countersunk, to be covered eventually by a brass bead, etc.

The falling footboard (Fig. 21) at back should be cut sufficiently large to allow of a projection of about $\frac{1}{2}$ in. at each side, which is to be treated in the same way as the ends of the floor and front board, so as to continue the bead; or if the alternative method suggested at Fig. 19 be adopted, then the side edges of the backboard may be merely rounded, or left square, and projecting beyond the sides about $\frac{1}{2}$ in. or $\frac{1}{4}$ in., the lower

Fig. 16 is the front sheckle, which is secured to the floor of the cart by two bolts, the "eye" being sufficiently large to allow of a rubber tube washer (Fig. 7) being inserted round the bolt which secures it in the socket.

Fig. 10 being a side elevation with section of shaft (diagonal shading), will explain, better than words, the details of this most important part of our work.

The shafts are fixed to the body at the back by means of square sockets (Fig. 8),



Details of Battlesden Cart. Fig. 3.—Front Spring Sheckle (2). Fig. 4.—Perspective View of Body. Fig. 5.—Dashboard and Mounting. Fig. 6.—Spring Couples (2). Fig. 7.—Rubber Sheckle Tube (2). Fig. 22.—Front Step (2). Fig. 23.—Back View, showing Details. Fig. 24.—Clamp, etc. (2). Fig. 25.—Wing Bracket (2). Fig. 26.—Alternative ditto. Figs. 1, 2, 4, ½ in. Scale. Figs. 5, 9, 11, 12, 14, 17, 21, and 23, ¾ in. Scale. Figs. 3, 8, 10, 13, 15, 16, 22, 24, and 25, 2 in. Scale. Other Diagrams not to Scale.

having a shank about 2 in. long with T-shaped end provided with two holes, by which it is bolted to the body, at a point about 6 in. from the bottom or floor of the cart.

These sockets should be of best Swedish iron, and must be carefully made, the shanks being at least ⅝ in. thick. The shafts are tapered, and the corners rounded from the transom to the sockets—*i.e.*, reduced from, say, $2\frac{1}{4}$ in. by $1\frac{1}{2}$ in. at the transom, to $1\frac{3}{4}$ in. by $1\frac{1}{4}$ in. at the socket; they should also pass through the sockets and project behind them about $1\frac{1}{2}$ in., the ends being simply rounded, or otherwise finished, according to the fancy of the builder.

From the foregoing directions, it will be seen that the shafts are placed about 2 in. from the body of the cart, and are secured only at two points, viz.: by the sockets and transom, between which points they are parallel; the length of the transom will, therefore, depend upon the distance between the shafts.

That portion of the transom lying between the ironwork which is attached to it at each end should be chamfered, or it may be turned in a lathe, but in the latter case care must be taken not to reduce its thickness to less than 2 in. diameter. The front portions of the shafts from the transom forwards should be "dressed" and tapered at the points, fitted with brass, or japanned metal "tips," and covered with rather thin harness leather for the length of about 22 inches from the points; they are also fitted with "tug" stops, loops for kicking straps, etc., and trace hooks, but I leave these minor details to the worker.

The springs are three in number, the side springs being secured to the body in front by the sheckle (Fig. 3), the V-shaped ends being made to take four stout ⅜-in. by 2-in. bolts, by which the sheckle is secured to the floor.

The side springs are attached at the back to the hind springs by loops or couples (Fig. 6), and the hind spring is fixed to the centre of the piece of ash, described above, at the extreme back of the floor. Between this and the spring, a thin block of hard wood of the width of the spring, and 7 in. long, intervenes, and the whole is firmly secured by two strong bolts about 4 in. apart.

The springs and sheckles may be had of any large ironmonger or dealer in coach-building materials, and are made in different degrees of strength; the width of the plates in the present instance should be $1\frac{1}{2}$ in., length of side spring 4 ft., hind spring about 3 ft., and four leaves in each spring.

Between the springs and axle, blocks of hard wood, 6 in. long, $1\frac{1}{2}$ in. wide, and about 5 in. deep, are placed. These are shaped on the top to suit the curve of the spring, and rest upon the flap of the axle, which should be solid, *i.e.*, forming a part of it; the spring, block, and axle flap are secured by iron clamps (Fig. 24), and details of fixing are shown at Fig. 20.

The best axle is that known as Collinge's patent, which, with boxes, costs about £1 10s. Axles are sold in two pieces, and when the required length is obtained, the axle is "closed" by being welded in the middle. This is a most important matter, and should be done by an experienced hand. The best way is to get the job done at the wheel works where the wheels are procured.

The wheels required for this cart are 4 ft. in diameter, and should be of a light make. When ordering, instructions should be given to have the wheels delivered perfectly clean without paint, and free from any flaws whatever, as although slight imperfections would be of little or no consequence were the work to be painted, in the case of varnished work like the present, they would be very unsightly and cause much trouble.

The sketches, Figs. 1 and 2, will explain to the reader the shape, position, and method of fixing the wings; they are usually of beech 6 in. by ½ in., and are sold ready bent. Fig. 25 shows one form of bracket with section of wing, and Fig. 26 is an alternative and simpler bracket. The front end of the wing is secured to the flange upon the front step as indicated at Fig. 22. When attaching these, allowance must, of course, be made for up and down movement of the vehicle upon the springs, and this will depend upon the strength of the latter. The upper edges of the wings should be bevelled or chamfered on both sides and back end, and the curve should be as nearly semicircular as possible.

The dashboard, Fig. 5, should be of American walnut, or of timber the same as the sides, etc., and is 2 feet long by 18 in. deep.

The mountings, by which it is attached to the front board, Fig. 2, are represented at Fig. 5, and are of half-round inch iron, joined at the top by a round rod; but this is not absolutely necessary, and the upright irons may be rounded off within an inch of the top of the board.

If lamps are required, the sockets, usually sold with them, are welded to a T-shaped bracket, provided with two bolt holes, and shanks to be sufficiently long and curved outwards, to allow the lamp to clear the side of the dashboard, to which they are attached on each side.

The inside of the body and bottom should, on its completion, receive two coats of priming colour; the outside should be kept as clean as possible, and any marks carefully removed with fine sand-paper.

If the body is of walnut, it may be varnished as soon as made, but if of elm, it will be greatly improved by being stained a rich walnut colour; vandyke brown ground in water, with a little washing soda added, makes a good stain; it should be applied warm, with a medium-sized brush, and when dry, the work should have a coat of best carriage varnish; a very little gold size is allowable, but only a very little. All varnishing operations should be carried out in a room which is as free from dust as possible.

The wheels are not stained, but when thoroughly cleaned with fine sand-paper are varnished in, at least, three or four coats. When the first coat is dry, rub down with fine pumice and water, until the surface is perfectly smooth; wash off all trace of pumice, and when the water has dried, give the next coat; when dry, again rub down, and repeat for each coat, until the final one, which should be laid on very evenly, and allowed to dry in a place free from dust, flies, etc. When this first coat is dry, wash well in cold water, and wipe with a chamois leather, as this will help to harden the surface.

The best method of varnishing wheels is to fix a strong bar of round iron in a heavy block or beam, about 3 feet from the ground, and at a slight upward angle. The bar being passed through the box, the wheel may be made to revolve during the process of varnishing, which will be found most satisfactory.

The above remarks as to varnishing apply to all portions of the vehicle, except the ironwork. This should have first two coats of priming colour, and when rubbed down with very fine glass-cloth, should receive an even coat of "quick" black. This consists of ivory, or vegetable black, ground and mixed in turpentine, to which is added a small quantity of black japan to give "body" to the mixture, which will dry quite "flat" and harden very rapidly.

When dry, give an even coat of black japan. At this stage the parts of the vehicle may be put together, and all nuts and bolts screwed up, and touched up with black japan, when the whole of the ironwork should have, at least, two coats of carriage varnish.

The inside of the body should have two coats of some warm brown, or drab colour. The movable seats are japanned and varnished, and the cart is ready for the "trimmer."

The backrest upon the front seat may be upholstered in American leather, or any other suitable material, but much padding is not advisable; in fact, two or three plies of thick baize, or part of an old rug or blanket, placed flat, and covered with the cloth, etc., will be found more comfortable than a cushioned back; besides, it takes up less room, which is a decided advantage in vehicles of this kind when both front and back seats are occupied.

The cushions are three in number, two 18 in. by 16 in. for the front, and one 36 in. by, say, 14 in. for the back seat.

If a higher seat is required for the driver, the right-hand cushion may be made much thicker than the other, and also about twice as thick at the back as in front. Or the front seat may be fitted with a light driving box about 4 in. deep in front and 6 in. at the back; the four sides to be covered with the same material as the cushions. This box is fitted to the seat with four loose dowels or "spuds" which allow of its being removed when required.

Each front cushion is secured in position by one, and the hind cushion by two leather straps (Fig. 1).

Two holes should be bored with a half-inch centrebit through the floor near each corner in front, to allow the water to escape when the cart is being washed.

Do not cover the floor with oilcloth, which holds the water and causes the wood to rot, but use a perforated rubber, or fibre mat.

The inside of the falling footboard at back may be covered with linoleum or oilcloth, cut to fit the opening at the back of the cart, and well tacked down and fastened with the shellac cement used for laying linoleum, etc., on floors.

I now bring this paper to a close, hoping that it may prove useful to any reader who, not knowing how, may wish to attempt the construction of a "Battlesden" cart.

MEANS, MODES, AND METHODS.

In commencing this department of Work, the Editor takes the opportunity to point out that it cannot fail to prove of considerable value to the readers, and to ask them to forward to him *pro bono publico* any "means, modes, and methods" of doing things that have been tried by themselves and found to be reliable and of advantage to the user. Every recipe given will bear the initials of the sender's name, and this ought to form a guarantee for its goodness and reliability.

Waterproof Cement for Glass.

Well mix together, litharge 3 parts; white lead, 3 parts; plaster of Paris, 3 parts; powdered resin, 1 part; each by measure. When about to use the cement, make this mixture into a paste with boiled linseed oil. The consistency of the paste will depend upon the quantity of oil used in making it up. It will set hard in the course of three days, and is an excellent cement for glass aquariums, and for cementing glass to wood where this is liable to be exposed to damp. —G. E. B.

How to Ebonise Door Knobs.

The best woods for ebonising are those white woods which do not show a definite grain marking—such as alder, willow, sycamore, and holly. The bobbins, or knobs, must be first turned smooth, or else glass-papered to the requisite smoothness, as they cannot be glass-papered after they are ebonised. The process requires the use of three separate liquids:—(1) Procure $\frac{1}{4}$ lb. logwood chips and boil them in $\frac{1}{2}$ gallon of water. Soak the bobbins, or knobs, in this hot liquid for half an hour, then dry. (2) Dissolve 1 oz. of green copperas and 1 oz. of bluestone in 3 pints of hot water, and add a teaspoonful of wood vinegar. Soak the dried knobs in this liquid for a quarter of an hour, then rinse in clean water. (3) Dissolve 2 oz. of common soda or potash in 3 pints of warm water. Immerse the knobs in this liquid for a few minutes, then dry. The first liquid will stain the wood a brownish-yellow tint. The second liquid will change the tint to a blue-black. The third will fix the tint as a dead black. Nutgalls do not improve the first liquid if the logwood is good and the liquid freshly made. Run the knobs or bobbins in a lathe when quite dry, fill in with white wax, and polish with a piece of linen canvas, or duck. They may be varnished, if so desired.—G. E. B.

Writing on Zinc Labels.

Zinc labels are used by gardeners and foresters to label their plants and trees. The names of the plants may be written on the labels with any ordinary black ink, but this is liable to be injured by the weather. A more permanent ink for this purpose is made by dissolving platinum bichloride in rain water, and adding to this a few drops of muriatic acid. The ink may also be made direct from platinum foil. Procure a wineglassful of muriatic acid and half a wineglassful of nitric acid, and mix them in a porcelain dish or saucer. Place this on the hob of the stove in a chimney corner, with a good draught to carry off the noxious fumes. Place in the warm acid mixture from five to six grains of platinum foil or fine platinum wire. The platinum will dissolve in the warm acid, and when this is completed, keep up the heat until all the free acid has evaporated, leaving a thick liquid similar in colour to treacle. This, when cool, will crystallise to a red mass. Dissolve this in a wineglassful of rain water, when it will form the amber-coloured writing fluid. Clean the labels bright, and write on them with a quill or gold pen. The writing will become a deep black as it dries, and then cannot be easily washed off. A cheap substitute may be found in a strong solution of copper sulphate, but the writing from this is not so black or so permanent as that from platinum.—G. E. B.

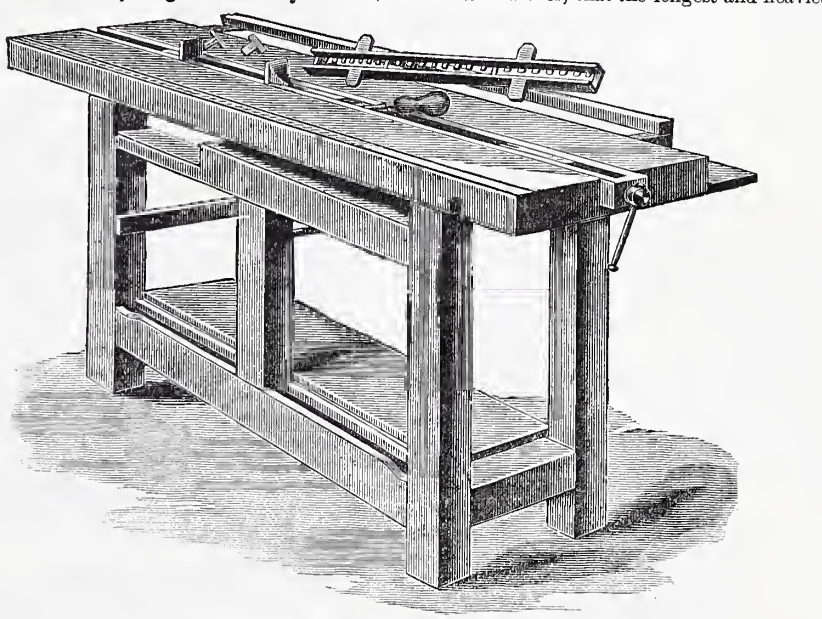
OUR GUIDE TO GOOD THINGS.

68.—Lister's Patent Screw Holdfast and Cramp Combined.

The accompanying illustration affords a representation of a New Patent Screw Holdfast and Cramp combined, invented and manufactured by Mr. F. Lister, 40, Beckett Street, Leeds, which is used in connection with, and forms an adjunct to, the ordinary carpenter's bench. I have not seen the actual appliance at work, and therefore I cannot speak of the invention from actual experience; but from a small wood model before me, which shows fairly well its construction and action, I am inclined to think that it will be found a most useful and serviceable means of carrying out the purposes which it is intended to serve.

The general relation of the Patent Screw Holdfast to the carpenter's bench, and the manner in which it is fitted to it, will be seen from the illustration given herewith. It is composed of various parts, fixed and movable, the fixed portion being a hollow casting of malleable iron, which traverses the whole length of the bench from end to end, and can be made of any length to suit any size or kind of bench that is used by joiners and cabinet makers. The casing is hollow, being formed of a bottom and two sides, each side being rebated, so as to leave a projecting flange along the top of each side on its inner surface, within which the parts about to be described can work backwards and forwards as desired. The upper end, or end most distant from the operator, is open in the model to admit of the entrance of the fittings. The lower end is closed and pierced to receive a screw, which is worked to tighten or release the grip of the jaws of the appliance when brought into play. The bottom is pierced with two rows of square recesses or holes, so placed as not to be precisely opposite each other, but in alternation, so that each hole is partly opposite the hole in the other row, and partly against the solid material which intervenes in each row between each pair of holes. This casing, it may be said, is placed in and along the centre of the top of the bench in such a manner that the top of the casing may be flush with the surface of the bench. Within the casing, work up and down two carriages furnished with jaws, to grip anything that may be placed between them. The top of each carriage is flush with the top of the casing itself and the surface of the bench; but the jaws project above casing, carriage, and bench for obvious reasons. The carriages are both movable along the casing, and that which is placed at the top of the bench is furnished with a catch which can be depressed or raised at pleasure, and is used in order to secure the carriage and the jaw it carries in any part of the casing by pressing the catch into the recess or hole nearest to that part of the recess at which it is desired to fix it. The action of the catch, it may be said, is such as to hold the jaw immovable. The second carriage intervening between the bottom of the bench, or end nearest the operator, and the carriage at the upper or more distant end, is in itself longer than the carriage at the top end, and is capable of being lengthened still further, the extension being regulated by means of a suitable screw. This carriage is also provided with a catch that is raised and depressed in the same way as the catch attached to the carriage at the top. "It can also be provided with as many stops as may be desired, according to the work required." I am now quoting from the maker's description. "These stops are placed into grooves, and they can be made to slide and stop at will, when they lock the moment you cease to slide."

The invention is certainly remarkable for its great simplicity, and the ease with which it can be worked. It is claimed for it that it completely supersedes the German bench screw, and provides a substitute for this which is in every way superior to it. Further, that the longest and heaviest pieces of work can be cramped and held in it with as much readiness as the smallest pieces, and that you can work and bevel short or long lengths of wood with the greatest ease when held in the cramp. The quickness and facility with which the cramp is applied, tend, moreover, to lessen the time and labour generally employed in cramping up; thus rendering it of value and importance to all who work by piecework or contract. For this reason employers will find it a most useful adjunct to the benches in their workshops, and amateurs who are without such an appliance will find it to their advantage to adopt it. It should be said that there is a centre jaw which can be introduced between the top and bottom jaws as may be required when dealing with short lengths of wood, or taken out and put at the lower end of the bench when cramping large work. Every particle of the Patent Screw Holdfast and Cramp is of malleable iron, except the screws, which are, of course, made of steel, and have square turned threads.



Lister's Patent Screw and Cramp.

The price of this useful article complete, with three sets of jaws adapted for different kinds of work, is 35s., carriage paid. To save inquiries, I had better add that, at present, it is to be had of the inventor and maker only. Every one, without dispute, knows his own business best, but it seems a pity that he keeps the sale of this bench appliance in his own hands, and does not, as far as I can see, push its sale among dealers in tools. The Editor.

A CORNER FOR THOSE WHO WANT TO TALK IT.

**** All Communications will be acknowledged, but Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

Log and Deal Frames, and their Advantages.—A. R. (*Scorrier*) writes:—"As I have written a little on the working of circular saws, perhaps a few remarks on frame saws will be acceptable by those who have little or no experience in the working of them. The frame saw has been in use a great number of years, and no doubt many men understood the working of it even before the circular saw was introduced. Yet though there is not near the practice or skill required to work the frame saw satisfactorily, many are ignorant as to the proper working of it. Some are of opinion that the timber should be fed to the saw when it is making the down stroke, which is a mistake; others think that the saws should be perfectly upright, which is a much greater mistake. All timber, whether it be a log or deal fed in log or deal frame, should be fed just after the saw or saws commence to make the up stroke, so that the timber may be stationary, to take the thrust of saws when making their down stroke. Again, should the saws be perfectly upright in making the up stroke, they will bring up the sawdust and choke the saws, consequently they become heated, and will run out of truth. All frame saws should have a lead—that is to say, the top of saw should overhang the bottom; the amount of lead should be governed by the length of saw. A good lead for saws in cutting soft wood is about $\frac{1}{16}$ in. to the foot in length of saw; a much less lead will do for hard wood; this lead will allow the dust to fall freely instead of being brought back into the cut. Again, the keying of the saws is of importance. Some men when they have a hammer in their hand, and commence to hammer, are like children, they don't know when to stop, and keep rapping away until they do some mischief. When a frame saw is strained enough it will give a sharp sound, when the hammering should at once cease. Many are not content with this sound, and keep rapping away until the saw, if soft, gives away in the rivet holes, and if it is hard or rash it breaks. Again, the saws should not be overfed; the feed should vary with the depth of timber and the number of saws at work; the deeper the timber and more the number of saws, the slower should be the feed. There are many advantages that the circular saw has over the frame saw, yet the frame has its advantages. We will suppose we have a large round and crooked log of timber to be sawn into 1 in., 2 in., and 3 in. planks; if sawn with circular saw on the rack bench, the diameter of saw has to be great and the plate thick, consequently a lot of power is required to drive it, and after every cut the log has to be brought back and moved, and so set as to cut the plank its proper thickness; and at the same time perhaps the log is far from being steady, which is very annoying. But it is not so when sawn in the log frame; the log is so clamped that it cannot move, and should there be six, eight, or more cuts to be made, the number of saws can be put into the frame and the log sawn to the number of planks required by passing through the machine once. The same with the deal frame: the number of cuts required is made at one and the same time, and if deals are very deep can be sawn with less power than could be done with circular saw, therefore you will see that where one saw could be worked to an advantage the other would be to a disadvantage. I hope these remarks, though brief, may benefit some of our readers; and I hope in a future issue to write a little on band saws, of which I have had some little experience."

About WORK.—R. B. R. writes:—"After taking WORK from the first, and reading it carefully, I am shocked to see what subjects you are taking up. It would just be fair on your part to give a lease of half the space that you take up with wood and devote to iron and steel. What I say is for the welfare of WORK, as I hear lots grumbling about the space you are taking up with burglars' alarms, papier-mâché, and "Monarch" Play Chair, etc. It looks very like as if it was an advertisement paper. I hope you will see the errors that I point out, and get a paper on something that is useful to practical men."—[I am sorry you are so easily shocked. It takes something of an entirely different character to shock me, and even then the shock is never very severe, as I have given up being surprised even at the letters I get from men like yourself. Perhaps you will be almost annihilated to hear that some men in a large upholstery establishment were wishing the other day for more cabinet making. "Every man for his trade, you know;" and "What is one man's meat is another man's poison." Scores and hundreds of practical men pat me on the back, and the patting amply makes up for the scratching. I cannot please everybody, unfortunately, so I rest content with pleasing the majority and—myself.—ED.]

The Scratch or Bead Router.—C. E. F. (*Boro', S.E.*) writes:—"Every man who tinkers at a bit of amateur work now and then will be glad of your present publication, WORK, and if he does not see anything in any particular number which may bear on the particular hobby of the time, still his general knowledge of mechanics must surely be considerably increased, and widened by a carefully conducted course of reading in your new technical journal; but quite apart from his wider ideas of general construction, I feel sure that we shall all, sooner or later, find the exact thing that we want, and have, or fancy we have, been looking for for some time, as the following will show. Some years ago I bought a large and handsome bookcase, from which, however, the sides of the cornice had been cut away to enable it to be placed in a recess. I tried in vain to match the moulding, but except at what I considered a very outrageous price could not get any one to undertake the job, so gave it up in despair. However, about three weeks ago I was sitting at tea, when I spied a short article about 'Scratch Moulding Tools' in your Magazine, and immediately jumped up crying 'I've got it.' The result was that I got a piece of 19 gauge sheet steel, and with three cutters which I made with files, and mounted, as your correspondent suggested, I succeeded in about six hours (three evenings) in producing 8 ft. of moulding, of which I enclose you a section as an example. I may say that the section is just as the cutters or scratchers have left it, and has not been touched up in any way. You can imagine my delight in selling my bookcase, finished at so small a cost. You are quite at liberty to publish this if you think fit."—[I publish your letter with pleasure, and heartily congratulate you on your success with the scratch. The bit of cornice sent shows that you have done a very creditable piece of work. The writer of the article was with me when your letter reached me, and was much pleased when he read it to think that he had rendered one reader at least good service. I trust you will find much in WORK from time to time that will be useful to you, and that your letter will enlighten some of those who appear to think that WORK is purposeless and hopeless, because it is not exactly in accord with their own peculiar notions on the general fitness of things.—ED.]

Home-made Planes.—BERT writes:—"Having been interested in the article on home-made planes and E. P. W.'s remarks, I think that he is quite right in his idea in having a piece over the mouth of the pattern. I have made two or three dozen of them myself. I am an iron moulder, and I find that to cast them with the mouth left open not only causes them to get hard but causes them to warp, being weak in the middle. And another thing I notice, the writer is very scanty with the taper, as most pattern makers are. He says the merest trifle will do. Now, I say it is not enough; if he wants a clean casting he should give a little more taper, then a moulder has a better chance to get his pattern out without shaking any of what we call the cod down—that is, the inside of the pattern—and if that is left intact he can depend on a good clean casting. I have taken WORK since the beginning, and I am very pleased with it. I see you mean to go in for all trades, but I have been wondering if you will go in for ours. I have taken in two or three journals, but none reached as far as that. If you could give a little about the working of a cupola, it would be very welcome to not only me, but some friends in the trade who take in WORK every week. I may add here that I succeeded in making a table of Mr. Adamson's design in No. 1 of WORK. I hope that my suggestions will not be considered offensive."

A Wood Worker's Eulogy.—C. N. (*Sherburn-in-Elmet*) writes:—"I will briefly introduce myself to you as a practical wood carver and fret cutter, it being seventeen years since I commenced to learn that art. I am a regular subscriber to WORK, and intend taking it weekly until some unlooked-for cause should deprive me of the necessary copper for its purchase. I have read all the articles on wood working, and I conclude they are a credit to the writers, and will considerably help great numbers of wood workers, both practical and amateur. WORK has not come out a day too soon. There has been great need of a paper of this kind. The papers I have taken before on wood working, etc., have not been as clear as they should have been; their articles have been too short, and as a result of this many men have been unable to understand them, more so the amateurs. Better far have one long and continued article, and that article understood and useful, rather than a lot of short useless articles, which are really a puzzle to the amateurs. How different are the articles in WORK. When I read them I can almost imagine the practical hand is executing the work before my eyes, they are so clear. No wonder, Mr. Editor, so many thank you for and wish WORK success. I have been going to write to you several times, but have held back, so that others might air their views. But after reading the article by F. Miller on wood carving in No. 13, I can refrain no longer. The designs are very good, and I take this opportunity of thanking F. M. for the pains he has taken to instruct in the art of designing. I shall benefit by the instructions, and I shall eagerly look for more. I am a poor designer, owing to my parents being unable to afford sending me to a school of art, and I thus missed tuition in drawing, which I now feel the need of. In the course of time I hope F. M. will contribute some designs for antique carving, such as panels, pilasters, and mouldings. I am afraid I have encroached too far on your space. Therefore I will conclude by saying I recommend WORK to all wood workers I come in contact with, and I wish WORK unbounded success, and may health, happiness, and God's blessing rest on all its staff."

Utility of WORK.—D. C. (*Marsden*) writes:—"Allow me to add my testimony to the value and worth of WORK. I anticipate for it a very useful career in future, and am expecting to cull from its pages much useful information and pleasure; it is just such a paper as I have been looking for a long time. I cannot tell you how delighted I was when I came across WORK accidentally at a newspaper stall when I was hunting for some such books or papers as would give me the information I was then seeking. I am very pleased to find that WORK is likely to supply all needed information. I am anxiously looking forward to the promised articles dealing with camera making, joinery, and cabinet making for beginners. I hope these last-named articles will deal with and show how to make good strong kitchen chairs, square tables with leaves or without, bookcase, and other useful articles of household furniture for a working man's home. I can assure you that I have been very much encouraged to write to you because of your cheerful and encouraging replies to your various correspondents, and especially for your very feeling reply to H. D.'s (*Bury, Lanc.*) queries, because my own circumstances are very much akin to his. My means are limited; I want to use them to the best advantage to myself in purchasing tools, etc., hoping to receive the same consideration at your hands as other correspondents. I wish every prosperity to WORK."—[A very good bookcase has been given, and others will follow. Everything mentioned in your letter will be touched on as speedily as possible, and good strong furniture of a plain character will not be neglected. Any special information that you require will be supplied whenever you may ask for it; but I do not notice anything in the above letter that requires more than a general answer.—ED.]

About WORK.—W. H. H. (*Bradford*) writes:—"I write to support the views held by T. J. H. (*Trowbridge*) and J. P. A., and expressed in your issue of June 8. (1) I quite agree with all T. J. H. has written, especially about the cover. I cannot imagine why you refuse to put WORK in a cover, unless it is that you think that if we got a cover we should want it made into an insurance policy. (2) I thought when WORK was first published it would form a good companion to the 'New Popular Educator.' I do not think so now; I do not consider it worth a more valuable binding (in its present form) than I could make myself from reading 'Binding made Easy.' One page out of every eight being advertisements, the other seven so amateurish, one has scarcely patience to read them. (3) I am a painter. The sign writing articles are very good, and well written, but far too elementary. I ask you, do you think there is any one who would buy WORK and be interested in its pages but what has got past the elementary stage? (4) I do hope, with a new volume, you will alter WORK considerably, taking for your model the 'Popular Educator,' and inserting in it good articles that would be of some use to others than amateurs. 'Or (to quote J. P. A.) before long you will not be able to number a practical man in your subscribers.' (5) I think you printed Fig. 27, border in dead gold for papier-mâché work, upside down. If so, perhaps you will correct the mistake.—[(1) Unfortunately you altogether mistake the functions of an editor, who is responsible only for the matter supplied in a magazine, and not for the form in which it appears. Curious as it may seem to you, I have really no more to do with putting or not putting WORK in a wrapper than you have. (2) Of course you must please yourself about the binding, and if you please yourself you will please me. WORK and the "New Popular Educator" are not modelled on the same lines, and there never was, and never will be, any thought or intention of doing so. They are as different in their constitution, aim, scope, and purpose as chalk is to cheese. Again, if fourteen pages were advertisements, and two text and illustrations, the arrangement would be altogether beyond my control, but with the fourteen pages of text and cuts you get value, and very good value too, for your penny. As to the "amateurish" tone, kindly remember that WORK is not a trade organ, but is intended for "all workmen, professional and amateur." (3) Yes; you are a painter, and find Mr. Benwell's papers on sign writing "very good and well written, but far too elementary." The great mistake made by many who know their own trade thoroughly is that because they themselves do not require elementary instruction nobody else does. As a painter you often have to climb a ladder, but I do not think you would be satisfied with a ladder that had a few rungs at the top only, the rest being all left out. We must all begin at the bottom, and even you would begin to recognise the value of the elementary rounds in such a case as that which I have just mentioned. As to the question you put to me with regard to the readers of WORK, let me tell you that I *know* that the magazine is largely bought by lads and young men just beginning practical life in the workshop. More than this, I have been told by a workman who takes an active part in Sunday teaching that sixteen lads in one school, with which he is concerned, and nearly as many in another, are buyers and readers of WORK. (4) I am afraid your hope will not be realised as far as considerable alteration, such as you contemplate, is concerned. When the second volume is reached I confidently expect that there will be even more practical men among its readers than there are now. (5) You are perfectly right in supposing that Fig. 27, in page 185, is presented upside down, and in accordance with your request I "correct the mistake," which will sometimes happen in dealing with cuts of this kind.—ED.]

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Jewellery Colouring, Soldering, etc.—YOUNG AMATEUR (*Douglas*).—YOUNG AMATEUR cannot colour his brooch as it is, for the process of (wet) colouring is not used in a general way for any quality less than 15 ct. gold, whereas he has soldered a 9 ct. catch on to a fine gold brooch with silver solder. Colouring is a process in which the surface of the article coloured has its alloy (silver and gold) taken out and the fine gold left. Consequently as silver solder is just the very material that colour acts on, the whole will be eaten away, and the 9 ct. catch will drop off, even if it be not destroyed as well, as it is very likely to be. Perhaps, to save further bother, in this case the brooch had better be electro-gilt. But as it is possible that others may have got into a similar muddle, I will give the method that I should follow, were the brooch put in my hands to do properly. First get rid of all the silver solder—for that we place the brooch in nitric acid; try nitric acid and warm water (1 part each) at first, and add acid until you see it works. This ought to eat all the solder away in an hour or two. But this is only to be done if your brooch is better than 15 ct. gold, and if it has not been soldered together anywhere else with common solder. Yes, I know YOUNG AMATEUR says his brooch is fine gold; but that title is often given to 12 ct. gold in a jeweller's shop window, and it is just possible that AMATEUR, being also young, has taken that as his authority. Most "jewellers' materials" shops now keep gold and silver and solders, so you can either send for some from Gray & Son, Clerkenwell Green, E.C.; Calipé, Poland Street, Oxford Street, W.; or King, St. John's Square, Clerkenwell. Now make your catch of 15 or 18 ct. gold, and solder it on, if a plain, solid article, with solder made thus:—15 ct. gold, 1 pennyweight; fine silver, 3 grains; fine copper, 1 grain. Or thus—Fine gold, 13 grains; fine silver, 6 grains; fine copper, 5 grains. If it be rather a light and thin affair you might try this, which is the commonest I use for coloured work:—22 ct. (that is, the same as sovereigns are made of), 1 dwt.; fine copper, 2 grains; easy silver solder, 10 grains. Melt the first two all together, but if you make the last, melt your gold and copper first, and add the silver solder when they are in a fluid state, and don't forget to use a fair amount of borax (to the last one especially), and also remember that it will not stand being melted more than once, as the zinc in the silver solder will go off (become oxidised, I think, is the chemical term). See that your brooch is scraped clean, and the catch too, where you are going to solder them together. After soldering, etc., polish your catch and brooch, then get it clean and quite free from grease. I prefer to anneal the articles when I can, and let them get cold by themselves, and black. Now tie the brooch on to two or three horsehairs (you can use platina or gold wire if you like, but there is no advantage in so doing), and it is ready to colour. I shall simply give the plainest directions to colour a plain article. First we must have ready some boiling water and a basin. Secondly, some colouring mixture well pounded up and thoroughly mixed, and in quantity sufficient to three quarters fill your pot, which for regular work is specially made of black lead, but for only an occasional job the ordinary crucible is good enough, and much cheaper. The ingredients are—Saltpetre, 2 parts; lump alum (not burnt alum), 1 part; salt, 1 part. The quantity you must judge for yourself by the size of the pot, which should be at least ½ in. wider halfway down than your work is. Add a little water to it—don't cover it all up with water—say, until it looks damp all through, and set it on the fire, heat it slowly, and stir it up occasionally with a piece of wood or iron, until it boils up; then put your work in, and keep it there for several minutes, moving it about all the time, in order to give every part of the colour a chance to do a little work; if it boils dry too soon, add just a little hot water, and put your work in again until it gets of a dark colour; this you can see by dipping it in some of your warm water in the basin. When it is dark enough—and only experience will tell you that—you must weaken your colour by adding hot water to it; then when it boils up again redip the brooch until it becomes of the rather pale yellow colour that fine gold has. The whole process from the time of boiling up the colour should not take longer than from ten to twenty minutes. Rinse it well, and it is ready for finishing, either by the scratch brush or burnisher, or if Etruscan work or a coin it may do as it is. One word more, and that is—single articles rarely colour well; a good bunch of them and a good size colour pot is what is preferred by H. S. G. To clean up jet work, a little powdered rottenstone, whiting free from grit or rouge well rubbed over it, will bring up the polish again. If the work is plain, use the ball of the thumb and whiting, and don't be afraid of rubbing hard and rapidly; if it is shaped you will have to use a brush, lap, dolly, bob, or whatever tool will get at the parts, and subject them to the friction required; then wash with soft brush and soap and water.—H. S. G.

Wood for Violin Making.—F. J. C. (*Brockley*). writes for the information of FIDDLER (*Highbury*):—"Your correspondent will be able to get this in any quantity, and at a moderate price, at J. Thibouville-Lamy, Musical Instrument Makers, 10, Charterhouse Street, E.C."

Indiarubber Stamps.—C. S. P. (*Greenwich*).—The name or inscription, whatever it may be, is first set in ornamental type or plain type, as may be desired, and a cast of the type is taken in plaster. Vulcanised indiarubber in a state of fusion is then run into the cast, and a facsimile of the type in a yielding material is thus obtained. The stamp is afterwards mounted. Of course, various appliances are required for carrying out the process; but to go into these would require a special paper, and you only ask to be told how they are produced.

Frame for Wardian Case.—W. P. (*Southport*).—The frames or astragals for cases made in wood are similar to window astragals for window sashes, a section of which is shown in Fig. 1. Astragals for corner uprights are made as shown in section in Fig. 2. The glass is set in and bedded with putty, the putty bedding being shown in each figure by dotted lines. An example of each kind of astragal, in which the glass can be set without putty, is shown in Fig. 3. The uprights are made without a cut-out cheek for glass, a saw draught equal in width to the thickness of the glass being sufficient to slip the glass into, the same being removable by unscrewing the vase finials shown at the top of the corner astragals in Fig. 4, which is the front elevation of a plain and simple wardian case in wood. These finials are filled with a double screw, one end of which enters the finial itself, and the other the upright astragal. The framing at the top of the glass is held down by the finials.

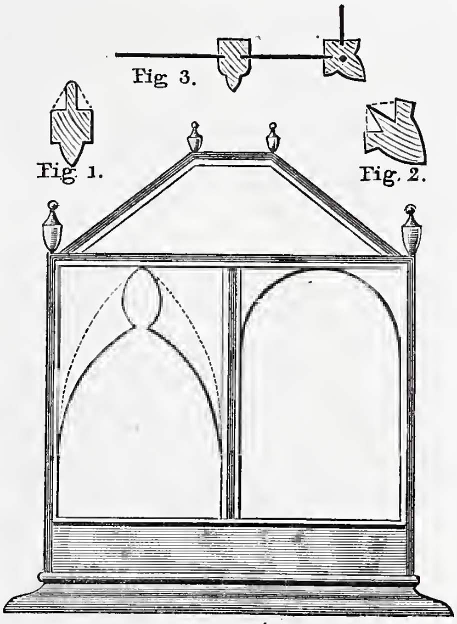

Fig. 4.

Etching Names in Cutlery.—J. W. (*Crooks, Sheffield*).—Your letter has been sent on to J. W. C. (*Walkley*).

Colonial Mouldings.—E. D. H. (*Tranmere*).—For chief importers refer to Kelly's London Directory, or apply to Gus. Rochfort, 29, Basinghall Street, London, E.C.—F. J. C.

Pocket Technical Guide.—P. J. (*Burnham*).—The price of Beaton's book, published by Crosby, Lockwood, & Co., is 1s. 6d.

Protecting Papier-Mâché Joints from Sea Water.—BOFIN (*Galway*).—Before this is read our correspondent will have become aware that his present question is answered with his former one. If the solution of gutta-percha which we recommended will protect the paper from the action of sea water, it will, of course, protect the glued joints also.—S. W.

Small Casts in Plaster.—W. R. (*Mile End*).—Directions for working even "small casts" must, to be of any use, be longer than could well be given in "Shop," especially as W. R. does not mention the kind of objects from which he wishes to cast; but we shall hope, before long, to give him full information on the subject in the other columns of this paper.—M. M.

Combination Lathe and Fret Saw.—J. H. S. (*Braishfield*).—I take it that you want a machine or tool for real work. The Britannia Company's No. 3 is certainly a useful tool in the hands of a practical man, and the price is low; but as you are an amateur in wood working, I would advise you to go a step further, and try the B. C.'s 4 in., and if so, you will find results more satisfactory, which is the great desire of both amateur and professional. This would also apply to your question respecting the fret and circular saw action, as attached to the lathe for steadiness. The amount of vibration given off and the want of power in roughing down a piece of wood in a 3-in. lathe is often a most discouraging start for an amateur, as also disappointment in the result.—G. E.

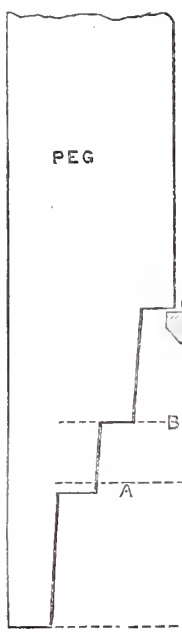
Joints and Cabinet.—R. M. W. (*Burnley*).—Don't apologise for troubling me. Letters such as yours are not regarded in that light. The desire is to make WORK useful, so that practicable suggestions and encouragement are always welcome and cheering. I am glad you, among others, have found the friendly hints to amateur wood workers helpful. Mr. Denning, to whom your thanks have been conveyed, has papers on both the joints you name in preparation, as well as other topics of a similar character, all of which, no doubt, you will find of assistance, and your "sincere hope" is cordially re-echoed. The cabinet, by which, if I am right in thinking, you mean the piece of furniture commonly known among cabinet makers as a nest of drawers, will have attention at an early date. In case you do not understand what a nest of drawers is, I may say it is a kind of square-cornered pedestal fitted with drawers only. These run from side to side, and are usually secured by one lock fitted on a hinged style to the right of them. If this is not the kind of thing let me know, and I will see what can be done to meet your wants. In any case I think I may safely promise that sooner or later a description of whatever the piece of furniture you wish to make will appear in WORK. Why not send me a rough sketch or diagram of the article? No matter how roughly drawn, a sketch often shows more plainly than any description what is really required, and when the subject seems likely to be of general utility, you may be sure that arrangements will be made for a paper on it. I am pleased to hear you are making one of the tables described in No. 1, and I trust it will come up to your expectations. Thanks for your good wishes.—D. B.

Cement for China Mending.—JEUNE ÉCOLIER (*Capel*).—We question whether anything short of rivets will mend china, so as to be safe under the rough handling it will have in constant use. White lead will resist boiling water, and make an exceedingly strong joint if sufficient time is given to it to set thoroughly, which will be a matter of weeks. It needs to be used neatly, as any smudge on the face is not easy of removal when hardened. The advertised cements are numerous; we have not tried the "Coaguline" mentioned. For mending china for ornamental purposes only, we know of nothing better, stronger, neater, more cleanly, or easy of application, than isinglass dissolved in acetic acid. Any one can make it himself, or buy it ready prepared at fancy shops. It is sold under different names as "Diamond Cement," and at the Soho Bazaar, London, as the "Soho Cement." The bottle containing it is placed in a cup of boiling water to liquefy it, the broken edges warmed, and the cement applied to both with a camel-hair pencil. It sets in about twelve hours. China thus mended should, however, be washed in cold or moderately warm water only—not boiling.—M. M.

Banjo Making.—R. Y. (*Canning Town*).—The best and most useful size to make your banjo will be one with an 18-in. finger-board and a 12-in. hoop or drum. By making your instrument to this size, if you wish to tune it to and play with piano, or any other instrument tuned to concert pitch, you will be able to do so. If you make the finger-board or neck any longer, you will not be able to tune it up to such a high pitch, and if you were to try to do so, you would find your strings would not stand the strain, and would break, which would make banjo-playing a rather expensive luxury, if you tried to pull it up to pitch very often. The exact measurements are—the hoop 12 in. diameter, 2¼ in. deep, or you could make it deeper if you chose to, but I should not recommend it to be made any shallower than the size I have given. Length of finger-board from the end that fits against hoop to the nut, 18 in. The nut is the small piece of wood or ivory, etc., that is grooved into the finger-board at the end where the peg head falls back, and in which notches are cut to keep the strings at equal distances apart. The distance from nut to thumb-string peg will be 6¼ in., and 6¾ in. to the small piece of wood or ivory that you will put in to carry the thumb-string. Length of peg head from nut, 5¼ in.; width of finger-board at nut, $1\frac{3}{16}$; at thumb-string peg, 2⅛; full at end; where neck butts against hoop, $2\frac{1}{16}$. These are exact measurements taken from an instrument made to be played on, and not merely for show. A great many 7-stringed banjos sold by music sellers are made with the finger-boards too narrow, making it impossible to finger the strings, and play some of the chords properly, therefore if you are wise you will work to these measurements I have given. Let the bridge stand on vellum about 3 in. or 3½ in. from edge of hoop. If my answer to your query is not sufficiently clear, or if you require any more information, I shall be pleased to put you right on hearing from you again (through Editor).—J. G. W.

Die Stamping.—BON FIL (*Birmingham*).—You do not state whether you possess apparatus and material for this work or no; if not, you must procure them before you can obtain even a glimpse of success. A press is essential, and cards and gutta-percha to make counterparts cannot be dispensed with, as great pressure has to be exercised, and the simple die cannot do its work unaided. You can obtain of Messrs. Hughes & Kimber, West Harding Street, Fetter Lane, London, E.C., anything that you require for the purpose, and the plant will cost you from £5, and upwards. I do not, however, think that your brass dies will be of much use, as I suspect they were originally cut for seals. If that is the case, don't expect from them more than impressions in which the ground is coloured and the engraving white, technically termed cameo stamping, or perhaps only white impressions called plain stamping. You might colour those impressions, according to the laws of heraldry, by hand, for die stamping in colours necessitates a separate die for each colour, and I imagine you do not contemplate going that length. I would also mention that steel dies are invariably used, which are cut in accordance with the style of stamping required. For plain and cameo stamping the die is cut to give an impression in high relief, and a cameo impression is obtained by passing a colour roller over the face of the die. On the other hand what is called relief stamping is akin to copperplate printing, inasmuch as the engraving is more on the surface, and lines are employed for shading. To obtain an impression from a die so engraved, colour is brushed into the incisions, and the face of the die is wiped clear of ink; the lines are thus left full of ink, and consequently only the parts that are engraved appear impressed upon the paper. Any further information I shall be most happy to give with the editor's permission through the medium of "Shop."—J. H. M.

Watchmaking: How to Pivot a Cylinder.—COUNTRY WATCHJOBBER.—The simplest way I know is as follows:—Take a peg, cut the bottom



flat, and rest on the bottom jewel hole; cut a step or notch, A, where the rim or band of scape wheel comes; another, B, the height of scape teeth; another, C, just free of top of scape cock; place the peg on a new cylinder and see if suitable for length by resting top of notch, C, where the balance is to go, and notch B halfway down pallet, and A in centre of space of cylinder. The bottom of peg shows where the shoulder of bottom pivot should be; cut off the plug, leaving suitable length for pivot; take off both end pieces, screw on cock, and take length by gauge and cut off top plug to it, leaving a little over for rounding off when finished. To gauge the size, if you have no cylinder gauge use the pinion gauges. The plugs are merely fitted tight and driven in. For running in cylinders I fill them with sealing wax or shellac; and for other jobs, half beeswax and half resin make a very useful wax, as it requires but slight heat to put on or off.—A. B. C.

Violin Carving Tools.—I hasten to correct an error which appears, *re* sharpening carving tools, in No. 11; in the last sentence the word *tool* should have been *oil stone*. If the fault be mine, please accept my apology for making such a blunder, and, if possible, insert correction in next issue.—B.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Indiarubber.—PERPLEXED (*London*) writes:—"Will some reader kindly tell me how to make such a thing as a glove of indiarubber, similar but a trifle stouter than the children's common air balls before they are blown out? It must be elastic enough to pull it on and off without tearing."

Cake Firelighters.—J. C. (*Dundee*) writes:—"Would you inform me, through your valuable paper, where a machine can be got for the manufacture of cake firelighters, and the materials employed in the manufacture of the same?"

Tuition in Carpentering.—AMATEUR (*Bayswater*) writes:—"Would you kindly inform me in your issue, whether there is any institution or place where a person desirous of learning carpentering might get some elementary practical knowledge?"

Incubator.—B. F. (*Liverpool*) writes:—"Can any reader give me a plan of a simple incubator, with particulars, for me to make at home? I have a large square tin box, which might come in for it, and can use the soldering iron."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

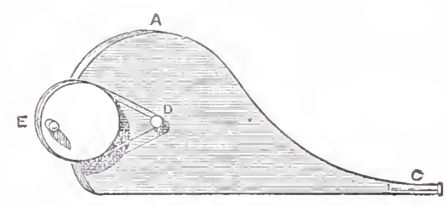
Fretwork Patterns.—MESSRS. CHARLES CHURCHILL & COMPANY, Importers of American Machinery (21, *Cross Street, Finsbury, E.C.*) write:—"*Re* Fretwork Patterns and W. E. M. in your issue dated June 1st. The book is one of our series, No. 4, 2s."

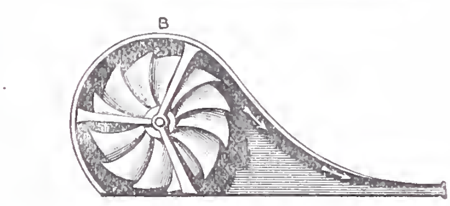
Fretwork Patterns.—W. H. J. C. (*Highbury*) writes:—"In No. 11 of WORK (see page 174), I note that W. E. M. wishes to ascertain the publisher's address of a pattern book on fretwork. I think I can give him that information, as, strange to say, I was at work on the first pattern of the book when I received my last copy of WORK. The book is Part 4 of an American publication, published by John R. Bowman, 40, Beekman Street, New York, at 50 cents (Part 4), and is very cheap, I consider, for the price; the only drawback is that no explanations are given for putting the patterns together, a fault with some English editions. If W. E. M. wishes for some really good and artistic patterns, I should advise him to get No. 10, published at 2 dols. One of the patterns I have forwarded to you out of No. 10 book. I cannot close this without wishing WORK a great success, for I think that it will be the means of brightening many a home by its very plain and intelligible articles on home decoration. I am not a mechanic by trade, but I spend my leisure time in fretwork and picture-frame making, and with the help of your valuable paper I intend starting on some article of furniture. I also hope that you will give us amateur fretworkers a few patterns now and again, something less elaborate than that cabinet issued with the first edition, which was a splendid pattern, only rather too difficult for me at any rate."—[You shall have some simpler fretwork designs.—ED.]

Moulded Indiarubber.—J. writes in reply to OSLEK (see page 190):—"David Moseley & Sons, Chapelfield Works, Ardwick, Manchester, can supply them."

Colouring Photographs.—F. H. Y. (*Kentish Town*) writes in reply to EXPECTANT (see page 174) on how to colour photos with water-colours:—"I think I can help him a little if he carries out the following directions: Rub the photo over with calcined preparation of magnesia, and use gum arabic and water to mix his colours."

Machine for Current of Air.—A. H. (*Wolverhampton*) writes in reply to BELLOWS (*Gloucester*) (see page 190):—"Seeing in 'Shop' an inquiry on how to make a machine for an intermittent current of air, I beg to submit the drawing herewith (if you can understand it). A is the apparatus complete, the sides being of wood, and the point, C, of brass. Inside as seen at B is a fan, which may be made of tin, and is worked by a





small pulley, D, and a wheel, E. If you wish I can, another time, give a fuller description."

A Pronged Ring.—J. writes in reply to E. C. (*Battlemore*) (see page 190):—"Harrison & Co., Malleable Iron Works, Lincoln, is a good firm."

IMPORTANT PRIZE COMPETITION.

THE Editor of WORK has the pleasure of informing his readers that Messrs. CASSELL & COMPANY, LIMITED, have placed at his disposal the sum of

THREE GUINEAS,

to be distributed in Prizes for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

FIRST PRIZE ... One Guinea and a Half.
SECOND PRIZE ... One Guinea.
THIRD PRIZE ... Half a Guinea.

Full particulars of the Scheme will be found in WORK No. 17, page 254.

Trade Notes and Memoranda.

THE citizens of New York are becoming painfully aware of the fact that the complex conveniences of civilised life in a big city are fraught with danger. Not a day passes without a break in the mains of the Steam-heating Company, which supplies both heat and power to the principal buildings in the city. The pipes form a perfect network under the streets, and owing to the enormous pressure of steam, constantly explode with a loud noise, hurling fragments of stone and quantities of mud, mingled with steam, into the air. The steam for that particular quarter of the town in which the explosion occurs has then to be shut off, leaving many of the establishments destitute of motive power. The gas mains also are put together so defectively that there is an enormous escape continually going on, so that the subways of the electric companies become invaded to such an extent that the men have to use great precautions when going underground. Disastrous explosions sometimes result from a break occurring in the electric conduits, which break produces an arc, so igniting the waste gas. In one of these which occurred recently in front of the Fifth Avenue Hotel, 200 feet of the pavement was torn up. Again, the overhead electric light wires which carry a powerful current often break, and have caused the death of several men and horses who have come into contact with the broken circuit. At the present time the relations between the electric light and the telegraph companies and the municipal authorities are somewhat strained, owing to the refusal of the companies to lay their wires underground as demanded by the municipality.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

SCIENTIFIC & ELECTRICAL MATERIALS.

IMMENSE STOCK of Appliances and Materials for Construction of **Electric, Optical,** and **Scientific Apparatus.** ELECTRIC BELLS, INDICATORS, WIRES, TERMINALS, CARBONS, BATTERIES, LENSES, AND FITTINGS. Electric Catalogue, 100 pages, 4 stamps.

H. DALE & CO., LTD., 26, LUDGATE HILL, LONDON, E.C.

(HENRY J. DALE, Manager.)

Specialty for Photographic Cameras, Lenses, Stands, Sensitised Paper and Dry Plates. New Patent Aneroid Barometers and Thermometers. Electric Light. A SUMMER-HOUSE OR GARDEN CAVE.

BY C. MAYNARD WALKER.

A SUMMER-HOUSE! "One of those sweet retreats which humane men erect for the accommodation of spiders," says Dickens. However true that may be, the writer in the following instructions will be unable to lay down any plan which will prevent these and other interesting insects from sharing the occupation with the owner. But Charles Dickens was not the first to discover this co-tenancy, for a very ancient philosopher, "good old Solomon," wrote thousands of years ago, "The spider layeth hold with her hands, and is in kings' palaces." However, these drawbacks notwithstanding, a summer-house of some sort is considered by most people a very desirable acquisition to a garden, more especially by London people, some of whose suburban edifices of this kind "are fearfully and wonderfully made," and present, when finished, admirable specimens of "patchwork;" and it is not until the intelligent observer has seen one of these that he has any idea to what extent a couple of empty egg-chests may be utilised in building operations.

The object of the writer in the present article is to give such instructions as will enable the reader to erect a substantial and commodious apartment, upon a novel plan, at a very moderate cost, even though he may never have tried his hand upon similar work before; in fact, I don't think any one can possibly go wrong in the matter, and for those who possess it, there is ample scope for the exercise of considerable artistic taste in the work, and moreover, the rough and perhaps clumsy work of a beginner is rather pleasing than otherwise in its effect, especially as Nature herself will give the finishing touches in due time. Fig. 2 effectively and graphically illustrates the appearance of a garden cave constructed upon this plan, and consists of a framework of galvanised iron wire netting laced to upright iron rods driven into the ground a few inches, and covered with rustic rockwork, formed with Portland cement and sand and ordinary rough gas coke, and is adapted to the requirements of a small garden. The dimensions, of course, may be varied indefinitely, but it is necessary that they should be decided upon before the work is commenced. Let us suppose that it is decided to have a rustic building, whose extreme height is 8 feet, constructed to stand alone (and let me say this kind of building should not be placed as a lean-to against a wooden wall or fence, or against any support which is not rigid), we shall require to set out a rough plan with pegs on the surface of the ground it is to occupy; I prefer to see an irregular polygon of, say, six sides of different widths.

In such case, it is necessary first of all to measure out the ground as in Fig. 3, regulating the width of the sides by the measurements of the galvanised wire netting, which you can obtain at any available shop; the wire netting should be of large mesh for obvious reasons, and it is moreover cheaper. Having settled this point, you will now

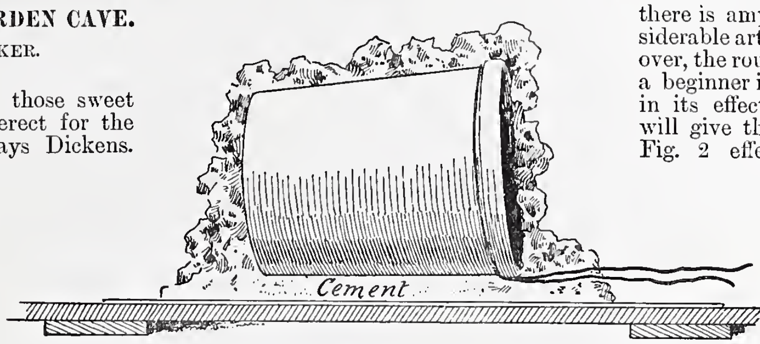

Fig. 1.—Section, showing Method of Making the Pot Pocket.

Fig. 2.—External View of Summer-house or Garden Cave.

require to set up six lengths of $\frac{3}{8}$-in. iron rod at the points indicated in Fig. 3. These should range from about 5 ft. 6 in. to 7 ft. 9 in., so as to produce an irregular appearance, and then a complete cage is to be formed over sides and roof with the galvanised wire netting laced to the iron rods with iron tying wire, the upper portion of these rods being carried crosswise to the highest point on the roof.

Take care that the whole of this caging is securely finished before attempting the next stage; the entrance or entrances must also be provided by cutting an irregular piece of wire netting out from one or more of the sides. Inlets for light here and there

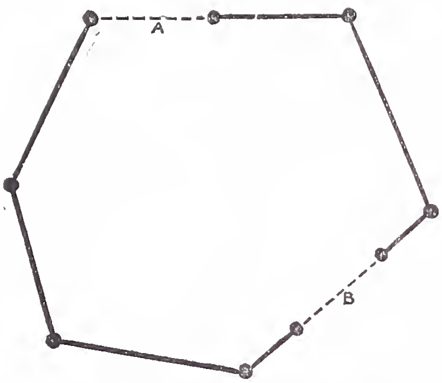

Fig. 3.—Plan and Position of Rods: A, B, Entrances.

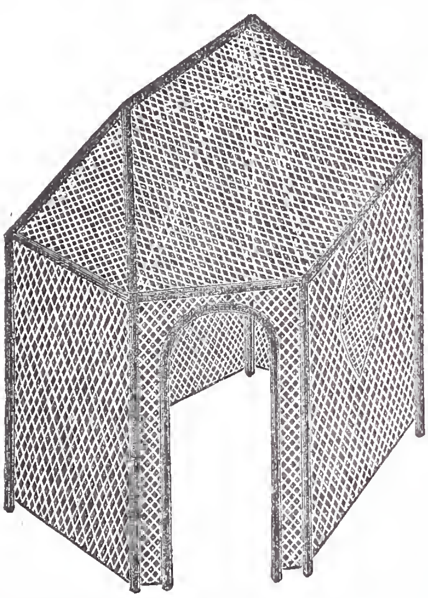

Fig. 4.—Iron Rods Laced with Netting on Irregular Hexagonal Figure.

may also be made in the same way. A charming effect may also be made in the finished cave by placing on the roof part at the highest points pieces of blue-tinted glass before making the rockwork. A most pleasing illustration of this effect may be seen in the Alhambra Court of the Crystal Palace, Sydenham.

With the view of making the summer-house or garden cave of still greater use, it will be well to provide it with a number of external pockets in which to grow ferns, flowers, or creepers; these should be made at this stage. Take a flower-pot, as in Fig. 1, and secure it round the rim with a piece of stout wire, leaving a convenient length of the latter; lay it on its side on a piece of board covered with paper, and having a layer of cement, and cover all over the surface of the pot pieces of coke well cemented together with Portland cement and sand. The coke for the whole of the work should be dipped in a thin batter of cement before use. Make as many of these pockets as are required, and put aside until quite set, when they can be secured to the wire netting by the wire, and left exposed for that purpose.

Having done this, the building up of the cave may be done. Having a good heap of cemented coke ready, and a bucket or slab of cement well mixed up with sand and water—about 1 part cement to 2 parts sand—one person should keep on mixing up the stuff well, while another cements the work. This should be done with a trowel. Take each piece of coke singly, and lay it so that a portion of it *goes into* the mesh of the netting, and see that each layer and every piece is well cemented, and as the work proceeds, every bit of the wire netting is hidden, and forms part of the rockwork, by going over it again from the inside; leave the roof part for a few days, and this will be much more substantially and neatly finished on the inside by temporarily fixing some boards under, and within about $\frac{1}{2}$ in. of the wire netting. Cover this with paper, so that it will hold a layer of cement laid on from the top, then when the coke pieces are laid in this and through the meshes, set hard, and the temporary boards removed, you will have a neat, secure, smooth surface on the under part of the roof. The form of roof being angular also gives it greater strength when cemented up.

The work of preparation is by this time all but finished, and having cleared up all the inevitable mess, the worker will probably think that the colour looks rather raw. Nature will change all that in due course, but a temporary tinting of the projectives may be done *sparingly* by mixing some boiled oil and colour, and lightly touching up the surface with shades of brown and green. There remains now nothing but the seats to be provided for, which may well consist of planks fastened to uprights of wood staked into the ground. An irregular border bed all round the base of the summer-house, except the entrances, will add very much to the pleasing effect, stocked, of course, with suitable plants. I think that the worker, looking to the substantial and tasteful character of the erection, will agree with the writer that he has succeeded in building a commodious and useful house at a most moderate cost.

THE WATCH: HOW TO CLEAN AND REPAIR IT.

BY A PRACTICAL HAND.

In this, and in papers to follow, I propose to describe the various watches in general use, plainly and concisely, showing how to take to pieces, clean, and repair them—at least, the repairs which an intelligent amateur can do. I shall keep as much as possible from using the trade names of the parts, etc., so as not to mystify, seeing I am not writing for those already in the business, as they will receive full information and experience in their apprenticeship by those under whom they serve. My object is to make the watch a pleasant study, and, as a rule, all intelligent men or women look upon a watch with a degree of wonder and delight, as a thing of beauty to be admired. I, though thirty years in the trade, feel, when undertaking to put a watch (so dirty and out of repair) into order again, that it is next to restoring life. An amateur, then, after his first attempt upon some old timekeeper, may well feel a glow of pleasure on its commencing to tick once more, and by his own handiwork. Many attempt such work, but on account of not knowing how to proceed properly, take some part to pieces, forgetting the spring, which being in full force, as the watch may have stopped by dirt, the consequence is smash goes one or two pinions—cost, two dollars to replace, and never as good as the original ones. By following the instructions, no one with fair care need have any such mishap.

The Watch.—This word is derived from the Anglo-Saxon word signifying "to wake;" and in the sense of timekeeping first occurs in a record of 1542, which states: "Edward the VI. had onne larum, or watch, of *iron*, case being likewise of iron gilt, with two plummets of lead"—in other words, it was driven by weights. The invention of the watch originated at Nuremberg, 1417, so that watches were nicknamed Nuremberg eggs. Many curious designs were made, some in the form of a skull; the top part opened with a hinge, showing the dial, where the brains were located. Catherine I., Empress of Russia, had a musical watch, in the inside of which were the Holy Sepulchre and Roman Guards; by touching a spring the stones moved away from the door, angels appeared, and the holy woman stepped into the tomb and sang the Easter hymn of the Russian Church. In the Swiss Museum is a watch $\frac{3}{16}$ths of an inch in diameter, inserted in the top of a pencil case. Its tiny dial not only indicates hours, minutes, and seconds, but also the day of the month. The watch of Queen Elizabeth of England—a great curiosity—may be seen in the Mayers' collection of the Liverpool Free Museum; and all the old style of verges, etc., down to one of the smallest and handsomest Swiss productions. Also in the Guildhall, in London, various forms are shown—the old alarum watch, repeating ditto, and those having "catgut cord," from the spring barrel to the fusee, in place of our modern chain, to give impetus to the wheels. They are shown in order of date when in use; so are the old grandfather brass dial, carved cased clocks. To me, and thousands of others, they were a great source of interesting thought of bygone ages, picturing the care bestowed upon them by the wearers, who would a couple of hundred years ago pull them out of their deep fob-pockets and look with reverence as they denoted the time, in a manner that an apprentice would scorn nowadays. Like Captain Cuttle's watch in "Dombey and Son," that required to "be put back half an hour in the morning, and a quarter of an hour in the afternoon; then *Waller*, my boy, it will do you credit." Those old verges were well finished, and as they have such a good coat of plating upon the movements, at the present day many thousands of beautiful perforated cocks (or covers to the balance wheel) are worn as brooches, necklets, etc. etc. Then the silver used in their unwieldy cases was of the purest quality. I can well remember the old men who used those verge watches undoing the outer case, or cover, and placing it on their left thumb until the watch was wound up, with solemn gravity! At the beginning of the present century they were regarded as heirlooms, and handed down from father to son. "The big auld watch, yance my father's pride."

The last thirty years watches have become very common, even down to schoolboys; but the market is flooded with rubbish not worthy of the name of watch, and, like "Pindar's razors, made to sell." They are minus jewels, finish to wheels, pinions, etc., and with untempered springs. Such cause a vast amount of trouble to those who have to clean or repair them, and, worst of all, are costly to the wearer, who in time pays the original price in repairs. The best and most reliable watches are made at Clerkenwell, in London, taking all things into consideration, durability especially. I know many desire to give preference to the Waltham watch, but that matter was freely discussed a few years ago, across the water, and the decision was in favour of Clerkenwell.

It is astonishing how a well-made and finished Swiss watch will wear and keep the best of time, though it is minus the fusee wheel and chain that English ones have. Many that I have worn, and tried well, kept accurate time, and I could rely on them equal to any lever, though only horizontal movement. One I had—a Swiss lever—went the most accurate of any watch I had in my lifetime, keeping time to my satisfaction, and better than a gold English centre seconds costing £20. Its price was only £3. But for those who have hard work, or who are careless in using a watch, they are unfitted; a hunting-case Waltham or English lever would be the best, and prove a good investment in the end. Having a watch cleaned yearly in the fall, to pass through winter, clean and unclogged with dirt or oil, also to wind it regularly every night, hanging it up in position worn during the day, will give the best results. Sometimes hanging up and sometimes laying down will cause variation, no matter how good. Try it. By regularly cleaning, and not running them until they will run no longer, you will increase the durability of the watch. You may say, Why? Well, simply because the holes get ground in time to an oval shape by dust and dirt. Some men will boast: "My watch has had nothing done to it for three or four years." They are only showing their own folly. In the next paper I will show how to clean and repair the verge watch.

JOINTING UP—FOR "'PRENTICE HANDS."

BY DAVID ADAMSON.

PLAIN GLUED JOINTS (*continued*).

IN my first paper on this subject I showed what was necessary to be done in order to make a perfect joint, but space prevented me from bringing my remarks to a close at that time. I hope, however, to be more fortunate on the present occasion, and to find room to finish all I have to say on the plain glued joints, which after all forms the first section only of my theme.

Carlyle's well-known definition of genius may be applied to the artisan by slightly altering it, for it is quite certain that the best workmen are those who are most largely gifted with the capacity for taking pains. Even in "jointing up" much care may be, indeed, must be, taken if the work is thorough. The good practical workman takes all precaution to make it so, bestowing an amount of care which the clever amateur who is so handy knows little of. May I, without seeming ill-natured, just suggest to these latter, that they would get many valuable hints if they would be content to learn and listen respectfully to any practical mechanic, instead of trying to teach him, as so many do. Excuse the hint, my friends, who have done a little joinery, or as you may think it, possibly, a great deal. We won't cavil about the magnitude of your operations; but the probability is, that any artisan did more before he was "out of his time" than you would do in a lifetime. The skilled artisan, therefore, naturally resents advice from amateurs; but, on the other hand, is generally willing to assist in friendly conversation. You, the clever amateurs, generally know too much, and the bench hand is so well able to gauge your capacity that he does not care to waste his time by giving you information or discussing matters with you. He is certainly not the loser, and neither will you be if you approach him properly, and are willing to profit by his experience.

Is this little bit of plain speaking too straight for some of you? I hope not; but if it seems somewhat severe let me say that I have had some experience with amateur workers and with journeymen; and in writing these lines it is my desire to help the former by showing them how they may learn from the latter; at the same time, perhaps, indicating why their efforts to get information from practical mechanics may not have met with much success. There may be, and, doubtless, are, churls among these as in every other path of life, but I may with confidence say that the practical mechanic is by no means so reluctant to convey information, or to talk about his particular craft, as he is sometimes represented to be. I should say, perhaps, that I refer specially to cabinet makers as I am best acquainted with them, and though they are, from the nature of their work, among the highest class of craftsmen, I imagine others are not unlike them. They will resent instruction from those not competent to give it, for here in the workshop the tool handler is master of the situation, and he is by no means ignorant of it. Therefore, amateur, whether young or old, whenever you get a chance of seeing a good workman at work keep your eyes open and watch. You are sure to learn something. It has been said that women and fools should never see unfinished work, and there is no doubt that many men come under one or other of these classes—they must decide for themselves which, when they enter a workshop, by offering their valuable "suggestions." Let them keep these back, and they will be as welcome as they are the reverse when they don't. Once more I hope these remarks will be taken in a friendly spirit, however awkwardly they may have been given, and, if acted on, I am convinced that the hostile feeling sometimes said to exist towards amateurdom will be greatly diminished, if not removed altogether. But we left the boards while referring to the feel of a perfectly made joint, and, of course, if they are found to be all right, nothing more is required except gluing together. It is, however, extremely unlikely that the edges will be so truly "shot," *i.e.*, planed or worked up, as to be in contact at all parts. If they rock, from one or both being planed away more at the ends than in the middle, do not attempt to glue them; but if the boards meet at the ends, but not towards the centre, then if the space is not great no great harm will result. Look upon absolute contact at ends as indispensable; but though the same may be of advantage throughout the entire length of short pieces, it is not necessary, indeed is not advisable, for long pieces. The space must not, however, be great, not more than enough to put the contact at the ends beyond a doubt. Perhaps the best way of conveying a notion of the hollowness of the edge towards the centre, will be to suppose we have a couple of boards 5 or 6 ft. long, with edges perfectly true. Now with the plane remove a shaving or two, just the suspicion of one at its commencement, a few inches from the end of the board, till there is, when the boards are placed together, a perceptible space between them tapering from the centre to nothing near the ends. Even at the widest the space must not be so great that it cannot be closed by pressure of the cramps, within which the boards will be placed while the glue is setting. This is really all that it would be useful to say about planing up the edges, and much will depend on width, length, and other qualities; but, to sum up briefly, it may be said that the edges of short pieces should be "shot" straight, while long pieces should be hollowed towards the middle. Now for gluing the joint. Let the glue be good, freshly and properly made, hot, with cramps and wood handy, so that the glue, when rubbed in, may have no time to harden while getting ready for fixing the two pieces together. No precise instructions can be given for every possible case. Short pieces may not even require cramping, and a few general instructions will probably be sufficient. Practice varies, and I have no wish to name one procedure and ignore others. One great matter is to have the edges of the board warm, so that the glue does not chill as soon as applied, but remains liquid and sticky. They must not, however, be too hot, but there is not so much danger from this as from being too cold. Do not put too much glue on; a very thin coat well rubbed in is all that is necessary. If one piece is held by the bench screw, it may very possibly happen that the glue has hardened on it, or at least is not in its most adhesive state when the other is put to it. There might be a slight film on its surface, and, of course, this prevents it adhering as well as it might to the other piece. Well, just let this be sufficiently warm to melt the glue again, and the adherence ought to be perfect. It will thus be seen that the glue may, or may not, be rubbed on both pieces. When placing the glued edges in contact, do not be content with simply pressing them together, but having brought them cleanly together, slide them slightly against each other, lengthwise, using as much pressure as convenient. This expels any air, as well as a good deal of the superfluous glue, the presence of which, were it suffered to remain, would be fatal to a good joint. It then only remains to cramp the two pieces together, and let them remain till the glue has thoroughly set, when the boards may be worked on as if there were no joint. It may be news to some that a properly glued joint ought to be stronger than the natural wood, that is to say, on splitting a board by bending or pulling it ought, except perhaps in the case of some tough woods, to split at any part rather than at the joint. With ordinary pine or bay wood, if the fracture is along the joint, depend on it that the workmanship or the glue is at fault. Should such a disappointment await the novice who applies this test, it must not be overlooked that all glue must be removed before applying any more; in fact, the joint must be "shot" afresh. Attention will next be turned to the dowelled and tongued joints, but these must form the subject of a future "chat." Meanwhile, a little practice in planing up edges will not be wasted.

JAPANESE MOTIVE FOR PANEL IN FRETWORK.

BY E. BONNEY STEYNE.

To obtain new effects in a method so limited as fret cutting is less easy than it looks, especially if the taste of the designer forbids attempts at purely pictorial renderings of common objects, which, in spite of their popularity (if we may judge from their frequency in trade catalogues), surely contravene ever recognised laws of fitness. For in fretwork even the art of silhouette presentation can hardly be employed as felicitously as in black-and-white design upon paper. In pen-and-ink work the clear definite edge of the design is valuable beyond question to express any simple form; but in fret cutting the thickness of the wood itself insists upon being seen, and consequently destroys the clean exactness of the outline. Then, again, the contrast between the cut-out wood and its background is hardly likely to be as definite as in a printed silhouette; even though the wood be black and the white pure white, the cast shadows will come in and confuse the pattern.

Bearing in mind these limits, it is doubtful if such a design as this one given here can be strictly defended. In it an attempt has been made to conventionalise, after the manner of the Japanese, a subject that is very popular with those wonderful decorators. That the design in any way approaches the beauty of true Japanese art dare not be said, but that it is not quite so abjectly hideous as many a widely-diffused travesty of that inimitable school of ornament the limner humbly hopes. To cut a thing that shall vaguely suggest a landscape out of wood is not easy. "Would that it were impossible," do I hear you say? Very well; you can leave it still undone, and so assist in making it so. But if a rococo treatment of a square panel is desired, and if a somewhat distantly removed view of Fusi-yama, from the frequently-recurring native treatment of that sacred mountain, is not too gross a breach of good decorative taste, I beg leave to submit it with a thousand apologies. In flatly treated painting this typical presentation of certain forms, easily recognised as clouds, moon, mountain, water, flowers, etc., may be used with unquestionably pleasant effect; but in cut-out wood—unless the wood be very thin, and the saw very truly and rigidly kept to its exact line of cutting—I fear the result may be not quite so good. Yet if I understand the noble ambition to do something fresh, that characterises the supporters of WORK, they will be ready like many worse, ay, and even a few better, men (if, indeed, such could be found) to pardon its faults in view of its one virtue—unexpectedness.

Japanese Motive for Panel in Fretwork. (Scale, half size.)

For future use such a panel may form one side of a hanging lantern, the cover of a blot book, the upright back of a bracket, the door of a small cupboard, or a hundred kindred purposes. It may be left untouched by stain or polish, but only, I think, if in self-coloured wood with no vividly prominent pattern. Should the wood be mahogany or oak, it should be stained or gilded to avoid the conflicting lines of design and natural marking of the grain; either tending to destroy the force of the other.

The Japanese rarely use fretwork without a low relief carving of its surface. To put it less correctly but more vividly, it is pierced carving they favour to the exclusion of what we imply by fretwork. The fret ornament of their marvellously intricate lattice-work panels is veritable joinery, and built up of small bars of wood, not saw cut.

But a series of actual patterns from the land of the Rising Sun were lately given in these pages, and this proof of my own admiration for such, with its evidence in the attempt to rival the beauties of the original in a disrespectful parody, is English, you know, quite English. But let us be sure that the work so freely lavished upon our ornamental trifles is as good as the Japanese finish. It seems to me that ornament should never be used, unless it is good of its sort; a well-finished piece of cabinet work, exquisitely neat in its construction, is far better left unloaded by vicious ornament. But if the ornament is applied let it be well worked, for wood carving vigour and bold sweep of its curves, with the parts well massed, are more important than precise accuracy. But in fret cutting, which so narrowly escapes the reproach of being mere mechanism, and can only by very capable use be raised to the dignity of an art at all, extremely dainty finish is not only pleasant but absolutely necessary to atone for the intrusion of a pastime like the craft of the schoolboy in honest cabinet making. Therefore, for all such work used to adorn a larger structure grudge no labour, use fine saws, keep conscientiously to the line of the pattern—the whole line, and nowhere but on the line—going as fast as the Flying Dutchman if you can, but never leaving the line. Then let the file and sand paper be used unsparingly. And if your design is a good one, and the tracing itself geometrically true, and a duplicate, if not an improvement on the published pattern—if all these items are done well, little fear but that the whole will be well done.

SOME LESSONS FROM AN OLD BUREAU.

BY DAVID ADAMSON.

(*Continued from page* 279.)

WRITING FLAP OR LID: ITS CONSTRUCTION—HINGES—TREATMENT OF INSIDE OF LID—VENEERED BORDER—LOCK AND ESCUTCHEON FOR KEYHOLE—FITTING OF INTERIOR OF DESK—ORDER OF FITTING PARTS—MUNTINS FOR BACK—PANELS FOR BACK—FINISHING—HANDLES FOR DRAWERS—LINING—HOW TO PASTE IT TO WOOD.

THE writing flap or lid may next be attended to as being the next part of our work. It consists of four pieces forming a frame, and a panel fitting into it. The frame is mortised and tenoned at the corner, where it should also be mitred, as this looks better than if the shoulder were left square. As the combined mitre and tenon may not be understood by those not well up in carpentering, the mitred end, with the tenon, is shown in Fig. 19, first in perspective, then in plan and elevation. It will be as well that the tenons should be on the ends of the two long pieces of the frame, those which form the back and front of the lid. Grooves must be prepared all round the inner side of the frame, and a corresponding tongue round the panel, so that the whole may be closely fixed together firmly and neatly. I do not know whether it is necessary to say that the whole of the lid must be flush on both sides—*i.e.*, the panel should not be sunk below the framing. At the ends and front of the lid a rebate must be made, that when closed it may rest on the ends and top without having the clumsy appearance it would present if left to its original thickness. It will be noticed that the inner top is shown in Fig. 4 (page 116) slightly below start of slope in order to allow for this rebate, which may be about ½ in. in depth. The top piece of all is also shown bevelled for about half its thickness in continuation of the slope of the ends for the same reason, as the front or top of the lid when closed should not project above the top piece.

The lid when finished in the wood is fastened to the bureau, with a couple of hinges sunk on the upper side of the lid and (inner) top. These hinges may be the sort specially made for desks, or the ordinary "back flaps" may be used. In either case they are fitted in the same manner, as they are to all intents and purposes the same in everything except proportion. The inside of the hinge must be uppermost to allow them to fold properly, and in case the projection of the knuckle above the table is objected to, the ordinary card table hinge, which, however, is hardly so suitable, may be used.

Next comes the treatment of the inside of the lid. This may either be polished or lined, preferably the latter, as the leather or cloth gives a pleasanter surface at which to write than the hard wood. The lining, however, must not be done yet, and it is only mentioned here as it is usual in tops so finished to have a veneered border. This border may be of any width, but should hardly exceed 2½ in., and it may very well be dispensed with altogether. Still for those who prefer having it, it may be stated that it can easily be laid with glue, the surplus of which should be thoroughly pressed out. The grain of the veneer should run in the same direction as that of the panel—viz., parallel with the length of the flap. The veneers should be damped on the upper surface before laying, otherwise the moisture from the glue will cause them to curl up. To lay such pieces the veneering hammer is generally used, but a good substitute may be found in a piece of wood applied to them with pressure, and worked along to squeeze out any excess of glue. Should this and any air bubbles not be properly pressed out, blisters will be formed. These, if suspected after the veneer is laid and dry, may easily be detected by tapping, or if they are very bad by merely passing the palm of the hand over the surface. The best way to lay them is to prick a small hole in the veneer, and then to press it down with an ordinary flat iron or a hammer head heated sufficiently to soften the glue, but not to burn it or the veneer. On the whole, however, it is hardly well for the amateur without competent guidance and practical demonstration to attempt veneering.

Fig. 19.

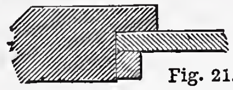

Fig. 21.

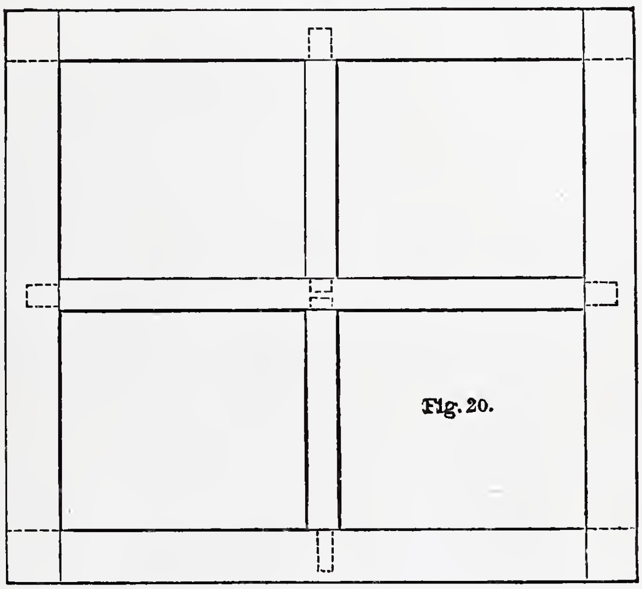

Fig. 20.

Fig. 19.—Tenon and Mortise. Fig. 20.—Panelled Back. Fig. 21.—Mode of Securing Panelled Back in Rebate.

A lock should be fastened to the flap, but if not considered necessary a spring catch will do instead, though if it is not desired to lock up the desk part, it is hardly worth while taking the trouble to attach any fastening, as the weight of the lid is sufficient to keep it closed. Any way, instructions for making the bureau could hardly be considered complete without mention of the lock. This should be let into the flap level with its surface, and for the sake of symmetry the keyhole should be equidistant between the two ends. I am not aware whether a special lock was made for this purpose when bureaus were more common than now, but I believe there is not now. The difference between them—if there ever were such things—and the ordinary drawer or till lock could be but trifling, so that a drawer lock will answer every purpose. A space for the bolt must be cut in the top, and this should be done very neatly, for it will be found that the wood remaining above the hole is very thin indeed, so thin that a very slight pull would tear it away altogether. The probability of such a mishap occurring appears to have been foreseen by old cabinet makers, and provided against by letting a slip of brass in along the edge of the top just by the bolt hole. The strip extends a short way on each side of it, and is fastened down with screws. The keyhole should be provided with an escutcheon plate to match the drawers. The fitting of the interior of the desk next claims attention. The fitting of the whole of these pieces is exactly alike, and it will be an economy of time and labour to mark the various distances where a partition is to be placed before commencing to cut the grooves across. For example, take the piece No. 17 (page 115), which is to form bottom of pigeon holes and top of the centre three drawers. Mark out on its upper surface the distances of the pigeon-hole partitions, and with the square draw lines right across. Now, on these lines cut grooves from the back to within a little, say, ½ in. of the front. These grooves should be just wide enough for the partitions to enter them, and they should not be more, at the outside, than half the thickness of the wood in depth. The half inch left in the front should be cut into a V-shaped groove, and the bottom of the partition for the same distance back cut to fit it. For such small work a mitre block would be rather an encumbrance than a help to most workers, but judgment in cutting will be required. It will not be necessary to mitre the pieces fitting into the ends and top, that is to say, the divisions between the drawers and the upright partitions will require only grooves.

The various parts may, perhaps, best be fitted together in the following order:—1st, the bottom piece of all, No. 16; 2nd, the pieces No. 18, separating the end drawers and the pigeon holes; 3rd, No. 17, forming the bottom of the pigeon holes. It should then be an easy matter to fit the other pieces in any order preferred. I think it will be understood that each piece is to be pushed in from behind. All the parts should fit firmly and tightly, but without any undue strain which might distort them. The front edges should be uniform and set back a trifle under the top. The appearance will also be improved if they are rounded instead of being left square. The small shaped pieces which are seen at the top of the pigeon holes are principally for ornament. They are cut to fit accurately between the spaces, and are secured with blocks glued in behind them. With this exception glue is not required in fitting up this part of the work, unless, indeed, the drawers are considered as part of it. They, of course, must be glued up. They are made precisely as directed for the larger drawers, and in fitting them there is scope for a nice display of the joiner's skill. In small drawers such as these, it is not generally considered necessary to run the bottom into grooved slips. The grooves are cut into the sides instead, as it can hardly be supposed that these small drawers will be required to support much weight. The back of the bureau is now the only part of the construction which remains. If it is to stand against a wall, a back formed in the simplest manner will suffice. For ordinary backs, muntins similar to those for the long drawer bottoms are generally used, as this form is decidedly preferable to plain boards glued up to form one piece, without involving much more labour. After what has been said about munted bottoms, it will not, however, be necessary to explain the construction further. It may, however, be said that a piece of muntin must abut against each end of the bureau, and take, as it were, the place of the grooved slips in the drawers. The number of muntins is not important, but four, including the two end ones, may be named as about the quantity for a job the size of the bureau. They should be at equal distances from each other, and be fixed perpendicularly, not horizontally.

Matchboarding will answer every purpose, and as it can be bought ready ploughed and tongued—*i.e.*, "matched"—it is very convenient to those who wish to avoid a needless expenditure of labour. The back, whichever way it is formed, should be let into a rebate run round the top, bottom, and ends of the bureau, and be fastened down with screws. It is, however, quite conceivable that the bureau may be destined to stand in some position where its back could be seen, and in that case the matchboard backing, though serviceable enough, may be rightly deemed out of harmony with the appearance of the rest of the work. A panelled back will be more appropriate, though its construction entails more work than the other. Still, work if properly applied means value, so it need not be grudged. The panelled back should consist of an outer frame of stuff, say, 3 in. wide × $\frac{3}{4}$ in. thick, the ends fastened to each other by mortise and tenon. Within these there should be a cross rail and upright also secured by mortise and tenon, or dowels, the whole enclosing four panels, for which $\frac{3}{8}$-in. stuff will serve (see Fig. 20). The panels may be either fitted to grooves in the framing—be it understood these panels are sunk, and not necessarily level with the surrounding frame—or the framing may be rebated on the inner side, and the panels let into it and secured with beads. This latter will probably be deemed by most the easier of the two methods, and it is shown in section in Fig. 21, so clearly as to prevent any misconception. It will be just as well for reasons which I trust have been made sufficiently clear already not to glue the beads to the frame and the panels, but to fasten them to the former only. Such a back as this should be fastened in with brass screws, as they look better than the ordinary iron. The bureau may now be considered made, as far as wood working is concerned, and those who have carried out the instructions given will find themselves in possession of a piece of furniture they may well be proud of, for it is a thing that will last, being made on sound principles. In this respect it will bear comparison with a similar thing whether of modern or ancient date. Even if the finish is not equal to the best the constructive details are, and if they have been manipulated with anything like skill the bureau may stand a very fair chance of becoming in time a genuine old bit of woodwork. Put the date on it somewhere, my amateur friend. It may some day interest somebody when he wants to tell his own decrepid, incapable generation that a former one turned out only honest work. We know better, but the prospective antiquarian will not be the only one who has made a similar mistake, and an excusable one, if all furniture were as well made as the newly constructed bureau.

Perhaps before closing a few remarks on finishing may not be out of place. Handles are wanted for the drawers. Those on the lower part should be good substantial brass handles, two to each of the long drawers, and one to each of the smaller. Fasten them on with round-headed brass screws. The small drawers in the desk part will only require a small brass knob each, except the long centre drawer, which should have two. Similar knobs may be fastened to the ends of the lid bearers, which, by the way, I think I have omitted to say, should be prevented from coming quite out by wooden stops similar to those under the drawers, nailed to the side. Polishing, also, should be attended to, but of this nothing need be said at present. The lining of the lid, however, affecting, as it does, the comfort of the writer, should have some consideration. The usual lining, as I have stated already, is leather, commonly supposed to be morocco, but in reality skiver, a thin leather formed by splitting a skin. All leather, however, is apt to get hard, and though now looked on as somewhat old-fashioned a cloth lining answers the purpose better. It is quite as durable, and moreover is a softer substance, so that a sheet of paper may be written on without the necessity of a pad of blotting paper underneath. These considerations are, however, for the user of the desk, and he can line it either with leather or cloth as he may prefer, but whichever it is the colour should not be too bright, but something restful and not tiring to the eyes. I may say that if the appearance of leather is preferred to cloth, the principal advantages possessed by the latter may be gained by interposing a layer of flannel between the wood and the leather. The lining, either cloth or leather, should be fixed to the wood with paste applied to the wood, not to the lining. The paste of ordinary bookbinders is the best for the purpose, and it should be well rubbed in before the lining is laid on it. A convenient way to apply the paste is to put a little in a piece of Hessian, or similar coarse canvas, and to rub it over the wood. This canvas serves as a kind of filtering medium for the paste, and prevents any lumps there may be in it from getting on to the wood. The lining should not be trimmed at the edges till after it has been laid and allowed to dry.

Before concluding this article I hope to show how the plain bureau may, without altering its shape or general construction, be finished in various styles, such as those of Chippendale, Sheraton, etc., so that those who wish for a more ornate piece of furniture may gratify their taste. Sundry modifications in detail will also be suggested for the advantage of those who, though unable to formulate exactly what they do want, are able to recognise the fulfilment of their requirements when it is placed before them. In the meantime the "Lessons from an Old Bureau" will not have been studied without, let us hope, some benefit accruing to those who have been disposed to follow and think over my remarks in the same spirit in which they have been written.

HOW TO SHARPEN PLANES.

BY B. A. B.

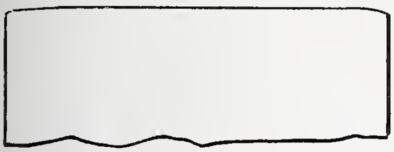
HAVING had opportunities of helping many beginners in woodwork, I take the first chance I have to point out in WORK the most common mistakes made by novices. It is not reasonable to expect a beginner to sharpen and set his planes, and yet how can he use them unless they are well set and sharpened? I recommend all young at the craft to take lessons in sharpening from a good workman, if they know one willing to instruct them; failing this, I will try to explain. Have a clean oilstone standing steadily on the bench with two or three drops of oil on it; observe carefully the angle at which the plane iron is set in the plane, and rub the iron on the stone lightly, with the chief pressure in the forward stroke, at an angle *less* than that at which the iron stands in the plane—that is, the left hand grasps the iron across, palm downwards, and the right hand holds the end, thumb uppermost; then be careful to keep the right hand lower than if held in the same manner in the block of the plane. Now rub lightly (if the iron is freshly ground very lightly), keeping the angle as constant as possible. This is the chief difficulty; wrist, elbow, and shoulder joints must each contribute some movement to make the hands a parallel motion. Do not stoop over the stone, or move the whole body. After a little rubbing feel the front carefully with the finger; if the steel has just begun to turn slightly forward, that is enough; if not, rub till it does. Then, laying the iron face downwards on the stone, rub this fine line of steel off by thrusting while rubbing—that is, chief pressure *from* you and against the edge. The face of the iron must be perfectly flat on the stone, and the fine line of steel must not be bent back by this last operation, but *removed;* if only bent back, try again with *less* pressure, both operations, till successful. It is obvious that any excess of rubbing only makes the "wire edge," as it is termed, too coarse, wastes time, and causes grinding to be needed sooner. Having sharpened the plane iron, screw the front iron on; first with the fingers, adjusting it about $\frac{1}{16}$ in. from the cutting edge. Do not let it pass the sharp edge, or it will injure its keenness; then with the head of the screw upwards, just close to, but not on the edge of, the bench, screw it as tightly as you can without letting the screwdriver slip.

Now get in a good light, and, with the plane in left hand, put the iron in, *holding it in* position with left thumb. You want the iron to project as much as the thickness of the shaving you intend to take off, or a trifle less, as the wedge now to be inserted and gently tapped with a hammer may, and most likely will, drive it out a little. The plane, on trial, should now work well, but if not, try to find out why it does not. You will easily remedy the defect if you are careful in the investigation. A likely fault is that the iron is sharpened obliquely, consequently giving a coarse shaving in the corner of mouth, where it can less easily escape, and leaving a series of furrows in the work.

It may be sharpened well, and put in obliquely, there is a little liberty and you may have taken it in the wrong direction, the front iron may have slipped, or shaving may have got between the irons. Do not keep striking the plane, or the iron, or wedge, as most beginners do, blindly hoping it will presently come right. Find out th fault; remove iron and wedge, and put together more correctly, as above described.

When successful in setting, be sure to keep behind the plane; you have more power, and should you come to a hard knot you are less likely to hurt your wrist. You are to make more use of the left hand than beginners usually do, as the pressure on front of plane very much checks those vibrations which, leaving a wavy appearance on the work, also very much weary the worker.

Now supposing the plane well sharpened, the cap iron well adjusted and tightly fixed, and the cutting iron projecting just enough, yet the tyro may find a difficulty still. He may find, as he passes his fingers across the work, those furrows like a series of shallow rebates that quite spoil its appearance; he may tap the iron first one way and then the other without curing the evil. The reason is that the edge of iron is either straight, or worse—concave; if so, he can never plane a surface wider than his plane iron without these marks, which show, too, that he is a beginner by their tendency to the near front corner. The cure is to very slightly round the iron in sharpening at the corners (as in the annexed figure) only as much as the



Edge of Plane Iron properly sharpened, showing rounded corners.

stoutest shaving he intends to remove. I hope I have made this important point clear. Let me put it in other words. Suppose the iron quite straight as to its edge; say it is $2\frac{1}{4}$ in. (a fair average width for jack plane); let 2 in. *remain straight;* let the $\frac{1}{8}$th at each edge be rubbed away, say $\frac{1}{40}$th of inch, at the corner. A shaving taken with a plane with iron so sharpened will not have a stout edge, but will gradually fade away to nothing at each edge.

Do not, however, in avoiding one error, fall into another; do not make the edge of the iron a segment of a circle in order to prevent the corners catching. Such sharpening is only allowable in planes for the coarsest preliminary work, and the beginner must aim at more careful sharpening.

Now, these two opposite errors may spring from one cause: viz., the inaccuracy of the oilstone. Given a wide oilstone used frequently to sharpen chisels upon, you soon obtain a stone that will cause the too rounding error, and if an attempt is made to rectify this error by rubbing the centre of plane iron on the marginal edges of stone alternately, as is often attempted, there is possibility of the opposite or concave error. The remedy is to rub the oilstone flat on a piece of paving stone with a little silver-sand and some water, taking care to dry the stone of water before again applying oil.

These directions for sharpening plane irons apply to jack, tying, and smoothing planes, and their fellows; not to rebate, moulding, or fillister planes. Rebate plane irons must project equally across the sole of the plane, and must be exactly the width of plane; fillisters nearly the same; moulding planes should either be sharpened so that the iron projects equally all over profile of moulding, or else *slightly* more projecting at the leading parts. For instance, say a bead: if the part of iron making the quirk takes off but little, and the hollow of iron which makes the round takes more, the worker finds it very difficult to make a good bead. Rapidity and good finish are best secured by leaving the quirk, the most projectant part of cutter, slightly more prominent than the rest.

If I have failed to make any beginner understand—and this article on sharpening is only for beginners—I will answer any inquiries; but in case any one fails, before asking try again, using less pressure on the oilstone, especially just as the finishing strokes are being made, as too heavy a pressure is a common fault among beginners.

BURGLAR ALARUMS:

How to Make, Work, and Maintain.

BY GEORGE EDWINSON BONNEY.

AUTOMATIC RELAYS—MAYFIELD'S ELECTRIC ALARUM BELL—DALE'S ELECTRIC ALARUM BELL—INDICATOR RELAY—PUTTING PARTS OF BELL TOGETHER—TESTING BELL—COVER FOR BELL.

Automatic Relays.—The action of an automatic relay will be more clearly understood by referring to the plan of one shown at Fig. 35. This relay is similar to that shown at Figs. 28 and 33. The trigger, L, of the relay is here shown on the face of the bell base, released from the catch, G, and drawn by the spiral spring into contact with a piece of brass, H. This piece of brass is connected by a wire leading up the back of the bell base (the course is shown by a dotted line) to the binding screw, B, and this is connected by a wire with one of the terminals of the battery, M. The other terminal of the battery is connected by a wire with the binding screw, A, and thus the local battery is thrown by the relay into short circuit with the bell, which is by this means rendered independent of current from the main line battery. When the circuit of the main line battery is closed by the act of opening a window or door placed in circuit, the current passes from A to D, then through the magnet coils to E, F, by the armature spring, to the contact post, K, then to C, and back to battery. As the current traverses the magnet coils, their cores attract the armature, and with it the hammer shaft; this movement causes the catch, G, to slip away from the end of the trigger, and the spiral spring at once brings it in contact with the small lug of brass, H. The lug, H, is connected with the binding screw, B, by a short length of insulated wire passing up the back of the base (its course is marked by a dotted line). The lever connects H with its pivot, I, and this is connected with the contact post. To render the action clearer, I must first explain that a wire is carried from A to D at the back of the base, and is brought up through a hole at D, and there connected with one end of the magnet coil wire; the other end of the wire is carried down through a hole at E, and connected to the metal frame of the bell by the screw, F. As the frame and the armature spring are connected together at S, the result is the same as it would be were the wire connected direct to S.

Mayfield's Electric Alarum Bell.—Fig. 28 shows an electric alarum bell, fitted with automatic relay, as manufactured by Messrs. Mayfield, Cobb, & Co., 41, Queen Victoria Street, London, E.C. The interior fittings of the instrument are similar to those shown on the plan, Fig. 35; but the relay is neatly placed in a recess cut out at the back of the base, as shown at Fig. 33. The fittings are well made, and are mounted on a metal frame, fastened to a base of polished teak, whilst the whole is protected from dust by a polished cover, made out of the same wood. The bell has a 3-in. gong, highly polished and nickel-plated, giving a good tone when rung. The instrument may be worked with current from one cell of the Gassner battery, sold by the same firm. I hope to give a notice of this battery further on.

Dale's Electric Alarum Bell.—Another form of electric alarum bell, fitted with automatic relay on the same base, is shown at Figs. 29 and 30, which illustrate a bell manufactured and sold by Messrs. Dale and Co., 26, Ludgate Hill, London, E.C. Fig. 30 shows the instrument with its cover off, exhibiting the interior fittings and working parts. It will be seen that the relay differs in form from that of Messrs. Mayfield, and is attached to the face and frame of the bell between the gong and the magnet coils. It is composed of the peculiar shaped trigger, shown at Fig. 21 (page 280), mounted on the pivot pillar, Fig. 11. This pillar is connected by a short piece of insulated wire, passing under the magnets, with a strip of brass attached to the right-hand binding screw of the instrument. A short contact post is inserted in the neck of the metal frame near the gong, and insulated from the frame by a wood collar. The tip of the screw from this post is made of platinum, and this comes into contact with another piece of platinum soldered to the trigger, when this is drawn to the post by the spiral spring. This post is connected with the middle binding screw by a piece of wire passing up the back of the base. The hook of the trigger engages with a catch attached to the armature, shown at Fig. 20, when the bell is set with the relay as an alarum. The action is similar to that of Mayfield's relay when the circuit is closed.

Indicator Relay.—When a house is furnished with a complete system of burglar alarums, with every room protected by suitable contact pieces to the windows and doors, the owner naturally wishes to know how he may locate the room into which the burglar has broken. Having been aroused in the dead of night by the ringing of the alarum, must he arm himself and search the house from top to bottom until he finds the thief, or the thief pounces upon him? He need not do so if an indicator relay or a set of these relays are placed in circuit with the various rooms. A neat polished case with glass front, containing a set of relay indicators, may be hung up on the wall near the alarum bell, and a glance at this will tell at once which room has been entered, or which door or window opened. Fig. 31 shows a small case of indicator relays, manufactured and sold by Messrs. H. Dale & Co., Ludgate Hill, E.C., and Fig. 36 is a plan of one of those relays mounted on a base by itself. In this form it is used as a single indicator, connected with a greenhouse or conservatory, either with a fire alarm or a burglar alarum. In the plan, Fig. 36, it is shown connected to one of Mayfield's circular bells, and worked with one cell of a Gassner battery. I may say in passing, that this well-made, excellently toned bell is quite an ornament to any room. The nickle-plated 4-in. gong is recessed into a disc of polished walnut, the edges of which are raised as a moulding around the gong. The gong serves the double purpose of a bell and a cover to the fittings beneath. I hope to describe its construction in a future paper when dealing with the broader subject of electric bells; the price of this is 9s. 6d. I have sketched this, together with Dale's relay and Gassner's battery, to show that this valuable instrument may be used with any form of electric bell, and can be worked with small battery power. The combination shown in sketch worked very well.

To show more clearly how this relay works, I have given an end view diagram of its working parts at Fig. 32, and this I will now explain. At the right-hand side of the plan, Fig. 36, will be seen a black knob connected to a brass rod. The end of this rod carries a curved brass lever, curved round so as to rest just under the lower edge of the indicator flag, D; a short transverse lever at H serves as a stop to prevent the curved lever from falling too low. When we wish to set the indicator relay, we give the black knob a sharp turn to the right; this brings the curved lever up smartly beneath the flag, and jerks it into the position shown at Fig. 32, with the white part of the flag covering the hole in the indicator case. In this position it is held by a pin projecting from the armature, A, engaging with the upper looped guide of the flag shown at N. When thus set, and contact is made in the main circuit by opening a door or window, the current from the battery traverses the magnet coils, B, B, magnetises the cores, C, C, of the magnet, and causes them to attract the armature, A. In doing this, the pin of the armature slips away from the guide, N, and leaves the flag without support, when it slips down the slide, E, to the bottom. As it does this, a stout, projecting pin, P, strikes the end of the thin brass spring, H. and forces it to break contact with the spring, I, above it, at the same time bringing it into contact with the brass spring, L, below it. (Both of these are guarded with platinum at their points of contact to prevent burning.) When this happens, the coils of the indicator magnets are out of circuit, and the current passes by an easier path to ring the bell, which it does with more vigour since relieved of the resistance of the magnet coils. As the flag falls, its upper or red part covers the hole in the face of the relay case, and shows at once the cause of the alarm. Any number of these indicator relays, up to fourteen, may be included in one case, and each number plainly marked as shown at Fig. 31, with a number corresponding with a number given to each guarded point, or the openings may have the names of the rooms printed beneath them. The bell may be stopped by taking off the switch shown at Fig. 36. In Fig. 31 this lever switch is shown projecting below the case. Any one of the indicator flags, or all of them at once, may be set by a sharp turn of the black knob at the right. The cover conceals all connecting screws, and is screwed on after connections are made; this acts as a deterrent to domestics who may have a desire to meddle and tamper with the movements inside the case. The switch is only turned on the last thing at night, when all doors and windows should have been previously secured. Should one of these be left open, or unsecured, its indicator will at once fall, and the bell ring until the faulty point has been properly guarded. Arrangements to guard the various points will be considered in a future paper.

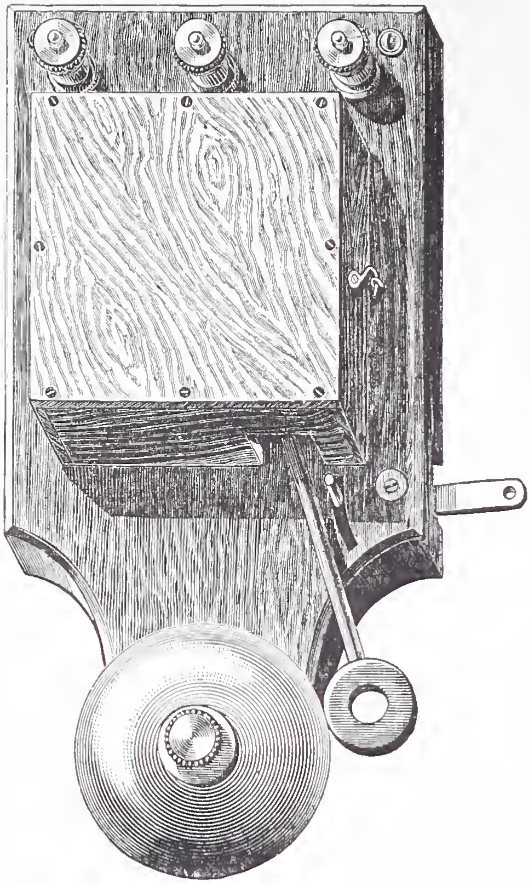


Fig. 28.—Mayfield's Alarum Bell with Automatic Relay.

Putting the Parts of a Bell together.—Supposing, now, that some of my readers have determined on making an electric alarum bell for themselves, and have got together the necessary parts mentioned in preceding chapters; we will next set about putting them together. But first let me say that each part must be proportionate; the metal frame suited to the base; the magnet coils and cores to the size of gong; the armature for the magnet; the spring of the right length and stiffness; and the hammer shaft sufficiently long to properly ring the bell. The relay must also be suited to the style of bell employed; but on this point much latitude of choice can be given, for the parts may be modified to suit each other. The right proportions for each part are given in pages 279 and 280, and most of the sketches of these parts are sketched full size to suit a 3 or 4-in. gong.

The metal base plate should have countersunk holes for the heads of the screws used in fastening this to the wood base; fasten this part on first. Next fasten the yoke of the magnet to the base plate; then attach the cores to the yoke, and slip the wound bobbins on the cores. Strip off the silk covering from the

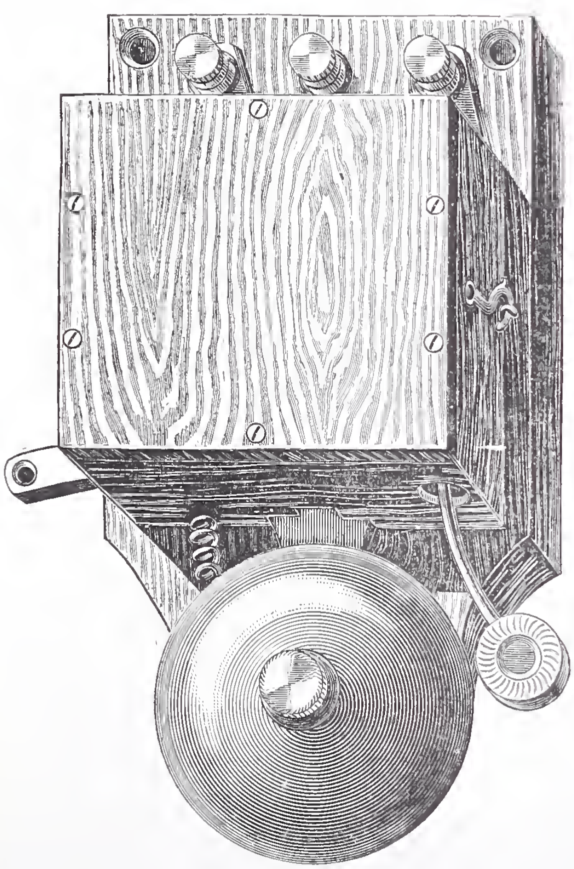

Fig. 29.—Dale's Electric Alarum Bell, Closed as when Fixed in Position for Use.

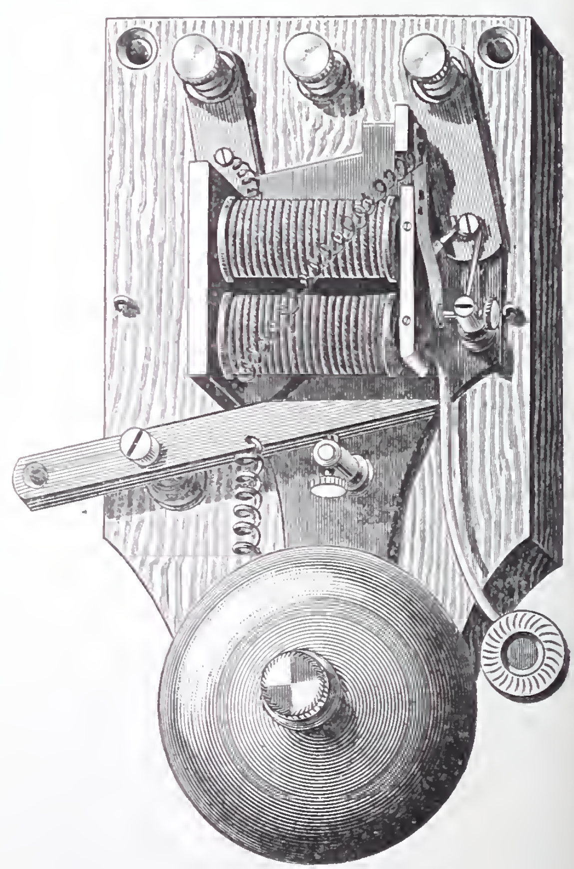

Fig. 30.—Dale's Electric Alarum Bell Uncovered, to show Automatic Relay and Working Parts of Bell.

inside ends of the two coils, clean the wires on a bit of emery cloth, and twist them together as a rope is twisted. Serve the outside ends of the coils in a similar manner, and attach one of these to the left-hand terminal, or binding screw, of the bell (see Fig. 35), and fix the other to the metal base plate or to the lug carrying the armature spring; in both cases with metal screws—clean metal touching clean metal. This done, fasten the armature to its spring, and this to the lug on the base plate by small steel screws or screw studs. The hammer shaft should be previously inserted in the end of the armature, and if the relay shown at Fig. 30 is to be used, the catch shown at Fig. 20 (page 280) should also be fastened to the armature before this is mounted in position. The contact

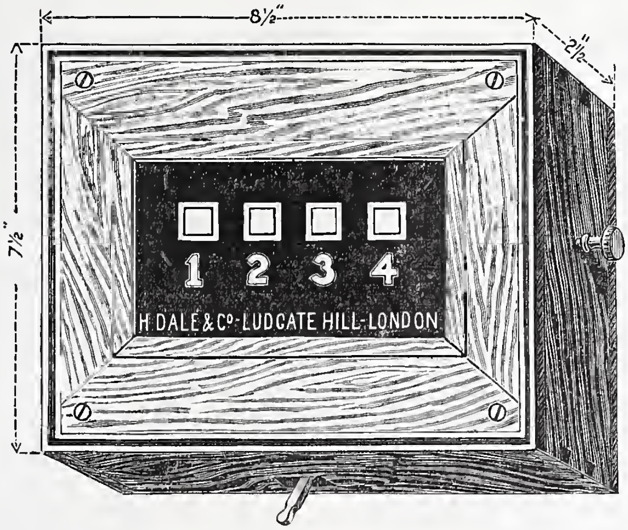

Fig. 31.—Dale's Indicator Relay.

The pin or the hook of the relay lever should not engage too deeply with the catch, but only just enough to hold it securely until the armature is vibrated with current from the battery. If it works too stiff the battery may fail to release it at the proper time, and if too tender it may be accidentally jolted into action. The right position can be found by actual practice.

Testing the Bell.—We may now set about testing our work. The three connecting terminals or binding screws, A, B, C (Fig. 35), having been screwed into the baseboard, the various wires are to be connected to them as shown in this figure, or in Fig. 30. It will be seen in both sketches that the central terminal (B, in Fig. 35) is connected with the contact post or piece of the relay; the right-hand terminal (C, in Fig. 35)

Fig. 32.—Plan of Side View of Working Part of Dale's Indicator Relay.

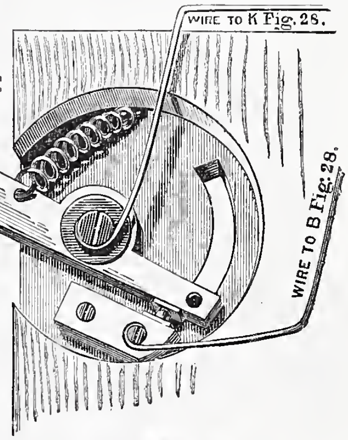

Fig. 33.—Back of Automatic Relay.

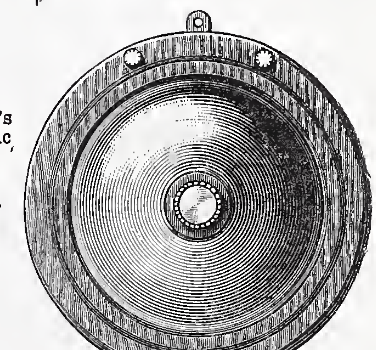

Fig. 34.—Mayfield's Circular Electric Bell.

pillar (Fig. 23, page 280) should now be placed in its place, and in doing this, see that the insulating collar (Fig. 22) entirely prevents the metal of the tang from touching the metal base plate. Next put in the gong pillar, and screw the gong in its proper place. Now proceed to adjust the various parts of the movement. The armature spring must be bent outward a little, so as to just touch the platinum tipped screw on the contact post, when the hammer is about a quarter of an inch off the side of the gong, and to be just a shade off from contact with the platinum tip when the hammer touches the gong. The various parts of the automatic relay may now be attached to the base with the same care as that used in fixing the other parts, and these must also be adjusted to work freely, and in unison with the movements of the armature.

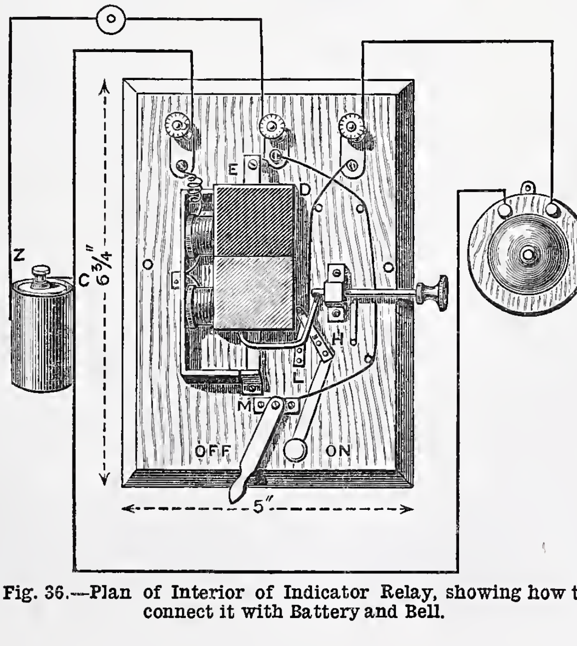

Fig. 36.—Plan of Interior of Indicator Relay, showing how to connect it with Battery and Bell.

is connected with the pivot post of the relay lever, and with the contact post (K, in Fig. 35) of the armature spring; whilst the left-hand terminal (A, in Fig. 35) is connected with one end of the magnet coil. All these connections may be made beneath the base of the bell, if so desired, to ensure safety from tampering, and for the sake of neatness. The wires are secured to the tangs of the various posts and terminals by small brass nuts recessed in the base, and the wires led along in saw cuts made in the back of the base. These recesses and cuts should then be filled up with paraffin or with elastic glue.

All parts having been connected, test the bell by trying to ring it with current from the battery. Adjust the contact screw of the "break," either by screwing it up tighter or unscrewing it, until the best tone is got out of the bell. If the armature strikes the magnet cores with a tapping noise as it vibrates, bend the spring a little outward so as to move it further away from the cores. If it vibrates feebly, bring this part nearer the cores by bending the spring inwards. It may be necessary to bend the hammer shaft a little, one way or the other, to ensure it striking the gong properly. The battery power used in testing and adjusting the bell should be the same as that to be used in working the bell. A weaker battery might just work the bell and a stronger prove too strong to ring it well, whilst it might ring well with a strong testing battery, but fail altogether with a feeble current from a weaker battery.

The Cover for the Bell.—As the working parts of an electric bell are very delicate, and liable to be injured by dust and damp, they must be protected from these by a suitable cover. This is usually made from the same kind of wood as that employed in making the base of the bell. It is really a little wooden box without a cover, turned upside down over the works. It is made out of ¼-in. wood, neatly put together with dovetail joints or mitred corners strongly glued, and is highly polished when finished. Holes or notches are cut to allow free working of the hammer shaft and lever of relay. The cover is secured to the base by two small brass hooks screwed to the sides, and engaging with two small brass staples fixed in the base. The top part of this cover is attached to the frame by small brass screws, in addition to glue, to give it greater strength; these screws are shown in Figs. 28 and 29. Two holes (bushed with brass eyelets) are drilled in the base close to the outside terminals, and the bell is hung by means of screws passing through these, or by pins, to a wall or a partition.

SADDLE BARS AND SAFETY STIRRUPS.

BY J. CHARLES KING.

The term "saddle bars," to attach stirrup leathers to saddles, is derived from the part of the "tree" which formerly held the stirrup leathers, the tree of a saddle being the wooden framework of a saddle, the "bars," one on each side, connecting the "pommel" and the "cantle" at front and back of "tree." This plan is still in use in some Continental and American armies for their cavalry.

Notwithstanding the improvements in much that pertains to horse gear, the saddle seems to remain much the same as it was a century or more ago in some of its leading points. A few improvements now and then slowly make their way to the front; amongst them are the releasing bars, or, as modified in form, "latches" have become the recognised term, as a spring is mostly used in the construction of them, to open and close a latch. In the hunting field this season, one lady and six gentlemen met their deaths by falls from horseback, and about six hundred were thrown, many of them receiving severe injuries; and it is stated that the accidents were to experienced horsemen and good riders, most of them young or in the prime of life. Some of the accidents were due to the riding habits worn by ladies catching in the pommel when they were thrown from their horses. The hinged pommel prevents this form of accident, or is supposed to do so.

The stirrup bars, or latches, are credited

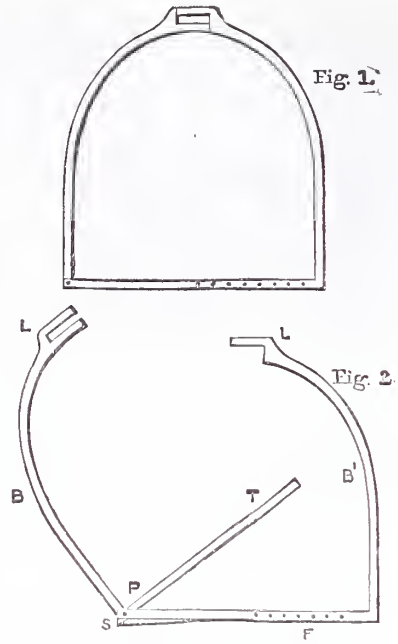

Fig. 1.—Stirrup with Joint at Strap-eye.
Fig. 2.—Same Stirrup shown half open.

with being the cause of many accidents, singularly enough from the very cause they are invented and patented for—"releasing a rider from the saddle;" but the patent goes on to state, "when thrown from the saddle, and preventing the rider being dragged by his foot in the stirrup." Now, being dragged by the stirrup holding the foot as in a trap is entirely prevented by the latch stirrup used by horse breakers and trainers for the past one hundred and fifty years; by the use of which the foot is released when hung up in it, without the chance of an instant's drag by it.

Fig. 1 shows such a stirrup, which, when

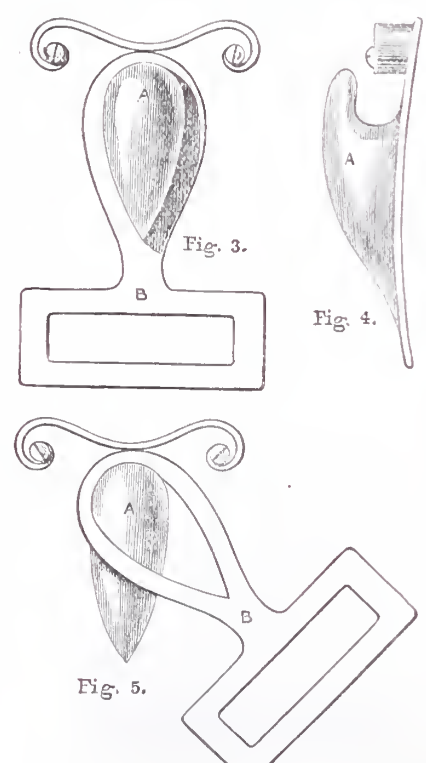

Fig. 3.—Stud (A), Cock-eye (B), and Spring for Stirrup Leather. Fig. 4.—Side View of Stud and Spring. Fig. 5.—Cock-eye pulled obliquely as when Rider is thrown or dragged.

new, does not show the opening joint at the strap-eye. In fact, it requires an expert to know if it is different from any other stirrup that does not open.

Why are they not general, as they suit for women as well as men? Simply because it is not the fashion; and many riders have little notions, easily swayed by their grooms and jockeys, about their saddle gear.

Fig. 2 shows the same stirrup half open; L L is an eye which is a jointed end of the stirrup bow, somewhat like a split ring, which gives the stirrup leather a release from the stirrup in case it is caught by a tree branch or a gate hook; this saves the saddle bar from being torn from the saddle, or the stirrup leather being broken. It will be seen that a portion of the tread of the stirrup, T, is solid with the bow, B. The other part of tread is solid with bow, B^1; this tread part is like the prongs of a tuning fork, between which the tread part, T, closes, and resembles an ordinary stirrup tread part, with its jags to prevent the boot sole slipping. The action is due to a pin at P going right through the prong-like ends of F, and the inner angle of the part that opens, F, B^1, L. As the bow gives way to the pull of the foot, the tread, T, rises and forces the foot free of the stirrup.

The actuating force which keeps the two halves of the stirrup close at the eye, L L, is a concealed spring, S, between the prongs of the tread, F. This is shown depressed at the point S, where it impinges with great force on the lower edge of the bow, B^1, at S.

We are pleased to hear that there has arisen a sudden demand for these stirrups, which cost about 18s. a pair of the best make; anything inferior should not be accepted. How is a buyer to tell? will be asked, and met with the usual advice, "Go to a good house and pay a good price." This is a poor assurance, seeing that the "good house" takes what the stirrup manufacturers offer; and if not good, the price becomes a fraud without the good house intending it. Here comes in the advantage, not of trade marks, but of grade marks, as of plate and swords, gun barrels, or any other thing capable of being tested. For about 2d. a pair a maker could get experts to mark the first, second, or third qualities to such goods.

But to return to saddle latches, which are desirable even with safety stirrups. We referred to accidents frequently occurring from the release of the leathers from the latches without the rider being thrown by his horse, but which caused him to be thrown by his faulty "latches" on his saddle. It would be only an advertisement to mention such, and they are numerous, and will be made and used till the simplest and best is found out and becomes generally adopted. What is known as the old spring bar is useful for a back pull, to allow the leather to come away from the saddle, but it is useless for a forward pull or overthrow pull across from one side of the saddle to the other.

A new saddle bar is patented about once a week in England, but they seem old patterns of worthless bars revived in too many cases.

The falls a man or woman get are not often serious if the distance the rider is thrown from the saddle is great. It is the short fall down from the saddle that is so dangerous, and the least hitch of the foot augments the force of the fall by the snatch turning the rider's head downward. Few of the latches serve for all kinds of falls. We illustrate one, as it embraces all that are of any worth, and has the advantage of being made at a lower price than any. The inventor, though patenting it with other saddle improvements, allows any lady or gentleman to have it put to their saddle by their own saddler, upon application for the permission. In this invention, the folding of the leather over the bar, which is the cause of breakage when worn, is entirely done away with; the leather is single half-way down to the stirrup; where it reaches the saddle it ends in a light nickel cock-eye, B, shown in Fig. 3; this hangs on to a notched stud, A, fixed to the saddle tree; a light cover spring, with bow and scroll ends fixed above it, holds the cock-eye down in the notch of the stud.

Fig. 4 is a side view of the stud and spring.

Fig. 5 is the cock-eye shown, being pulled obliquely as if a man were being flung out of the saddle with his foot in the stirrup, dragging the stirrup leather; a hard pull more obliquely is necessary to effect detachment of the loop from the stud. It is obvious that release is sure, whether the pull be backwards, forwards, or directly over across the saddle. If the sporting papers were to devote a little of their space to the records of faulty saddles and saddle bars that cause accidents, it might lead to the adoption of the safest to ride with, and save some valuable lives.

OUR GUIDE TO GOOD THINGS.

69.—The Rolymeter, or Automatic Measurer.

In the accompanying illustration a representation is given of a handy little instrument, to which the inventor and patentee has given the somewhat curious name of the "Rolymeter," from the principle of its action when at work—that is to say, the rolling of the wheels on discs that appear one at each end of the transverse portion of the appliance over the surface to which it is applied. As may be seen from the engraving, a short wooden handle, $4\frac{1}{2}$ in. in length, including the portion that enters the brass socket immediately above it, is attached to a cylinder of brass which is fixed to it in a direction transverse to its axis, and at right angles to it. The cylinder assumes an octagonal form at and along the upper part, so as to present three flat sides, of which the central and upper one is slotted along its length to permit a pointer to travel along it from end to end. The surfaces on each side of the slotted surface are engraved with figures from 0 to 10, which represent feet; the central part along which the pointer moves being divided into ten parts, which in their turn are subdivided into fourths. Thus, practically, the graduated scale along which the pointer passes is divided into equivalents of feet, each foot space being again divided into parts representing 3 in. Through the centre of the brass cylinder a screw-cut axis passes from end to end, and to its extremities are attached wheels or discs, about 1 in. in diameter, with milled edges. The screw works in a traveller, to which the pointer is attached, and at each revolution of the side wheels the pointer passes over a space on the graduated scale representing 3 in., or $\frac{1}{4}$ ft. Thus, it will be seen, the Rolymeter is possessed of sufficient capacity for the measurement of 10 ft., after which the wheels must be canted to revolve in the opposite direction for the measurement of the next 10 ft., and so on. It will be found useful for a variety of purposes in which linear and superficial measurement is involved, and its use will save much time. Thus, in estimating the quantity of paper required for any room, the height and circuit of the room can be quickly determined by aid of the Rolymeter, and the area to be covered ascertained. The instrument has been submitted to me by Messrs. Richard Melhuish & Sons, 85 and 87, Fetter Lane, London, E.C., who will doubtless soon have them on sale, if they are not at present actually in the market. The price of the Rolymeter is 4s. 6d.

70.—Cook's Patent Level.

Another handy appliance which I have lately been permitted to examine through the courtesy of Messrs. Richard Melhuish & Sons, is Cook's Patent Level, manufactured by Messrs. Davis and Cook, Watertown, New York, U.S.A. For constant use in a shop I know of nothing more handy than this instrument, which is a plumb and level combined, enabling the workman to test the level of horizontal surfaces, and to see that vertical surfaces are perfectly upright by a half turn of one and the same appliance. I regret very much that it has not been possible to give an illustration of it, but its form and dimensions will doubtless be understood from the

Automatic Measurer for Effecting Linear Measurements with Rapidity.

following description:—First of all, the body of the Patent Level consists of a piece of hard wood 16 in. long, $3\frac{1}{8}$ in. wide, and $1\frac{1}{4}$ in. thick. This wood is secured from damage and wear-and-tear at each end by a stout cap of metal, nickel-plated, and attached by three screws—one at the end and two at the sides—the metal being bent, so as to extend $\frac{3}{4}$ in. up each side. On each side of the wood two circular rebates are cut $2\frac{1}{2}$ in. in diameter, to receive nickel-plated rings rather over $\frac{1}{2}$ in. in width. These rings are each attached to the wood by three screws, and the centre of the rebate in each case is $5\frac{3}{4}$ in. from the end of the appliance. Within these metal rings are flat pieces of glass, which protect from injury the tubes which form the plumb and level. These tubes are placed in circular holes carried completely through the wood, the centre of the holes themselves and the centre of the circular rebate coinciding. The tubes containing the spirit and air bubble show a length of $1\frac{3}{8}$ in. to the eye of the observer, and are $\frac{5}{16}$ in. in diameter. They are set in a circular metal carrier about $\frac{1}{2}$ in. in width, which is fastened to the wood, in the case of the plumb, with strong brass pins; these pins, however, do not appear in the metal ring that holds the level. A ring is painted round the tube on its external surface to indicate the level or plumb, as the case may be, by determining whether the air bubble is exactly central or otherwise. On one side of the instrument is a metal plate, also nickel-plated, and attached to the wood with screws; and in this plate are also two screws each marked "Adjusting screw," which are used to keep the instrument in perfect truth. The tube which is used in levelling is set parallel to its length, and that which is used as a plumb is set transversely to its length. The inscription, "This end up," on each metal disc that holds the plumb in place and protects it, leaves no doubt in the mind of the workman as to which end of the instrument is really to be kept uppermost when using it as a plumb. Its price is 10s. 6d., which is not a high figure, considering its manifest utility. It should be kept ready at hand for the use of workmen in every shop throughout the country.

71.—Cheap Mathematical Instruments.

There must be many a lad just commencing work, and men too, for a matter of that, who are not able to go to any considerable outlay in the acquirement of a set of mathematical instruments who will be glad to avail themselves of some cheap sets of German manufacture recently brought into the market. The cases which are before me as I write are respectively $7\frac{3}{8}$ in. by $2\frac{7}{8}$ in. by $\frac{7}{8}$ in., and $6\frac{5}{8}$ in. by $2\frac{5}{8}$ in. by $\frac{7}{8}$ in. They are covered with paper, grained in imitation of morocco leather, and are lined with cotton velvet. They are fastened by a pin working along the front edge of the box for half its length, and entering an eye fixed in the front of the lid. The smaller box contains a saucer for Indian ink, a cake of Indian ink, a pair of compasses with pen and pencil points, a small case containing leads for the pencil point, instead of a pencil, and an appliance for tightening or loosening screw at head of compasses. In addition to these are a small set square and graduated 6-in. rule, both in wood, retained in places made for them in the lid by means of a brass holder or button. The longer case contains, in addition to the articles already named, a ruling pen and a brass protractor. They are sold at 3s. 6d. and 5s. respectively.

72.—"A 1." A Magazine for Family Reading.

Part 19 of this magazine, whose aim and scope are sufficiently indicated by the above heading, has been sent me by the publishers, Messrs. S. W. Partridge & Co., 9, Paternoster Row, who call attention to two instructive and pleasantly written articles by Mr. Frank Rede Fowke—one on "Furniture and Woodwork at South Kensington," and the other on "Mosaic, Fresco, and Mural Decoration at South Kensington." Both articles are appropriately illustrated: the first giving examples of a Roman bed, or rather bedstead, and of a mediæval bed and chairs, and an illustration of a writing-table used by the ill-fated Marie Antoinette, the wife of Louis XVI. of France. Reference is made to a curious doll's house from Nürnberg, about 200 years old, and the *cassoni*, or elaborately carved chests which contained the trousseaux, etc., of Italian brides, and linen for the households over which it was their destiny to preside. In the second paper the most noticeable illustrations capable of being utilised as patterns are a piece of Indian mosaic from the Taj Mahal, and a specimen of sectile work from Monreale.

I find that I have omitted to say that Cook's Patent Level is made in different sizes ranging from 16 inches to 3 feet in length, and, as a matter of course, the larger sizes will be found better suited for general use in workshops. Prices range from 10s. 6d. upwards, but the progressive rate in price is not in proportion to the progressive increase in length and dimensions generally. The actual rate of increase has not been supplied, and so I am unable to state it.

The Editor.

SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** NOTICE TO CORRESPONDENTS.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

An Appreciative Subscriber.—H. H. W. (*Blackheath*) writes:—"At the end of the year will you issue an alphabetical index to WORK? as I think it is well worth binding, and will be extremely useful as a reference. I fully appreciate its value; it explains everything so accurately and clearly that any one with the least amount of common sense cannot go wrong in following the instructions, and I sincerely hope that its circulation may increase more and more, as it will help numbers, and also show that the several articles by yourself and our other friends are thoroughly appreciated. I see in part for May 11th AN AMATEUR complains of the advertisements. How a disfigurement? It is only one little corner, and I have found the information extremely useful."

About WORK.—F. J. C. (*Brockley*) writes:—"Allow me to add my vote to those you have already received respecting the advisability of adding a cover to 'our' paper. I say 'our,' as I feel for my own part quite a personal interest in its success, and greet its appearance each Wednesday morning with joy. The suggestions *re* cardboard covers for the weekly issues are all very well for those who only look at the paper at home; but I for one have a copy as my constant companion in the train, and elsewhere, and by the time the week is over my poor WORK is in a sad state about the corners where it has been doubled to go into the pocket. Now, a cover would certainly be a great protection; it would help to keep the paper for binding after being read, and would do away with the necessity of binding all the advertisements with the volume. A paper cover would also have greater space for the advertisements, which would more than pay for the extra expense involved in its adoption."—[A contributor to WORK, when with me the other day, told me that he always bought two copies of WORK, one for daily use at the time of publication, and the other to be put away for binding. As WORK is issued at a very low figure, and contains an amount of technical information that cannot be found in any other paper, I venture to suggest this course for the adoption of yourself and others, who wish to preserve WORK entire and intact for binding. It is impossible, as I daresay you know, to eat your cake and have it too.—ED.]

About WORK.—ALEXIS writes:—"It was with great disgust that I read the tirade of J. P. A. in the issue of June 8th, and with your permission I should like to have a cut at him. He seems, from his letter, to think that all the information and instruction promised in the prospectus was to be found in the first number, and because he found nothing to suit him condemns the whole thing. How selfish to complain because full instructions are given to make what he calls trifles, or to expect that all articles, whether cabinet making or anything else, are to be written up to the level of the professional. I flatter myself that in my own trade I am as good as the next man, but I expect to learn something from WORK, and I reckon that J. P. A. will, too, if he continues to take it in. Then with regard to his advice to the editor to follow on the lines of the 'Technical Educator,' and Dr. Dresser, and Professor Church, and so on, I fancy that for every one subscriber gained of the J. P. A. kind there would be fifty leave it off. The *English Mechanic* is a good paper, but I am prepared to maintain that hundreds abstain from taking it because it is too scientific, and takes up too much space in discussing what I call fads, and though a subscriber to it for years I prefer WORK, and I say long may it prosper, which I believe it will, in spite of the grumbling of a dissatisfied few."

Building Construction.—F. W. L. (*Norwich*) writes:—"I have pleasure in stating that I take the weekly numbers of WORK by Messrs. Cassell, and have done so from its commencement, and can truly say it supplies information which has long been a want felt among our artisans in the building trade. I have read with interest the remarks of W. P. and A. E. D. (why don't they sign their names in full?) with reference to building construction in WORK No. 13, and quite agree with them that it would meet with the great approval from many artisans, who, like myself (a bricklayer), wish to live and learn, but are debarred by excessive charges of art classes, and the dear rate of papers connected with the building trade. I wish your paper every success, as I know that Messrs. Jarrold in this city have a good sale for it."

An Opinion on WORK.—CENTRE BIT (*Tullow*) writes:—"I like WORK very much; it is a very useful paper. I am an amateur carpenter, and it is a great help to me, and by its aid I have turned out several very nice pieces of furniture described in it, viz., one of the small tables in No. 1, and the summer fireplace fitment. As a hint to other amateurs like myself, I enamelled it in Aspinall's electric blue, and then painted several of the Japanese designs in japan."

Fret Cutting.—A 'PRENTICE JOINER (*Glasgow*) writes:—"I enclose you two simple patterns which may meet with your approval, and others. I take a piece of white cartridge wall paper, lay it flat on top of pattern, get or take a flat piece of cork, or other soft wood, a piece of common upper shoe leather, 3 or 4 in. square; apply it to the cork as you would a square of sandpaper, rub back and forward on the top of the paper, and you will have a correct copy. Afterwards glue or gum it to the piece of wood you wish to cut it from."

Wrought Iron and Steel Girder Work.—H. W. (*Oakworth*) writes:—"I was rather surprised at FEN MON expressing a hope that the paper on this subject should be discontinued. I assure him that this subject is well worth the room that it occupies. Though I am not in the trade I shall follow it till its completion. I wish all success to the editor and staff for all the subjects they are taking under hand."

About WORK.—A 'PRENTICE JOINER (*Glasgow*) writes:—"For the first time your paper last week caught my eye. I bought it, and after perusing it I must say it is a valuable little paper for all classes of workmen, especially mechanics and young lads of the rising age; and by them carefully perusing it now when mind and memory are free, much could be learned and committed to memory, which would prove of incalculable value to them in after years, and a well-spent penny weekly. For as books so are papers judged, not by their covers, size, or number of pages, but by their contents. So, again, I wish your paper every success, and after this be able to have my penny always at hand and eye ready for your next coming issues."

Men Worth Knowing.—HELP EACH OTHER writes:—"I should like to add my share of praise as to the usefulness of WORK, and must say I look forward to each Wednesday for a pen'orth of something fresh, and am never disappointed; if not exactly my hobby I always pick up some wrinkle, and though an old amateur joiner, etc., am always open for improvement. May I venture to recommend two makers with whom I have been in the habit of dealing? One of these is Mr. Massey, of Spalding, from whom you can get a good new 3-in. slide rest for 35s., and very well made. Doubtless, many readers, who, like myself, have their hobbies, will be glad to hear of such a cheap and good maker as I have found Mr. Massey to be. I should also like to recommend C. Pool, Hockley, Nottingham, as the cheapest and best maker and dealer in tools I have come across. I enclose my business memo., and can assure you I have not the slightest interest in either of these people, further than having had goods from them, and found them very good, and 20 per cent. cheaper than most people from whom I have had lists."—[Thank you for your letter. I am always glad to give the names of cheap and good makers. I have been compelled to omit part of your letter. You know, doubtless, what Mrs. Malaprop said about comparisons.—ED.]

Chamfer Plane.—J. W. (*Burton-on-Trent*) writes:—"In page 61 of WORK I see you give a description of a chamfer plane sold by Melhuish and Co., but you omit to describe one of its chief advantages, that it not only works the chamfer but cuts the stops. I made one myself about two years since from a working drawing published in the *Carpenter and Builder*, and can highly recommend it, for it saves quite half the time spent in the ordinary way, and cuts a nice clean stop, which is one of the chief points with a stop chamfer. If you like to insert this in 'Shop' it may induce some brother chips to become purchasers of a tool that I am sure they will prize. I wish every success to WORK."

Wrought Iron and Steel Girder Work.—BOILER MAKER (*Liverpool*) writes:—"I am surprised that FEN MON should show himself so selfish as to express a hope that the paper on 'Wrought Iron and Steel Girder Work' should be discontinued. I have been taking in your paper since the first number was issued, and have been very much interested in all papers relating to wrought iron work, and I sincerely hope you will continue them. Also give us a little on boiler making and iron shipbuilding. There are plenty of subscribers in Liverpool who would be glad to read them. I may say I am deriving great benefit from your 'New Popular Educator.'—P. S. Excuse writing, as twelve months ago I could hardly write my name, and what I know now I owe to Cassell's papers."

Oil for Watches.—J. T. (*Birmingham*) writes:—"I see in WORK No. 15 reference is made (in 'Shop' column) to watch and clock oil. I quite agree with your correspondent that Kelly's oil is an exceedingly good oil. But it is capable of improvement—viz., by mixing with another make of oil. At our works we use a deal of oil, and after repeated trials the best oil for watches (clocks I have never had much to do with) we find to be a mixture of Kelly's and Stretton's. Proportions, three bottles of Stretton's to two of Kelly's. It is extremely important that watch oil should be of the very best quality, as all in the trade know, and while each of the oils mentioned is good, mixed as above, they are all that can be desired, and if your inquirer will try them I feel sure he will endorse this opinion. Allow me, Dear Sir, to add my thanks for your excellent production, WORK; it is the best paper I have ever met with. I wish you every success; you deserve the thanks of every mechanic, and I feel sure you have the thanks of all who know of your paper. We quite look for it week by week here. I hope soon to see some articles on the various branches of watch making; they would be very welcome in our works, I am sure."—[Articles on watch repairing are begun in this number. They will form the stepping-stone to papers of an advanced character for the professional workman.—ED.]

Violin Clamps.—WREN (*Glasgow*) writes:—"I am glad to see that some of our violin makers are walking into the 'Shop.' I see in page 222 of WORK that J. G. writes to E. P. W. on fiddle clamps. I say, with him, that it is a cheap method of making them; but I cannot agree with him in saying they give satisfactory results. If J. G. has no way of fixing his top piece of wood to the head of the nail, what is the outcome? It is this: if the bottom piece be the least tight round goes the nail with it, and where are you then? It is thirty-two years since I put a fiddle together with the same sort of things; but the way I screwed them up was with a screwdriver. They have more faults than that after being used some time. I have got the back and belly of a violin made, and working at the corner blocks and handles. This time if I can get screw nails to fit I will try another plan by running the top piece of wood hard up to the shoulder of screw; it will hold tight enough for all the pressure you need put on the lower piece of wood. The screw on the nails will require to be $2\frac{1}{2}$ in. long. If they cannot be got I will fall back on the nails I have, and file off two sides of the head, then sink them into the top piece of wood, and fill up with glue and sawdust to hold them fast. There is a short article on fiddle making by H. P. in the *Boy's Own Paper*. He gives a drawing of a cheap substitute for fiddle clamps. It appears to be a piece of wire with a knob on the end of it; it is screwed up to the knob. There are two round pieces of wood; one is screwed up to the knob, the other on the point. He calls them shutter screws. I have been looking for them, but they know nothing of them in Glasgow."

Classes in Handicrafts.—H. N. (*Kingston-on-Thames*) writes:—"I have had sent to me a copy of your paper, WORK, for June 1st. Allow me to state I was very pleased with it, and I have every sympathy with the effort you are making to extend a real and practical interest in such subjects. I wish to ask your advice, for I can imagine that from your position and your experience you and members of your staff would be fully able to give it me; or, if you think better, would you put my case in those useful columns at the end of your paper, where those who want information ask for it? My case is this. We have a club here for young men—many of our members are of a right, good sort—and we can count upon a certain amount of financial support; we have too certain offers of personal help from practical men. In this club the committee are anxious to arrange classes in handicrafts—*e.g.*, carpentering, brasswork, moulding; but we are rather shy of making experiments in the dark, for we are not practical men, and the first expenses seem very heavy. Can you, or any of your staff, or any of your readers, give us any directions how to make a start, or tell us of any place or institution where, in a small way, such classes are worked with some success? I must apologise for troubling you. I can only say your paper suggested to me this idea of seeking your advice."—[I think it to be the better course to give publicity to your appeal in this section of "Shop." I do so in the expectation that some reader of WORK who has taken part in the establishment of such classes will write a paper describing the course of action he himself has taken, and the results of his experience. Such a paper cannot fail to be helpful to many who may be seeking to establish technical classes in town or country during the winter months.—ED.]

On Trial.—E. Y. (*Liverpool*) writes:—"I cannot tell you how pleased I was when I first saw your advertisements of WORK, or how anxiously I waited for the first number to come out. I have taken in several of your publications, from the first 'Popular Educator,' onwards, and was always well satisfied; so much so, that when I heard of WORK, I said, 'Why, here's the very thing I want.' I am always trying to find out something I can make at home in my spare time, and, so far, I have succeeded very well, being rather handy with tools of all sorts; but I am sorry to say WORK does not come at all up to my expectations, yet I can't very well say why. Anyhow, I am going to take in the first volume, and hope by that time to like it better, or be able to state my reasons more definitely; but at present I see so many letters speaking well of the paper that I am afraid there is something wrong with my judgment. At the same time I wish you every success with your new venture, and hope it may at least be a means of encouraging men to work at home and keep out of public-houses. I may just mention that I have lately bought a small lathe and fitted to it an arrangement for fret sawing, entirely my own idea, which will take in either fret saws or frame saws up to 9 in. long, and table wood up to 2 ft. square by $\frac{3}{4}$ in. easily, and truly square on edge. Some time I will try and let you know how I have done it. I hope you will excuse me if I have taken up too much of your time."

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Advertisement Pages.—A WELL-WISHER OF WORK (*Kirkcaldy*) must kindly accept the reply given to AD FINEM, page 263, as an answer to his communication.—ED.

Clocks.—G. H.—(*Hetton-le-Hole*).—By sending your business card to Grimshaw & Co., 35, Goswell Road, Clerkenwell, you can get their illustrated price list of everything; or from Morriss Cohen, Kirkgate, Leeds, from either of which you could get most of what you require; while for clock wheels and parts you can't do better than J. Mayes, 55, Red Lion Street, Clerkenwell, of whom I get all wheels, castings, forgings, etc., for all the clocks we make.—A. B. C.

Mixing Plaster of Paris.—A SUBSCRIBER (*Birmingham*).—For ordinary casting plaster is always mixed with water. In waste moulding, the water for the inner mould should be tinged, and nothing is better for this purpose than common black ink—a few drops will suffice. It is well when thus tinging water, as also when colouring it with yellow ochre, Prussian blue, etc., for tinting an actual cast, to thoroughly mix the colouring matter with water in one vessel, and pour off into another for use, so that no sediment may be allowed to go into the plaster.—M. M.

Composition.—A. W. (*Great Yarmouth*).—The price per column of news (14 ems brevier), including distribution and corrections, is 8½d. per 1,000 ens. The cost of a column would depend on its length, which is not given in the question.—J. T. P.

Automatic Application of Brakes.—C. J. W. (*St. Mary's, Beccles*).—Your invention is simple and ingenious, and with properly-formed levers would work satisfactorily. The levers must be so shaped as to be actuated without concussion, but this detail you would settle before drawing your specification. Before applying for a patent I should advise you to have a careful search made to see if you are anticipated, as there have been so many patents granted in this connection that this question cannot be answered off-hand.—F. C.

Instructions for Making a Model Locomotive.—A CONSTANT READER (*Dublin*).—Your best book would be Pocock's "Model Engine Making," 2s. 6d. (Sonnenschein & Co.).

Circular Saws.—A. R. (*Scorrier*).—Those who criticise an author should be at the pains to ascertain his meaning. A. R. takes me to task *re* my article "The Saw: how to use it," page 162 of WORK, saying, I "am of opinion that himself (J. H.) nor any other man ever saw a hand saw with teeth as shown in Fig. 6, if so, I am confident that no man, let him be ever so skilled in the working of the hand saw, could work it either in soft or hard wood with rake there given." Now it so happens that I said the same thing, but in other words. I was comparing cutting action with that of scraping, and the words I used were, "It will be noted that the rake of the teeth" (the hand saw teeth in Fig. 1) "is such that there can be no true cutting action. For the teeth to cut truly they would require to be formed with a good deal of rake, as in Fig. 6. But the quantity of rake thus represented would unfit a hand saw for general work. Actually, then, the hand saw teeth are in principle an assemblage of scrapes, and as such they have little penetration."—J.

Bordering for Garden Paths.—T. H. C. (*Maidstone*).—It is difficult for me to say what would be the *cheapest* bordering for garden paths in your locality, because I do not know what local material may be available there. Edging tiles and cement coping in lengths are certainly expensive, and liable to be broken if spade or roller come in contact with them. A wood edging is not costly, for if you use 9-in. boards and rip them down the centre you will get 24 ft. run out of a board 12 ft. long, and the edging will be 4½ in. deep. If you use 6-in. floor boards, ripped down in the same manner, it would be even cheaper, if you can content yourself with a 3-in. edging. In Devonshire, the stone of the country, which readily splits into thin layers like

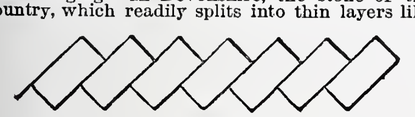

Fig. 1.

Fig. 2.

scales, is largely used; and slates themselves may be utilised in the same way; but to you, in Maidstone, they would prove an expensive mode. Flints from the chalk carefully set in the soil form a nice edging, though they are liable to get disturbed, and present a pretty appearance when backed by aubretia, yellow or white alyssum, or any dwarf-growing plant. Box, I think, is as pretty an edging as any, its only fault being that it often affords a harbour for slugs, especially the small greyish-white slug. If you can get hold of a number of old bricks and have the mortar that adheres to them cleared off, you may make a good edging of them by setting them on end in the soil in a slanting position, as shown in Fig. 1. Again, a rustic edging may be made by obtaining a number of sticks, such as are used for staking dahlias, hollyhocks, and kidney beans or scarlet runners, cutting them into lengths, and stringing them on wires, as in Fig. 2. In this the sticks are disposed alternately in long and short lengths, but other forms may be produced. At intervals—say, from 12 to 18 inches—a long stick sharpened at the end should be introduced, to be driven into the ground to impart steadiness to the edging, and the intervening sticks should be long enough to be buried, say, to half their depth in the soil.

Galvanic Battery and Shocking Coil.—A. S. (*Falkirk*).—An instrument for "trying the nerves," as you express it, by sending through them a current of electricity, is named a "shocking coil." It is made up of a short coil of covered copper wire wound on a bobbin furnished with an iron core. Outside this coil is wound another very long coil of fine, covered, copper wire. The current from a galvanic battery is sent through the short coil and made to pass by way of a breaking apparatus or interrupter, which causes the current to go through the coil in jerks and spurts. These are transmitted to the outside long coil of wire, and sent by it through any part of the human body placed in contact with its two ends. The sharp jerks or tremors sent through the nerves are said to "try" them, because only those persons with a strong nervous system can suffer them to be thus shocked. A full description of this instrument would be too long for "Shop." If readers desire such a description, I will try to prepare an illustrated paper on this subject.—G. E. B.

Cracked Piano Sound-Board.—F. K. (*Hinckley*).—The reason your piano sounds thin from E? to B?"' is not because of the crack in the sound-board, but that your sound-board has sunk, and probably caused the sound-board to split. I expect it is weak just under the bridge, or it has had too much down pressure on it. You will have to strengthen it. Take out the backing material which is tacked at the back of your piano. Now you will be able to see the damage. Make some feather-edged pieces of soft wood and glue them in the crack as well as you can; then level it off; it will be rather awkward for you, as you will find the uprights in your way, but with patience you will get over it. Now, where you can get to it, glue and screw, with small screws, some pieces of wood 3 in. wide over the back of the bridge where it was split; use thin wood, such as is used for cocoa or blacking boxes, that you can obtain at some shop in your locality. Having done this, get three or four large corks—such as are used for quart bottles—and where you found the tone thin, cut the cork so that you will have to press it tight between the uprights and the sound-board—the tighter the better. This will have the effect of raising your sound-board up, and restoring the tone. Put one cork to every upright in the line of the crack. It would be better to do this after your pieces of wood have dried a day. It would assist me much in giving answers about pianos if the writer would state what kind of piano it is—cottage, square, or grand—maker's name, and whether new or old, wood frame or iron, as I wish these answers to be as complete as possible. If you would communicate the result to the editor it might help some other reader.—T. E.

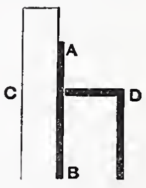
Application of Reeds to Pipe Organ.—J. C. (*Cannonburgh*).—There are many objections to the method you suggest of fixing harmonium reeds in the sound-board channels of a small pipe organ. One of the most important points to be considered, in order to make a harmonium reed speak properly, is its distance from the pallet hole; for instance, C' must be exactly opposite the hole, and not more than ½ in. below it; pitch C should not be more than an inch away from the hole, and half an inch below it; and 8 feet C should be about its own length distant from the hole, and 1½ in. below it. Now, although your idea is to reverse the usual system, by having the reed above the pallet, it would still be necessary to keep the same relative distances between them. And then again, how would you manage to turn them? If you have made up your mind to adapt a set of free reeds, by all means let them have their own pan, and separate pallet action. I cannot suggest a method of doing this without knowing how your organ is constructed. If you will send a small sketch showing a section of the key, sound-board, and pallet, with position of bellows, I may be able to help you.—G. N.

Restoring Piano Keys.—H. W. (*Sheffield*).—The method usually adopted for restoring the colour of ivory piano keys is by planing, scraping, and polishing; but as I presume our reader may not be possessed of the necessary tools to accomplish it in this way, I must simplify the procedure. Raise the top of piano, draw forward the door containing the fret or panels, then you can raise the part which covers the keys; take this out, also a slip of wood which lays behind the keyboard. Having done this, you raise the key up, until it clears the pin in the centre; then draw the key forward. It would be as well to try a few at first and see the result. You will find them worn more in the centre of the piano, as it is used more; be careful not to rub through the ivory. Get 4 sheets of 1½ glass paper, also 4 sheets of 1, also 4 sheets of 0. Now lay these on a level table, or bench, take the key in your hand, and rub it on 1½ first, and then on the other two sizes of glass paper. This will take the scratches out; as you rub, give it a rotary motion; you will see it come whiter as you rub it; now serve the remainder in the same way. Now, to polish them you will require a piece of wood about 3 in. square, and wrap round it a piece of white flannel. Now get half a gill of methylated spirits, rub some whiting on your rubber, and sprinkle the spirits on, until it forms a rather moist paste; then rub to and fro quickly until you see the polish; now clear off all superfluous whiting with a damp cloth and wipe dry. Having done this through the set, take a little tallow candle and rub on the palm of the hand, and rub the ivory sharply; then rub with a soft cloth, and your keys ought to be white and polished. I should be pleased if you would communicate the result of your work.—T. E.

Reed Holes, etc., in American Organs.—S. M. (*Croydon*).—You cannot purchase American organ reeds separate from the board into which they are grooved; and even if you could do so, it would be impossible for you to make the reed board, as the boring of the cavities can only be done by very costly machinery. Both the reeds and reed boards have to be imported from America, for there are no makers of them in this country. They can be had in several sizes, the largest of which contains four 5-octave sets—viz., one of 16 ft., two of 8 ft., and one of 4 ft. pitch, and these are arranged so as to work with one pallet. 2-ft. reeds can be obtained by special order to the makers, but are not carried beyond top F. Very few makers of organs use them, as the effect produced is certainly not worth the extra work entailed in putting them in. It is difficult to give the size of the "exhauster" (erroneously termed the bellows) sufficient for 8½ sets of reeds, without knowing something of the instrument for which it is intended. To make a rough calculation, each primary exhauster should have a wind capacity of about 2,200 cubic inches, and the size necessary for this would be 2 ft. 4 in. long by 1 ft. 8 in. wide, with an opening of 8 in. at the widest part. The wind capacity of the reservoir should be nearly double that of each primary exhauster. I can supply you with a reed board, containing unvoiced reeds, at the rate of 10s. 6d. per 5-octave set.—G. N.

Making Electrical Dynamos.—H. E. A. (*Hackney*).—Electrical dynamos are machines for converting the dynamical force generated in any motor into electricity. Such a machine is furnished with two large iron electro-magnets wound with coils of insulated copper wire. These are named the "field-magnets." In their field—that is, within their influence—is caused to revolve a cylinder, or ring of iron (named an armature), wound with another coil of wire. The ends of this coil are fixed to a commutator, which arranges the current of electricity set up in the armature, and sends it around the coils of the field-magnets. The current is taken off from one end of the field-magnet coils and one of the brushes of the commutator. This, briefly, is a description of "the construction and action of an electrical dynamo." Doubtless it is valueless for the purpose you have in view. To understand how to make a dynamo you will have to read a long series of articles, or a book, on the subject. I can recommend to you Mr. Bottone's book on "The Dynamo: How Made and Used."—G. E. B.

Summer Fireplace Fitments.—KILDONAN writes:—"I am at work on the summer fireplace fitment described in No. 9 of WORK. Can you give any suggestions as to the construction of a fitment, equally substantial and tasteful, for a fireplace where the ribs of the grate project beyond the stone jambs and lintel, and the mantelpiece is not a plain pilaster structure such as his design shows? It is an old-fashioned affair, though elaborately ornamented, the pillars being very light, and shaped something like the architraves round a door or window, while above the lintel there is a series of alternate friezes and mouldings up to the shelf itself, which forms the finishing member of the topmost moulding. I cannot specify it as an architect would, but it is not suited for taking in a frame like that shown."—[I know precisely the kind of grate you mean. You can use the design just as it is given, and hide the gap caused by the projection of the bars of the grate by strips of wood of the proper width nailed to the edges of the top and sides of the fitment, thus boxing in the grate. To ensure stability in the fitments, I think sheet metal hooks, of which a side view is given in the annexed diagram, should be screwed on to the cross piece that holds the bracket, to hook over and on to the topmost bar of the grate. In this, A B is the plate to be screwed to the cross piece; C, shown in section; and D is the hook.—ED.]



Polish for Cedar, etc.—H. A. (*Batley*).—French polish is generally used as the finish for these woods. It may be made by dissolving shellac in methylated spirits—say, 4 oz. of the former to each pint of the latter. Bleached shellac should be used if white or colourless polish is wanted. Mahogany and open-grained woods should have the grain stopped by rubbing in a filling of some kind. Whitening and turpentine with a little colouring matter—such as rose-pink for the woods you name—to match the wood, is a very good one. To enrich the colour, the wood is generally oiled with raw linseed oil. The polish is applied with a rubber of cotton wool enclosed in a piece of soft rag, the finish being obtained by lightly using a rubber moistened with spirit only. Pencil cedar does not require any filling. This is an outline of the process, which, I hope, may help you. To give details would occupy more space than can be devoted to any subject in these columns; but, as you will have seen from answers to previous inquirers, a series of articles on French polishing, etc., will appear as soon as practicable in WORK.—D. A.

Polishing Dining-table Top. — W. H. B. (*Peterborough*).—The dead surface is produced by oil polishing. The process simply consists of rubbing linseed oil, and polishing with a soft rag. The oiling and polishing must be continued at intervals till the requisite shine is obtained. To get the best results takes time and friction. Oil polishing is not difficult, but it is decidedly fatiguing and tedious. The more the surface is rubbed the better, and the process may be extended over some weeks. —D. A.

Screw for Wooden Copying Press.—COPYIST.—You ask for "some simple method for making the wooden screw" for the copying press described in WORK by Mr. David Denning, "and the threaded block through which the screw revolves." The simplest method for you to adopt, and the best one too, is to buy one of any ironmonger and dealer in tools who keeps such things. You would get one for 2s. or 2s. 6d. These screws and the blocks in which they work are cut by what is called a box and tap, which would be costly for you to buy for the sake of cutting a single screw. You give me no clue to your place of residence, but if you live in a large town you might pick one up cheap among the odds and ends of some marine store dealer.

Hatching Machine. — G. P. (*Birmingham*).—I note your request for instructions for making a "hatching machine," or incubator, as it is generally called. At present the pressure on my space is too great to enable me to give a paper on it promptly, and it must form the subject of a paper, or even two, for it is not possible to deal with it satisfactorily in "Shop." Perhaps this reply will bring offers to write on the subject from some reader who has taken the task in hand for himself.

Subjects for Work.—W. H. A. (*Gorton*).—For "Design in Textile Fabrics" you could not have a better work than the book of that name, by Mr. T. R. Ashenhurst, published at 4s. 6d., as one of the series known as Cassell's Technical Manuals. I am waiting for promised papers on the spinning wheel and simple hand-loom, as these are wanted in some of our Colonies. Then possibly we may go on to higher subjects in this direction. I cannot make any promise about oleographs and chromographs. If you want any special information with regard to their production, if you will state your difficulty I will endeavour to get it answered. I do not think it desirable to enter on the feeding and rearing of silkworms and their treatment, as there is no likelihood of the production of raw silk being attempted in this country on a large scale. It was tried, if I remember, some years ago, and the worms were fed on the leaves of the Ailanthus. Silk manufacture is different, but if I begin too many subjects at once, one will stand in the way of the other.

Watch and Clockmaking.—R. D. (*Rathgar*).—Papers on this subject will be found to be commenced in the present number. No specific promise of papers was made in the preliminary prospectus of WORK. It was only sought to give a list of the chief trades relating to which papers would be given at sometime or other.

Sheet Metal Working.—ST. MUNGO.—You will have noticed that a beginning was made in "Sheet Metal Working" in No. 17 in the paper contributed by Mr. Robert Alexander. Instructions will be given independently of these for the manufacture of fern cases, aquariums, etc. It is well to take care of the numbers of WORK, as the Magazine will constitute a valuable reference encyclopædia for workmen of all trades. I am not acquainted with any book that deals exhaustively with sheet metal work.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Book Machine.—J. M. F. (*Dublin*) asks:—"Could any of your correspondents inform me where a machine could be had which would make an ordinary book rim with a single stroke?"

Rickety Table. — A. J. T. (*Holborn*) writes:—"Could you advise as to cure of above? It is a substantial two-leaved dining-table on castors. The legs screw on and off. If you happen to knock against it at tea 'over goes the show.'"

Model Engine.—W. H. M. (*Nottingham*) writes:—"Will some reader of WORK say if it is possible for an amateur to make a small gauge for model engine boiler about $1\frac{1}{4}$ dial, and to register about 30 or 40 to the square inch? If so, kindly describe its working parts."

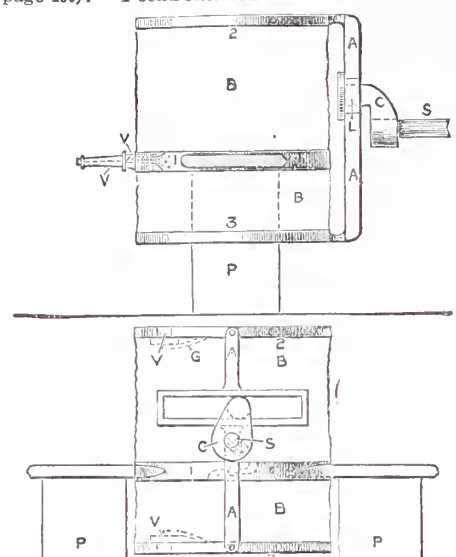
Paint on Leather. — J. B. S. (*Nottingham*) writes:—"Would a correspondent inform me how to prepare leather to receive paint, or how to prepare paint to put on leather, so that when the bag or portmanteau is in use it will not crumble off?"

Illuminating. — H. C. (*Lincoln*) writes: — "I wish to know how to illuminate upon parchment. Is there a preparation to apply to the surface before working upon it? I have been using ordinary moist pan colours; they are not sufficiently brilliant. I have also used the gold and silver in shells, but these are not satisfactory. I shall be grateful for help."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Joiners' Composition.—A. F. W. (*Upper Tooting*) writes in reply to F. B. (*Guernsey*) (see page 158):—"I forward a well-tried recipe—viz., melt in a tin in the oven, or on top of a stove, 2 oz. shellac, 1 tea-spoonful resin, a piece of beeswax, size of half a walnut. When melted add any dry colour to match your wood, then pour out a little on a board and roll out in sticks like sealing wax. To use get a piece of iron or an old file, hot, not red hot; hold the end of one of the sticks over the crack or hole, apply the iron, and rub the stopping well in. Clean off with scraper and glass paper."

Machine for Current of Air.—C. H. (*Birmingham*) writes in reply to BELLOWS (*Gloucester*) (see page 190):—"I send enclosed sketch of machine of



my own invention, hoping it may be of use to your correspondent BELLOWS. 1 is a circular board which forms an end of each bellows; this board is stationary. 2 and 3 form the other ends of the bellows; S is the revolving shaft on which a crank, C, is fixed. The crank pin works in a grooved piece of iron, L, and as the crank revolves this is lowered or raised. Attached to this are two arms, A A, one fastened on each of the ends, 2 and 3. Then as one board is raised, the other is lowered, producing a constant stream of air. The nozzle is divided, and a valve placed in each side, so as to prevent the suction of one bag taking the air from the other."

Cleaning Oil Paintings.—C. H. (*Birmingham*) writes in reply to L. S. (*Lower Broughton*) (see page 190):—"I may state that hydroxyl (a compound of hydrogen and oxygen, which may be obtained of the principal chemists) will clean oil paintings, without injuring the colours, and restore them to their original freshness. The oxygen of the hydroxyl oxidises the lead sulphide (the blackening material) into lead sulphate, which is white, while all the original colours remain unaltered."

Blue Prints.—A READER writes:—"After reading in 'Trade Notes and Memoranda' 'An American writer's Note on Blue Prints,' it occurred to me that it would be greatly beneficial if blue prints could be coloured, thereby saving tracing cloth for shops, and lessening labour, the tracing from which print was taken being ready at any time necessary to make another print. I dissolved some soda in water, and used same to mix colour with, then applied to print. The soda in the mixture had the desired effect on print—*i.e.*, changing colour of print, and leaving colour on same as bright as when applied to drawing paper. I then followed our "Cousin's" directions regarding red ink, which I used for centre lines, and a similar method for blue ink, which I used for dimension lines. I was pleased to see they came out very clear, and answered the purpose well. I afterwards used some soda water for figuring in the dimensions, but finding the solution blurred, I added a little gum, which overcame the evil, and good, firm figures, and clearly white, were obtained. I dare-say this would be useful to some readers of WORK, as I presume the aforesaid are to be found in all branches of industry, and I should be greatly obliged if you would enter this in your column."

Organ Builders' Tools.—W. J. C. (*Clapton Park*) writes in reply to W. P. (*Grantham*) (see page 190):—"Noticing your correspondent's inquiry *re* organ builders' tools, I would suggest that he make inquiries of (or, if a resident in London, call personally at) Messrs. Thos. Syer & Co., 75, Chiswell Street, as I have often obtained through them things which I could not get anywhere else, and feel sure, from my own experience, that if they have not got in stock what our fellow-worker wants, they will get them for him, and think it no trouble."

Trade Notes and Memoranda.

THE Chelsea Public Library Commissioners have awarded their premiums for the plans sent in for the new building to be erected in Manresa Road, King's Road, S.W. The premium holders are—(1) Mr. J. M. Brydon, F.R.I.B.A.; (2) Mr. E. W. Mountford, A.R.I.B.A.; (3) Mr. C. Pemberton Leach, A.R.I.B.A. The proposed South-Western Polytechnic will probably be erected on a site adjoining this library.

THE California Electric Light Company, of San Francisco, has erected at the Chollar Mine the largest electric power plant in the world. It comprises six 120-horse power Brush dynamos, each driven by a Pelton water wheel with water under a head of 1,630 ft. The water is conveyed through two pipes of 8 in. and 10 in. in diameter respectively. The station is situated in the shaft of the mine, and the exhaust water is carried off by a tunnel to the Caron River. The current is led to the mill, where it drives six Brush motors of 125-horse power each.

IMPORTANT PRIZE COMPETITION.

THE Editor of WORK has the pleasure to offer his readers Prizes to the value of

THREE GUINEAS,

to be distributed for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

FIRST PRIZE ... One Guinea and a Half.
SECOND PRIZE ... One Guinea.
THIRD PRIZE ... Half a Guinea.

Full particulars of the Scheme will be found in WORK No. 17, page 254.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

3 months, free by post .. .. .. 1s. 8d.
6 months, " .. .. .. 3s. 3d.
12 months, " .. .. .. 6s. 6d.

Postal Orders or Post Office Orders payable at the General Post Office, London, to CASSELL and COMPANY, Limited.

TERMS FOR THE INSERTION OF ADVERTISEMENTS IN EACH WEEKLY ISSUE.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

It is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

GRATEFUL—COMFORTING.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 21.] SATURDAY, AUGUST 10, 1889. [Price One Penny.

LOCK REPAIRING AND KEY FITTING.

BY THOS. WILSON.

Back-spring and Tumbler Locks.

No doubt most if not all the readers of Work have at some time or other had occasion to employ a locksmith. Now, I do not say that after reading the following article they will be able to entirely dispense with his services, but I purpose showing how any workman, professional or amateur, can keep his own locks in repair. There are several reasons why they should do so, and before commencing this article I will mention one or two.

In the first place, there is the saving of money. Workmen's time in London and most of the large towns is charged for at the rate of a shilling per hour, and although the number of hours are not generally specified in the bill, that is the price the customer has to pay. I have frequently seen bills made out as follows: Man's time, taking off, cleaning, repairing, and fitting new key to lock—two shillings and sixpence. This represents two hours' time, and sixpence for the key. In the country the customer would probably be charged three hours' time at ninepence. If the reader follows the directions I am going to give him, I think he will be able to save two shillings out of the half-crown.

Besides the question of cost, there is a graver reason why householders should do their own locks as far as possible.

"It is an ill bird that fouls its own nest," and I have not a word to say against workmen in general, but there are black sheep in every fold. What is to prevent a man when fitting a key for a front door or safe lock from fitting an extra one for his own use? Of course, he would not use it at once; it would be laid by for a year, perhaps two, but he would be sure to use it at some time or other. For my part, I am convinced that many burglaries take place in this way.

One more reason, and I have done. When a workman takes a lock into the shop that requires a key, he has a key or blank served out to him, and it is charged to the job. If, through carelessness or ignorance he cuts the key wrong, he will have to apply for another, and will come in for a "wigging" from the shop foreman. Sooner than do this, he will take out the wards or alter the levers of a lock, and so fit the lock to the key, instead of the key to the lock, thereby reducing a good lock to the level of a bad one. Having, I hope, shown why locks should be repaired at home, I will now proceed to show how. First as to tools. Well, the only tools absolutely necessary are a vice, hammer,

screwdriver, and a few warding files and chisels. Other tools will be described for the benefit of those who may care to purchase them, but, although, of course, it is better to have them, they can be dispensed with. Every house possesses a hammer and screwdriver of some description, so that brings us down to the vice, warding files, and chisels. Most amateurs possess a vice, but those who do not can get one for about half a crown that will answer the purpose; though it will be better to give a little more if it is intended for any other use. Some vices have small square anvils, or heads, attached to them, and these will be found of great service in key fitting. Warding files can be purchased for threepence or fourpence each, and chisels for about sixpence.

Having got our tools together, and the vice fixed, we will now commence work. We will commence with the ordinary backspring and tumbler locks, as they are more frequently used than any other, and will afterwards take the Bramah and the various kinds of lever locks.

The one shown in Fig. 1 is a fairly good one of its class, but it will be seen that a skeleton key of the description shown in Fig. 6 will open it as easily as the original. The keys of a tumbler lock rarely, if ever, have corresponding wards in the lock to more than one or two cuts in the key, as will be seen on looking at the illustration. Skeleton keys are made in a variety of patterns, and will pass almost any warded lock; in fact, warded locks, although still made by thousands, are gradually being superseded by lever locks. If a skeleton key will not pass the wards, they can easily be found by first holding the key in the flame of a candle, lamp, or gas, until it is blackened, or covering it with a film of wax, then inserting it in the lock, and pressing it against the wards. On removing the key the impression of the wards will be found on it, and when these are cut away the key will pass easily enough.

It is much quicker though (if a skeleton will not pass) to use a pick. These are made in various shapes; a few of which are shown in Fig. 2.

To open the lock shown in Fig. 1, it would be necessary to use two picks like A (Fig. 2), one to raise the tumbler, A, and another to throw back the bolt, B.

A locksmith or (I presume) a burglar always carries a bunch of skeleton keys and picks with him when he goes to pick a lock, and if the lock is a warded one, he never fails in opening it. We will suppose that a new key is required for the lock shown in Fig. 1. This is rather a difficult key to cut, and it will be better, if possible, to get a blank, with the bridge and collar wards also cut, as shown on dotted lines, Fig. 7.

If, however, he is unable to get anything better than a blank, he will have to cut these wards himself.

As I mentioned before, there are not so many wards in the lock as one would imagine by looking at the key; but we will suppose them to be there, and that it is necessary to cut the key as shown in the drawing.

If the reader has a small drill, it will be better to drill a hole at A (Fig. 4), and cut the L wards, B B first; if he has not, he must cut the bridge ward, C C, first. To do this he must make a straight cut with a warding file through C C. After cutting the bridge ward, he must lay the key on a flat surface (if there is an anvil or head on the vice, use that; if not, a flat iron held in the vice will do), and cut the L wards with a key chisel. Great care must be exercised in cutting these wards, or the key is liable to break at D D. The collar ward, E, must also be cut with a chisel. It is not necessary to cut the whole of the wards with a chisel, but only sufficient to allow the point of the warding file to enter. The two wards, F F, can easily be cut down with a file.

It frequently happens that the spring of a lock breaks. If it is a Scotch spring, as shown in Fig. 3, it can be purchased for about threepence; if a feather spring (G, Fig. 1), it will not be more than a penny. No directions need be given for fixing these, as the way they are put in is obvious to any one.

Should a new follower (C, Fig. 1) be required for this lock, it will have to be riveted in. To do this, it is necessary to take out the bolts, etc., and hold the face of the follower on the small head of the vice, if it has one, or on the face of a hammer held in the vice, and then rivet it on to the back of the vice. It must not be riveted on too tight, or it will not work. After riveting, it will probably require cleaning out with a small square file, or the knob spindle will not pass through. The price of a follower for a lock like this would be about three halfpence.

If the lock requires cleaning, all the movable parts must be taken out, and the case washed out with paraffin or benzoline; the bolts, staples, etc., must then be held in the vice and cleaned with emery cloth. Although not necessary, as far as the working of the lock is concerned, it is as well to clean the ledges of the case and the heads of the screws, as it gives a much better appearance to the lock. A drop of oil should be put on all parts where there is friction.

DOWELLED JOINTS.

ANOTHER PHASE OF "JOINTING UP."

BY DAVID ADAMSON.

For these the preparation of the edges must be the same as for plain joints, but, before going further, I ought to explain what dowels are. No doubt all who read these lines are familiar with them by name, but as dowels are invisible when work is at the stage in which it is most commonly seen outside the workshop, viz., when finished, it is quite possible that some may never have seen them, and may have very hazy ideas about them. Those who have access to an ordinary extending dining table may be referred to it as a familiar instance of the use of dowels. Open it, or look at one of the loose leaves. Little wooden pegs will be seen. These are dowels to all intents, but one end of them is unglued and merely fits tightly into a corresponding hole in the next leaf. In the dowel joint the dowel is fixed into both boards permanently with glue. Now with a fair notion of what a dowelled joint is, a clear start may be made to put its execution into practice. With a little attention it is not a difficult joint to make, always provided that the worker can plane up edges truly, but it may fairly be questioned whether there is any superior to it, either for strength or for speed of construction, as well as the number of situations in which it is available. We have, however, for the present only to consider it in jointing up boards for width, and we can hardly get a better example than by supposing two of the dining-table leaves glued together.

From the very nature of the dowel joint dowels are hardly ever used in wood under $\frac{3}{4}$ in. in thickness, but for anything above this they may be employed with advantage. The ordinary thickness of dowels is $\frac{3}{8}$ in., but beyond this being a generally convenient size there is no special reason for it. It is, however, very important that whatever their thickness it should be the same as that of the bit with which the dowel holes are bored. The dowels must fit tightly in if they are to be of any use. Where they are used in large quantities, the dowels are bought ready made, or, rather, the lengths from which the dowels can be cut when wanted are got. They are not, however, any better than those which any one can make for himself, but are preferred because it is cheaper to buy them. Those who wish can, of course, buy them, but I do not think they are to be got in our smaller towns, and it will be just as well for the amateur to make his own. To enable him to do so a dowel plate will be required. It is merely a piece of iron, or better, steel, with a hole through it. This hole is bored clean and true, with square sharp edges. For occasional use a good serviceable dowel plate may be made out of a stout iron hinge flange. The screw-hole nearest the centre should be enlarged to $\frac{3}{8}$ in. diameter, or just sufficient to pass the bit which will be used for boring the dowel holes. The plate thus prepared may then be screwed on to the bench, through which a hole must be bored at least as large as that in the plate, or to a piece of hard wood of, say, an inch or so in thickness. This latter is the more convenient of the two, as the plate can not only be put out of the way when not required, but a groove can be cut in the dowel while it is being formed. This groove is not invariably found in dowels, but there can be no doubt, for a reason which will be apparent later on, that it is advisable. It is not generally found in the bought machine-made dowels, from which, instead of it, a shaving should be taken off, or the dowel stuff passed through a block such as that about to be described, not all round, but enough to flatten it slightly at one part. In the block to which the plate is screwed a hole must be bored, as in the case of the plate being fastened to the bench. Through the thickness of the wood, say midway between the under and upper surface, insert a screw nail till the point just comes through into the hole sufficient to catch against anything fitting tightly into and passing through the hole in the plate. The plate is now ready, and may be used; but before attempting to do so, attention may be given to the dowel wood and its preparation.

Almost any straight-grained, strong wood will do for dowels, but beech and birch are those generally employed, though I do not know that they possess any qualities which may not be found in several other sorts. Waste pieces of any strong wood may be used instead of them. The pieces are cut into sticks roughly rounded, and then hammered through the dowel plate. This removes any irregularities, and the screw beneath it forms a rough kind of groove or furrow in the stick as it passes through. The length of the sticks is not of much consequence, but on account of the liability to breakage it is not convenient to have them more than nine to twelve inches, and they may be considerably shorter. I may as well say that the dowels to be effectual must be as dry as possible. If not, they will shrink, and not retain their proper hold on the wood in which they are inserted. Neglect of this precaution, and one or two other small matters, is, I take it, the reason why dowel joints are not altogether in favour in some quarters. When made carefully and intelligently, it is an open question whether they can be improved on by any other form.

With this, we may now dismiss the dowels themselves, and proceed to see how to use them. Now, it is quite evident that as the pin or dowel is inserted in two boards, half of it being in each, the holes bored for its reception must be exactly placed. To do this is not difficult. Presuming the boards have had their edges trued, place these side by side, and either hold them together in the bench screw or any other way that may be handy. Now with the square mark off across the edges of both at intervals of from 8 to 12 in.—more or less according to circumstances. If the boards are then placed edge to edge, it is clear that the lines on each must correspond with those on the other. Now, with the gauge set to about half the thickness of the wood, mark off a point on each of these lines. This point, of course, gives the centre of the hole to be bored in each. An ordinary centrebit may be used, but a twist bit is better, as it leaves a cleaner hole. In marking off with the gauge be careful to work from the same surface of the two boards, either from the face of both or from the back of both. Fixed, as they are supposed to be, in the bench, and then applied edge to edge, the necessity for this will at once be apparent, though, unless attention were directed, it might be overlooked.

Before preparing the edges it will be as well for the workman to look at the surfaces of the boards. Both may be equally good, but it will often be found that one side of a plank is better than the other, and it is just as well to let the better one be on the visible side. The dowel holes should be bored to a uniform depth of, say, one inch, and in practice it will generally be found better to bore them in pairs than to make them all in one plank before beginning with the other. To do this, of course, it is assumed that they are left in the bench screw and bored right off after marking. In order to get all the holes the same depth, a very simple contrivance may be used to prevent the bit boring further than necessary. Expert workers can do without it, but even they will often find it more reliable than guess work, sufficiently accurate though this may be. When I say that the little appliance suggested is merely the ordinary wooden stop so well known in the principal workshops, no further description can be necessary for the professional artisan. For the sake of the amateur, it may, however, be explained as being nothing more than a piece of wood with a hole bored through. The length of the wood—it is generally bored along the grain—must just be such that one end when the bit is passed through the hole will be against the stock, and from the other the length of the bit, equal to the required depth of the hole, will project. Those who do not care to take the trouble to make even this little arrangement may bore the holes fairly equal by noting the number of turns of the brace given to the first one, and making the others with the same. The mouth of the holes must then be widened with the rhymer or rose bit. This bevels them off at the edge, and not only facilitates the insertion of the dowels, but is useful for other reasons, which, however, need not be enlarged on. The rhymer must not be used too freely. One or two turns according to circumstances, in fact, barely more than necessary to remove the sharp edges, and any burr there may be from the bit used in boring the holes will be sufficient. By the way, as boring the holes has a tendency, more or less marked according to the wood and the kind of bit used, to raise the wood round the hole, it is sometimes advisable to run the plane over the edges again afterwards. This, of course, levels them, and though it may not always be necessary to do so, no harm can result from having recourse to it.

I said just now that the widening should not be too great, and it may be interesting to beginners and to amateurs as well to have their attention called to the reason. It is this :—The object of the dowel being to hold the boards together, it is important that as much as possible of the dowel should be in contact with the wood in which it is inserted. Now if the rhymer widens the hole to the depth of a quarter of an inch, that is, if the bevel formed by it commences at this distance from the surface of the wood, it must be evident that this space is waste so far as adherence of the dowel is concerned. Repeat this distance in the other plank, and we have at once a space of half an inch, which is practically wasted. Not of much consequence, perhaps, but, as I have more than once said, it is just by such small indications that the difference between the best and medium workmanship may be recognised. Too often one sees dowelling done in a careless manner, perhaps because the want of care is not so visible, nor attended with such disastrous results as it would be in some other operations. For similar reasons to those given for not widening the mouth of the hole too much, the dowel ought to go right to the bottom. If it does not, it is no unusual thing to see the surface of the wood joined plainly indicating the fault. There will be a hollow just above the empty space, especially when the wood is comparatively thin. It may be some time before this defect becomes apparent, but there is always a risk of it, a risk which should not be incurred, as it may easily be avoided by a little care.

In order to facilitate the dowel entering the hole, it is usual either to round off the entering end or to hammer its edges just sufficiently to make it slightly blunt. Both methods are practised, but the latter is to be preferred. If the end of the dowel is rounded by cutting or filing, of course some of the substance is removed, and in practice no bad results follow if the rounding is not too great. Mind, only the edge must be removed, and that it is neither advisable nor necessary to taper the pin, nor yet to make the end into a hemispherical shape. Perhaps this seems very similar to telling one how not to do it, so I may explain that the reason for calling special attention to improperly rounded dowels is because one frequently finds careless workmen shaping them so. Personally, I prefer hammering the ends. This removes none of the wood, but compresses the fibres, so that to all intents and purposes the end of the dowel is tapered off, but swells again under the action of the glue when it has been driven home, thus making a perfectly tight fit. Let us now suppose that two boards are to be fixed together. We take a piece of the dowel wood, whatever its length may be, and round one end with the hammer. Then glue the inside of the hole, though some adopt the somewhat speedier, but not so good, plan of dipping the end of the dowel in the glue pot. It is a slovenly way of doing, though, and it is better to glue the hole. In doing this, do not fill the hole with glue, nor yet put only a drop in, leaving the dowel to force it round. The best way to glue the hole is either to have a small brush with short end just about filling the hole—a suitable brush with short fibres can easily be made from a piece of cane—or to use merely a piece of stick a little less than the thickness of the dowel. This carries enough of the glue and disperses it easily in the hole. As quickly as convenient, so that the glue may not set before it is done, hammer the dowel home. The reason for the groove in this will now be apparent, for if there were no such channel there would be no means of escape for the glue, which will be forced down to the bottom by the dowel, nor yet for the imprisoned air. This latter might seem of small consequence, but it will be sufficient to say that if no allowance were made for it there is considerable risk of the board being split by it. Glue which may exude should not be allowed to set, or

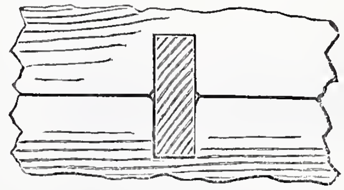

Fig. 1.—Dowelled Joint properly made.

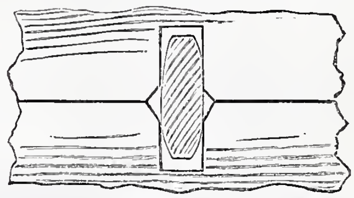

Fig. 2.—Dowelled Joint improperly made.

it would interfere with the close contact of the two boards. A small quantity will not matter if the joint is to be completed at once, and any there may be in the widened mouth of the hole may stop there. It can't do any harm even if it does no good. When the dowel is driven home saw it off, or rather saw off the excess, leaving the projection from the wood just the length of the corresponding hole in the other piece, or as nearly as possible so. In practice it is usual to cut a trifle short, for the obvious reason that if only a trifle too long the edges of the two boards could not come into close contact. All the holes are dowelled in the same manner in one of the boards, and the projecting ends rounded off by means of a file or a special dowel end rounder. Hammering naturally cannot always be so conveniently done on the second end. Perhaps some might like to know what the appliance for rounding the ends referred to is, but there is no sufficient reason for its description, as, unless a large quantity of dowels are to be trimmed off, a rasp will do just as well. I ought, perhaps, to insist on the necessity of the dowels being thoroughly dry before they are inserted, so that they will not shrink subsequently and, in so doing, lose their "grip." It now only remains to glue the edges of both pieces of wood, one of which, at least, should be warmed before doing so, and, of course, glue the holes which are not yet filled. All being ready, the boards are brought together and clamped up, when they should be left till the glue has set. Perhaps, by way of conclusion, the two illustrations may be given as a kind of summing up of all the foregoing. Fig. 1, given above, shows a properly-made dowelled joint, while Fig. 2 shows the joint, or, rather, the various faults which are most to be guarded against.

SOME FORMS OF BITS AND DRILLS FOR THE LATHE.

THEIR USES AND HOW TO MAKE THEM.

BY OLLA PODRIDA.

The D-Bit, Rose-Bit, and Enlarging Drill.

When a number of similar holes or boxes have to be prepared, a considerable saving of time and cost is effected in the long run by making special tools for the purpose. To this the increased accuracy of the work must also be added, which in itself should compensate for any extra cost involved in the preparation of the tools. The writer proposes dealing with a few of the simpler forms of these, so that their construction and use may be made clear to those unfamiliar with the subject.

Commencing with the D-bit, this tool is peculiarly adapted for boring long or deep true holes of diameter too small to permit of their being bored by means of an ordinary bar or tool. Fig. 1 is an elevation, Fig. 2 a plan, and Fig. 3 an end view showing the cutting part. The general shape in section is semicircular, from whence the name of D-bit. The tool is made out of a piece of square steel, forged down to form the cutting part, at which end it should be, when forged in the rough, of the form given in Fig. 4, a small projection being formed in the middle to accommodate the lathe centre in turning. The material should also be worked up at the corners or sides as shown in Fig. 4, so as to permit of its being gauged or callipered to size. After being forged, the tool must be softened to permit of its being turned and filed up. The softening process is accomplished by heating the part to a cherry-red and burying it in fine ashes or quicklime until cool, when it may be manipulated with comparative ease. In the case of a half-round forging the turning can only be accomplished with the assistance of a slide rest. If, therefore, hand tools only are available, it will be necessary to forge the cutting end circular in section and form the flat part afterwards, and this in the case of a moderately large tool would be tedious. In turning the tool it is carried between the lathe centres in the usual way and driven through a carrier fixed on the square end. The turned part must be made nicely parallel and finished smoothly. The end may be roughly faced to assist and guide the act of filing up the front rake or clearance, as shown in Fig. 1. Not more than three or four degrees, rake or clearance should be given, as the tool works steadier the nearer the front cutting edge is kept square to the axis of the tool. This edge must also be slightly slanted or bevelled, as shown in Fig. 2, and whatever radius is given to the cutting corner, as shown in plan, must be slightly increased as the corner is followed round so as to make sure of its clearing itself. The top side must be filed down to the centre line, and this will be facilitated by drawing a line across the end for guidance. For cast iron and brass, the upper surface forming the cutting edge may be left straight, as shown by the full line in Fig. 1, but for wrought iron the cutting angle should be reduced by filing the relief shown by the dotted curve.

The tool having been carefully finished to size and requirements, it must be tempered. This is done by first heating the cutting end to a bright or cherry-red heat, and immersing it in lukewarm water to a depth of about one inch gradually, and then plunging it in bodily for a moment, withdrawing it and immediately brightening the end with a piece of sandstone so that the colours may be noted as the heat from the partially cooled shank spreads back to the end which was gradually immersed at first. The temper should vary according to the material to be operated upon. For brass and cast iron a dark brownish straw colour will stand well, but for iron or steel it should be somewhat softer—say purple, or dark blue tinged with red. Always remember that the lighter the straw colour the harder the tool, and as the blue tints become paler so the temper softens, making the tool more unfit for resisting fatigue. In any case, immediately the colour is reached the tool must be plunged into the water and finally cooled. If possible, use the tool while slightly warm, and if the material is hard it will stand better if used without grinding.

The method of using D-bits is as follows:—Suppose the work to be operated upon is set and fixed in the chuck, the first thing to be done is to bore a short distance at the mouth of the hole to the exact size of bit. A distance of about half an inch will be sufficient or just enough to cover the bevelling on cutting edge, and ensure a fair bearing for the bit to start upon. The tool should be held in the slide rest by the square shank, but it must be very carefully set to agree with the lathe centres. It may be used supported and fed or advanced by the poppet head, the centre in the end of shank being utilised for this purpose, and the tool kept from revolving under the pressure of the cut by means of a spanner held in the hand or a carrier fixed on the shank and supported by the T or slide rest. In all cases the tool must be kept thoroughly well lubricated from start to finish, and this in small deep holes will be readily accomplished by the aid of a syringe or "squirt." Before leaving this form of bit, it should be noted that the turned half round part should never be less than two or three diameters in length, and it should never be allowed to become rusty or be otherwise neglected.

Fig. 5, the next in order, and Fig. 6 give profile and end view respectively of a very useful tool, specially adapted for accurate work or where interchangeability is necessary.

Fig. 1.—D-Bit: Elevation.

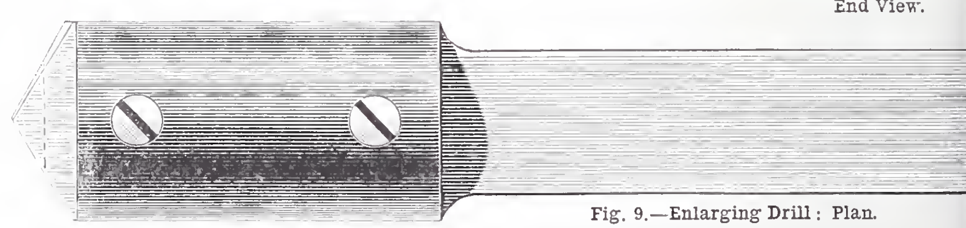

Fig. 9.—Enlarging Drill: Plan.

is not suited for heavy cutting, and i[s] therefore, chiefly employed for finishi[ng] holes which have been rough drilled [or] bored within a slight fraction of the finish[ed] size. The rose-bit, as this tool is com[-] monly called, is better adapted for ve[r-] tical work, such as in a drilling machin[e] than for the lathe, on account of the dif[fi-] culty of lubricating it sufficiently while in [a] horizontal position.

The making of a tool of this descriptio[n] is a simple matter. It is only necessary [to] obtain a piece of steel of suitable size [to] allow for turning. The end may be tapere[d] and squared, as shown in Fig. 5, to fit th[e] spindle of drill if it should be required [to] use it in a dual capacity. This done, an[d] the material softened all over, according [to] the directions given above for the D-bit, [it] must be turned up to the required size an[d] nade just easy to the callipers or gauge. he gauge part, which is cleared to the hank by a shoulder, must be made quite arallel; in fact, it is safer to make the utting end a shade larger than the other nd of the gauge part to ensure against amming. The conical part, out of which he teeth are formed, must also be turned, nd the centres should be left in both ends f the tool for future convenience. The rooves shown running along the gauge part re for lubrication, and may be conveniently ut in the lathe by fixing a round-nosed tool n its side in the slide rest, and traversing he rest or saddle by hand. The teeth are ormed by filing, and care must be taken hat they are all truly cut to the cone. The quare taper part must be well fitted to the lrill spindle, as nothing injures a socket nore than a badly-fitting shank. For such urned tools as this, the square should be preferably replaced by a turned taper secured by a key or setscrew; it is a matter of difficulty to get a square driven bit to run true. The tempering of this tool may be carried out exactly as described for the D-bit. All scale must be cleared off, and the bit polished after tempering to secure a smooth hole. It must not be used at a high speed, especially for deep holes where expansion from heat might prove troublesome. When this tool is used in a lathe, it is held as described in the last case of the D-bit, namely, by means of the poppet head.

A very handy and cheaply made form of drill is that given in Figs. 7, 8, and 9, being elevation, end view, and plan respectively. It is more suitable for enlarging holes which have already been bored, but it is a serviceable substitute for the more expensive D-bit. This tool consists of a piece of flat steel of suitable length and thickness, the latter being proportionate to the width or diameter of hole, say about one-fourth of the width. The cutting end is formed like a common drill, but it need not be brought to a point; the dotted line would give enough cutting edge. The tool is turned on the edges for a portion of its length, and pieces of hard wood fastened on each side, and also turned to the size of hole required. The duty of the wood is to keep the drill central and steady while cutting. These pieces are secured by screws passing through the bit as shown. Where a heavy cut has to be carried, it may be necessary to cut clearance for the chips through the wood; but this is very detrimental to the latter, and it is therefore better to withdraw the tool and clean out the hole at intervals. This tool is held up to its work in the manner described for the D-bit. The procedure of tempering is also precisely similar, except that it should not be made quite so hard on account of its being thin, thereby rendering the corners liable to give under a heavy or sudden cut. The centres should be left in the ends of this tool to facilitate the mounting of fresh wood packing from time to time.

The tools described above will be found extremely useful, and no metal worker will experience much difficulty in making them. This, of course, is said chiefly for the encouragement of amateurs, as all professional workmen are well accustomed to manufacture special tools to meet the exigencies of certain special work that frequently demands their attention. Indeed, even when a tool suitable for the work in hand may be purchased, it has been found to save time to make the tool rather than to waste it in waiting until the purchased tool has been brought or sent home according to order.

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

Fitting and Erecting—Plate and Angle Iron Joints—Rivets and Rivetting.

THE material having passed through the general processes already described, the next stage is fitting and erecting. This may be for temporary or for permanent purposes, the former applying to large work which is first put up and tested, and then taken down again for shipment abroad; the latter course being adopted for home work, for the execution of which, if of sufficient magnitude, workshops are frequently erected adjoining the site of the proposed structure. It sometimes occurs that a considerable number of girders of one pattern are required for foreign and colonial railways, and in such cases it is desirable to have the parts interchangeable, as this is a great convenience in re-erecting; and in such cases the great advantage of pressing, over hand smithing, angle iron knees, and similar details, becomes manifest.

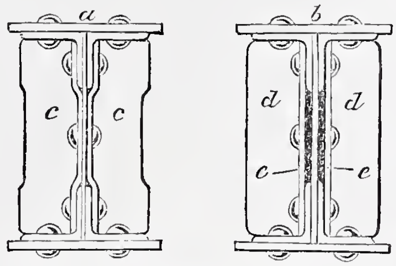

Fig. 9.—Joggled and Packed Stiffeners.

The staging upon which the girder is to be erected must be made with the proper camber, usually a central rise of one inch for every forty feet of span, which is given in order that, under its full load, the girder shall not deflect below the horizontal line connecting its extremities. This allowance is ample, as it is generally considered that in well-designed and properly-constructed girder work the deflection under a full load should not exceed one inch in every hundred feet of span.

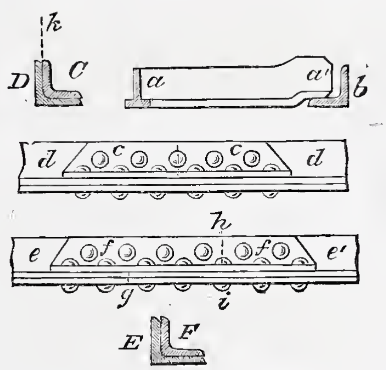

Fig. 10.—Angle and T Joints.

I should feel inclined to lay especial stress upon the necessity of employing great care and very experienced hands in the fitting and erecting department but for the fear of detracting from the importance of the preceding manipulations, and they are really all of such character that negligence is not to be risked in any branch of the work, otherwise it will not be brought to a satisfactory completion. The erection of the structure is always a test of the accuracy with which the material has been prepared, and will be straightforward work if the templates have been properly made and accurately worked to, but, otherwise, it will be involved in much trouble and difficulty. At this stage, too, will the character of the joints become evident, and show whether the details have been properly considered.

When the girders are built up before rivetting, the parts are held together by bolts called service bolts, of which a sufficient quantity is used, passing through the rivet holes, to hold all the parts in close contact. The plates, having been properly planed, should come together without any trimming, but the ends of angle bars may require some chipping to make good joints, and the knees, if hand-smithed, may require easing off at some of the bends. In some instances, the emery wheel may be found a useful adjunct in this work. All knees, stiffeners, angle pieces, and gussets should be made to fit truly, as upon them the general squareness and freedom from twist and winding will depend. If it is found that any piece falls short of the surface it should touch, it should be thrown aside, and not worked in by the aid of packing, which should never be used unless it is a part of the design. Packings, generally speaking, are to be avoided as much as possible; they add to the weight without increasing the strength of the girder, and impair the solidity of the work; but in some cases it is convenient to use them to avoid joggles. As shown in the sections Fig. 9, *a* and *b* are cross sections of plate girders stiffened by T irons, *c*, *c*, in one case, and *d*, *d*, in the other. The T irons, *c*, *c*, are shown joggled over the angle irons. When the girder is of considerable depth there is no inconvenience in this; but in shallow girders the joggles come very close together, and neater work may be secured by using packings as shown at *e*, *e*, of thickness equal to that of the angle iron. Unless the girders are more than fifteen inches deep it will be best to use packings.

It sometimes happens that errors occur in the shop which may be made good without wasting material, but where this involves any alteration in the construction, however slight, it will be necessary to obtain permission of the engineer in charge of the work to make it, hence this course will only be pursued when the quantity of material at stake is considerable. A mistake of this kind came under my own cognisance some years since: the flange plates of a heavy plate girder (108 ft. long by 8 ft. deep and 2 ft. 6 in. wide) were planed too short; in fact, through a change of foremen the plate ends were planed twice, and, therefore, when erected, failed to meet by half an inch. In the bottom flange, where the joints are in tension, this gap would not signify so far as strength is concerned; but in the top flange, which is in compression, it is highly important that the joints should butt fairly together. In this case steel wedges were made with a very slight taper to fit the spaces between the plate ends, and solidly driven in. The result was highly satisfactory, and the bridge, when tested, showed a higher degree of stiffness than is usual in such structures.

In the case just referred to, there could be no doubt that the joints did in reality butt, but in the ordinary run of work it is impossible to find out, after rivetting up, whether the plate ends are in contact or not throughout their width, and that is why in English practice compression joints are made with a full complement of rivets sufficient to carry the whole strain from one main plate to the next, but every care should be taken to make all joints, in whatever position, butt as truly as possible, in order that the girder may not become distorted during rivetting, and also to assure solid work. To this end, also, all the parts should be drawn together to true bearing by the rivets to avoid the occurrence of unnecessary cross strain. When a plate girder is completely riveted up, and supported through its whole length on the erecting stage, it is evident there ought to be no strain upon any part of it of a transverse character, but if the details do not fit together properly, all sorts of strains may be set up by the contraction of the rivets in cooling.

In Fig. 10 are shown some angle and T iron joints. *a a'* is an elevation of the end of T iron stiffener which beds upon an angle iron, *b*, shown in section. The end, *a'*, which is removed a little from the angle iron, *b*, that its form may be clearly seen, is shaped to fit the curve in the root of the angle iron against which it bears, so that the rivet may bring the two solidly together; ends such as this may be chipped to form, and smoothed off when necessary on an emery wheel.

Angle iron joints are usually made square as shown by the ends of the bar, *d, d*, which are butted and joined by the angle iron cover *c, c*, the joint of the angle irons being indicated by the dotted lines. *D* and *C* are the main and cover angle irons shown in section; the cover is rolled with a round back, which fits close into the root of the main angle bar. It is, of course, necessary that, if the full strength of the angle iron is to be carried through the joint, the sectional area of the angle cover shall be equal to that of the main angle iron, and, therefore, as it measures less upon the sides its thickness must be greater; thus, if the main bar is $3\frac{1}{2}$ in. by $3\frac{1}{2}$ in. by $\frac{1}{2}$ in. thick, its sectional area is $3\frac{1}{4}$ square in. thick. The cover bar for its edges to lie flush with those of the main bar will be 3 in. by 3 in. on the sides, and, therefore, to have a sectional area of $3\frac{1}{4}$ square in. must be $\frac{5}{8}$ in. thick. This gives an excess to the cover, but it is the nearest size commercially obtainable above that found by calculation. This additional thickness sometimes causes a difficulty with the rivets. Setting out the rivet centres, as described in No. 8, p. 117, those in the section *D* will be $1\frac{1}{2}$ in. from the surface, *k*, of the main angle iron, and deducting $\frac{5}{8}$ in., only $\frac{7}{8}$ in. from the inside of the cover, *C*; this is very little room to make up the head of a $\frac{3}{4}$-in. rivet in. With the view of using thinner covers, the angle joints may be placed where from necessity the strength of the main angle irons is in excess, and thus greater facility for good and neat workmanship will be given. It is, of course, impossible, practically, to make the section of the girder in exact proportion to the strain at every point in the length; the excess in the flanges of a well-designed plate girder, including cover plates, amounts to 10 or 11 per cent. of the theoretical weight. This excess necessarily existing, it should be taken advantage of wherever opportunity occurs so to do.

The next sketch shows a more complicated angle joint, which I once encountered in some colonial work. It is certainly a very bad form, about as bad as can be, but it was insisted upon and accordingly worked to. *f, f*, is the cover plate, the only peculiarity of which is that it is much longer than is necessary when the ordinary joints are used. The end, *e*, of one bar is cut off square at *h i*, and then has its horizontal table cut away from *g* to *i*; in like manner the end, *e'*, is cut off square at *g*, and the vertical limb cut away from *g* to *h*. Between *g* and *i* the contact of the angle bars is the same as in a mitre joint. *E, F*, show a section of this joint, and it will be seen that from *g* to *i* the root of the angle iron is cut through, so that, regarded as an angle iron, all strength is gone from the main bar, and its duties are transferred to the cover, *f*, which, being further off the work connected, is less efficient in securing its solidity. There is no compensating advantage in this arrangement, and the metal cut away is wasted.

The ends of bars and the joints having been properly fitted, the work is to be firmly secured in position by the service bolts, which should fit the rivet holes with sufficient accuracy to ensure that of the positions of the different component parts, which will then be ready for rivetting up. Sometimes bolts with cotters are used to hold the work together, but this is a practice to be discouraged, as cotters are never so reliable as nuts.

We now come to the rivetting of the girder together, and, in order to appreciate the care required in the conduct of this operation, it is necessary to consider the duties of the rivets and the way in which they are carried out. Some engineers allow a considerable percentage of rivets for defective work, but this should certainly not be necessary, especially if the manufacture is properly inspected by a competent and honest official appointed for that purpose.

The strain upon the rivets may tend to cut them across, or to pull the heads off, and in any case there is this latter tendency during the period of their cooling after the heads are made, so that in any case the rivets should be so proportioned that they are at least as strong to resist the heads being stripped off as to withstand tearing asunder through the body. The working strength for iron rivets in tension is five tons per square inch of sectional area taken square to the length. The cross sectional area is equal to the circumference multiplied by the diameter divided by four, and the circumference is equal to the diameter multiplied by $3\frac{1}{7}$, therefore the resistance to tearing across is equal to the square of the diameter in inches multiplied by four very nearly, this giving the working load in tons with sufficient accuracy for practical purposes. The resistance to pulling the centre of the rivet out of the head is four tons per square inch of the surface stripped, and that surface is equal to the circumference of the body of the rivet multiplied by the thickness of the head in line with the body; therefore the working resistance to stripping is equal to the diameter of the body multiplied by $3\frac{1}{7}$ and by four times the thickness of the head, and this must be equal to the resistance to tearing—four times the square of the diameter; therefore the thickness of the rivet head must not be less than the diameter multiplied by 7 and divided by 22, or, as a practical rule, the thickness of the head must not be less than one-third of the diameter of the body of the rivet.

The action of the rivets in drawing the plates together in cooling will cause such frictional resistance to their sliding one upon another as very materially to aid in the strength of the joints, but, as the amount of such resistance is not accurately ascertainable, it is not relied upon, but goes as margin. Its outside value, taking the friction of the plates to be one-fourth of the pressure pressing them together, in tons, will be twice the total sectional area in square inches of all the rivets in the joint, as the pressure due to the rivets cannot exceed the elastic limit of the metal, which is about eight tons per sectional square inch, and it probably is much less.

The rivetting up is almost exclusively done now by hydraulic riveters, hand rivetting only being resorted to where the hydraulics cannot be brought to bear. It is much better, as the rivets are more quickly closed, and the jarring effects of the hammering are not brought upon the work, and this must, where it occurs, tend to derange the positions of the parts put together with service bolts. As it is obvious that the rivet will expand when heated, the rivet rod used in their manufacture must be somewhat less than the rivet holes, which are made the size of the finished diameter of the rivet. One-sixteenth of an inch is usually allowed; so rivets that finish three-quarter inch are made from $\frac{11}{16}$ rod. The rivets are supplied with one head made, and there should in their length under the head be allowed, in addition to the thickness of plates passed through, $1\frac{1}{2}$ diameters to make the other head, which is formed by a die called a snap fixed in the jaw of the rivetting machine; or in hand rivetting held by an assistant on the rivet end after the head has been roughly knocked up by the hammers. Plenty should be allowed for the rivet head, and should it be a little in excess and form a collar round the base of the head, it should not be cut off for fear of damaging the plate beneath.

BASINS, BATHS, AND BATTERIES.

BY GEORGE EDWINSON BONNEY.

BARIUM—BARIUM CHLORIDE—BARIUM SULPHIDE—BAROMETER SCALES—BASINS—BATH—BATH BRICK—BATTERIES.

Barium.—Chemical symbol Ba. Combining weight 137. A mineral found in heavy spar and witherite. It combines with oxygen, chlorine, and sulphur to form various salts, only two of which are of interest to us here.

Barium Chloride.—$BaCl_2$. Is prepared by dissolving witherite (Barium Carbonate) in hydrochloric acid. Its solution is used to detect the presence of sulphuric acid and sulphates in solution. These decompose barium chloride, and the free sulphuric acid unites with barium to form sulphate of barium, which falls as a white crystalline precipitate insoluble in water and in dilute acids.

Barium Sulphide.—BaS. This salt has been employed by Mr. A. Watt to give a warm bronze tint to clean copper articles. The solution employed was made with four or five grains of this salt to each fluid ounce of water. The articles to be bronzed are immersed in the solution, and allowed to remain in it until they acquire the desired tint. All the salts and solutions of barium are more or less poisonous.

Barometer Scales.—These, together with thermometer scales, and the metal dials of clocks, are silvered by the simple silvering process, or silvering by simple immersion. See notes on *Silvering by simple immersion, Whitening Clock Faces*, etc.

Basins.—Porcelain basins are handy adjuncts to the plater's plant of tools. Small quantities of solution for experiments can be readily made up and used in them with safety. They can also be safely used as dippers in dipping out solutions of all kinds from cisterns and vats. Earthenware glazed basins of the common sorts cannot be trusted to hold acids or strong solutions of salts for any given time, as the glazing soon gives way, and the ware is then speedily pierced by the solution. Acid-proof stoneware bowls and basins can be obtained from Messrs. Doulton, Lambeth Potteries, London.

Bath.—This name is applied by electro-platers to all solutions used in the workshop in which articles are immersed to be cleaned or to be plated. It is also meant to cover the name of a solution and the vessel in which it is contained ; hence, when we hear a plater speak of his gold or silver baths, it means the vats and their solutions as they stand. In this series of notes, the various "baths" will receive attention under the several heads of *Gilding Solutions*, *Plating Solutions*, *Pickling Solutions*, *Dipping Solutions*, etc. See also notes on *Copper*, *Gold*, *Nickel*, *Silver*, etc. The various vessels to contain the solutions will be described under the note headed *Vats*.

Bath Brick.—Finely-powdered and sifted bath brick is used in cleaning the surfaces of articles intended to be left "dead" or "frosted." It is not suited for the preparation of articles intended to have a smooth surface when finished, except as a first scouring material to be followed by more finely abrading powders. The powdered bath brick should be used dry, and brushed over the surface of the articles whilst these are being held in a scouring tray.

Batteries.—The word battery, as applied to electrical apparatus, belongs strictly to a collection of Leyden jars charged with static electricity. These discharge their store of force in a violent manner, totally unlike the equable flow of current obtained from collections of voltaic or galvanic cells. French electricians speak and write of such generators under the name of "Piles," doubtless in deference to the form of the first voltaic generator of electricity made—the pile of metal discs invented by Volta. English electricians apply the word battery to all apparatus in which electricity is generated by chemical decomposition, and also to those forms of storage cells known as accumulators and Leyden jars.

A list of the batteries in use by electro-platers is given in the annexed table, which will also show at a glance those most suitable to the work to be done.

The Fuller might be added to this list, but should even then be regarded as a make-shift should none other be available. The Wollaston is also used in some workshops. Each battery has its own peculiar characteristic which renders it fit or unfit for the work to be done. Thus, the Bunsen battery, as ordinarily constructed, is the best for nickel-plating and copper-plating in alkaline solutions, because its electro-motive force is high, enabling the current to push through high resistances. But even then we must not use small cells except we are doing small work, that is, plating a small number of small articles. This battery, however, is not suitable for the work of silver-plating, gilding, and electrotyping, because its high E.M.F. causes the metal to go on too fast and in a granular condition. In all these operations the Daniell will be found to be the best because its E.M.F. is lower than that of the Bunsen, and its current equally constant in volume. The Smee, and also Walker, are eminently useful cells for giving a current suitable to the work of electro-gilding small articles of jewellery. Batteries with a high E.M.F. cause gold to go on too fast, and give the deposit a high colour. The French gilders and platers make up the Bunsen with sulphuric acid in the porous cell with the carbon, and thus get a constant generator with a lower E.M.F. This form is also less troublesome to keep in working order than the ordinary Bunsen, and it has the merit of being free from noxious fumes. Nearly all the batteries given in the list may be altered and modified to suit the wants or conveniences of the operator. A modification of the Bunsen has just been noticed. It may also be noted in the table of batteries, that I give various strengths of acid solutions to be used in the zinc compartments of the batteries. These suggest other most important modifications, the E.M.F. of the battery varying with the quantity of acid used. For instance, the E.M.F. of the Bunsen charged with a solution of one part sulphuric acid to eight parts of water may give an E.M.F. of 1·95 volts, but when charged with a solution of one part sulphuric acid to 10 or 12 parts of water the E.M.F. may fall to even less than 1·80 volts. The Daniell, Smee, and Walker may be modified in like manner. Mr Smee, in writing about his own battery, says :—

"The liquid generally adopted to excite this battery is a mixture of one part by measure of sulphuric acid and seven of water, which will be found amply strong for all purposes. The electro-metallurgist will frequently find it advisable to use dilute sulphuric acid, only containing from $\frac{1}{10}$th to $\frac{1}{16}$th of the pure acid, and adding some acid when the first is exhausted ; taking care, however, that the quantity of acid never exceeds the $\frac{1}{4}$th of the original water, for any excess above that quantity will be useless, as the liquid will then become saturated with the sulphate of zinc." Still further modifications may be made in the battery by enlarging or diminishing the size of the negative or the positive element, or both of these, and in altering the size of cell containing them. As a rule, the enlargement of elements and cells tends to an increased output of current, because the internal resistance of the battery is lowered, and there is, consequently, more available force for the outer circuit. Enlarging the negative element will frequently bring about the desired result of lowering the internal resistance of the battery and increasing its volume of current. This is specially noticed in the Daniell, Smee, and Walker batteries.

Large cells (holding from one to 10 gallons each), and large elements to suit them, become a necessity when articles of a large size have to be plated, or when a large number of articles have to be plated at the same time. This necessity may be partly met by employing a great number of small cells coupled in multiple arc, but small cells thus coupled up soon run down, because, being placed on short circuit, their charges of acid soon get used up. The best work is generally obtained when the elements of the battery present a slightly larger surface to the liquids within the battery than that of the anodes to the solution in the vat.

Lastly, the current obtainable from a battery may be modified by the manner in which the cells are coupled together. If the E.M.F. is too low, we may couple the cells up in series until the required E.M.F. has been obtained ; or, on the other hand, if the E.M.F. is too high, we may take off cells and thus reduce it. It is never good practice to couple two or more cells of a different style of battery together to obtain the needed E.M.F., as the weak cells always pull down the current to their own level, and the current from the stronger cells will heat the solutions in the weakest, thus impairing the efficiency of the battery.

TABLE OF BATTERIES USED BY ELECTRO-PLATERS.

Name of Battery.	Negative Element and Solution.	Positive Element and Solution.	E.M.F. of Cell.	Approximate Resistance of each Cell.	Work for which it is most Suited.
Daniell.	Copper in saturated solution of sulphate of copper.	Zinc in sulphuric acid solution, 1 to 12 or 15.	1·079 volts.	2 to 5 ohms.	Electro-gilding, silver-plating, and electrotyping.
Smee.	Platinised silver in dilute sulphuric acid, 1 to 10, 15, or 20.	Zinc in dilute sulphuric acid, 1 to 10, 15, or 20.	0·47 volts.	0·5 ohms.	Electro-gilding, silver-plating, and electrotyping.
Walker.	Platinised carbon in dilute sulphuric acid, 1 to 10, 15, or 20.	Zinc in dilute sulphuric acid, 1 to 10, 15, or 20.	0·66 volts.	0·4 ohms.	Electro-gilding, silver-plating, and electrotyping.
Bunsen.	Carbon in nitric acid.	Zinc in sulphuric acid solution, 1 to 15 or 20.	1·7 volts.	0·8 to 0·11 ohms.	Nickel-plating and copper-plating in alkaline solutions.
French Bunsen.	Carbon in strong sulphuric acid.	Zinc in sulphuric acid solution, 1 to 15 or 20.	1·6 volts.	0·11 ohms.	Electro-gilding, silver-plating, copper-plating in alkaline solutions, and nickel-plating.

Batteries for electro-deposition are fast giving place to dynamo-electric machines, the current from these being in every respect more suitable to the work of depositing metals than that from the best batteries. They are also more cleanly in working, less costly, and more easily managed. See notes on *Dynamo-electric Machines*. For information on amalgamating the zincs of batteries, see notes on *Amalgamation*, *Zinc*, *Mercury*, etc. For information on how to connect cells together, see notes on *Binding Screws*, *Clamps*, and *Connections*. See also notes on *Bunsen Battery*, *Daniell Battery*, *Smee Battery*, *Walker Battery*, *Wollaston Battery*, etc.

A TRAY FOR LOOSE LETTERS, WITH INK-BOTTLE.

BY E. BONNEY STEYNE.

THE penny post is, of course, a big blessing, and although in England, the home of its birth, we are yet not so thoroughly well served, at once so cheaply and expeditiously, as, say, Belgium, for example, yet a good many of us get even more letters than we want. Now the future storage of these is not an easy matter, if they are to be at once tidily put away, and yet available for immediate reference.

There is a very true proverb that says if you want a thing done, the most busy man of your acquaintance is more likely to do it than the laziest; and, in similar fashion. the man who has dozens, or it may be a number reaching at times to hundreds, of letters daily, is tolerably sure to have some system in force. But the average private correspondent is reduced to a survey of his wardrobe and to start an expedition as amateur pocket-picker on his own coats (or dresses, if it be a she, hanging up like Bluebeard's wives). Such a way is, however, more suggestive of a student of the Jew Fagin's academy than a respectable letter writer,

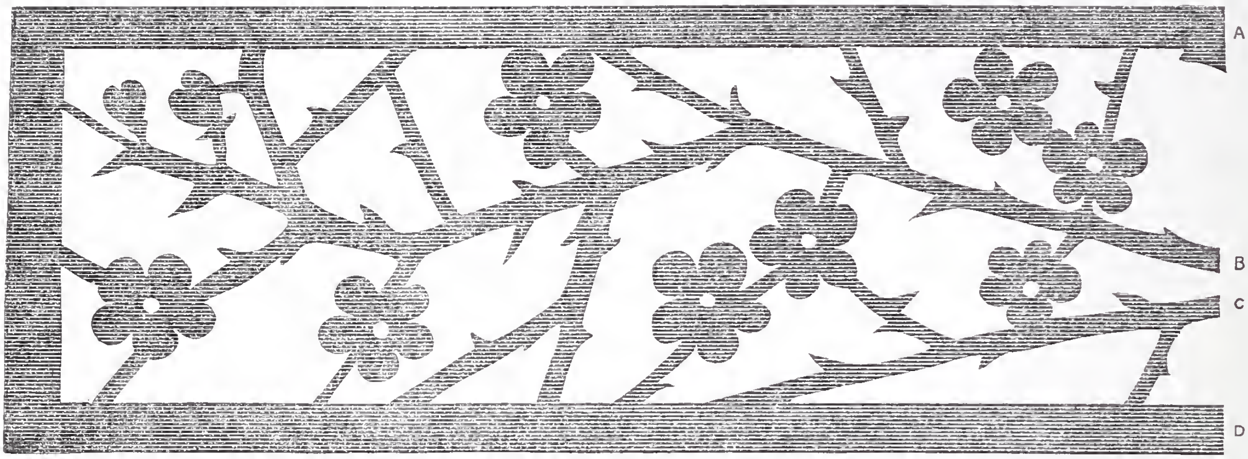

Fig. 2.—Left-hand Part of Side of Paper Tray—Cut Two; A, B, C, D show Points of Connection with Fig. 2a.

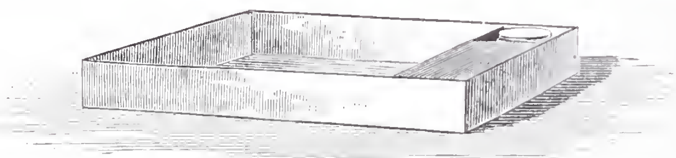

Fig. 1.—Rough Design of Paper Tray Fitted for Use as Inkstand.

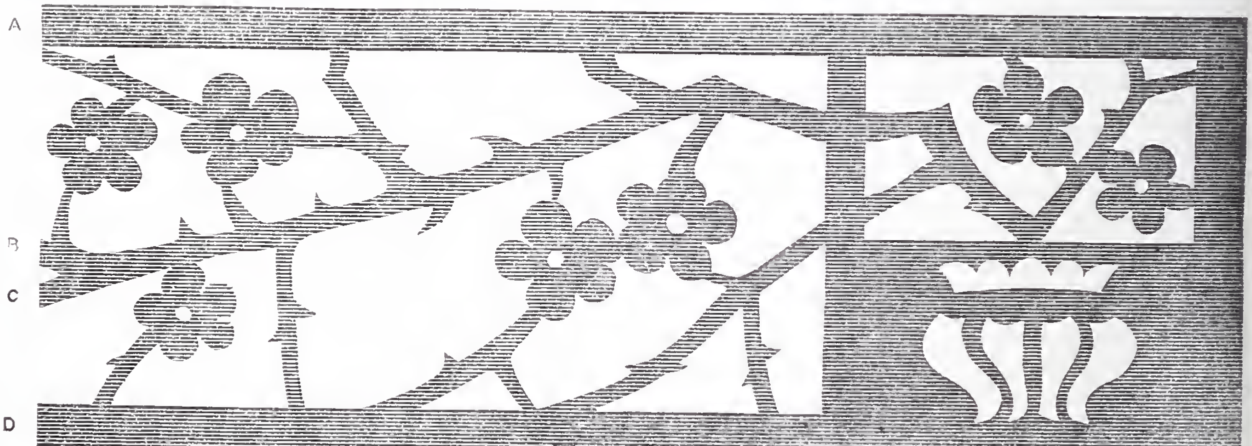

Fig. 2a.—Right-hand Part of Side of Paper Tray—Cut Two; A, B, C, D show Parts of Connection with Fig. 2.

who finds suddenly an important address, or a question needing reply, has escaped his memory, and lies dormant in some mislaid missive.

The first few minutes after reading a letter is generally the crucial time for its future chance of existence in a definite locality, and the majority of those received must needs be immediately disposed of; yet while, of course, a certain class of correspondence is never open to public perusal, save in the deplorable event of an action for breach of promise, there are a great many purely formal ones that are in no way "private and confidential," which may be at once placed on the writing table for consideration at a convenient season.

But a writing table specially set aside, with needful appointments, is not in every room of a middle-class house. In fact, the presence of such a table for real workaday use, and not merely of the "elegant davenport" order, is a sure sign that the household has intellectual tastes, or is intimate with the usages of what the old novelists called "polite" society.

For the ordinary house, or bachelor's apartments, a tray to contain invitations, business letters of no great importance, and the usual missives awaiting reply, is a great advance upon the frame of the looking-glass, or the hundred and one odd corners where such things are banished.

If this tray has an inkstand and receptacle for pen-holders, sealing-wax, etc., it is doubly useful, for then it converts any table into a writing table for the time being when placed upon it.

Such an one is shown in the design now given. Fretwork has been selected for its ornamentation, because it is the most available method for many who like to make useful little additions to their surroundings, or suitable presents to their friends. But the idea is often to be seen in shop windows, made in leather and various other materials.

The baskets so largely used for MSS. are, no doubt, the same things practically, but the addition of an ink-bottle makes this more convenient for private use.

The wood should be polished each side, unless, as in the case of oak, it is left entirely plain. Bearing in mind the foregone certainty of blots near an inkstand, it would be best to stain the wood with ebony stain before polishing, using the proper French polish for black finish.

In such work as this, it is best to fit all the pieces together with neatly dovetailed or tongued joints, as the skill of the worker is able to command, before the actual sawing of the design is undertaken. See also that the wood is brought to a fine, smooth surface before pasting on the design, as after use of sand paper is apt to dull the sharp outline of the fret cut line. The bottom of the tray should be lined outside with cloth or baize; inside with leather Japanese gold paper, or some other substance, to give it a finished appearance.

As small covers, if left loose, are generally lost or broken long before the article to which they belong is worn out, it would be as well to hinge the lid to the pen-holder compartment—which plan keeps that receptacle free of dust, a distinct gain to the majority of careless writers who do not wipe their pens after use.

The given size, 12 by $8\frac{3}{4}$, is fairly useful, but enlarged to about 15 by 12 it is more so, as then the compartment for papers admits quarto and cut foolscap, and the pen division takes full-sized holders. But for private use the size shown is, perhaps, large enough.

Such a thing ought to sell well at bazaars, or be a most acceptable present to any adult. It is easy to construct, and displays all the work expended upon it well in sight, an important item to the amateur, who naturally likes his labour to yield its full effect. With little more work in its construction than an ordinary fret-sawn bracket or photograph frame, it may claim to be of really practical use, and form a thing with reason for existence evident and provable.

Some parts of the designs, it will be noticed, are shown in black on white, while others are the reverse. This is not a merely fanciful alteration to give variety to their ornament, but has a practical reason. Figs. 1 and 4 are for the end that provides receptacles for the ink-bottle and for pen-holders. Fig. 1, it must be noted, is worked in duplicate, since it supplies the end pieces of the tray and the division between the part to take loose papers and the other. Note also that Figs. 2 and 2a (really one piece divided for mechanical reasons imposed by the necessities of space) must be traced twice and cut in reverse. That is to say, the right hand end of the one piece must be the left-hand portion of the other. Then the solid part of the design explains itself, for all those parts enclosing the bottles and holders are treated in this fashion to exclude dust, so far as is possible in fretwork. Fig. 4 is the cover for the pen-holder compartment, intended to be hinged to the division piece, Fig. 1. A piece of plain wood to partition off the ink-bottle space is, of course,

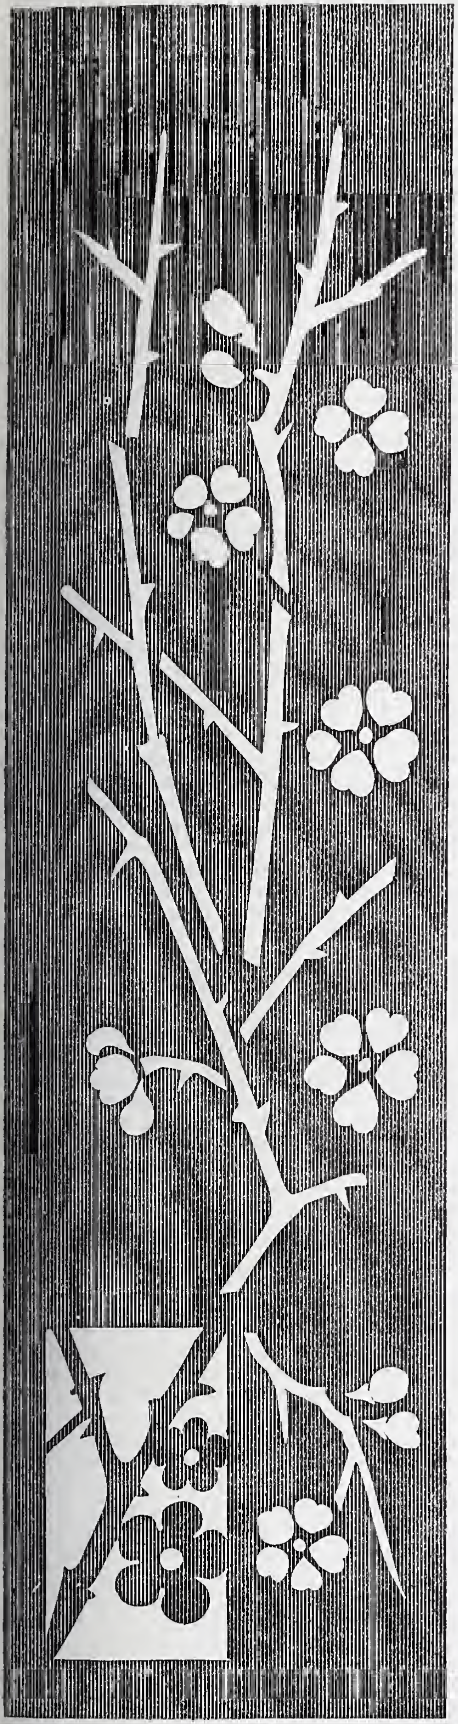

Fig. 3.—Inkstand End and Division of Tray—Cut Two.

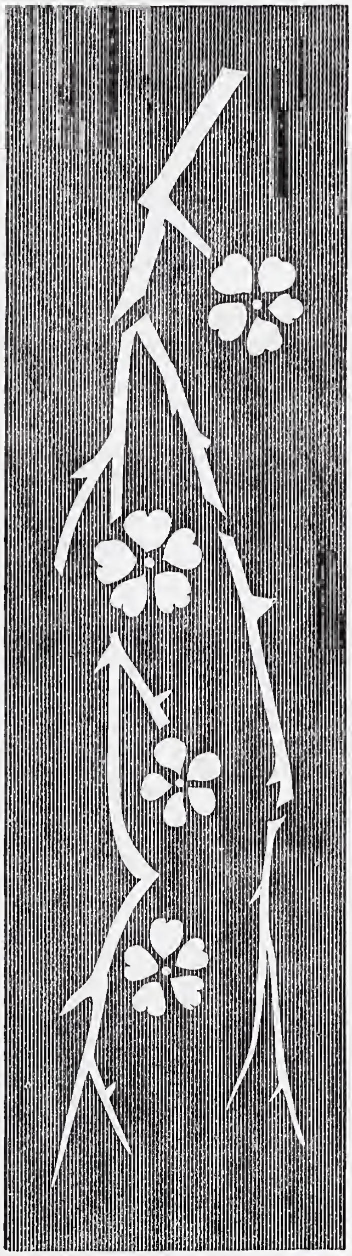

Fig. 4.—Cover of Pen Box, hinged to the Division Piece—Cut One.

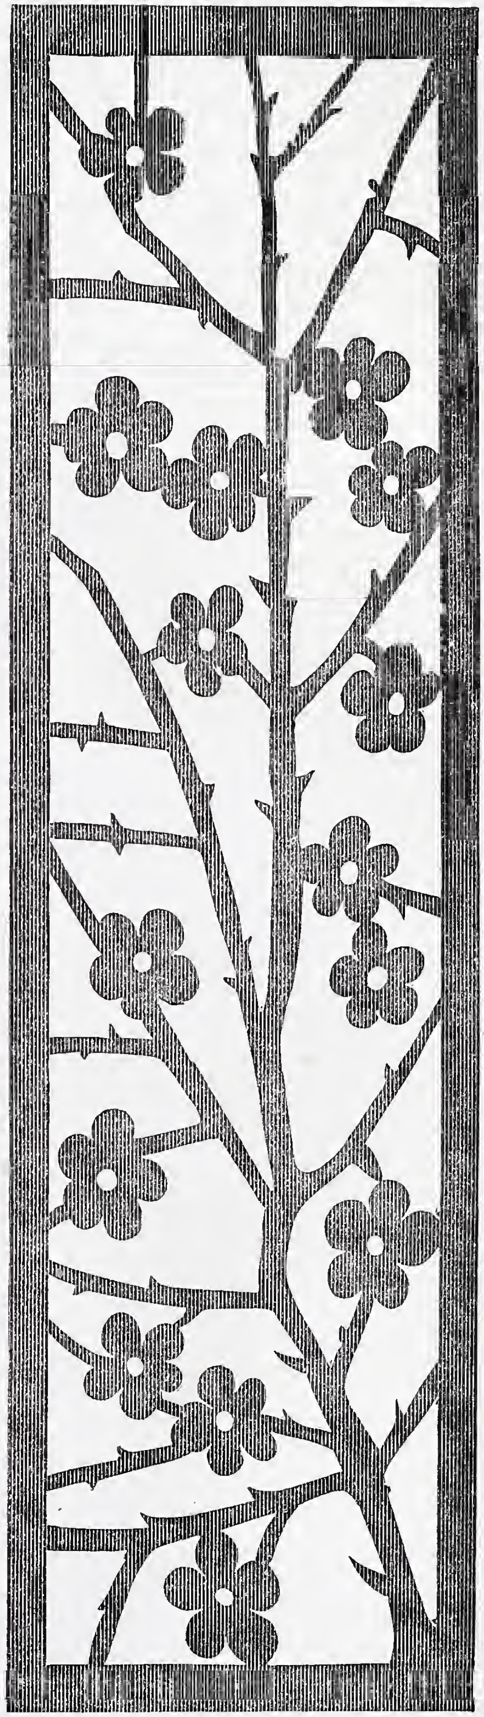

Fig. 5.—End of Tray, opposite to Inkstand, etc.—Cut One.

also needed, likewise a piece to catch the lid as in ordinary boxes. It is easy to say all these petty details should be apparent to the meanest intelligence; but taking my own as the average—the very mean average—I feel that the extreme difficulty of explaining these things briefly, yet clearly, is yet not so appalling as the labour of translating such attempts into actual handiwork, for words are at best variable things.

Here I must leave the further consideration of the designs to each reader, who must determine for himself whether or not he will take them in hand. I will content myself with suggesting that the patterns may be so adapted and manipulated as to make glove and handkerchief boxes, which will be both pretty and useful.

VENEERING.

A CONSIDERATION OF THE OBJECTIONS URGED AGAINST IT AS A SHAM.

BY DAVID ADAMSON.

PROBABLY no operation or mechanical detail connected with cabinet making has been more unfavourably commented on, even when it has not been utterly condemned, than that known as veneering. This, as almost every one is aware, consists in covering a piece of wood with a thin layer of some choicer wood, the latter being the veneer. Perhaps before explaining how to veneer it may be well, in order to remove prejudices, to glance at some of the objections most commonly urged against veneered surfaces, and see whether they are valid or not. Personally, as one who has given considerable attention to the subject, I can unhesitatingly say that I see no objection to it when properly done, and in this I imagine I shall have the support of all practical cabinet makers.

One reason which is sometimes brought forward against the process is that veneering is a sham, and therefore degrading in its tendency both to the workers and to the public, the users. No more mischievous assertion than this could be made, and it is one which it is difficult to think could ever be seriously urged. Were veneering generally practised with the intention of deceiving there might—nay, indeed would—be strong grounds for condemning it, but can any one with the slightest practical acquaintance think for a moment that veneer is put on with the intention of implying that the substance is the same throughout its entire thickness? I only now refer to those who have some knowledge of both material and construction, for it may be conceded that others occupy a somewhat different position, and their views may for the present be disregarded. To the cabinet maker therefore, whether professional or amateur, who may not have any definite ideas on the subject, a few suggestions are offered for consideration. They may help the former class of worker especially in enabling him to refute any assertions which may be made by customers and others against veneering. Perhaps in this latter sentence I may seem to the fastidious amateur to be talking too "shoppily," but while there is no wish to tread on his toes, I may say that I am only too familiar with the frequently absurd notions of the public —that is those whom I have classed as "customers"—not to be desirous of giving sound argument, or rather by suggesting how some of these notions may be combated. In the pages of WORK we meet on neutral ground, where those who know what they are talking about in practical matters can state their views without any fear of being misunderstood as to their motives. For example, were a cabinet maker in the ordinary course of his trade to inform a customer prejudiced against veneer—I use the word prejudiced advisedly—that his or her objections were unfounded, that customer would probably, or let me say possibly, go elsewhere. The cabinet maker may make a mild explanation about the propriety of veneers, and with a reasonable person may succeed in carrying conviction, but the chances are his explanation, in the great majority of cases, would be put down to personal interest. This can hardly sway any one writing for WORK, so, however wide my views about veneering may be from those of some readers, please remember that did I think the process immoral I should have no more hesitation in condemning it than I have in upholding it.

As has been stated, no cabinet maker could long be deceived, even were he momentarily so, by veneered wood. As a rule a very slight inspection, a cursory glance, shows him what the construction is; therefore, so far as he is concerned, there is no deception. To him veneering simply offers a ready way of decorating a plain wood, and to employ a well worn simile it is no more deceptive than the gilding on a picture frame. No one would, because this looks like gold, ever imagine that either the maker or owner intended to imply that it was formed throughout of the precious metal. But, it may be urged, gold and wood are not analogous materials, that no comparison can be drawn between them—the one being of such extreme value, and the other common enough. This is correct to a certain extent, and only so, for though gold and wood are not of the same value, it is only the choicer kinds of the latter which are generally used for veneers, either because they are too costly to be worked up solid, or, as is the case with some of them, because they cannot be used in the solid form. On examination we find that similar processes are practised in almost every branch of manufacture and art. If we are to be logically correct according to those who object to veneering, we cannot stop short at this form of decoration. We must not only denounce it, but every other method of surface or superficial adornment, for they are all to the same extent debasing and false. We might varnish our front doors, for instance, just as a preservative, but paint them, oh dear, no, because that would be done with the intention of persuading passers-by—perhaps in time deceiving ourselves—that the humble pine of which they are made is a nice olive green throughout. Does, for instance, the æsthetic individual who paints his woodwork ivory colour do so with a thought that possibly some one may be deluded into believing that it is actually of ivory? If that is his intention, he certainly is not less blameworthy than the cabinet maker who is so unhesitatingly found fault with for decorating his plain wood. In the one case a thin coating of paint is used; in the other a thin coating of wood. Where the difference in principle lies I for one cannot conceive, the distinguishing feature between them being that one is laid on in a liquid, the other in a solid form. Of course the æsthetic individual, be he professor or other man of light and leading, would indignantly repudiate any intention to deceive, but none the less he is quite ready to impute all sorts of bad intentions to the wicked tradesman who dares to adorn a piece of, let us say, American walnut with a piece of choice "burr." Oh, the ignorance of such would-be teachers, who have unfortunately, however, got the public ear by virtue of their position, for admiring this self-same wood or variety of wood, burr walnut; they would say, "It ought to be solid, else is it a sham, and we will have none of it." How many of them are aware that it, and many other woods, amboyna, thuja, and others, *cannot* be used in the solid form. They are merely superficial decorations, the same as the aforesaid ivory paint, and could not by any possibility be used structurally more than it.

If veneering with wood is wrong in principle, then also is coating a surface with paint or other adhesive covering for the purpose of rendering it more pleasing to the eye. To allege this latter is, of course, ridiculous, but it may well be asked, is it any more so than to say that veneering is wrong? It is difficult to know where to draw the line between the false and the true in art, and no attempt is made to do so in these remarks, which are merely made to explain what one can only suppose are erroneous conclusions, founded on an inaccurate and imperfect knowledge of the process and intention of wood veneering.

Even Ruskin, if I remember rightly, does not object to thin sheets or veneers of marble being used for the adornment of buildings in Venice, and surely what is permissible in them there, can hardly be wrong in furniture in this or any other country. The materials are different, but the principle is the same. If it is not proper to cover a base wood with a more valuable one, it can hardly be right to cover a common stone with a choice marble. But this brings us very near to the adornment of brick buildings with an outer coating of more or less ornamental stucco; and it may be asked if this also is to be considered as a veneer, and to be advocated for the same reasons. Such a question is a very natural one, and is not lightly to be dismissed, though to discuss it at length would lead far from the present subject. It will be sufficient to suggest that properly applied veneers on furniture, and stucco on buildings, are scarcely the same in character any more than in material. The object of both is the same, viz., to render a surface more pleasing to the eye by external finish than it would, to the majority of people, be without it. Here, so far as our present purpose is concerned, the resemblance ends.

Undoubtedly, one great reason why veneering is regarded with disfavour is on account of the faulty manner in which it is sometimes used, and the facility with which it may, by unscrupulous people, be taken advantage of to hide defects in work or material. I am far from saying that all veneer is correct, either in application or intention, for unfortunately this cannot be affirmed with accuracy. It must be admitted that sometimes one finds veneers used in a manner which cannot be justified, but at the same time the whole blame must not be attributed to the workman or the manufacturer, for if certain classes of the public did not demand articles at impossible prices, the production of low class furniture would, to a very great extent, cease.

When veneer is used on an unsuitable wood, or otherwise improperly, it is, of course, not to be commended, but might not the same be said of any other operation? It is not the veneering itself which is wrong, but the mode of work which is at fault. Even when furniture is made without veneer, it is quite possible for it to be defective; but no one on that account would say that it is wrong to make it solid, *i.e.*, without finishing it with veneer. The remedy lies in seeing that all the work is properly executed, not in abandoning a process. Taking a further and usual mode of finishing furniture, French polishing, it might with equal justice be urged, that because this is occasionally badly done, therefore no polishing is to be regarded with anything but feelings of reprehension. It will be observed that nothing is said about personal likes or dislikes of brightly polished surfaces, as that does not affect the comparison. I only want to show the unreasonableness of utterly discarding a process which is commendable, or, at any rate, allowable and useful, simply because it is sometimes abused.

OUR GUIDE TO GOOD THINGS.

73.—The Smallest Thing out in Planes.

A correspondent has called my attention to what may be called the smallest thing out in planes, and has sent me a specimen for testing. The body of the plane, which is of iron apparently nickel-plated, is barely $\frac{7}{8}$ in. long, a little over $\frac{1}{4}$ in. wide, and a little less than $\frac{1}{4}$ in. deep. The interior is cut away from the top, so that the hollow thus formed has a **V** shape, the sides being inclined to one another at a right angle. There is a slot at the bottom to allow of the projection of the edge of a tiny cutter, about $\frac{3}{16}$ in. in width, which is attached to one of the sloping sides of the interior by a small screw. At one end is a split ring, by which the plane may be worn on the watch chain. The cutter is made of the best steel, and being sharp and capable of being sharpened at pleasure, the plane, small as it is, may be used to take off the fine edges in delicate cabinet work, or to sharpen pencils. I am told the price of the plane is 1s., and that they can be purchased of Mr. E. Walker, 20, Legge Street, Birmingham, of whom any further information respecting them can be obtained.

74.—The "Firm and Safe" Step Ladder.

The step ladder shown in Fig. 1 of the accompanying illustrations shows the best form of this useful household appliance that has yet been introduced. The old make of step ladder, for use chiefly in the dwelling-house, was similar, it is true, in general appearance to the "Firm and Safe" Step Ladder, but it will be remembered that the only means whereby the back was kept from spreading out to too great an extent from the front was by a couple of pieces of cord, which permitted the extension of the steps just so far as their length would permit, and no farther; and sometimes if the cords were not fully extended, the ladder might sometimes slip under the weight of the person who was going up the steps, and a serious fall result from the slipping. This step ladder, however, is fitted with Gibson & Glazier's Patent Locking Stay in lieu of cords, and it is in this fitting that its firmness and safety are found; rendering it the means of supplying to perfection a long-felt want, namely, a thoroughly well-made and absolutely safe article, both for domestic and trade purposes: for the Patent Locking Stay gives strength and stability where it is absolutely required, thus rendering the step ladder under notice the best and most reliable article in the market.

The form and nature of the Patent Locking Stay is shown in Fig. 2, in which it is represented when the ladder is being closed. It consists of two parts, a straight bar, one end of which works in a socket, screwed to the bottom of one of the steps in the front of the ladder, to which it is secured by a pin riveted without the socket at each end. The other end also works on a pin passing through the straight bar, which is placed between two curved bars, which work on sockets screwed to a rail across the back of the ladder. When the ladder is closed, the straight bar is erect, and drops into a notch cut for it in the step to which it is attached. The curved bars are also erect, or very nearly so, and are in the framing of the back above the rail to which they are attached. When the ladder is opened, the bars gradually descend until they come into one and the same plane, forming a rigid extension between the front and back of the ladder. When in this position they are locked and prevented from moving by a brass bolt or button shown at A, which is clamped to the straight bar and travels along it. When this is withdrawn, the locking stay can be lifted, and the step ladder closed.

In addition to being secured in this manner, the step ladder itself is also well and stoutly made of good, sound inch timber. The steps are grooved into the sides and securely nailed, and under the bottom step and second step from the top, a turned wooden pin, $\frac{3}{4}$ in. in thickness, is placed, which, it is claimed by the manufacturer, makes a much sounder and stiffer job than iron pins, or even tenons, on the ends of one or two steps. The top rail of the framing which forms the back is purposely kept below the uppermost step but one, so that when the step ladder is open it will not be in the way of the feet of any one when standing on that step. Moreover, this arrangement permits pulling through a scaffold board on that step, which is frequently required by painters, decorators, whitewashers, etc., for whom a couple of sets of step ladders will serve as admirable trestles for forming impromptu scaffolding. For the use of tradesmen, such as those just mentioned, larger ladders are made, somewhat heavier, and it is absolutely impossible, on account of the rigidity afforded by the stay, for the back legs to wriggle or twist about, as is the case with steps that are fitted with cords. The ladders have a nice appearance, being stained

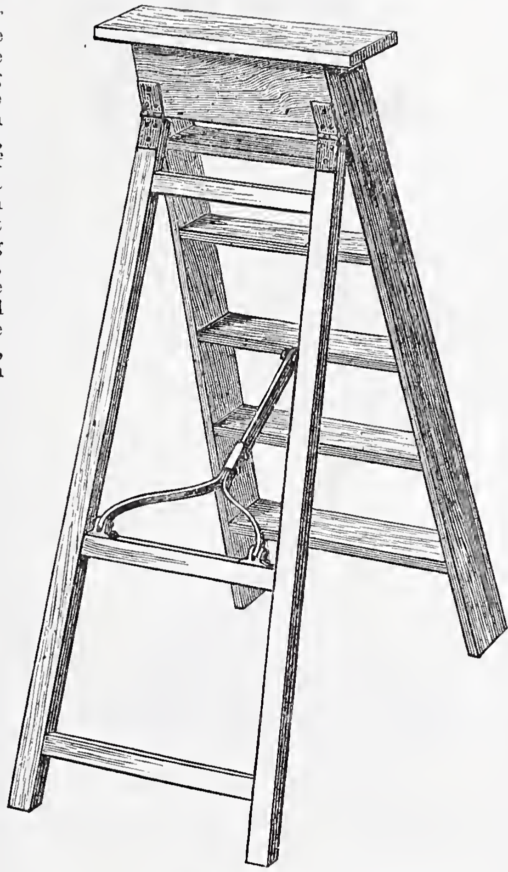

Fig. 1.—Step Ladder Opened and Locked for Use.

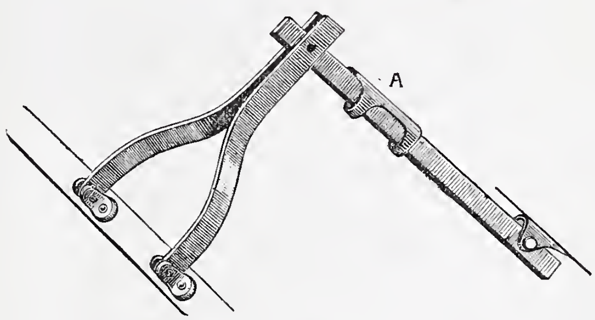

Fig. 2.—Position of Stay when Ladder is being closed.

and varnished before being sent out. I can speak favourably of them, having had one in use in my own house for some few weeks in order to test it thoroughly, and the result is that the old steps with cords have been turned out to make room for the new comer. I should say that the "Firm and Safe" Step Ladder is manufactured and supplied by Mr. William Glazier, 97, Tulketh Street, Southport, Lancashire. The price of each ladder depends on the number of steps of which it consists, the price per step being 1s. 3d. The locking stays are supplied for fitting to any make of ladder, in three sizes, sold respectively at 18s., 21s., and 24s. per dozen. I strongly recommend carpenters and joiners who are in the habit of making these appliances for sale, to provide themselves with a supply of Gibson & Glazier's Patent Locking Stays, and to send out no step ladder without it; and upholsterers will be wise to add the "Firm and Safe" Step Ladder to their stock, and exhibit its decided advantage over the old steps with cords to all customers who may be in search of such an appliance for home use.

75.—Vevers' Registered Plate Lifter.

Mr. C. C. Vevers, 12, Market Street, Briggate, Leeds, sends a new edition of his "Practical Amateur Photography," which is sold at 6d. This handy little book is divided into two parts, in the first of which the different processes in the art of taking a photograph, from the operation of taking the negative to the finishing of the point, are described in clear and simple language, calculated to make each step intelligible to the amateur beginner. One formula only is given for each operation, which is beneficial in enabling the learner to avoid the uncertainty, both of mind and action, which invariably sets in when a number of recipes are given at the same time, without any indication of the best for the beginner to take in hand and test under particular circumstances.

The second part of this *brochure* is more advanced, and therefore better suited to those who have mastered the rudiments of the process, and are ready to proceed beyond the beaten path described in detail in Part I. Thus the second part contains directions for working the Celluloid and Eastman films, for carrying out the carbon, platinotype, gelatino-bromide, and other printing processes, with formulæ for various developers and toning formulæ.

The "Registered Plate Lifter," sent by Mr. Vevers, looks very much like a thimble without a top, with a piece of metal extending from one side of the finger-socket for about 2 in., in the form of an elongated finger nail. The plate lifter is placed on the top joint of one of the fingers, and the plate is lifted from the bath by means of the metal projection already referred to. Of its utility or advantages I am unable to speak, but Mr. Vevers states that an enormous number have been sold since the time that he first introduced them, which was only a few months ago. Some, however, consider that its use would be detrimental, inasmuch as the plate might be scratched by the point of the metal. Be this as it may, it would certainly keep the tips of the fingers clean if it did nothing more. It is right to add that at the end of the book a set of chemical labels, printed in bold type on paper gummed at the back, will be found. The photographer will find these extremely useful, as they can be detached when required by the aid of a penknife or scissors, and attached to the bottles containing corresponding chemicals or solutions, relieving the owner from the trouble of preparing written labels for the purpose of distinguishing the contents of the bottles on which they are placed. Among other new matter will be found notes and remarks on the new platinum process and the hydroquinone development. A frontispiece is also added, which affords a good example of flash-light photography, reproduced in photographic zinc etching. The Editor.

SHOP:

A Corner for Those who Want to Talk It.

*** Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

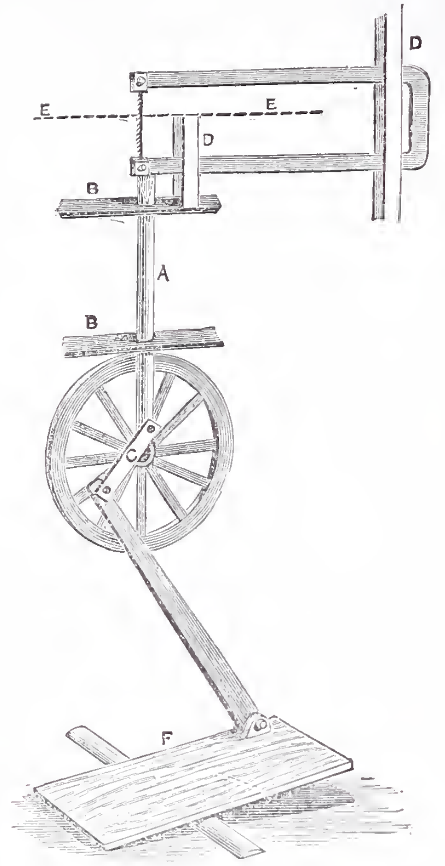
I.—Letters from Correspondents.

Pit Frame Saws and Paste.—G. W. (*Bournemouth*) writes:—"Is same inserted in No. 15 simply to fill space, or to give some superannuated wheeler a lift? His construction may do for a coster's wheel or perambulator. How about wheels, say, from 2 to 6 in. tyre? Had he taken the trouble to look in any good London wheelwright's shop he would see the *pit* is a necessity, and not confined to the country. If it is meant for amateurs it is merely waste of valuable space. If for pro.'s they will simply 'smole their smile,' as not one in 500 will undertake such laborious ill-paid work as wheeling. Should they feel like it, let them apply your tip. French prepared wood may now be bought (at less cost than English stuff in the rough) ready to put together. The cost of putting together machine stuff is for labour only from 6s. to 16s. per pair; barrow wheels, 1s. each. You will see it is about as useful as teaching how to make a hatchet. How does the set stick work? Is mortise cut long? The way of securing the nave weakens the frame, causing it to spring at every blow. Could send you simple, cheap, secure fastening (sketch of). J. H. seems to know something of saws. Some amateurs may not be able to procure a set. To them I would say push on with what you have. I made three carriage bodies with nothing but a piece of hand saw. If a sharpener is not handy, do it yourself. If for hard wood sharp, with square points, or not quite so pointed as J. H. recommends—that is, where only one saw may be at hand. J. R. will be answered, no doubt, in your papers on coach building. I much doubt whether paste will answer for office work, being too long drying."

Advertising and Advertising.—Handel St. Clair writes:—"Your note to hand regarding advertising plans for cottage. You misunderstand me. I only sent the design for the benefit of your readers, and to let them know that they can obtain full drawings of same for small sum, as all are invited to do in *Illustrated Carpenter and Builder*. As to its being an advertisement, what are all these lathes, etc., that you exhibit and recommend for the Britannia and other companies, but advertisements? Be that as it might, I do think you should try to introduce plans for houses. You might do worse than follow one of your correspondents' advice—to give prizes for best designs. I am certain it would prove an interesting study for everybody, and be something practically useful instead of filling your periodical with fretting, carving, embossing, repoussing, and such like rubbish, fit for none but professional amateurs who have more time than talent, and more money than sense."—[When you asked me to publish designs for cottages, and acquaint readers that they can obtain full drawings of same for small sums, you simply asked me to advertise your designs in Work, and I wrote, telling you to apply to the advertisement department, who would give you terms, etc. The notices that I give in "Our Guide to Good Things" are not advertisements. Makers and dealers invite notice of their goods in precisely the same way that publishers invite notice of the books they publish in newspapers and literary journals. Everything is reviewed on its merits, and whenever you like to send me any article you have invented or made for general sale, I shall be happy to do the same for you as I do for others.—Ed.]

Scribing Wheel.—J. W. (*Burton-on-Trent*) writes:—"I beg to ask your opinion of what I think would be an advantage or improvement in compasses. Sometimes in scribing skirting down to a floor with the ordinary compass, the leg marking the wood is apt to follow the grain, unless great care is used, thereby causing wood to be cut away where it is not wanted. What I would suggest is that one leg should have a small revolving wheel, instead of the ordinary point, the wheel to be ground to a fine edge, and toothed. I think it would then run over the surface of the wood without following the grain, and it would answer quite as well as the ordinary compasses for describing circles, or any other purposes to which they are put. If you will kindly reply in 'Shop' and tell me what you think of my suggestion I shall feel greatly obliged. You need not put it so that any readers of Work would understand it, as I should like to have the advantage of it if there is any."—[I give your letter in full. I need only add that your idea is correct in theory, and will be found so in practice. It is the principle of Barrett's improved combination roller gauge described in No. 13, page 203, to which I may refer you. In this the ends of the bars are fitted with revolving wheels, which will leave a mark even on the hardest knot.—Ed.]

An Easily-Made Fret Machine.—W. R. S. writes:—"The fret machine here illustrated claims to possess the following recommendations to the amateur:—A vertical stroke, easily constructed, and can be made for a few shillings. The parts required are as follows:—A wheel 12 in. in diameter; two pieces of bar iron ½ in. × 1 in., the frame of an ordinary iron hand fret saw (one with a spring in the back will be found best), costing 1s.; and 2 ft. of ½-in. brass gas-pipe. First fix the wheel about 18 in. from the ground; above this place the two pieces of bar iron, B, bored with a half-inch hole in the



An Easily-made Fret Machine.

A, Piece of Brass Gas-pipe. B, B, Pieces of Bar Iron, with half-inch hole bored in the centre of each, to take the Shaft, A. C, Treadle Crank. D, Slide for the Frame to run in. E, Table. F, Treadle.

centre, placed a foot apart in these holes; insert the piece of gas-pipe, A, having previously bored a hole, and flattened the end nearest to the wheel. Great care should be taken to see that the pipe comes exactly over the centre, as the successful working of the machine will depend upon this. Drive a piece of beech, or any similar hard wood, in the other end, and in this strongly fix the iron frame. The far end of the frame and the part under the table should have two slides, D, made of mahogany; this will steady the frame when running. The treadle can be made in the ordinary way; of course the throw of the machine will be double the distance from centre to centre of the piece marked C. I have tried to make the description as lucid as I possibly can; but should any difficulty be experienced by the reader, I shall be happy to answer queries through the columns of 'Shop.'"

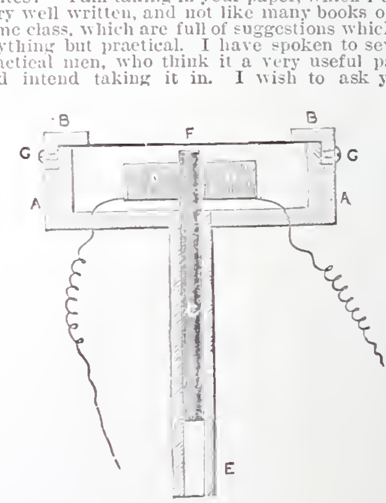
Elizabethan Twist in Lathe.—W. P. W. (*Newport, Mon.*) writes in reply to C. C. E. (see page 109):—"C. C. E. still believes there is no lathe in existence in which the spiral can be cut and finished by the tool. He says it might be fairly done by a complicated apparatus in ivory or hard wood. But he will be surprised to know it can be done in any wood. I have a piece cut in yellow pine 1½ in. pitch, with only the cutter, and I believe sand-papered afterwards. There is no costly or complicated apparatus required for this work; any lathe having an overhead gear, and any means (whether screw cutting or not) to determine the pitch, is equal to this task. My own lathe is a 4½ in. centre screw cutting with overhead gear. With this I have no difficulty in making a 'convex curve die into a concave without a break,' as easily as shelling peas. If C. C. E. was referring to me when he said 'he had found such men as you referred to, but could never run them to ground,' he will have no such difficulty with me. You are welcome to give him my address, and I am willing to show him my tools, or, as I promised before, he can have a specimen cut."

Back Numbers.—X. M. T. C. C. (*Belfast*) writes:—"Having had the good luck to fall in with No. 14 of your very valuable little paper, I am determined to take it constantly, as I find a great deal of good information in it. But I am sorry to say that I missed the first number of it, so that is what is making me write this miserable letter to you. I want you to let me know, through the medium of 'Shop,' if you could supply me with Work, from Nos. 1 up to 13, as I have got 14 and 15. If you have them, please let me know the cost of sending them to Belfast, and I will send name and address. Hoping that you may have all the numbers of Work that I want, I wish you every success with your undertaking."—[Nos. 1 to 13 of Work can be had by order of any newsagent, or the publishers can send the thirteen numbers free by post, on receipt of your remittance for 1s. 3d.—Ed.]

About Work.—A Well-wisher (*Dover*) writes:—"Being an amateur workman, I have often wished for a book that would be useful, but have always found them beyond my means, with the exception of one or two works with which I had to content myself until I first saw your valuable publication, Work. I should like to thank you for your endeavours to meet the requirements of such as me. I cannot tell you how valuable Work has been, is, and I trust will be, to me; nor how I long for Wednesday to come round that I may get the next edition. I have not yet made the overmantel nor the bureau, but I am making a cornice similar to the one given in Work. 'Shop' is a proper corner of tit-bits for every one."

Enlargement of Work.—Kildonan (*Inverness*) writes:—"Permit me briefly to enter my dissent from the suggestions of F. A. C. (*Bradford*), and others, as to the enlargement of Work, and its consequent increase in price. Personally I should be quite willing to pay 3d. weekly for a larger paper, and would not feel it a very heavy tax on my resources; but what about the hundreds, it may be thousands, of young workmen, apprentices, and poor working men with large families and small wages to whom the present cheap and good publication is a great boon, if the price were raised? It may be a paltry sum for well-to-do tradesmen, and others in comfortable circumstances, the extra 4s. 4d., or 8s. 8d. annually, but it is not so to many an artisan, and I think it would be opposed to the traditions of the great house of Cassell & Co. to place their publications beyond the reach of the working classes. I am speaking, of course, of the poorer sections. I have no doubt the publishers know their business quite well enough without outsiders like myself poking our noses in and offering suggestions as to what should or should not be done; but it occurs to me (and I offer the suggestion in all humility) that when the volume is bound the advertisements on the last leaf of each number will not be pleasing to book lovers generally. If a coloured (or any) wrapper were issued with each number, would not the advertisements pay the outlay arising therefrom? This would throw open two more pages of Work for the editorial staff (N.B.—No *pook* meditated here), while the cover would be valuable in keeping the numbers clean while being read or used from week to week. I do not by any means wish it to be understood that I would not like to see Work enlarged; but I hold that it is an excellent pennyworth as it is, and knowing from past experience the scarcity of pennies with many lads learning their trade, I think it would be a pity to raise the price. I have not noticed any one taking this side of the question, and seeing so many advocating the extension in size and price, I have taken the liberty of glancing at the other side."

Telephones.—J. W. C. (*Clapham Common*) writes:—"I am taking in your paper, which I think very well written, and not like many books of the same class, which are full of suggestions which are anything but practical. I have spoken to several practical men, who think it a very useful paper, and intend taking it in. I wish to ask you a



few questions on telephones. I see in Work for June a note in 'Shop' in reference to this subject, from which I am led to infer that it will be put off for an indefinite period. I wish to make telephones that would not cost more than 5s. not including the batteries, and that would be strong enough to work a distance of about 50 ft. of wire between the two telephones. The sketches on slip enclosed will show my idea of what might be done. A A, B B, might be a tooth-powder box and cover; what size? C, bore of iron wires to coil; what diameter? D D, coil; what kind and quantity of wire? E, a wooden cylinder with hole drilled through centre to admit end of core, and to fix it, and then glued into a hole at bottom of A A. F a vibrating plate of some description; what made of? same size as edge of box to snap on with cover; or if that is not firm enough, a small screw to hold it on the cover as at G. The circular hole in cover to extend nearly to inside edges of A A. What batteries would be required of Leclanché's pattern? This is something similar to a sketch I saw eight or nine years ago."

II.—Questions Answered by Editor and Staff.

Mechanical Drawing.—R. R. W. (*Glasgow*).—If you are unacquainted with drawing, you cannot do better than join the local school of art in connection with the Science and Art Department, South Kensington. You will at least get the rudiments then; but if you wish to teach yourself you can hardly have more reliable guides than Cassell's Popular and Technical Educators. You must not, however, think that you can get much practical knowledge without experience under a competent draughtsman in the special line you wish to study. By all means try and get into an office as soon as you have acquired a slight knowledge of what is required and have a general idea of what to do. Your scholastic and practical training might very well be pursued together.—D. A.

Hammering Saws.—Tancred.—You wish for a practical paper on striking a buckle out of a hand saw, and say that there is hardly one joiner out of a hundred that can do it. I quite agree with you in this. The difficulty is in determining precisely where each successive blow should be delivered, so as to take out the buckle and bring all the atoms of iron that form the blade into one and the same plane, relatively speaking. Each blow tends to alter the position of certain particles, and to drive them one way or the other, and the percussion must be continued until a proper distribution of the atoms is once more brought about. I doubt the possibility of dealing with such a subject otherwise than theoretically, for I feel sure that every buckled saw blade would require different hammering, so to speak, and it is only an expert who has been long accustomed to the work who would at once recognise where to strike and how hard a blow to deliver. By my reply I have given publicity to your inquiry, and if any reader can, and will, give us a paper on the subject, I shall be glad to receive it, and produce it in Work at the earliest possible date.

Clay for Making Earthenware.—Potter.—Devonshire and Dorsetshire furnish most of our clays for this art; much depends on the mixing and preparing; and it will probably be best to buy clay ready prepared from a pottery. At such an establishment as Messrs. Doulton's, Lambeth, we imagine that almost any variety desired would be procurable. The exact speed of the potter's wheel we cannot tell; the rate is not uniform, but constantly varied according to the requirements of the "thrower" (the workman who shapes the vessel), and in obedience to his directions.—S. W.

Protecting Papier-Mâché Boat from Sea Water.—Bofin (*Galway*) may protect his papier-mâché boat from the action of salt or other water by painting it with a solution of gutta percha or indiarubber. As he may find a difficulty in buying such a solution at the shops to which he has access, he may make one by dissolving gutta percha in naphtha and adding a little shellac; the consistency should be that of thinnish paint.—S. W.

Electric Gas Lighter.—H. (*Brighton*).—You evidently refer to Clarke's patent gas lighter. I cannot give you detailed instructions, or how to make one of these instruments. I do not consider the price at all prohibitive. There is much fine and exact work in one of these little instruments. They are really miniature cylinder machines for producing static electricity.—G. E. B.

Electric Belt.—Tinman (*Homerton*).—"A medical galvanic belt" may be made by linking 1-in. discs of lozenge-shaped pieces of zinc and copper to each other alternately. Two of such chains should be sewn in a flannel belt with a piece of flannel between the chains; the alternate links of each should form galvanic pairs. When the flannel is moistened with vinegar or with sweat, a current of electricity will pass on joining the ends together. But what good purpose will this serve? Will such belts cure or alleviate pain or disease? I have never known them to do so.—G. E. B.

Wood for Engraving.—Tom.—The wood on which woodcuts are engraved is boxwood—a yellow wood, hard and close in texture. Letters for printing may be cut in apple or pear wood. I cannot tell you where evening classes are held, if held at all, at which the art of wood engraving may be learnt. Were it not good for trade, I should be sorry to hear you have already lost Nos. 2, 3, 5, and 7 of Work. All numbers are kept in stock, and can be obtained at any time through a bookseller or newsagent who also supplies serial publications.

Arts and Crafts Exhibition.—E. S. (*Salisbury*).—For regulations for exhibitors and form of application for entry, apply to the secretary, Mr. Ernest Radford, 45, Great Marlborough Street, London, W. I shall be happy to give publicity to all forthcoming industrial and other exhibitions, in order to bring them under the notice of workmen, professional and amateur, who may be readers of Work.

Cutting Bevelled Recessed Mounts.—W. A. R. (*Hanley*).—A professional mount cutter when cutting cushion, oval, dome, or any fancy shapes, depends upon his eye and steady hand, after marking out in pencil size and shape requisite. In cutting straight bevel or square openings for water colours, photographs, etc., I use a cardboard bevel edge as a guide for regularity of bevel, which is made by cutting a slit in a long piece of card, thus:—

Tools for mount cutting:—Steel straightedge, for marking straight lines; knife blade and handle; one pair dividing compasses; black lead pencil; eraser (piece of indiarubber); lining pen for making gold lines; 3-ft. rule; cotton and pins for marking ovals; oilstone; one set square; one bevel slot; which are not usually sold, as there is a certain amount of jealousy against the amateur. There is no book published, that I am aware, of practical utility to frame makers, etc. The City Frame Company is willing to supply any article for frame making, mount cutting, etc., and show amateurs their works.—G. R.

Papier-Mâché.—Fairflax (*Dartmouth*).—We see no reason why ordinary brown paper should not do for pasting panels, if porous; though so far as we are aware nothing so stout has been used in the trade. The glue is put into the paste by guess; it is hard to name an exact quantity, but for such stout paper ¼ oz. to the half pint would probably not be too much. At any large tool shop, a curved rasp may be got; or an ordinary rasp, which any blacksmith can bend to shape, will answer the same purpose. Black japan (black tar polishing varnish) may be got at Thornley's, 8, Snow Hill, Birmingham, at about 3s. 6d. per gallon; but Fairflax can doubtless obtain current price by writing to that address.—S. W.

Wood for Suite.—J. A. (*Castleford*).—A good deal depends on the kind of suite you want to make, but from your reference to table I presume you mean one for a bedroom. If so, red pine free from knots would do for cheap work, but ash is more suitable, and is frequently used for light bedroom furniture. Birch is another favourite wood for the purpose, though not so much used as formerly. Speaking generally, any of the lighter-coloured woods are suitable for your purpose.—D. A.

Picture Moulding Sellers.—L. S. B. (*Stepney*).—I should think if you apply to City Frame Company, 29, Basinghall Street; they supply every requisite for frame making and mount cutting at most reasonable prices, and undertake to supply at a special discount subscribers to Work. As an example, they would supply your glass in 300 ft. cases, picture quality, at 1½d. per foot, ⅜ best washable gold moulding, from 5d. per 9 ft. length, or 4s. 6d. per dozen, etc. etc. If you write or call, they will supply you a set of samples and prices of anything you may require.—G. R.

Regilding Looking Glass. — B. N. (*West Ham*).—Firstly, take your frame without the mirror, and thoroughly dust it; take a bowl of warm water, and wash the old size off, leaving gold but clean. Apply a thin coat of japanners' gold size with a soft brush, and then put the gold leaf on with a gilder's tip, and wipe off with cotton wool, so as to make it smooth when dry, then apply a coat of clear vellum size, which adds softness to the gold, and keeps it much longer.—G. R.

Patents.—W. H. W. (*Liversedge*).—(1) The £1 you refer to is the Government stamp for a provisional protection, which is generally a preliminary to applying for a patent. The provisional protection extends for nine months, but has not the entire advantages of a patent. (2) You can apply for your complete patent any time within nine months from the date of the application for your provisional protection. (3) The Government stamps in all for both these matters are £4. The address of the Patent Office is 25, Southampton Buildings, London, W.C.—G. H. R.

Brickmakers' Clay for Modelling.—W. G. C. (*Sudbury*).—The clays used for brickmaking vary widely; that of which fire bricks are made is very good for the purpose; but most ordinary brick clays are impure, and not sufficiently plastic to work well. Still, if W. G. C. cannot readily get Devonshire pipe clay, or any other comparatively pure clay, he may make shift with the clay nearest to hand by thoroughly well tempering and beating it up, and sifting in some fine sand to render it more plastic. As regards instructions, he will soon see all he wants in Work. Comprehensive articles on modelling, by a professed figure modeller, are already written, and will appear shortly.—S. W.

Electric Lighting.—T. P. (*Hull*).—This subject will be taken up and thoroughly dealt with in time. As I have had occasion to say before, it is beyond possibility to handle every subject at once.

Right and Left of Drawings.—R. H. H.—On the stage, right and left is according to the position of the actor as he faces the audience. R, signifies to the actor's right hand; C, the centre of the stage; and L, to his left hand. In drawings, however, the convenience of the person who is looking at them is consulted, and that part or side of a drawing which is opposite to his right hand is spoken of as its right, and that opposite to his left hand as its left. I trust this will make the directions already given perfectly clear.

Beaton's Pocket Technical Guide.—P. J. (*Doncaster*).—The price of this handy waistcoat pocket volume, published by Messrs. Crosby Lockwood & Co., Stationers' Hall Court, London, E.C., is 1s. 6d.

Alleged Mistake.—B. S. T.—Your letter having neither name nor address might be disregarded as anonymous, which, when an assertion such as yours is made, should not be. However, *pour encourager les autres*, I give it attention. Of course, if the article you comment on were made according to the diagram you send, the result would be as you say; but it is nowhere stated by the writer that both pieces are to be of the same length. The hinder one must naturally be shortened at the free end sufficient to give clearance, and in writing the description it was taken for granted that readers would understand this, especially as the illustration, Fig. 1, shows that one support projects further than the other. The drawing being in perspective, you have probably overlooked this. If you object to this formation, you can easily adapt supports which are of equal length, by hingeing in the same line and meeting in the middle. When extended, they will project equally, but will not afford the same stability, and for that reason are hardly so suitable. I think you will now see that there has been a mistake, but not where you suppose, and that if you had made up the work you would have seen that the objection you urge, if it be one, is entirely theoretical. I am always pleased to help inquirers, so that if you meet with any further difficulty you may write again; but if you will re-read the paper referred to now, I have no doubt you will find everything quite clear.—D. A.

Battery for Alarum Clock.—A. E. B.—The Leclanché battery is one of the best for this purpose. If, as you say, the battery soon runs down, the fault is not so much in the battery as in the other arrangements. Your connections or line wires are faulty, and so badly constructed or set up as to cause leakage of current. In this way the battery is at work day and night always, and no battery will long withstand such usage without running down. The wires leading from the battery to the clock, from the clock to bell, and from bell back to battery, must be well covered with cotton or silk, and two *wires must not be run along together* under one staple. The battery must not be kept on a wet shelf. On the clock, the little trigger that sets the alarum going must be insulated from the rest of the clock. The whole must be switched off in the daytime. Attend to all these matters, and don't let the alarum ring for more than five minutes at a time; then your battery will last from two to three years. If this don't mend matters, ask again.—G. E. B.

Bichromate Battery for Electric Lighting.—Electricity (*Middlesborough*).—(1) The bichromate battery in its ordinary form is not suitable for electric lighting, because it polarises so quickly after the circuit is closed. But when the cells are used with chromic acid in solution, instead of bichromate of potash, they give more satisfactory results. The solution is made up in a similar manner, and with similar quantities of ingredients, using only the chromic acid instead of bichromate of potash. The number of cells required will depend upon the resistance of the lamp. Find out this, and allow one cell or one pair of elements for each 2 ohms resistance in the lamp, and then one cell to overcome resistance in the wires. (2) A 3½-in. (diameter) ring armature will be quite large enough for the gramme dynamo. You have not mentioned the other parts. Is this all you wanted to know about?—G. E. B.

Electro-Motor. — J. W. (*Handsworth*). — The bobbins for an electro-motor should be wound in opposite directions—one from left to right, and the other from right to left. The outside or finish end of one coil should be connected to the inside or commencing end of the other, so that winding of one coil should be to the other as the lower part of the capital letter S is to the upper part. In connecting the wires, proceed as follows:—Connect one end of a bobbin coil to a binding screw connected with the battery. The other end of the other bobbin coil must go to one of the commutator springs (or brushes), as they are named. The two ends of the armature coil are to be connected to the two sections of the commutator. The other brush or spring must be connected to the opposite pole of the battery. The bobbins may be of brass if the wire is well insulated; but boxwood or ebonite is preferable for bobbins on small machines. In referring to back numbers, please quote title of article and page on which the article is printed.—G. E. B.

Telephone.—J. W. C. (*Clapham Common*).—The telephone sketched by you in your letter is an old form of this instrument brought out by amateurs several years ago, and then named the "pill-box telephone." The wooden pill or tooth-powder box may be anything from 1¾ in. to 2½ in. The core may not be of iron wires, but must be a round bar magnet held in the wooden handle, and protruding into the box far enough to hold a bobbin filled with wire, and with its end close to, but not touching, the diaphragm, as shown in your sketch. The diameter of bar magnet may be from $\frac{3}{8}$ in. to $\frac{1}{2}$ in. The steel must be hard and well magnetised. The bobbin should be of boxwood or of ebonite, and the reel ends from $1\frac{1}{4}$ in. to $1\frac{3}{4}$ in. in diameter, to suit the size of box. The bobbin must be filled with No. 36 B.W.G. silk-covered copper wire wound on in regular layers. The ends of the wires should be run through holes in the handle to two small binding screws at the sides for convenience of connecting to the line wires. The vibrating diaphragm, or disc, must be of very thin charcoal iron plate, or the ferrotype plate used by photographers. It must be pinched tightly between the edge of the box and cover all round equally, but free to bulge in and out in the middle. The cover may be held on with three fine screws. It must be hollowed on the outside from the edges to centre, or to edges of $\frac{3}{4}$-in. hole in the middle, as you suggest. No battery will be required, as this is a magnetic telephone, worked by current from the magnet. The lines should be of No. 18 or 20 copper wire well insulated and supported on insulators. It must also be kept away from the rear neighbourhood of telegraph wires and electric bell wires. The range of action in this telephone is limited, but I think it is effective up to fifty yards. Of course you must have a pair of these instruments—one for transmitting, and one for receiving the sounds.—G. E. B.

Folding Chair and Table.—A. J. B. (*Dover*).—Your combined folding chair and table seems to be a compact arrangement, but has the disadvantage that the user once in the chair will require an attendant to bring anything he may wish to put on the table, unless he first puts all he may require on the ground beside the chair before shutting himself in.—F. C.

Binn's Endless Blind Cords. — J. J. M. (*Leicester*).—This is not a new invention. In fact it is so old, I think, that the patent rights must have expired. I do not know the maker, or if made still; but Pitman, Son & Co., Wells Street, Falcon Square, E.C., are, I should say, the most likely people to get it from. It is quite impossible to give answers in "Shop" until a few weeks after they have been received.

Terra-Cotta Figures.—E. P. W. (*Stratford*).—Terra-cotta figures may be bought in Piccadilly, London, at Bellman & Ivey's (37), or at F. Ahrend and Co.'s (165). Plaster figures would, however, look as well when bronzed, and would be much less costly.—M. M.

Index to WORK.—W. H. R.—As it has been already stated, an index will be prepared for each volume of WORK.

Electro-Motor for Steam Launch.—ELECTRO.—In reply to your request for "a paper or two on the construction of an electro-motor accumulator, etc., to drive a small launch about 20 feet long, for up-river work, my object would be to get the greatest amount of power with the lightest possible accumulator." I can only say that the subject will be taken in hand as soon as an opportunity occurs.

Silver-Steel Hand Saw.—G. B. P. (*Birmingham*).—Messrs. Spear & Jackson, Ætna Works, Sheffield, send out their saws in quarter dozens, so that you might get one for yourself direct from the manufacturers, if you can prevail on two of your friends to take the others. I am astonished to learn that you cannot get the saw noticed in No. 8 of WORK, page 124, in Birmingham, at any dealers in hardware. If you give the order to any retail dealer, I imagine he would procure a quarter dozen, and take his chance of selling the other two. Of course, R. Melhuish & Sons would get one for you, but what a roundabout way of getting a thing in Birmingham from Sheffield, *viâ* London!

Serial Papers in WORK.—H. W. (*Edinburgh*).—Various things are under consideration, which, if adopted, will in all probability commend themselves to most readers of the Magazine, and that which you mention in your communication will receive attention. Your other question is answered elsewhere.

Map Mounting.—H. G. (*Brentford*). — Map mounting as an amateur has always been more or less a failure, so far as I am concerned; but the least unsatisfactory result was with a coarse, white muslin, which is so open that it allows the parts to work through freely. I paste the map well, and then lay the muslin lightly over it, waiting until it is nearly dry to fold it, with white paper inserted between the surfaces, and then press it under a light weight.—E. B. S.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Bronzing a Gun Barrel.—LANCASHIRE JACK (*Preston*) writes:—"As an anxious reader of your valuable paper, I beg leave to ask for a recipe how to bronze a gun barrel."

Distempering Wood.—BELL asks:—"Can you give me directions for distempering wood?—a process often used, I believe, for decorating plain deal dressing tables, etc. I understand the mixture is useful to give articles a coat with previous to painting, as it fills up knots and the edges of a cut across the grain."

Mechanograph. — H. M. (*Oldham*) writes: —"Would you please tell me how to make a mechanograph, as I cannot buy one in our town—Oldham? There are two sorts, one that is made of five or six sticks, about 6 in. long, and the other of a piece of wood the shape of an egg, with a wire hoop, at one end a piece of string."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Bevelled Cog Wheels.—B. F. (*Liverpool*) writes in reply to POTTER (see page 222):—"POTTER does not state size. I have seen small ones about 1 in. diameter, or less, for 6d. each, in a tool shop near Lord Street, Liverpool; they are to be got at most of the watch tool shops in many towns, where the clockmakers go for what they require, also the model makers, Bateman, London, and others; and I often see them in brokers' shops, second-hand machinery dealers, etc., Booth & Co., Park Lane, Liverpool; or if you require bevel helical spur or double bevel the maker of every sort for the trade is Urquhart, Lindsay, & Co., Blackness Foundry, Dundee. Write for price list, and say size required."

Books on the Power Loom and Weaving.—J. W. C. (*Liversedge*) writes in reply to D. B. (*Perth*) (see page 253):—"One of the best books on weaving and the power loom is 'Weaving,' by T. R. Ashenhurst, of the Bradford Technical College, and may be had from Messrs. Emmott and Co., New Bridge Street, Manchester, 12s. Also a good book is 'Cloth Manufacture,' by Mr. R. Beaumont of the Yorkshire College, Leeds; and can be had either from the author, or Messrs. G. Bell and Sons, York Street, Covent Garden, London, 7s. 6d. I enclose my card, and any further information in any branch of the textile trades I shall be glad to supply you with. I am a weekly reader of WORK, and wish you success."

Marbling Washstand Tops.—F. P. (*Newport, Mon.*) writes in reply to W. H. J. (*Stratford*) (see page 222):—"If W. H. J. is a practical man, understanding the nature of the ordinary pigments and vehicles of painting, I should think there must be something very special, either as to time given for marbling or the style of imitation required, in the work mentioned for such a question to be submitted. Most cheap furniture work is got up and grained in distemper; but assuming the top to be paint, and a cheap finish only required, a coat of quick-drying white lead painted (mixed with equal parts turpentine and japanners' gold size) can be spread and marbled upon with willow charcoal at once; soften the veins by lightly drawing a brush over them, and in a couple of hours it could be varnished. If cheap imitation of sienna is desired, paint first with quick white, and when dry, marble with the usual tools and pigments, using equal parts turps and gold size for the wash—that is as water is used in water-colour painting. Any further questions would be cheerfully answered by F. P."

Flat or Dead Black.—F. P. (*Newport, Mon.*) writes in reply to OPIFEX (see page 218):—"Without wishing to question the practical value of the recipe given for making the above, a line on the subject from one who has prepared and used, professionally, gallons of such liquid may be acceptable to some readers. Purchase the 'drop' black (ivory drop black is the correct name), already ground in turpentine, thin with more turpentine, and add sufficient of japanners' gold size, about one-eighth part weight or bulk, to 'bind' the black. Any copal oil varnish will answer the purpose equally well, providing too much is not added, as the more varnish or gold size used the more lustre the black will dry with. Black japan and pestle and mortar are quite unnecessary; such round-about recipes as we sometimes get on similar subjects might well give place to the results of practical and professional experience and usage."

Gear Wheels for Lathe.—C. J. W. (*Beccles*) writes in reply to C. E. H. (*Warrington*) (see page 254):—"Messrs. Lloyd & Co., Steelhouse Lane, Birmingham, supply wheels in rough so cleanly cast as hardly to require any finishing beyond boring. The following are about prices in rough; any number of teeth, odd or even:—

15 to 24 teeth	... ...	4d. each.
25 ,, 30 ,,	... ...	5d.
31 ,, 40 ,,	... ...	6d.
41 ,, 45 ,,	... ...	7d.
46 ,, 51 ,,	... ...	8d.

And so on in proportion. I should say these are of 14 pitch for 3-in. centre lathe, but no doubt these pieces will be a guide to C. E. H."

Flour Paste Souring.—BING writes in reply to J. R. (*Skerries*) (see page 238).—"One pennyworth cobblers' paste, thin with warm water; when cold add one teaspoonful methylated spirit; well mix. I have used this for same purpose, and it will keep for a month."

IMPORTANT PRIZE COMPETITION.

THE Editor of WORK has the pleasure to offer his readers Prizes to the value of

THREE GUINEAS,

to be distributed for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

FIRST PRIZE ... One Guinea and a Half.
SECOND PRIZE ... One Guinea.
THIRD PRIZE ... Half a Guinea.

Full particulars of the Scheme will be found in WORK No. 17, page 254.

Trade Notes and Memoranda.

THE Fifty-seventh Annual Exhibition of the Royal Cornwall Polytechnic Society will open at Falmouth on Tuesday, 10th September, 1889. Medals and prizes are offered in special exhibitions of domestic lighting, mechanics, chemistry and electricity, fine arts, photography, natural history, and "Lander" competition. Lists of prizes and all further information may be obtained from the Secretary, Edward Kitto, F.R.Met.S., the Observatory, Falmouth.

THE South Wales Art Society and Sketching Club will hold its second annual exhibition in the Public Hall, Queen Street, Cardiff, on or about August 21st, as will be hereafter announced. Works will be received at the Public Hall, Cardiff, on Wednesday and Thursday, August 14th and 15th. The committee are prepared to receive the following for exhibition:—Recently-executed pictures, drawings, and sketches in all mediums, and on all materials ordinarily in use. Sculpture and modelling, carving in wood, stone, and other material efficient for the purpose. Metalwork, inlaying and mosaic in panels. Small articles of furniture or fittings, etc., which display artistic design or workmanship.

ALTHOUGH we have been building steel steamers for ten years past, the first Canadian steel steamer has only recently been launched for active work. The name of the pioneer vessel is the *Manitoba*, constructed on Lake Superior for the Canadian Pacific Railway Company to run between Owen Sound and Port Arthur. Her carrying capacity is 400 passengers, and 73,000 bushels of wheat.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

3 months, free by post	1s. 8d.
6 months, ,, ...	3s. 3d.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 22.] SATURDAY, AUGUST 17, 1889. [Price One Penny.

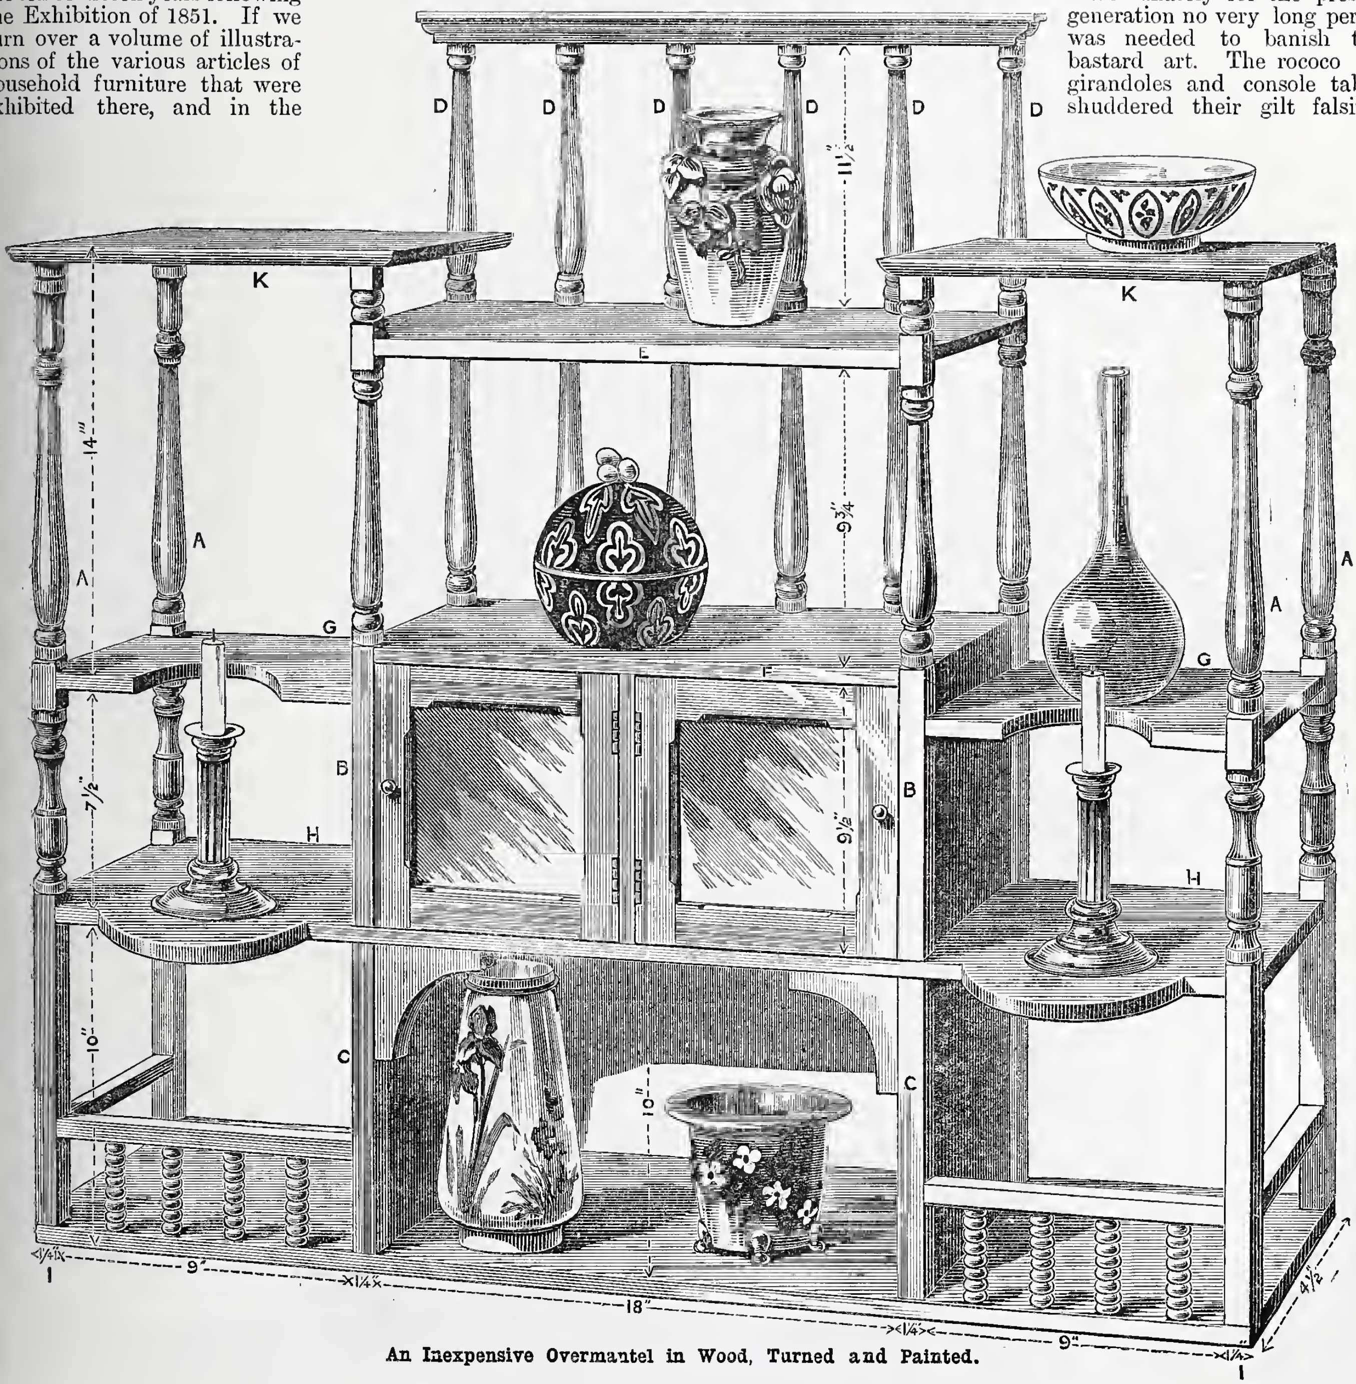
AN INEXPENSIVE OVERMANTEL.

DESIGNED FOR MORNING ROOM OR BED-ROOM.

BY J. W. GLEESON-WHITE.

Probably the national taste in domestic matters never touched a lower ebb than in the ten or fifteen years following the Exhibition of 1851. If we turn over a volume of illustrations of the various articles of household furniture that were exhibited there, and in the succeeding show of 1862, we are struck by the cheapness and vulgarity of the idea in their designs. A new attempt to beautify the surroundings of ordinary people was evidently beginning, but its first result appeared to be to oust all the merely solid and useful furniture of old form, ugly but fit, and to replace it by designs not one whit more beautiful, but overladen with tricky ornament. This practice of endeavouring to atone for commonplace and ungraceful shapes by applying lavish decoration, itself poor in quality, was even worse than what it aimed to improve upon.

Fortunately for the present generation no very long period was needed to banish this bastard art. The rococo gilt girandoles and console tables shuddered their gilt falsities



An Inexpensive Overmantel in Wood, Turned and Painted.

away quickly, but none too soon, and the bare meanness of their native composition became evident. The capital C's in violent agony stuck all over unmeaning curves of sideboard backs and sofas, shone in glittering varnish for awhile, and they too vanished into the great darkness. Into the night have gone one and all of these things; no longer gold and white wall papers chill us with their vapid flat surfaces; only third-rate apartments at the seaside, and such places, keep the frightful legend of their triumph; in every decent home they are gone, let us hope for ever.

But hardly had these things lost their popularity ere a new taste set in, growing suddenly into favour. Domestic Gothic, so-called, had almost overmastered us. A fierce faction fight between Gothic and all other styles seemed ending in favour of the former. Long considered the only suitable style for ecclesiastical use, it was rapidly invading our homes. From the modest and spiky Oxford frame, to the enormous monstrosities of the followers and imitators of Eastlake and Pugin, we were nearly in the bondage of Victorian Gothic. Our teachers, not content with proclaiming its infinite adaptability and inexhaustible resource, embodied in their creed a crusade against shams of all sorts. This movement in taste was preached with the fervour of a religion; an awful purity was insisted upon as necessary to artistic salvation. Nothing was to pretend to be other than it seemed to be. Nay, it was to exaggerate its honesty and be offensively obtrusive in setting forth that lately acquired virtue. Brick walls were to show their interior surfaces of bare brick; plaster was hardly less a deadly sin than stucco; plain paint (which surely is as honest as the plain wood) was scouted, with imprecations only less rigorous than those against the deadly artistic sin, the crowning of all wickedness—a grained imitation of oak. Rabid fanatics scarcely allowed varnish to preserve the surface and give a finish to the bare wood. In construction also, honesty was to be had at any price; joints were to be shown boldly; if any mortise was used, a protruding piece of wood, with a peg stuck through in full evidence, was to proclaim itself. Ceilings were forbidden to hide the rafters of the roof; padded chairs and sofas were to be replaced by hard wood seats with movable cushions. The motto was, "Perish comfort, appearance, everything, but simple honesty." This was excellent in theory, but in practice the result was as full of incongruities as the old mongrel style. It was out of place to imitate the vein of marble or the grain of wood by paint, or to line a plaster surface to suggest stonework; but to use a solid beam capable of carrying a roof for a small work-table, or to model a crusader's tomb in parian and adapt it as a match-box, were permitted things. It was held a pretty conceit to decorate tea-cups with raised sprays of the tea flower, to embellish marmalade jars with oranges, to decorate a night lamp with the deadly nightshade. To make a sideboard simulate a high altar, or a piano reproduce a reredos, was a noble aim; but to employ classic detail, however fitly, or use turned wood in place of a chamfered bar of rectangular form, put the artist outside the pale of sympathy.

No doubt such failures to embody workable every-day principles are natural incidents in a new search after beauty. The taste so long dormant had lost its fundamental rules, and the caprice which led its knight-errants upon such strange quests, was nevertheless an instinct groping in the dark after the right way, and vaguely and tenaciously trying almost any path save those lately trodden, which might bring it to the goal of beauty.

But it would be wearisome to multiply instances of the vagaries of the new Gothic and Vandal. When his havocs are fully known, it may be the period that saw the restoration of our old cathedrals and a revival at last of real domestic art, will be found in its course to have done damage irreparable, and beyond the worse neglect of the Georgian indifference. But just as Gothicism was triumphant, a small body of young men experimented in a free classic style, chiefly Dutch, that for some mystic reason they called Queen Anne; and straightway the elaborately built-up system of the new Gothic went to pieces. This fresh movement, by its adaptability and extreme catholicity, certainly did a few very wild things, but side by side with the so-called æsthetic movement, and the real art produced by men of the stamp of William Morris, and others, a new style arose. Some decorative artists to-day have done work worthy of placing beside that of any epoch, and if, as we hope, beauty is now to be found waiting for any who will welcome it to their houses, to all such in their different ways the good influence may be traced.

The Queen Anne school revived the banished art of the lathe, and in its desire to reassert that honest and entirely legitimate use of wood has, in the hands of its imitators, somewhat ridden it to death, chiefly, it would seem, by using an infinity of small balustrades and spindles; for even yet the influence of the Gothic craze rather shirks the employment of massive turned work, such as held sway in the Jacobean period. Yet, at its very worst, this fashion is not quite so absurd as the shapelessness of the unmeaning walnut and green rep period, or the huge timbers of the style known in America as Eastlake, and with us church milliner's Gothic.

Turnery is an ancient art, and well deserves all praise, for it is excellently proper in its treatment of wood, reducing for purposes of ornament the superfluous material, with very small loss of strength; and in its subtle shadows giving more pleasure than the angular framework of the Gothic period when used without the lavish carving which is a needful part of that style.

In saying so much in praise of turned work, and then recommending the purchase of machine-turned wood, I feel I am likely to gain opposition.

The amateur of feeble attainments is looked down upon by masters of the craft. They actually prefer the best solid carving to inferior ill-designed fretwork, and really choose inlaid marble pavements, rich with mosaic work, in place of cheap oilcloth. Excellent people! to have such splendid virtue, and such well-filled pockets! But the amateur workman may neglect such wise counsel, and do his best with what tools and skill he possesses to please himself. The want of a good lathe powerful enough to turn large work is often felt, for cost and skill are not the only items that prevent it. Time and space are equally exacting, and defeat too often his desired end.

A year or two since, at one of the exhibitions, the steam turnery on view was a fascinating exhibit; and looking at the display of specimen balusters and newels, at a price less than the raw material itself would cost a private buyer, it seemed a good idea to endeavour to utilise them in home-made furniture.

Painted chairs and tables in bright decided colours were then uncommon, but while this long-delayed notion has been waiting for time to set it forth, painted furniture has taken great hold of the public, and the apology then necessary is now needless, since every upholsterer's window has its strawberry-ice colour milk stools, its sealing-wax red five-o'clock tea tables, and its art-colour brackets. Art colour—that terrible compound work is enough to condemn anything. Is not any colour an art colour if you have the art to use it rightly? And cannot magenta itself, the most difficult of all, be used by a master wisely and well? But as some colours naturally come well together with less care in grouping, and the secondary and tertiary subdued peacock blues, citrines, and dull yellows, may be thrown together almost hap-hazard and yet be harmonious, these and similar are dubbed art colours. Yet ignorant nature uses the crudest to be found, but uses them so deftly that her un-art colours beat your best attempts hollow. If you are uneducated in colour, how can you be expected to compose a colour scheme, any more than write a symphony with no knowledge of music, or solve an astronomical calculation ignorant of the simplest rules of arithmetic?

But the painting is the last item of the work, and will be returned to later on. The article under notice to-day is the first experiment in the use of these cheap turned balusters mentioned above. Messrs. M. C. Duffy and Co., 66, Storks Road, London, S.E., at the International Exhibition, 1885, had a splendid exhibit of machinery and work turned out by them. On a price list they issue, a hundred designs of these wonderfully cheap balusters will be found illustrated. When the cost ranges from 1s. 6d. a dozen, cheapness promised by the title of this paper, may be claimed to be secured. The same patterns in pitch pine cost almost double the price. For some of the larger scale designs the cost is a trifle more, so, too, the more elaborate spirals and intricate designs are naturally somewhat dearer; but even the most expensive are absurdly cheap set against the time, skill, and plant required to produce their equals at home. For our purpose, in this first chapter, but two designs in 1¼-in. deal will be required; these, at the minimum price of three halfpence each, will suffice for constructing a really useful, and in its way artistic, piece of furniture.

Before proceeding to explain the construction, it is as well to note the novel points in this design. It is the result of an attempt to make, first of all, a more really useful adjunct to the toilet, and a desirable addition to the ordinary fittings of a bedchamber.

The cupboard, itself useful for keeping odds and ends out of sight, serves the purpose of a toilet glass more thoroughly than usual, since its doors opening at any angle give a reflection of each side of the face. For shaving purposes, or the magic art of putting on a bonnet, this is no mean gain. But as daylight is not always available, special efforts to gain the utmost light from a couple of candles are also within the purpose of the design. It is claimed that, by the arrangement of shelves here shown, a strong light is cast upon the face (as I can speak from actual use), and thereby assists the delicate operation of the amateur barber, or the manipulating legerdemain of he culminating touch on the coronation of a iew bonnet, with no small gain of ease and omfort.

The glass doors are set at a height likely o be useful to most people; but as mantel-ieces vary a little, and personal stature even nore, may be the maker will find other level he most pleasant. This must be found in-lividually; at present it suffices to say that he size given answers its purpose tho-oughly. To harmonise with its surroundings t is finished in pure white enamel, has on ts shelves old blue and white china and orass candlesticks, and in its place would iever suggest its humble and economic rowth, but appears like a fairly expensive onstruction that would cost a few pounds o acquire.

The overmantel here set forth and de-cribed, was primarily intended for a bed-oom, and has particular features designed pecially to be useful for purposes of the oilet. But after the work was finished, hese said features presented no outward ign of their purpose, and it was debated vhether it should occupy the position in-ended, or be placed in a study. Before ointing out the object in view, it might be s well to remind the reader that, in spite f nearly a hundred patterns in these cheap alusters available from designs kept in tock, yet only comparatively few are so lanned to be useful for furniture, as those atterns which have no square stops, where he features of the turning give way to the lain wood, are not so suitable for the pur-ose, nor capable of being explained away n the design. Therefore, if the design here iven is not carried out literally to the direc-ions, the trouble of modification will be reater than it appears. This, of course, pre-umes that the amateur has not the power f turning his own spindles to order, but re-ies solely on Messrs. M. C. Duffy's stock, or he marketable produce of some kindred irm to provide the turnery of his work.

The chief hindrance in planing this piece f furniture was to group the uprights that he shelves would not be carried across the vhole façade at the same level. For in hat case the effect would be merely that of piece of ordinary shop-fitting. To avoid his disfigurement was much less easy than t seems, and only secured by arranging the ctual balusters themselves, a quantity of vhich the makers kindly placed at my dis-osal for practical experiments. As the alusters have each their own number in the rice list, it will suffice to indicate them o, as in each case I shall give a duplicate ketch of the piece itself as it stands upon he makers' pattern sheet.

This overmantel will require eight of No. 1 ($1\frac{1}{4}$ in.) and four of No. 50, also $1\frac{1}{4}$ in. ection. The few spindles used for the bot-om rails were turned specially for me by he makers, costing, if I recollect rightly, fraction under one penny each, by the ross. They are most useful; a gross nd a half disappeared in a very short ime; but when I look at the many at-ractive pieces of painted furniture of vhich they are the sole decoration, I feel hat a more useful and inexpensive ally has ardly ever been brought within reach of he non-lathe-possessing amateur before. The only materials required beyond these alusters are a few pieces of ordinary wood, leal, pitch pine—any, or every sort it matters ot, since all will be covered with enamel —and the two looking-glass panels of the loors. If the mirrors are of ordinary silvered glass, the expense is but a trifle; it vould greatly improve the whole to use thick bevelled squares; the cost of these, for the size given, was, if I remember rightly, 5s. 6d. or 6s. the pair. As, however, it was rather a trouble to get them sent to me, I used ordinary glass, but feel that the improvement gained by the bevelled plates would well repay the difference in the price.

The four No. 50 uprights, A, at the outer angles of the erection, are used with the waste wood at their base exactly as they came from the makers; planed and sand-papered of course, and otherwise made ready for painting. But the two No. 1 that are in the central portion of the front, B, start from the shelf, H, which runs right across the mantel and forms the floor of the cupboard. To keep the line of the upright, pieces of wood, C, cut off, the other balusters used against the wall were fitted below the shelf running down to the base-piece. In the design this explains itself easily. At the back of the whole, six of No. 1 are planned to carry the shelf, E, and form, as it were, the motive and central idea of the whole design. These might be limited to two, but from experience I strongly advise the use of the number shown; it is just this comparatively lavish use of the balusters that gives a certain character to these designs, and in the finished work takes away a poverty-stricken effect they would otherwise be likely to offer. As this thickly-set railing is intended to be the feature of all the designs in this series, it is needful to emphasise its importance. The whole design may fail to please many; in that case I would say discard it entirely; but if you work it, at least try, by a preparatory rough fitting together of the several parts, the effect of the work as illustrated in the sketches, before attempting to be economical in the use of the turned rails, which are the characteristic element of this group.

It will be seen that the two uprights, B, are cut off at a height corresponding with that of the outer pillars, A. As what was cut off at A is waste wood, it explains itself, but at B a part of the baluster itself is sacrificed. The way I managed it was to cut from the upper feature of No. 1 all the pear-shaped portion, and use, as it were, the base of the upper half and its capital, without the pillar itself. Consequently the upper part of B is in two pieces, but for so short a support, carrying no particular weight, this matters not, the gain to the eye in making the level line of the top shelf being more than enough to reward the maker for the slightly increased trouble. The six rails, D, carrying a top moulding, are so clearly explained in the diagram, that more need not be said.

Now concerning the shelves, it will be enough to note that the shelf I at the base runs across the whole width, so too does the shelf H, but at its either end it has half circles of the same thickness added, for reasons explained elsewhere. In the short shelves, G, at the sides, a corresponding piece is cut out, not necessarily corresponding in size, but both the added curve and the cut out are exactly over each other, to allow a candlestick placed on H to keep clear of the shelf, G, and avoid setting fire to the upper shelf; the shelves, K, at the top of the sides are too far off to be dangerous in this respect.

The shelf, F, above the cupboard, is placed almost close to where the square wood of the upright yields to its turned portion, the space thus offered being closed by two doors, *hinged upon a central upright*, between shelves H and F. These doors are mortised frames of ordinary design, chamfered but not otherwise decorated; the panels of looking-glass are let into a rabbet like an ordinary picture frame, and backed with plain thin wood. Of the small bracket-pieces below the cupboard, and the low railing at the foot of each side compartment, it will be needless to speak.

The balusters themselves decide the right position of all the other pieces, and the measured diagram shows clearly when they fit with regard to the adjacent parts. Looking at the finished structure, I feel that a photograph of it, were it possible, would show a much more tempting article than my sketches suggest.

If used for some apartments, ebonising might replace enamel. Personally, I think the scale too heavy for black finish, and would rather use a peacock blue or scarlet enamel, but that is after all a mere fancy of the owner. Varnished pitch pine would look clean and wholesome, and match the popular bedroom suites in that material. But to each person who is interested in it, a different finish will probably suggest itself, so that to-day we may leave it, and in our next try other pieces of furniture made from the same materials, or with the addition of others equally inexpensive.

THE MICROSCOPE: HOW TO MAKE IT.

BY O. B.

INTRODUCTION—GENERAL METHOD OF FOCUSSING—MODE ADOPTED BY WRITER—FOCUSSING ARRANGEMENT—FOCUSSING SCREW—STAGE—ARM—STAND—POWER TUBE—OBJECT GLASSES—EYE PIECE—MIRROR—FINISHING INSTRUMENT.

OF all instruments employed in physical research, there is hardly one of such universal interest as the microscope. To all thoughtful, cultured men, a telescope is of great interest; but even cultured men cannot command "the clouds and the rain," and the number of nights available for astronomical work in a year is fewer perhaps than most people would imagine, or, at least, in our country, so remarkable for its fogs and rain.

Electrical apparatus are also of great interest when used with a certain amount of previous knowledge, but little else than amusing to the uninitiated, or, at most, wonderful. But the microscope is equally interesting and instructive, even to a child, and objects are everywhere abundant. To be able to bring invisible forms of life into view; to reveal the marvellous decorations which are so wonderfully lavished on multitudes of minute organic forms, is at once an education and an enjoyment. But a good microscope is an expensive instrument. No doubt a great deal is paid for appearance and finish, yet it must be understood that to a great extent the value of the instrument is in proportion to the amount of labour expended on it. Apart from the optical part, its value depends on its steadiness and smoothness in use. Its moving parts must be accurate in their adjustment. Every tremor or shake becomes magnified, and unless the stand and adjustable parts are rigid, but little satisfaction can be derived from its use.

Most people have seen street vendors with little globes of glass filled with water sold for the universal penny. The writer remembers, when a boy, seeing with wonder, by the aid of such a magnifier, such creatures as eels in paste and vinegar.

Years after he tried his mechanical skill in making a microscope by the aid of tinplate and pasteboard. It was a rough affair, but by its means he was able to trace the circulation of blood in the tail of a tadpole, and which sight was esteemed as a fair equivalent for the labour bestowed. Since then he has tried his hand on many an optical instrument, but perhaps the pleasure derived by using his microscope with a tin tube and pasteboard stand was as genuine as any derived at a subsequent date by the use of more finished instruments.

The instrument which I have designed, and which I propose describing for the readers of Work, is, as far as I know, original in its construction, and will be found not only as easy to make, but in some respects more efficient than some of the ordinary types as far as its focussing arrangements are concerned.

The general method employed to focus is that of the rack and pinion, either acting directly on the power tube or through a bar in the stand, the latter method being employed in the more expensive instruments. Another plan is that of a chain instead of a rack, but I have not seen many of this type. But these methods are simply for coarse adjustment; for high power something far more delicate is required. This finer adjustment is obtained generally by a screw operating on a lever.

In the arrangement I have designed I have done away with the rack and pinion, which, unless well made, is a constant source of trouble; and also with the lever. A fine cut screw acts directly on the focussing bar, so that an object may be focussed to any degree of fineness, depending on the number of threads to the inch on the focussing screw. It can thus be used for measuring thin films up to, say, from a 2,000th to 4,000th part of an inch thick. If due care is observed in working out the details, a good and substantial instrument will be the result. I assume that my reader can use a few tools, and has in possession a lathe, and can cut a screw. If he cannot do the latter, then in most towns there are brass finishers, who, for a small consideration, would do all the screw cutting required. Besides this, there is nothing that an ingenious worker cannot do except the few castings in brass.

The principal parts of our instrument are, first, the focussing arrangement; second the stand; and third the optical tube. As the first part mentioned is somewhat more complicated than the others, we will commence with it. Procure three lengths of brass tubing, one piece $5\frac{1}{2}$ in. long by 1 in. diameter, one piece 5 in. long by $\frac{5}{8}$ in. diameter, one piece $3\frac{1}{4}$ in. long and large enough to slip over the smaller of the two tubes; whilst it will admit the tube there must be no shakiness. In Fig. 1 the tubes are lettered *b*, *c*, *d*. Tube *d* must have a ring of brass $\frac{1}{2}$ in. wide, soldered at one end as shown in Fig. 7. Before driving on the ring, file the inside bright, also the outside of the tube. If too tight put a fine saw cut in the ring, and spring it on. Moisten the parts well with the soldering fluid, and then with a hot bit cause solder to flow in the joint. By making the brass hot, the solder will run through the joint and the work will be solid. If a gap is left where the ring was cut, a thin slip of brass must be soldered in it.

Now take $\frac{1}{2}$ in. of tube, *c*, and having cleaned it on the outside insert it in the same end, and solder it; cut out roughly a disc of brass $1\frac{1}{4}$ in. diameter, and solder it to the end. Put the tube in a chuck and turn down the collar, chasing a thread on it, and turn down the end with a central hole $\frac{1}{4}$ in. diameter. When this is done, draw a line down the tube with a sharp point; be careful that it is parallel with the axis of the tube, as if it is not our whole action will be imperfect; the reason of this will be seen as we proceed. With a saw or file slot down the tube to the collar. If a circular saw for brass is attached to the lathe, there will be no difficulty in cutting the slot correctly, which must be, say, $\frac{1}{8}$ in. wide.

We must now proceed with tube *c*. Each end of this must be plugged with a short length of tubing. We will suppose it rather too large to work smoothly in *d*; we will therefore put it in the lathe and true it up, and bring it to such a size that it will work without a shake. Cut a strip of brass 3 in. long, and, say, $\frac{1}{4}$ in. wide and $\frac{1}{8}$ in. thick;

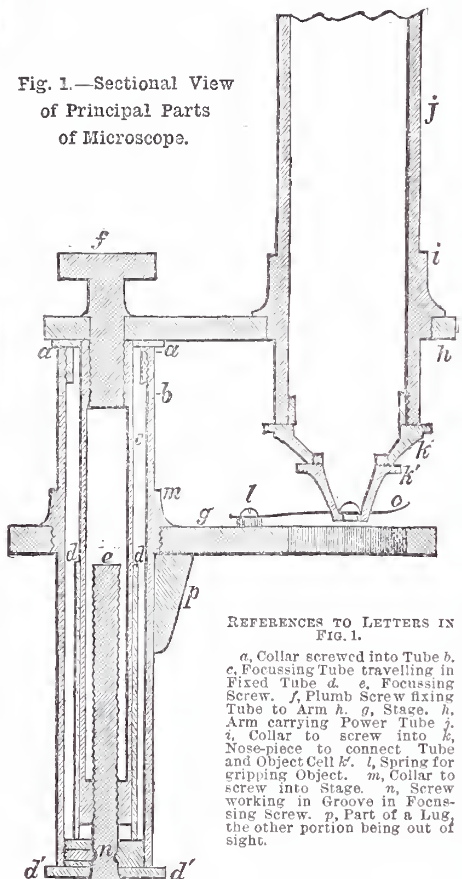


Fig. 1.—Sectional View of Principal Parts of Microscope.

draw a line down the centre and file down to it, leaving three pins as represented.

On the lower half of tube *c* draw a line parallel with its axis; bring the strip just made to the bottom, and mark where the pins come, and drill holes to receive them; this must be soldered to the tube. When filed up, it must just fit the slot in tube *d*. A thread must be chased in each end as shown. We will now take tube *b* in hand. One inch and a half from the top a ring $\frac{1}{2}$ in. wide must be soldered, and over this another $\frac{1}{4}$ in. wide. The tube must now be chucked in a lathe, and the rings must be turned down as in Fig. 1, with a thread chased on it. A thread must also be cut in each end—the lower end to take the collar of tube *d*.

To a ring $\frac{1}{2}$ in. deep, and too large to enter the tube *b*, a disc must be soldered; this must be turned down, and a thread chased on it to fit *b*. In the centre of the disc a hole must be turned large enough to admit tube *c* without shake.

We now must make our focussing screw *e*, Fig. 1. This may be made either of steel rod, with a brass head cast on it, or entirely of brass; if the latter, we can either have it cast, or we can make it of $\frac{3}{8}$ in. brass rod, and screw and solder a disc $1\frac{1}{4}$ in. to it. This, of course, will be a little less expensive, but will not look quite so well. It must be turned up true, and a thread cut on it to within $1\frac{1}{4}$ in. of the head.

The number of threads per inch on this screw is a matter of consideration; 25 will be a desirable number, for reasons to be dealt with afterwards. Place the tubes one in the other as shown, and insert the screw, screwing it as far as it will go. In the collar of *c* drill a hole and tap it, and make a screw to fit, with its end rounded off; insert a scribing point in the hole and mark the focussing screw, and either with a rat-tail file or in the lathe, cut a hollow, as shown, to receive the end of the screw in the collar. It will now be seen that when the focussing screw is engaged with this little bolt and turned around, the tube *c* will be forced out of the larger tube. The bar in *c* travelling in the slot of *d* will prevent the tube turning around, and in proportion as our work is good, so will be the smoothness of the motion. By turning the head once round, the tube will travel $\frac{1}{25}$th of an inch; by turning $\frac{1}{4}$ around we shall regulate it to $\frac{1}{100}$. But any definite degree of motion can be obtained by the screw—thus: when the screw is in the lathe, mill the edge of the head, then turn the edge of the head off square, so as to show the milling like the cogs of a wheel. With a magnifying glass count off, say, twenty teeth, and with a fine-pointed graver cut a line from the edge to the centre. When they are all marked off they can be again divided into tens. With small steel punches the lines may be numbered, say, by twenties. We will suppose there will be 200 serrations on the milled head. If we turn the screw from 0 to 10, the tube will be moved through a space equal to the 500th part of an inch; or if we move it to the extent of one degree the movement will be the 5,000th part of an inch. I admit that great accuracy in working must be observed to arrive at such results, but with care and skill it can be done. If this idea is carried out, an indicator with a needle point should project from the lower part of the tube, to come almost in contact with the head.

Our next business will be the stage. For this purpose we shall require a piece of brass $4\frac{1}{2} \times 3\frac{1}{4} \times \frac{1}{4}$ in.; it may be either cast or worked out of sheet—the latter will, perhaps, be the easier plan. Fig. 2 shows both the under and upper sides. In A is shown the position of the lugs; these must be $2\frac{1}{4}$ in. apart. First of all, finish the stage as far as its outline, seeing it square and true. Fix upon the centres for the holes, these centres being exactly $2\frac{1}{2}$ in. apart. Mark with a compass the curved outlines, and file down to the line. The top side of the plate must now be filed dead level. In the absence of a better tool, a piece of plate glass will be a good substitute to test its surface. Rub a little grease on the glass, then press the stage on it, when its inequalities will be made manifest. These must be scraped or filed down till the stage shall touch the glass on its whole surface. The holes should be cut in the lathe; fix them in the face plate, and push the head centre forward until the point touches the stage. Move the stage until the punch marks are opposite the centre, and clamp the stage in position. Be sure by measurement of the size of the rear hole, as it must fit, when chased, the collar in Fig. 1. On the under side mark off two lines equidistant from the centre, and with a square determine the position of the lugs. These must be made of sheet brass of the form showed at Fig. 10; two pins must be left on the top edge, as shown by dotted lines. They should be filed up together so as to be exactly alike; it would not be amiss to fasten them together by a touch of solder. Whilst joined, drill the bolt hole. It is of the utmost importance are perfectly square and true with each other. If the pins are a good fit, and the soldering is good, the lugs will be just as strong as if they were cast. B shows the top of the front part of the stage; three holes must be drilled at e, f, f', and carefully tapped.

Two pieces of thin steel must be bent, as shown in Figs. 1 and 2. Any watchmaker will supply a broken watch spring for the purpose. Take out the temper, drill two holes, and bend to shape as shown; harden, polish, and then temper again. These will of the hole in the stage e and a, and then drawing a circle on the revolving diaphragm. This circle will then indicate the position of the centre of each opening. A short tube must be soldered to the under side of the plate, around or in the largest opening, as shown in Fig. 11; the use of this will appear further on. The stage can now be screwed to the tube collar, Fig. 1.

The arm, Fig. 3, now claims our attention. This may be cast or worked out of $\frac{1}{4}$-in. sheet. The centres of the holes must be

that these should be coincident when they are filed up to proper form; the sides must be made perfectly true by the same means as have been employed for the stage. Place a lug on the stage by the lines marked, and see where the holes for the pins have to be drilled. Let these be $\frac{3}{16}$ in. deep. Now file the pins so that the lug will bed dead on the plate. With a square test it so that it shall stand perfectly square and true. Run soldering fluid around the joint, and with a hot soldering bit run solder well into the joint. See that there is plenty of solder, and that the tool is hot. Now treat the other lug in the same way, being careful that they be screwed in position as shown, with brass washers under them. Cut a circle of $\frac{1}{16}$ in. brass $2\frac{1}{2}$ in. diameter. Make faces true—it will be better if the edge is milled; it must have a centre hole to take a small bolt, by which it is to be screwed to the under part of the stage as shown, with a washer between. Four holes must be drilled: a must be the same diameter as the opening in the stage; b, c, and d must graduate smaller, as shown by dotted lines. Care must be taken that the centre of each hole is coincident with the centre of the opening in the stage. This can be secured by measuring the distance between the centres $2\frac{1}{2}$ in. apart. The form should be marked out with the compasses, carefully marking with a centre punch the position of the holes. The arm must be finished off with care, and be dead true. The holes should be turned in a lathe. It must be bolted to the face plate, and its position found by the aid of the dead centre. The large hole must have a thread chased in it; the small hole must be large enough to admit a headed bolt f, Fig. 1, which screws into the live focussing tube c. The head of the bolt must be milled.

Our next work will be the stand. Now, an essential quality of a stand is that it shall be heavy and steady on its feet, as the least unsteadiness is fatal to microscopic work. We shall now, I am afraid, be compelled to seek the aid of the brass-founder, so we must prepare our pattern. Out of $\frac{1}{8}$-in. well-seasoned wood, say mahogany, cut a pattern as Fig. 5, but $\frac{1}{8}$ in. less all round. From heel to toes 6 in., across the toes 6 in., across the sole $3\frac{1}{4}$ in. Cut strips of pine $\frac{1}{4}$ in. and $\frac{1}{8}$ in., boil them, and whilst hot, spring them to edges of the pattern; it will be advisable to cut them a little wider than $\frac{1}{4}$ in. so as to allow for dressing off. The wood can be easily bent to all the curves except in the circular part between the toes. Perhaps the easiest plan will be to turn a piece out solid, as a disc $\frac{1}{4}$ in. thick to fit the curve, cut across the diameter and fix by glue, and then with chisel and round file work it out.

The toes and heel must be finished off $\frac{1}{2}$ in. deep, as shown in Fig. 6; when finished off perfectly true, black-lead it and take it to the brass-founder. The casting must be accurately filed up and trued as before described. The edge at toes and heel should be filed off as shown by the shadings. Two standards must be cut out as Fig. 4, 4 in. high, and $1\frac{5}{8}$ in. wide at the base. Two pins must be left as shown. These, like the lugs, must be worked up together and the bolt holes coincident. Measure the exact width outside the lugs on the stage; this must be the measure of the distance between the standards. Find their position on the stand by the method described for the lugs, and drill holes for the pins, which, in this case, may go through the plate; be sure the standards are true with the foot and with each other, as accuracy here is everything. In this case more care must be observed in soldering than with the lugs, as now we are working on the top of the plate. The plate should be soldered first where the standards are to come as well as the bottom of the standards and pins, and then sweated together. If, when put in position, a hot bit is brought close to the joint, the solder will melt and allow the two pieces to come together. It will be done best as a three-handed job, as care must be taken that they are perfectly square with each other.

Two bolts and nuts must be made as shown in Fig. 6, by which the stage and the stand may be fastened together. Observe—no thread must be cut on the inside end of the bolt which goes through the standards, and the hole must admit the bolt freely.

The next matter for our consideration is the power tube. For this, we shall need a tube 8 in. long, and, say, $1\frac{1}{2}$ in. diameter; $1\frac{3}{4}$ in. from the lower end solder a ring $\frac{3}{4}$ in. wide, and over that another as described before. Chuck the tube in the lathe, and turn down a collar with a thread chased on it to fit the arm already made.

Although for convenience in writing I have referred to the arm before the tube, yet in actual work it will perhaps be best to make the tube before finishing the arm. Whilst the tube is in the lathe, a thread must be chased on the inside of the lower end. A small casting must be made as K, Fig. 1., as a nose-piece to screw in the tube, and to take the object glass tube K′.

I will not recommend an amateur to mount his object glass, at least, if it is a good one; the better plan by far will be to send the nose-piece to a practical man, and get such object glasses as are desired mounted on tubes to fit the nose-piece.

The object glasses I would recommend are, to begin with, a 2 in., 1 in., and $\frac{1}{4}$ in. It is a great mistake to suppose that the higher the power the more any one can see. The fact is, the eye needs a lot of training before a high power can be used with great advantage. Beside which, with a high power a very small portion of an object is seen at once, which to the unskilled would be meaningless; whilst with a low power a large field is presented and a moderately large object can be taken into view at once, which to the amateur microscopist is both more interesting and instructive. Even a 3-in. object glass is a useful power with some objects.

We must now proceed with an eye-piece. These, like object glasses, are of different powers, known generally as A, B, and C. An optician would supply the power needed. We need $1\frac{3}{4}$ in. of tube that will slide easily into the power tube. If it is slightly too large, it can be turned down; on the inside of each end a thread is cut.

We shall now need two castings. Fig. 12 gives a section of the cell for the field lens. At *b* is seen a small ledge or gallery; this is for the lens to rest on; this need not be more than the 32nd of an inch thick. At *a* the brass must be turned away until it will bend easily. Chase a thread on the outside and inside; the thread on the inside is for the purpose of attaching a polariscope to the eye-piece. When the cell is finished, it should be large enough to take the field lens without pinching. Chuck the cell with *a* at the right hand, place the lens in position, some one steadying it with the end of a clean finger, turn the lathe slowly, and with a burnisher turn the edge over on the lens, as shown in Fig. 9. The cell for the eye lens must have a slight increase of thickness around the hole; this is to allow of a bed being turned out for the lens. The brass will be turned away so as to allow a ring to stand around the lens for the purpose of bezelling it. In the focus of the eye lens a stop must be placed as shown, with a central hole two-thirds of the diameter of the lens.

The next work will be to fix a mirror. Fig. 8 will give a plan of this. A mirror in a cell can be purchased from 2s.; it would therefore be unwise to buy simply the mirror and make a cell—it would not be worth the labour. Still, if one purposes doing so, proceed as follows:—Cut off a ring $\frac{1}{2}$ in. wide from a tube large enough to admit the mirror, turn the ends true and cut a thread on the inside of one end, and solder a bottom to the other, letting the edge of the bottom project far enough to mill it. A ring with a flange must be made to screw into the cell; the flange edge must be milled. Place a little cotton wool in the cell on which to lay the mirror, and screw on the ring. In the diameter of the cell two small hollows must be made with a fine-pointed centre punch.

A collar must be made to slide on the focussing tube *b*, Fig. 1. This can be made of tube that will hardly go over the other; put a saw cut in it. The spring will now allow it to go on, and at the same time will grip it firmly. The clip should be $\frac{1}{2}$ in. wide. In the centre, as at *b*, Fig. 8, a small stud must be screwed and soldered; this may be made of small brass tubing.

A circular arm, *c*, must be made; it should be $\frac{1}{2}$ in. × $\frac{1}{4}$ in. in the centre, tapering at the ends. A screw fastens it to the stud. A washer should be placed under the head of the screw. Screws pass through the ends; these are pointed, and enter the centres which have been provided for them in the cell.

The mere mechanical part of the work is now finished. The various parts must be polished with rottenstone and oil; not a trace of a scratch must be left, the whole being lacquered. This is a difficult job for an amateur; a hint or two perhaps may be helpful.

After they are polished they must not be fingered, as finger marks will show when the lacquer is laid on. They must be heated as hot as the hand will bear with comfort; rather vague directions truly, but practice alone can give the requisite degree of heat. The lacquer must be put on with one stroke of the brush; no painting, as the brush marks will show.

If care is employed in carrying out these details, the result will be an instrument equal to any work which the average student will be called upon to do. It is a well-known fact that practical men, as a rule, do not employ instruments elaborate in their mechanical arrangements; these are left for wealthy amateurs, who are fond of exhibiting costly toys.

In constructing the eye-piece, I have calculated field lens 2-in. focus, and eye lens 1 in.; these are separated one-half their combined focus, that is, $1\frac{1}{2}$ in.

PHOTOGRAPHIC TRANSPARENCIES.

BY DAVID ADAMSON.

AMONG my acquaintances are some who go in for photography. As is not unusual, they are "photographic mad," a common complaint amongst amateurs; or, stated in other words, they are enthusiastic votaries of the art of photography. Strange and wonderful attempts some of them make in the higher branches of the art before they have mastered the rudiments. They want to make beautiful transparencies before they can manage to take a decent negative. Occasionally they get one which is fit to be seen, and when they can make two or three good ones in succession they want to go ahead. Far be it from me to dissuade any beginners from their laudable desires to make progress; only I think they would often get on better in the long run by remembering that we must creep before we can walk. It is no doubt a strong temptation to many of us when we read of the beautiful results obtained by skilled workers to try and do likewise, but experiments run away with both time and money needlessly, when undertaken without sufficient experience to warrant a reasonable prospect of their being successful. However, this has not much to do with the subject of the present article, though it all leads up to it, and transparencies made on the ordinary albuminised paper may well be recommended for the consideration of those who are as yet not equal to the task of producing them on glass. Nothing more than ordinary negatives and the common paper which every photographer uses more or less, and beginners solely, for printing purposes are required — of course, with the necessary chemicals as well. To produce such transparencies no difficult manipulation, requiring great nicety in application, is called for. They can, in fact, be produced by any one who can take an ordinary photographic print, no more skill or expense being necessary for one than for the other.

As every one who has given his attention to even the smallest extent to transparencies knows, on glass they must be much more dense than an ordinary negative, and for this reason special plates for transparencies are made and sold. The same rule holds good with regard to silver print transparencies. The print may be quite right seen in the ordinary way; it may even be a trifle too deeply printed; but on rendering it translucent, and viewing it by transmitted light, it will be found wofully thin and poor-looking. However well it looked before, it does not do as a transparency. This thinness, I take it, is the chief reason why the plan of making transparencies of silver prints has not found more favour among amateurs who wish to adopt easy methods of work, which, without being so good as the processes which in skilled hands are found the best, shall yet afford fair results.

I do not know that the process by which dense silver prints may be obtained is any novelty. For aught I am aware, it may be a well-recognised plan, though it can hardly be called a well-known one. So far as I am concerned, I found it out accidentally. One day, inadvertently, a piece of paper was put in the frame with its unprepared side in contact with the negative. On examining it in due course this mistake was discovered. On the sensitised side a print much as usual, only fainter, showed itself on the other—the side next the glass. The print was also distinctly visible, but details were not well defined. The effect was peculiar, and not altogether pleasing. However, the print being partly formed, it was left for further exposure to see what the result would be, more from curiosity than from any other motive; though at the same time I thought possibly dull prints could be got in that way. I have since seen it mentioned somewhere, I fancy, by my old friend—Henry Sturmey, of cycling celebrity—that dull or matt prints can be obtained in this way; but without disputing the dictum of so well known an authority, it may be said that the want of detail is objectionable. At least, in my hands they have never shown much detail, though for broad effects they are admirable.

If I may venture on a comparison, they may be said to bear a similar relationship to prints taken in the ordinary way that a charcoal drawing does to an engraving, or a picture of the impressionist school to a minute Dutch painting.

Mentioning painting, reminds me that photographs printed on the wrong side of the paper are admirable as a groundwork for colouring, either in water or oils; but this branch of work cannot be enlarged on at present. I hope, however, to refer to it at no very distant date; so, in the meantime, attention may be confined to transparencies.

In due time the print above mentioned was toned and finished along with a batch of others. It could not be called satisfactory either on one side or on the other, though on both the picture was distinctly visible. On holding it up to the light, however, I was struck by its density. If I had been on the look-out for a dense print to serve as a transparency, the result could hardly have been happier.

With this there is little more to be said, for the way by which silver prints may be made available as transparencies has been clearly indicated. All that is required is to "make a mistake" in putting the paper in the frame. Printing takes a good deal longer than in the usual way, but it must not be so long continued as to form a really good picture on what is now the reverse, the albuminised side. It is possible to get this, but then the print is too dense as a transparency. A few trials, however, will soon show the extent to which the printing should be carried, and be of more practical use than pages of instruction.

It will be understood that the prints are to be fixed and toned in the usual way, after which they are rendered translucent and mounted.

Perhaps the best medium for rendering them less opaque is Canada balsam, thinned down with a little turpentine. I find it a very good plan to soak the photos in the latter, and then to rub them over with the balsam, leaving the print for a few hours between a couple of pieces of glass (old negatives) till the balsam has thoroughly incorporated itself with the turps and soaked into the paper. The only object of the glass is to prevent the balsam and the turps drying before all the tissue of the paper has become saturated. If they do, opaque spots soon show themselves, and do not add to the beauty of the transparency, which, when well done, should not show any granulation. Instead of Canada balsam, which is a nasty sticky stuff to handle, any of the preparations named in the recent articles on crystoleum painting may be used; and melted wax or paraffin is not to be considered as by any means the worst medium for rendering the prints transparent. Perhaps it is the most durable of the lot, though rather more troublesome than some of the others in its application.

When the transparency is ready, it may be preserved between two pieces of glass; old negatives again come in very conveniently. These are joined at their edges in the manner described by Mr. Beckerlegge in his articles on crystoleum—already referred to—and then mounted in a suitable frame. This, of course, should be the same on both sides, if it is visible from the outside of the house; for, however beautiful a transparency may be when seen from the inside of a room, the ordinary picture frame is hardly presentable as an object of beauty both in front and behind. To describe the construction of frames is, however, hardly within the scope of this paper, which, having described a process of easily making transparencies by novices in photography, has served its purpose.

It has frequently occurred to me that such paper transparencies might be made available as a magic, or, to give it its high class, first "chop" name, optical lantern; but on this point I cannot speak definitely, as I have not much acquaintance with this kind of work, or, should I say, scientific amusement? Possibly, to some of those who do, the hint may be of service, and induce them to give fellow-workers the benefit of their experience.

In the meantime I may, however, just suggest that the paper will form a pleasanter ground on which to paint than the glass on which magic-lantern slides are usually prepared. Of course, transparent colours only are permissible, and in considering the effect to be thrown on the screen, the colour to which the photograph has been toned must be taken into account; for example, with a brownish tone it must be remembered that strange pranks will be played with the blues and the greens with which the photograph may be tinted. This refers only to coloured transparencies, or, as they may perhaps be called, lantern slides; and it need hardly be said that if left in the plain unpainted state that they will be better than if badly coloured. While proposing the use of these paper transparencies for lantern purposes, the obvious saving in weight may somewhat counterbalance disadvantages.

PAPIER-MÂCHÉ.

How to Mould It, and how to Ornament It.

BY SYLVANUS WARD.

DECORATION (*continued*). FINISHING BUILDINGS ON PEARL—FLOWER AND FRUIT PAINTING ON PEARL—FIGURES IN PEARL—ORNAMENTS IN PURE PEARL ON COLOURED PEARL GROUND—SCRAP PEARL WORK—BRONZE WORK—STENCILLING AND DUSTING-IN.

OUR attention must now be directed to finishing subjects inlaid with pearl by painting.

Buildings in Pearl.—There are different methods by which pearl buildings may be finished; we will describe two applicable to buildings which are supposed to be in a perfect state, and a third which is considered most effective for the treatment of ruins.

In all cases, the main features of the building have first to be sketched in, and in doing this, the T-square and set-square will be found useful accessories. We will suppose this done, with the structure to be finished by our first method, and we have now to give our high lights to those parts on which the light in our picture falls most strongly—such as string courses, the fronts of buttresses, etc.; and this is done by gilding those parts with pale gold. The shadows have next to be broadly put in with transparent varnish colour. For this purpose, although the effect produced by it cannot be called a natural one, purple has been the favourite colour. The purple used is compounded of Prussian blue and carmine; or, instead of carmine, the cheaper crimson lake may be employed. After this the darker shadows are put in with a deeper shade of the same. For shaping out windows or other architectural details of the parts in shade, a little black may be added to the purple. On those parts of the building which are in light, a mere line of purple will usually serve to bring out a pilaster or any similar feature. It will thus be seen that, according to this method, pale gold serves for the high lights; the pearl itself for the middle tones; and purple for the shadows.

Or, secondly, in place of gold, flake white may be used for the high lights, life and variety being freely given to it by occasional tints and minute touches of such colours as a legitimate water-colour painter would suppose to exist in the stone, and would give to it. Instead of purple, a grey may be employed for the shadows, this also being enlivened by a little bright transparent colour, so as to give a variety of warmer or cooler greys. By this method a less showy, but a more natural and artistic, representation of the building is obtained.

With ruins it is found better to deal somewhat differently; but before describing the manner of doing so, it will be desirable to make some supplementary remarks on the actual inlaying of work of this kind if it happens to be on any considerable scale. The Gothic window, Fig. 37, will serve as an example. The masses forming the arch having been cut out in pearl, and fitted up on those which form the walls, the knife-saw must be used to cut strips of suitable width for mullions. Some of these strips, cut shorter, will also serve for those parts of the tracery which approach straight lines. Other strips, divided into small pieces, will also serve for the circular parts of the tracery, if cut and arranged, as shown in the diagram, like stones forming an arch. Cusps (the little triangular projections in Gothic tracery) are afterwards put in with pearl colour at the beginning of the painting process. These cusps are for distinction shown black in one-half of the figure. The angular lines of the tracery are changed into curved ones in the painting process. All this applies to Gothic windows of considerable size only; if small, they are laid in solid, and the tracery is formed by blacking out between.

To return to the method of finishing ruins. The older plan was to light with gold and shade with purple, as mentioned above; but this was abandoned for a better. Owing to their unsheltered exposure to weather, ruined walls become much more covered with mosses, and such like vegetation, and acquire much more varied colour than those which are protected by roofs. Hence it has been found that more characteristic effects are to be produced by painting in the high lights with flake white warmed up with different tints, somewhat as in the process last described, and painting the other parts with patches of varied transparent colour, blended into each other. In the half-tones these tints will, of course, be very sparingly employed, the pearl being left as much as possible to produce its own effect. It will be in the shaded parts that most colour will be used. Such pigments as verdigris, Italian pink, carmine or crimson lake, Prussian blue, or mixtures of these, are fitted for this purpose. Tube colours will doubtless be used, but they must be sufficiently diluted with varnish and turps. Ruins thus painted are best lined out with a mixture of crimson lake and vegetable black, which will form a kind of dark purple. This will not have to be confined to the shady side of the work; on the light side also a line of it occasionally, as down a pillar or the recess of a window, will be equally necessary.

Ivy or other foliage growing on such ruins may either be done in bronze powder (of which mention will be made further on) mixed with varnish, the high lights and shadows being expressed by stronger or weaker touches of bronze, and afterwards stained with transparent colour; or it may be merely painted with varnish colour. The worker has a like choice in the treatment of trees, etc., which may surround his ruin, and of the ground on which it stands.

Mention has just been made of "varnish colour." This is supposed to imply ordinary tube oil colour mixed with varnish; but the old practice of japanners was to use colour ground in turpentine, varnish about equal

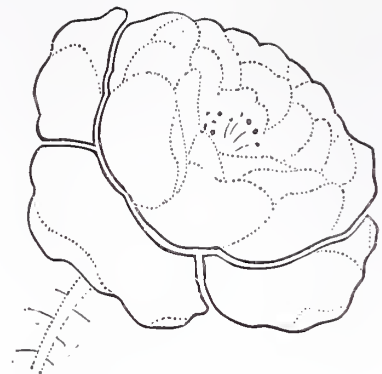

Fig. 38.—Flower Painting on Pearl.

in quantity to the bulk of the colour being afterwards added, and the whole well mixed with the palette knife. This sets more quickly, but involves much loss of time in hand-grinding.

Flower and Fruit Painting on Pearl.—In representing such natural objects as these on pearl, it is usual to introduce leaves but sparingly, and to confine the work as much as possible to the actual flowers and fruit.

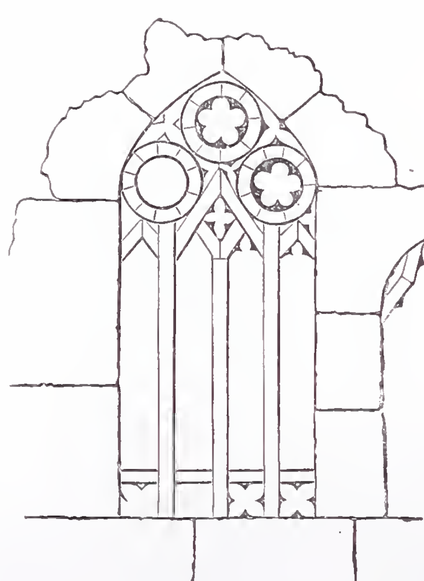

Fig. 37.—Pearl Inlaying: Gothic Tracery in Pearl Ruins.

Before inlaying, the pearl is cut with the scissors so as to suit the forms of the different parts of the group as far as may be. Flowers and fruit need but a very slight sketching-in of their more prominent features with the black-lead—indeed, a skilful workman is contented to do the sketching almost entirely with his brush as he goes on. If, as is frequently the practice, the leafage and stems are to be in gold or silver, this gilding or silvering should be done first.

We will assume that we have a flower group to paint, in which is a rose (red), a horn-poppy (yellow), and a convolvulus (blue). Our flowers have been cut out and inlaid in pearl, as may also probably be a leaf or two, to make the composition balance, for in work of this kind the pearl asserts its importance, and first and chiefly strikes the eye. The balance of pearl in a composition has therefore to be duly considered. Our stems and leafage generally have been gilt. Our less important buds we may perhaps

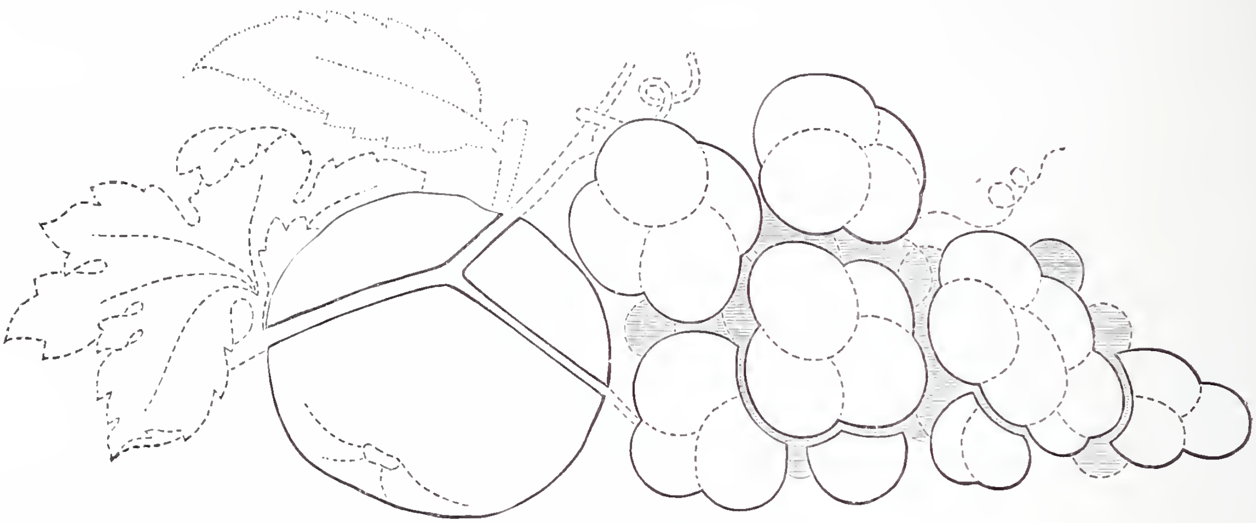

Fig. 39.—Fruit Painting on Pearl.

have laid in with silver, but we shall probably content ourselves, as regards them, with flake white only.

But here it should be noted that if, for want of sufficiently large pieces of pearl, our rose or other flower has to be inlaid in more pieces than one, the divisions should be made to coincide with the outlines of the petals, as exemplified in Fig. 38. To render the joinings as little apparent as possible, paint them over with pearl colour, or, what is still better in flower or fruit work, before beginning the painting process, go over the joints with varnish, in which a spot of oil is mixed, and stump over with white bronze.

But to proceed with our painting: beginning upon our rose, we take a brushful of thin transparent varnish colour, and put in a broad wash for the middle of the flower, letting the colour flood towards the centre where the greatest depth is required. With the same colour we go over the under part and other portions which are in shade. Then we slightly define those petals which are in light. Mixing ultramarine with our varnish, we now paint in the convolvulus to the same stage; and that done, with Italian yellow (usually called Italian pink) we make like progress with the yellow poppy, and such parts of the convolvulus as may require this colour.

While the flowers dry we shade down the gold stems and leafage till they appear to recede into their proper places. For the stem of the rose we shall use burnt sienna, with perhaps a little crimson lake added, and vandyke brown for the deepest shades; while the leaves will require verdigris, Italian pink, burnt sienna, and vandyke brown.

When the flowers are sufficiently dry, we shall proceed to paint them up, using a drier colour and one of deeper hue than before. A firm line or touch of flake white tinged with crimson lake, if used in finishing, will be found to bring up the high lights effectively without interfering with the brilliancy of the pearl.

The treatment of fruit on pearl is much the same as that of flowers. As may be done with flowers, the stems and leafage may either be inlaid, or gilded, or merely painted, as best suits the composition and the taste of the worker. Some of the difficulties of fruit inlaying are dealt with in Fig. 39. It will be obvious that an entire bunch of grapes would be too large to be formed of a single piece of pearl, and the usual method of procedure is that shown, the pieces of pearl being marked out by a continuous line, whilst the individual grapes are bounded by dotted lines. Some two or more grapes adjacent to each other, or perhaps single grapes if they come near to the eye, are inlaid with separate flakes of pearl, whilst more distant grapes—shown as shaded in the diagram—are merely painted in with pearl colour in the intermediate spaces. The apple is also so large a fruit as to present difficulties. One way of meeting these is that shown in the diagram, where a grape-stem is brought across it, so as to conceal the joinings of the three pieces of which it is composed. Another way is, in a streaked apple, of hiding the joining by a streak. These joints have, of course, to be covered with pearl colour or white bronze, as mentioned above in connection with the rose. A third way is by inlaying so much only of the apple as will serve for the half-tones, and trusting wholly to painting for the high lights and shadows.

Greek and Etruscan Figures in Pearl.—Statuary and the flat figure compositions on antique vases are well suited for treatment by pearl inlaying. The figures are cut out in the pearl, the outlines being afterwards corrected with black, whilst black lines are introduced to indicate the features, drapery, etc., wherever needed. Groups of flowers and fruit have sometimes been treated in a similar manner with black lines only, the finer stems, etc., which are too delicate to be cut in pearl, being merely laid in with paint.

Ornaments in Pure Pearl on a Coloured Pearl Ground.—Such ornaments are most readily produced by painting over the whole surface of the pearl with the grounding colour, which may be purple, yellow, or any other which is desired, a little oil being added to the varnish with which the colour is mixed, to make it set more slowly. On this, before it is thoroughly set, and as soon as it is dry enough to work upon, the required ornament is painted in *oil* flake white laid on freely. This is allowed to stand so long as will suffice to soften the ground colour beneath, and is then wiped off with a little pad of cotton-wool, the pad being tightly squeezed together, so that no fluff may come off it. The flake white brings with it the grounding colour, and the ornament is thus left in pure pearl, as desired.

Scrap Pearl Work.—The scraps of pearl which accumulate from inlaying may occasionally be used to good purpose for filling formal spaces in ornamental designs. The method is to fit them in quite at random, and then to stain them with different transparent colours. Simple as is this work, it has a very pleasing effect. Scraps of pearl may also be used for foliage of trees, in connection with inlaid ruins, connected and worked up with gold dotting or pencilling; or in other cases with dots of green or autumnal tints.

Bronze Work.—We now come to a highly-interesting method of decoration, and one which, in the hands of an ingenious decorator, is applicable to many other materials than papier-mâché, and that is by bronze powder. Somewhat more than half a century ago, bronze powders were extensively employed in the decoration of papier-mâché; not in the rude and hasty way in which we now see them applied to iron goods, but in ornamentation of a higher and more elaborate character, by means of a kind of stencilling and dusting-in process. The bronzes used were chiefly pale gold, deep gold, copper, flesh, orange, green, and silver bronzes. Landscape and figure subjects were sometimes carried out in this work, and these required in addition a "pencil bronze," *i.e.*, bronze mixed with copal varnish into a kind of paint, and applied like paint with a brush. The bulk of the work in bronzing was, however, done by stencilling and dusting-in—a process requiring no particular skill or knowledge, only care and exactness.

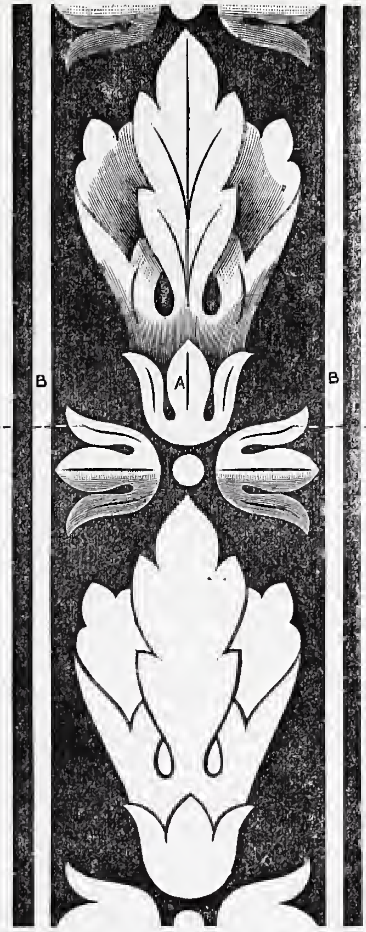

Fig. 40.—Bronzing.

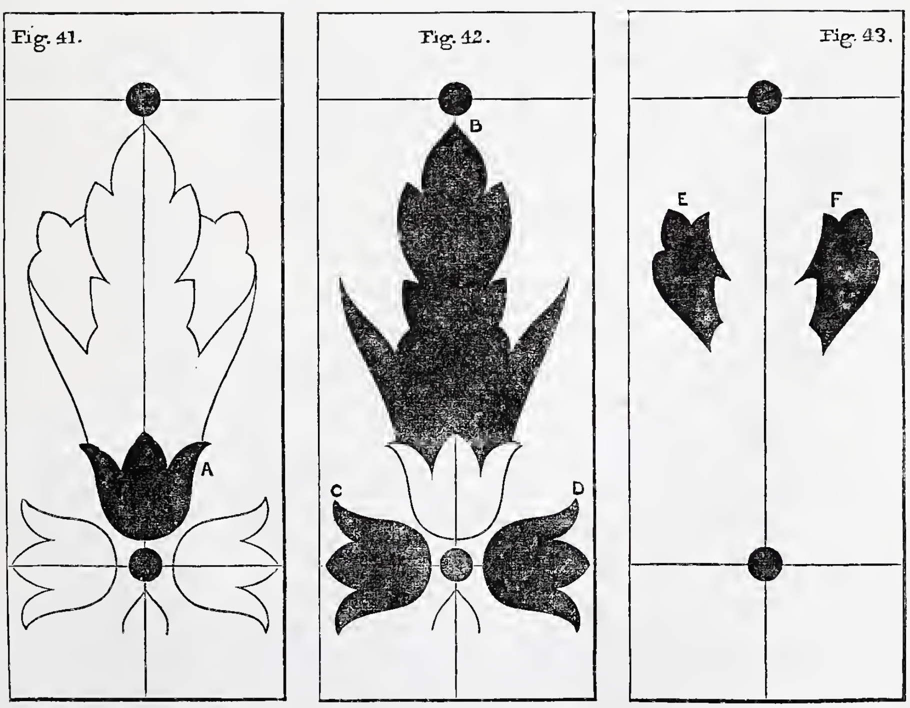
Fig. 40 is a design for this work, and the first step towards carrying it out will be to cut from stiff, but not thick, paper three stencil plates, as shown in Figs. 41, 42, 43, where the portion to be cut away is given in black. These will, of course, be traced for cutting from the design. A band as wide as the design extends has then to be sized with gold size on the black ground of the article, and allowed to get nearly dry, much dryer than for gilding, for the slightest tackiness suffices to hold bronze powder; and if the sizing be not dry enough, the stencil plate is apt to adhere and make difficulties.

The part intended to be solid bronze will have to be first dusted in through the stencil plate. This will be the husk A in Fig. 41. And here it should be noted that when two forms are close together on one plate, as are this husk and the round dot, it is not necessary to stencil both with the



Figs. 41, 42, 43.—Stencil Plates for Bronzing.

same bronze. One of them, in this case the dot, may be masked with a piece of paper; the mask being afterwards moved, and the second form dusted with a different colour. In the present design the husk will be solid copper, and the dots solid gold bronze. It should also be explained that the dots are cut through in *all* the stencil plates, that they may serve as a "register" or guide by which to lay the different plates with accuracy upon the work. Thus the first plate being done with, the second plate (Fig. 42) is adjusted so that the dots already laid in shall exactly appear through the openings which correspond to them; but the operation now to be performed is somewhat different from the first. The bronze is not now to be laid in *solid*. A very little gold bronze is taken up with a *dry* hair pencil and dusted on, beginning nearly solid at the top of the form (B), and growing gradually less solid towards the bottom by diminishing the quantity of bronze in the brush. This will produce a sort of shading, dying away towards the solid husk A. Then, changing the hair pencil, we take up a little copper bronze, and in like manner dust in the two husks C and D, which are to be made nearly solid at the points C and D, but shaded off below. Then removing this second stencil plate, and, instead, adjusting the third, Fig. 43, we make the dots register as before; and with a third bronze—say, orange or green—dust in the parts marked E and F, shading them as before, as is indicated in Fig. 40. The pattern is now complete, except as regards the two straight lines which bound it. These have to be drawn in, after the stencil work has been well dried, with gold size—by hand if the worker has the requisite skill; or, if not, by stencilling, and rubbed in solid with bronze; if drawn by hand, these lines are generally gilded.

After the whole of the bronzing process is completed, the black fibres and lines necessary to complete the pattern have to be put in. A person skilful in the use of the brush will do this with his "etcher" and black oil paint mixed with varnish. One who has not that skill may adopt instead a process known as "scratching up." This is done with a sharp-pointed piece of steel, by which the bronze and gold size may be removed, and the black ground exposed wherever a stroke is taken. This should be done before the work is quite dry. For the advantage of the little-skilled worker, it may be observed that "scratching up" may also be used in connection with dead gold and silvering; the effect, however, is never so good as that of lining with the brush point.

It will be seen that this bronze-work is a process far too valuable to be allowed to sink into oblivion. Its simplicity recommends it to the attention of only moderately skilled workers, and bronze offers a considerable variety of colours, each of which may be dusted in so as to form shading of the most delicate character. There are many purposes to which it might be applied beside papier-mâché work. Cabinet work suggests itself to the writer as one such purpose, the decoration being there applied on a black ground.

Thus far I have ventured to carry the reader in the preparation and decoration of papier-mâché work, and another brief paper will bring my instructions to a close. I can only hope that what I have said will prove suggestive in other ways for the ornamentation of household furniture.

"TIPS" FOR TYROS.

BY OPIFEX.

Bushing worn Wood Chucks.

Sometimes a wooden chuck which may be a favourite becomes so worn that it cannot grip the nose of the mandrel. I have found the following plan work admirably, and although it may not be new, I have never known of its being done, and give it for what it is worth. Heat the inside of the wooden thread with a hot iron, and give it a rather thin coat of cycle cement; now cut a piece of thin sheet brass, as used for covering curtain poles, etc.—*i.e.*, about as thick as stout paper—and sufficiently large to cover the inside of the hole in the chuck, and allowing about ¼ in. over. While the cement is hot press the brass in, and screw on the chuck tightly into its place; unscrew in a few minutes, and you have a perfect bushing of brass in your thread. Wipe off any cement which may adhere to the surface of the metal, and you will find that your chuck will have obtained a new lease of its life.

Colouring Brass.

Repoussé workers, etc., should know that they may colour their own work, and thus save themselves the trouble of having either to hunt up a professional or do without colouring at all, in which latter case the appearance of even the best work is spoiled.

The brass must be perfectly free from grease of any kind. To ensure this, wash well in very hot water with plenty of washing soda and a stiff brush, and rinse in clean cold water; drain off, and when dry dip the metal for two or three seconds into a mixture of two parts nitric acid, one part sulphuric acid, adding a very small quantity of common salt. Remove quickly, and plunge into a large vessel of clean water; rinse well, and dry in hot beech, or boxwood, sawdust. A tin biscuit-box, etc., suits well for keeping and heating sawdust in. When the brass is placed in the sawdust move the box about until the metal is dry, when it will be found to possess a beautiful, rich gold colour.

Avoid touching the brass with the fingers, as the least taint of grease will spoil the after process of lacquering.

The operation of dipping should be carried out in the open air, or in a specially ventilated room, and the fumes of the acids should be avoided, as they are most injurious; but if ordinary care be observed, there is not the least danger to be apprehended.

Brass wire, or a brass tongs, should be used to hold the article while dipping, and there must be no stint of water in the rinsing.

In case acids are not available, a fairly good gold colour may be imparted by boiling in a strong solution of pearlash, or even washing soda, care being taken to plunge the work into water before it has time to dry, *i.e., instantly* upon taking it out of the pearlash, etc., otherwise it will become stained.

Should it be desired to brighten any portions of the work by burnishing, this should next be done, a piece of clean paper being kept between the metal and the worker's hand.

Lacquering Brass.

The object of lacquering brass work is not to improve its appearance by imparting lustre, but to retain as much as possible of the lustre it already possesses.

In fact, the process detracts from the appearance of the newly-coloured work, as every worker knows who can appreciate the beauty of the metal as it comes from the water after "dipping," or from the sawdust when dry. But it is "too fair to last," and if exposed to the atmosphere for any length of time, would become dull, and finally black. However, a thin coat of spirit varnish, or "lacquer," will serve to protect the surface from the air, and the result is that the metal preserves its colour and lustre for years.

"A thin coat of lacquer!" how simple it *sounds*, yet there are few things harder to do—at least to do well; and many an amateur, and professional worker too, has experienced heart-burnings, as well as finger-burnings, in his attempt to acquire the art of lacquering.

The work, when finished and coloured, is slightly heated by placing it on a hot metal plate. It is then given an even coat of lacquer, using a broad camel's-hair brush, and being careful not to go over the same spot twice, but beginning at the top of the work and holding it so that the lacquer, supplied and guided by the brush, shall run down and over the metal. This requires practice, as owing to the brass being hot the volatile varnish quickly dries, and if the brush passes a second time over a spot where the lacquer has, even partially, "set," the result will be a brown seam, which, in a most provoking way, invariably appears upon the most important part of the work.

When this operation is satisfactorily accomplished the metal is heated, considerably more than before, until the lacquer is dry, but the amount of heat should never be greater than can be borne by the hand—applied to the back of the work—else the lacquer will be burned.

The brass is now let stand until quite cold, when it may be handled with safety.

The above is the usual method of lacquering, and, as before observed, appears a simple process *on paper*, but it is far from being so in practice; and the present "tip" consists in this, that as the chief difficulty lies in the fact that the metal being hot the lacquer dries very quickly, this difficulty may be obviated by applying the lacquer to the *cold* brass, allowing it to dry spontaneously, and then giving another coat. Do not mind if the first coat becomes milky, but, having applied the second, subject the metal to heat, as before directed, when it will dry bright and clear.

Utilisation of Old Negatives.

Amateur photographers often don't know what to do with old or spoiled negatives, and sometimes need a greater number of printing frames than they possess.

The connection between these two facts consists in this—that the old negatives may very easily be turned into printing frames, or rather printing contrivances, for there is no frame needed; but we will call them frames for convenience.

To make a printing frame for half-plate photos, we only require two old quarter plates. Cut a piece of strong black linen a little larger than two quarter plates placed side by side, and paste them down securely in that position to the linen; place this on a flat surface, and lay a heavy book, etc., upon them until quite dry; then trim off the linen to the exact size of the glass with a sharp knife.

Next procure four spring clips, as used for fastening clothes on a line, and the printing frame is ready for use.

To make a print, place a piece of sensitised paper of the required size upon the ɔgative, and then a piece of white blotting ıper, half-plate size, upon the back of the ·int. Next lay the quarter plates hinged ith black linen, glass side down, upon the lotting paper, and secure with the four ips, placing two at each side of the frame, ɔ that each half of the folding back shall be rmly held in position. The print may be xamined by removing the clips from one nd and raising the half, as in the case of an rdinary printing frame.

For carte-de-visite size, a quarter plate cut ıto equal parts, and for printing from /hole-plate negatives, two half plates, backed /ith linen as above, may be used; for the ırger sizes eight clips will be required in ɪrder to ensure perfect contact between the ɪrint and negative.

OUR GUIDE TO GOOD THINGS.

76—Gaseous Fuel: Its Production and Application.

Readers of Work who are interested in the production and application of gaseous fuel, including water gas, will derive much information on the subject from this little volume, which is the reproduction in book form of a lecture delivered at the Association Hall, Peter Street, Manchester, on March 29th, 1889, by Mr. B. H. Thwaite, C.E., author of "Our Factories, Workshops, and Warehouses: their Sanitary and Fire-resisting Arrangements;" "Liquid Fuel: its Advantages for Steam-raising Purposes;" "Mill Engines," etc. Opening with strictures on the national waste involved in the consumption of solid fuel, the writer calls attention to the vast subterranean stores of natural gas, whose discovery and application to various manufacturing purposes for which coal is now used in this country has transformed the black and smoke-stained region of manufacturing industry in Pennsylvania into one almost as pure as those parts in which agricultural pursuits predominate. This is followed by a brief reference to the Aspheron Peninsula and other places in which natural gas has been discovered and utilised, the chemistry and composition of natural gas, known to miners as firedamp or marsh gas, its origin and geographical location, the method of drilling a natural gas well, and the distribution, transportation, and application of the gas itself.

Space forbids any attempt to summarise the contents of the volume throughout, and it must suffice to say that it is brought to a conclusion by a statement of the author's project for distribution of gaseous fuel produced and distributed at the different coal fields of the United Kingdom, the supply for the metropolis and the midland towns being derived from three gaseous fuel-producing installations—one in South Wales, one in Staffordshire, and one in South Yorkshire.

"The coal," says Mr. Thwaite, "would be converted into gas at the coal fields, and delivered to the distributing mains under great pressure by means of compression engines, and could be distributed in the towns in the daytime for heating purposes by the ordinary mains, and by means of special incandescent burners the gas could be utilised for illuminating. The saving in cost of fuel by this system in its application to the metropolis will be understood from the fact that, in the year 1887, 12,055,000 tons of coal were delivered into the London district. The total cost of this coal at the coal fields would be fairly estimated at £3,013,750; the amount paid by the London populace for this coal would be about £12,657,750 per annum. The difference between cost of fuel at the source of supply and at the place of use is, therefore, £9,644,000. This amount is absorbed in cartage, merchants' profits, railway carriage, and London Corporation dues. Assuming one third of this amount represents the reduction in the price of fuel to the consumers, this would leave a balance of £6,429,324 to pay for cost of generating gas and interest on capital invested on plant and pipe lines and maintenance. There is little doubt but that the net profit would justify an expenditure of fifty millions sterling in gaseous fuel installations and distributing pipe lines.

"The advantage to the metropolis by the general distribution and application of gaseous fuel would be a colossal one. The increasingly heavy and dangerous fogs, which are greatly due to the condensation of the aqueous vapour on the atoms of unburnt carbon and sulphur, would soon disappear. The splendid architectural monuments of modern Babylon would be relieved from their dirty covering, and London would be metamorphosed, and might rival Paris in the clearness of its atmosphere, after allowing for the different climatic conditions."

Such are the writer's views of the economy of the substitution of gaseous fuel for coal in all large towns and its results, as applied to London. Nothing could be more desirable than the removal of all products of combustion, or rather, of non-combustion, which permeate the air in all manufacturing towns and large areas, overspread with buildings and dwelling houses, closely packed together and extending their serried ranks of streets for miles and miles towards every point of the compass as in London. Whether they can be, or ever will be, realised, remains, in all probability, for a future generation to determine, as there seems but little inclination at the present time to move in the direction indicated.

It only remains to say that an appendix shows the value of ammonium sulphate, which could easily be recovered for utilisation as a valuable manurial agent, if the fuel now used in the form of coal was converted into gaseous fuel at the coalfields, to be conveyed thence for heating and illuminating purposes, instead of being burnt in furnaces, stoves, and open grates. He also gives analyses of chimney gases, resulting from tests and trials of boilers, heated in the one case by ordinary steam coal, and in the other by gaseous fuel, the results in the former showing a solid carbon percentage, by weight of smoke, of 4·18 per cent., while in the latter they showed absolute immunity from combustible or unburnt gases and smoke. The superiority of gaseous over solid fuel in the metallurgic operations is also shown, and some valuable notes on water gas are added. In these the relative thermic values of producer gas and water gas are shown and contrasted, and it is clearly shown in what point the real value of water gas is to be found—namely, in its high thermic character per unit volume, the ratio of thermal units in any given equal volume of producer and water gas being as 60·8 to 277 in favour of water gas. This portion of the appendix is doubly interesting at the present time when public attention is being called to water gas, and its merits, in point of cheapness of production, are being strongly urged. The book, it should be said, is published by Messrs. Whittaker and Co., 2, White Hart Street, Paternoster Square; but the publishers have omitted to state the price, which should always be named, whether in the case of book or mechanical appliance, as it is useful in assisting the reader to determine whether to buy or not to buy.

The Editor.

SHOP:

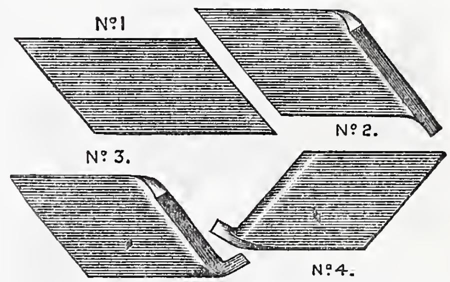
A Corner for Those who Want to Talk It.

*** Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

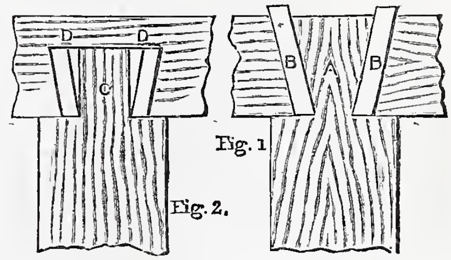
A Warning Note.—Thomaso writes:—"Your 'Shop' is increasing in size remarkably quick. If it goes on increasing at the present rate, we shall have nothing but 'Shop;' and it will probably become necessary at no very distant date, to commence that important section of Work about the middle of the previous week. As to the quality of the 'Shop' talked, well, it seems as if somebody had 'cribbed' the editorial trumpet, and taken it on a provincial tour. This surmise receives a certain amount of confirmation from the fact that you do not perform on it yourself; the loss of the instrument probably accounting for this. It is quite clear that it has not fallen into good hands. Some toot away at it until they get quite light-headed, and write hysterically, a style of composition which makes any man of feeling blush—for the writers. Others blow so gently, that one quite marvels at their taking the trouble to write at all. Then there is the 'toot patronising;' the writer graciously intimating that he is 'pleased' with Work. This class of correspondents is obviously composed of those to whom adulation is unpleasant; but I suppose they feel bound to conform to the prevailing custom, and may even labour under the impression that an answer to their query will not be forthcoming unless they use a little soft saponaceous matter. Absurd! There is just one thing more I wish to refer to—*i.e.*, the enlargement of Work. Now, it is a striking circumstance, and one by which I justify this letter, that the 'tooters' are practically the only persons who clamour for an enlargement! Therefore, hearken unto me, ye disinterested trumpeters! When you write, have less to say about 'admirable magazine,' 'brilliant staff,' 'lucid style,' 'just what was required,' and other platitudes, however appropriate they may appear. By so doing, several columns weekly might be saved. Come, now! don't you think you have had a good innings? Give the Editor a chance of adopting a really practicable plan for the enlargement of Work."

Glazing Without Putty.—Delta writes:—"Take 5 lb. sheet lead, cut into strips $\frac{3}{4}$ in. wide, then with shears clip into slips like No. 1; next place about $\frac{1}{2}$ in. in vice; bend over and hammer into shape No. 2 with a light hammer; take out of vice, and with pliers bend point down as in No. 3; trim point with shears to thickness of glass, punch hole for tack ($\frac{3}{8}$-in. copper preferred) with sharp-pointed awl—that known as a saddler's awl I use—and the



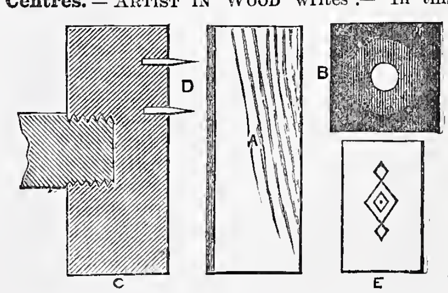
clip is complete. No. 4 goes through the same process, but is bent in the vice in the opposite direction for other side of bar. Two of these clips are sufficient for sheets of glass 12 in. by 18 in.; the top of last sheet in glazing is, as a rule, let into a groove in the ridge board. The bars may be prepared for glazing either with a bed of soft putty or a coat of very thick white lead paint. A dozen of these clips might be knocked out while writing this description, and one square foot of sheet lead will turn out about three hundred clips."

Firm Joints for Woodwork.—Artist in Wood writes:—"I send you two sketches of firm



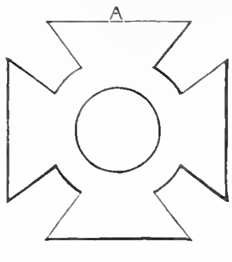
joints for woodwork. Fig. 1 is the dovetail tenon, A the tenon, and B B straight wedges. Fig. 2 is the dovetail mortise. The taper wedges are placed in the end of tenon, and driven in by coming against the bottom of the mortise."

New Machine Tool for Making Inlaid Centres.—Artist in Wood writes:—"In this



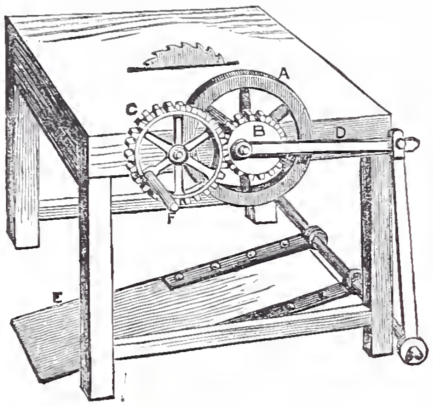
machine tool, B is the inlaid centre, and C and D constitute tool for making it; A is a block of wood with veneer pasted on it ready for cutting. In E is shown the way of using the inlay for centres of panels. File the cutters thin, and to a bevel point, cut just through the veneer, and no more, having three sorts of wood, and change the colours."

Machine Tool for Working Beads, etc.—ARTIST IN WOOD writes:—"The following sketch of a machine tool that I use for working beads and mouldings in hard, cross-grain wood, is made



from a solid block of best tool cast steel. The part marked A is filed to fit the form of mould required; they are very useful for grooving to receive inlaid lines; they are just the thing for art furniture makers."

Powerful Rip Saw.—ARTIST IN WOOD writes:—"I send you a sketch of a powerful rip saw; it will cut very easy up to 2½ in. thick. A is a fly wheel, 50 lb.: B, cog wheel, 7 in.; C, cog wheel, 19 in.; F, handle; E, treadle; D, rod, to fit pin on B wheel. A and B wheels fit on saw spindle; crank pin on B wheel is 2½ in.; if wanted for heavy work,



A, wheel, may be 60 or 70 lb. The treadle has only about half the rise and fall of the common treadles; a 10-in. saw is the best size to use for light work; C, wheel and handle, will not be wanted. It should be made so that it will take off."

Denham Bros.' Patent Filler, etc.—J. W. M (*Halifax*) writes:—"I have great pleasure in recommending a remedy for sweating in French polish to your correspondent, T. A. (*Belfast*), whose inquiry appeared in WORK for June 1st, but which I failed to notice at the time. I am a practical cabinet-maker, and in common (I suppose) with all others, have had more or less trouble with sweating. For some years past I have had my polishing done by the firm whose circulars I enclose, and since they began to use their patent filler—about two-and-a half years ago, I believe—there has been no sweating whatever, in any part of the work they have done for me. The printed matter enclosed will sufficiently describe the preparation, and I need only add that I have no interest whatever in the matter, beyond a desire to act on Charles Kingsley's advice of 'Helping when we meet 'em, lame dogs over stiles.' I am much pleased with your new venture, upon the whole, and wish you every success. Your article on 'Circular Saw Rigs for the Lathe,' was particularly helpful, as I was just at that time rigging up a saw for some special work. In the course of my efforts I evolved one or two notions all out of my own head, which, I think, might be of use to your readers, and if you will allow me I will try to write a supplementary paper on the subject on approval. Messrs. Denham inform me that their preparation can be bought in Belfast."—[Reference to Messrs. Denham, Bros.' patent filler has been made in the present No., page 350. I am glad to find that the paper on "Circular Saw Rigs for the Lathe" was useful to you. I should like to have the paper you propose, on approval.—ED.]

About WORK and Watches.—DEAN FOREST (*Mitcheldean*) writes:—"I beg to thank you for the answers to the questions I asked some weeks ago on hard soldering, which were answered in the 'Shop' column of WORK. I may say I had tried to obtain the one or two 'tips' which AUROLECTRIC gave me in his answers for a long time and in many ways, but unsuccessfully. I would, therefore, say that WORK has my best wishes as well as it has of those who have already paid it so many compliments, and given it so many good wishes. But I should like to see it enlarged, so that we might have a larger supply of 'good things' every week. In Nos. 16 and 17 I notice with pleasure the paper on 'An Overmantel Clock Case,' written by J. H. Moody, and I trust that many may profit by it, as I am sure they will. But if you will allow me, sir, I will take a step more than J. H. M., and advise any of my fellow-readers of WORK who are in the possession of the movement of an old verge watch to try and turn it to good account by making it into a timepiece, which it is very possible for anyone who can work a little in metal as well as wood to do. Of course it would be somewhat more difficult than our friend J. H. M.'s construction, but nothing worth the mentioning to those who are used to overcoming difficulties. I give this suggestion to any who may care to act upon it, because, having one in my possession at the present time, and knowing that a verge movement when put to such a use will often prove a fairly good timekeeper, I think that this would be putting it to a better use than it is put to when, through being unable to compete with our modern watches as a correct timekeeper, it is, as it were, thrown out of the race, and gets cast aside either to be practised upon by one of those persons who seem to be in possession of a faculty for taking constructions (mechanical and otherwise) to pieces to see 'how they are made' (after which that which might have been made useful is often made useless through various of the works being bent, broken, or lost), or else to be sold for a small sum to a watchmaker. I therefore throw out this hint to those who will receive it, knowing that even in the construction of a small timepiece like what I refer to there is plenty of scope for the exercise of some of the talent possessed by many of WORK'S readers in construction and ornamentation."

Protection of Wood and Metal from Weather.—J. C. K. (*Paris*) writes:—"Mr. Heald, of San Francisco, is like the man who went to Greenwich for the first time: he claimed that he had discovered Greenwich. Mr. Heald has found out what has been known for ages, ever since turps was mixed with pigments for paint to protect wood and metal from the weather. One part linseed oil, three parts turps and red-lead, white-lead, sulphate of copper, or any powder of minerals, is the common priming coat of paint everywhere. Mr. Heald should remember the old saying, 'If you don't know, ask.' I ask the painter."

Hollow Metal Work.—TINNER (*Stockton*) writes:—"Being a reader of your weekly paper, WORK, I noticed under the heading of 'Hints on Hollow Work in Sheet Metal,' in which you say plumbers and silversmiths are interested; you do not mention tinners, who have all kinds of hollow work to do, such as kettle tops and lids, pan lids, and copper balls for cisterns. This is only hammered on polished heads to be planished, or to be made hard; it is hollowed on a block of wood with a rounded hammer, called a blocking hammer, and can be annealed afterwards if required. The way you describe will be a very long and tedious job, and will require a lot of practice before it can be done properly. The other will be found the quickest and easiest way for an amateur. I wish you every success with your valuable paper."

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Parts of Lathe.—J. K. (*Richmond*) writes:—"I hardly know how to commence, but the fact is I have, or rather had, been, looking out for a practical paper for the amateur, but I had no idea of dropping across one which has already proved itself a great boon to me as an amateur carpenter, and I am sure it has to a great many others. Now what I want to get is a small rough lathe. I have a nice little workshop, I have made my own bench, and have got a good bench vice, iron vice, iron drill bits, etc., and, in fact, almost every sort of tool for ordinary carpentry or rough ironwork, and I have made some very good furniture, and I have some in progress from your designs. Now, what I want you to tell me, through WORK, is how I could make myself a small lathe for wood, to turn, say, uprights for whatnot, or such like. I have every opportunity for getting that done, I mean in the shape of ironwork, which I could not manage myself; the wood part I can easily get over. I have made the dog-chuck you gave in No. 2, so if you could kindly give me a few hints to help me, you make will greatly oblige me as well as help me, for I small things in my spare time, and sell them to add to my funds, and I find myself greatly in want of a little lathe. I don't want to buy any more of it than I can help, so if you can give me the hint you will greatly oblige me."—[I give your letter in full so that all readers may be aware of your inquiry, and what you are doing to help yourself. Supposing that you can make the wood frame of your lathe, the headstock, wheel, and crank could be obtained in Clerkenwell Road, late Wilderness Row, E.C., at any of the cheap tool shops that are to be found therein, and I would suggest a visit to Messrs. J. and S. Miller, 66 and 68, Clerkenwell Road. Anything less that a 5-inch centre lathe would be more of a boy's lathe, and not by any means a practical tool, especially to an amateur. A plain fly wheel and crank, headstock, mandrel pulley, and poppet head of a 5-inch centre lathe would cost you from 25s. to 30s.—G. E.]

Tobacco Pipes.—SMOKE.—The manufacture of clay tobacco pipes will not be treated in WORK. I am not acquainted with any book on the subject. The material used is a fine clay, well worked. They are made in moulds, and the perforation of the stem is effected by means of a wire.

Battery, Porous Cells, Accumulators, etc.—F. TUCKER (*Bristol*).—(1) I cannot find any reference to the battery named by you in Watt's book, latest edition. When copper forms the negative element in a solution of sulphuric acid it speedily becomes coated with a film of hydrogen, and the battery becomes polarised. This means a serious loss of power. In the Daniell cell this gas is absorbed whilst copper is being deposited. The cost of working a Daniell is less than that of the battery named by you, since the deposited copper is a valuable commodity. (2) In the earlier edition of Watt's book he may have given a recipe for making porous cells from plaster of Paris, but he does not repeat this in his last. The reason is obvious. That the game is not worth the candle you have now proved for yourself. It is one of the last things I should think of doing whilst porous cells of good quality can be obtained so cheaply. (3) Just think for a few minutes on the prime or first cost of accumulators (not less than £1 per cell), then the cost of acids for charging them, then the cost of the battery needed to form the plates, and then remember that you will only get about 80 per cent. of the power back again as electric current—that is to say, it will cost you 20 per cent. more to get the same current by the way you propose (leaving out cost of accumulators) than by using current direct from a primary battery. Where does the economy come in? Some day I may write on the subject, but it won't be just yet, for other more important subjects claim attention. (4) I do not clearly see what you mean by giving information in WORK in "a piecemeal fashion." The article on the Bunsen battery did not promise you a number of "glorious experiments" to follow, therefore I cannot see how you could expect them. The article was meant for *work*, not for play. You, and those who wish for it beside yourself, will have enough to occupy your hands, and minds too, shortly, in a series of articles dealing "exhaustively" with the way to make "electrical apparatus." I do not aim at pleasing my readers with a variety of subjects, but form a purpose and go ahead with it. I have not forgotten the fable of the "Old Man and his Ass," nor the lesson taught in it. This you will learn as you become better acquainted with WORK. Your complaint respecting "gigantic advertisements" is uncalled for. Neither the Editor nor any of his staff is in any way interested in a pecuniary manner with the things recommended in WORK, or in the firms whose names are mentioned as vendors of the goods named. *You* may not be interested in knowing where to get a good lathe or a good tool, but the information may be welcome to hundreds of other readers. In this we must study to please or serve the majority.—G. E. B.

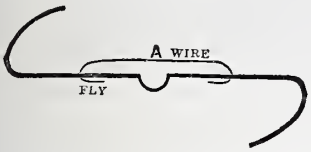
Venetian Blinds.—J. A. H. (*Chepstow*).—A paper on this subject will appear shortly.

Repairing Chloride of Silver Battery.—CHLORIDE (*Plaistow*).—Your Gaiffe battery has failed because the chloride of silver has become exhausted. You must, therefore, coat the silver plates with fresh chloride of silver prepared as here directed. Place half a wineglassful of nitric acid mixed with a teaspoonful of rain water in a saucer or a cup, and put on a warm hob in the chimney corner. Add to this as much old silver as the acid will dissolve. This done, pour all into a basin two-thirds filled with rain water, and add common salt until all the silver has been thrown down as white chloride. Pour off the liquid, and wash the chloride with clean water, by pouring in the water and allowing the white powder to settle. Do this several times, then drain off all water, and dry gently in a saucer. When dry, spread a layer of it over each silver plate, and warm over a spirit lamp until it seems to melt and run over the plate, forming a dirty grey coat. This is horn silver, or fused silver chloride. Coat each plate in this way and then restore them to their places in the battery.—G. E. B.

Whitening Brass.—NIMROD (*Birmingham*).—Articles made of brass or copper may be whitened with a coating of tin or of silver as may be required, by boiling them in either one or other of the following solutions:—(1) Dissolve as much cream of tartar in boiling water as the water will take up, then add to it a little chloride of tin. Previously well clean the articles from all grease and corrosion; immerse them in the above solution together with a handful of grain tin, and stir all well together, whilst still boiling, until the articles are well coated with tin. Well wash in warm water, and rub in hot bran until bright. (2) Mix together 80 parts of cream of tartar, 80 parts of common salt, and 1 part of chloride of silver. Dissolve the whole in boiling water, and boil the articles in this solution, treating them as directed above. The deposits of tin or of silver from these solutions are very thin, and not so durable as coats of the same metals electro-deposited.—G. E. B.

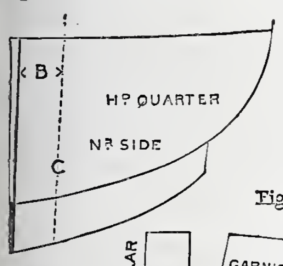
Air-tight Joints in Wood.—H. W. (*Edinburgh*).—To make joints in wood air-tight, you can plough the meeting edges and tongue with hoop iron, or with wood secured with white lead.—J.

Clockwork Model.—SUBSCRIBER (*Sandbach*).—The only thing I can suggest is to make a fly long in shape, as long as the rest of the works ill allow, if working in the frame; if working outie the frame, of course, you may not be so recricted for room. Make it from very thin brass or i, and then bend the shape of letter S, the bent irt pointing the way the fly goes. See that it is cely balanced, that is to say, that when perfectly rest the arms are horizontal, not vertical. To sten to the arbor of pulley, make across the intre, the short way, a hollow, so,



o fit the arbor; now, about half an inch each side f the hollow, and in the centre, make a small hole, nd pass a piece of fine brass or iron wire, A (as ketch above), and in the arbor make a little groove o fit the wire; this will act as a spring, and keep y tight to the arbor and in its place. The longer our fly the slower its action; the width does not natter so much. Try this; if no better, and you ike to pack up and send to me, enclosing cost of eturn carriage, I will see what I can do, free of harge, unless very much is wanted. Perhaps your pring is unsuitable, that is to say, too strong when vound up, not properly or evenly tempered; try another, or fit stop-work to it, only using a few of he centre turns of it. In any case, let me know he result. You can find me through the Editor, if you want to send it to me.—A. B. C.

Cranked Hinges in Carriage Building.—Young Bodymaker.—I assume you mean not how to fix, but how to find the exact position in which the hinges (better known as outrigger hinges, in the coach trade) should be fixed, to ensure the proper and correct working of the outrigger, and also the concealed hinge above it, as if only slightly out of "true" with centre pin of the concealed hinge, the door, whether of a brougham, landau, or any other carriage upon which it may be fixed, could never be made to open or close properly, to the intense annoyance and disgust of all concerned, in that particular door. I will now try and explain the best method I know of, for the finding centre, and then briefly state one or two generally adopted methods of fixing the hinge to the door and body. As outrigger hinges are most generally used at the bottom of landaus and other carriages with equally short doors, with only one concealed hinge above, and that one fixed with the upper



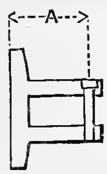


Fig. 1.

Fig. 2.

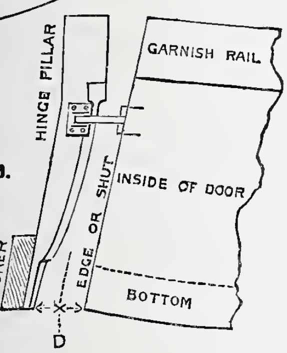

Fig. 3.

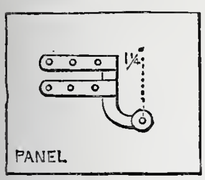

Fig. 4.

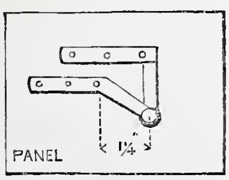

Fig. 5.

edge of its brass flap directly under the elbow line joint, we will take as our subject a canoe, or boat-shaped landau. Assuming you have already let in and properly fitted concealed hinge—we will suppose the size to be what is called 1¼ in.—take the exact distance from *shut*, that is, brass plate of concealed hinge, to the centre of pin on which hinge turns. Thus Fig. 1 A, with rule, or still better, a pair of dividers, place one leg of these exactly on edge of panel at the rabbet, and mark a point on the panel with the other leg, as at Fig. 2, B, from which point drop a perpendicular line, square down to the bottom of body, C, Fig. 2., that is, the centre of bottom hinge from door rabbet. Now fix hinge to door, and fix brass flap with door attached to hinge pillar; open the door as far as it will come out, square with body, support door so as to take the dead weight of the concealed hinge, and measure the exact centre of the open space, between outside of body where the outrigger is to be fixed, and the edge of door, as in Fig. 3 at D, that is, the centre of bottom hinge from outside of body. Now, if the bottom of body at that point is square across, it will be a good place to fix the hinge, so tack a piece of ½-in. pine on bottom of rocker just under the centre just found, keeping it parallel with horizontal line of body. Mark the centre on the top side of this piece of board; also mark outside of rockers, and around bottom of hinge pillow, and outside of body to this centre; now shut the door, and mark along outside of door at bottom, also up to centre; take off the piece of board, and mark off outline of hinge enclosing the centre before mentioned, like Fig. 4 or, again, like Fig. 5. In either case, if the door bottom is level with bottom of rocker, you must have the bottom half of hinge cranked up, or the top half of hinge let into bottom of door, to allow flaps of hinge to bed on to their respective places, and close over each other; the spaces in between flaps of hinge on Figs. 4 and 5 is the clearance to allow door to close without touching at those points—*i.e.*, edges of flaps. Fig. 4 shows the hinge with back edge of flaps level with door rabbet, Fig. 5, with bottom or body flap coming square out from centre line, and the top or door flap level with door at rabbet, but outer or neck piece cranked or curved to meet that centre. Care must be taken that the centres of both hinges exactly correspond, both perpendicularly and at right angles, and as the bottom of door and body are curved, the smith, when setting the hinge, will arrange to have the knuckle arranged as described. Now, as to the best place to fix: some coach builders place this hinge immediately under the bottom side, when it projects far enough out from the rocker piece below it; personally I consider this a wrong position. Firstly, being too high up, too near top hinge, and consequently causing a loss of steadiness; and secondly, as being rather unsightly, and breaking somewhat the easy and graceful flow of the bottom line of moulding; it has, however, two advantages, a much shorter hinge is necessary, and is not so liable to vibration; but, again, is likely to wear out the bolt and holes in the knuckle quicker; this is a decided drawback. Now, if the extreme bottom of body is made level across, and not bevelled on outer edge of rocker and door bottom, I consider that the best place for fixing the hinge, the only drawback being that a longer and stronger hinge is required, to come out far enough to reach the centre. At that point, the upper and lower hinges being much farther apart, they are a much steadier support to the door, do not wear out so quickly, and what is of great importance, are vastly easier to fix or to repair when disarranged by use or accident. I fear this will appear rather a long instruction to Y. B., but he will know that almost any part of coach-making requires minuteness of detail, if it is to be properly understood; and if I have not made this sufficiently clear to him, I will endeavour to do so in reply to his queries in "Shop." The question, as he gives it, certainly does him credit, being somewhat difficult to impart so as to be thoroughly understood, except by personal supervision, and yet very easy of accomplishment when required by actual practice, at least it has been found so for years past by Phaeton.

Curling Iron Stand.—M. K.—The cost of the provisional patent for nine months is £1, and by deducting this from the amount asked by the patent agent, you can see how much would go to him as his remuneration for work done. I am afraid there is not much to patent in the invention. It is only an old article put to a new use. The idea is certainly good, but I scarcely dare venture to tell you to go on with it, because you have no means of pushing a sale when you have had them made. It will cost you £1 to get provisional patent for nine months, and at the expiration of that time you will have to pay £3 more for complete patent. It will not be difficult to find a man to make the articles, but you will find it difficult, and perhaps expensive, to promote the sale of them. If you accept the offer made by the patent agents, it may be that they will sell it for you, that is to say, sell the right to someone to manufacture the article. I cannot say anything with regard to the probability of your making money by it. Ask the patent agents plainly if they can manage to sell the invention for you, and at what price. If they can, so much the better for you, on the bird-in-the-hand-worth-two-in-the-bush principle. Failing this, write to the Editor of the "Girls' Own Paper," and see if he will accept a description of the thing itself, with illustrations, and pay you first. This is all I can suggest, but if you prefer to obtain protection, and want to know a person capable of making it, I can, and will, give you the name of a trustworthy person who could make the stands: but whether he will or will not do so is more than I can say.

Designs for Fretwork.—J. A. J. (*Stratford*).—I am sorry to learn from you that an accident which has caused injury to your spine prevents you from ever working at your trade as a carriage maker again. I know it must give you the heartache to be compelled to drop out of the ranks, and do but little when you would fain be doing much, and you have my sympathy to the utmost. You say you have taken to fretwork to earn a little, but cannot get good patterns, having tried many who advertise designs, only to meet with disappointment. Have you tried Mr. Henry Zilles, 24 and 26, Wilson Street, Finsbury; and Mr. G. Busschotts, Park Lane, Liverpool? These dealers supply continental designs, and some are extremely good. Indeed, I do not know any dealer that has not good things amongst his designs; and, I think, if you procure the miniature sketches that most dealers send out, you will find among them something to your mind. With fret cutting, I should also try wood carving. Again, if you are fortunate enough to be able to expose articles for sale, either at your own residence, or in any shop kept by a friend, you might find it of advantage to make models, games, doll's furniture, etc., all of which would be light work that you could manage without much fatigue. There will be some pretty designs for fretwork from the pencil of Mr. J. W. Gleeson-White in forthcoming numbers of Work, but it is difficult to give full size patterns without large sheets, which are very costly. Among other things, if you cannot draw with ease by all means study drawing, and see what you can do in the way of ticket writing, for which you will derive assistance from Mr. Benwell's paper on "Sign Writing and Lettering." You ask me to help you, and it seems to me that I can best do this by the hints and suggestions that I have endeavoured to place at your disposal.

Building Construction.—Pixie (*Granite City*).—It takes some time to get on to such a subject as building construction, and possibly it may be found needful to hold it over for another volume. "Monumental and Stone Carving" is a subject on which it is very difficult to find a writer. I was speaking the other day to a man who was accustomed to cut letters on granite, and apparently a first-class hand at the work, but he could not write himself, nor could he tell me of any one who could.

Fret Sawing Machine.—J. F. W. C. (*Hull*).—The best fret sawing machine at present in the market is the Britannia Company's No. 8 machine. If you will write to the Company, Colchester, you will be supplied with all particulars. It is intended to construct a small lathe to be used in combination with this machine, and any requirements on your part with regard to fittings could be easily satisfied.

Wood Screw Cutters.—J. H. E. (*Shepherd's Bush*).—The screw boxes and taps for cutting screws in wood are illustrated in page 64 of Messrs. Peugeot Frères' catalogue, or, rather, price list, and prices are given according to the index in page 50. On turning to this to give you the information you require, I find that my price list is imperfect, pages 47 to 50 being missing. If you write to Messrs. Alex. Von Glehn & Co., 7, Idol Lane, London, E.C., the prices, I am sure, and the sizes in which the screw boxes are made, will be at once supplied.

American Saddlers' Tools.—W. O. (*Rochdale*).—I am not aware that there is any difference between the tools used by American saddlers and those in use among English saddlers. The tools comprise punches of different sizes, creases of various kinds, cutting gauges, head knives, round knives, bridle cutter's knife, edging irons, pliers, pincers, saddler's palm, punch pliers, screw punches, etc., stuffing rods for making collars, awls, and other articles, all of which can be procured through any ironmonger or hardware merchant. If you cannot get them at Rochdale, write again, and I will give you the address of a London dealer who can supply them.

Violin Tools.—J. W. (*Battersea*).—The fine-toothed veneer plane, which, like the tool you describe, bears an upright blade, will do all you require for reducing veneers to the proper thickness. As you say, some of the trade purfling is certainly "rubbish." I do not know any one except myself who has the black veneers. To make good mitres it is not necessary to use three separate strips. First cut your mitre to fit, and then bend the purfling over a warm iron. It is rather awkward to give instruction as to colouring a varnish to match without seeing the original, but I have an impression that the varnish you mention is not a *coloured varnish*, but a spirit varnish over a wood stain. The violoncello sound-hole punches you can buy at Lafleur's, Green Street, Leicester Square; all the others you can get from Withers & Co., 51, St. Martin's Lane.

Japanese Patterns.—Miner.—Books of Japanese Pattern are not easy to obtain. Mr. B. T. Batsford, 52, High Holborn, W.C., has them now and again, and Messrs. Liberty, Regent Street, W. They range from 9d. to 5s. or 10s., but the cheap ones are more useful for ordinary purposes.—G. W.

French Polishing and Veneering.—T. A. (*Glasgow*).—Articles on these subjects are in preparation, when all that relates thereto will be fully dealt with.

Amateurs and Wood-buying.—F. W. H. (*Upper Tooting*).—A paper on this important matter is being prepared for the advantage of all readers.

Papier-mâché Panel.—A. L. W. (*Aberystwyth*).—Messrs. McCullum and Hodson, Summer Row, Birmingham, will, doubtless, supply the article required.—S. W.

House Painting and Graining.—W. H. F.)—Our correspondent asks us to give "the certain proportions for mixing oil colours" for the above purposes. This is a question which would involve more than the entire weekly space devoted to "Shop" to answer fully. In the first place, in mixing ordinary white lead and oil paint, there are no certain proportions. The amount of each article used in its mixing does, or certainly ought to, very materially depend upon the work undertaken. Independent of preparation—which is a very important item in good house-painting—the nature of the paint should be very different when painting, on the one hand, new woodwork, and on the other new parian, or plaster walls. Of the four coats each should have, the proportions of lead, oil, etc., would be different each time in both cases—that is, if painted by a tradesman who knew his craft. To speak of colours and graining in this answer is quite out of the question, as our correspondent makes only a general, unlimited inquiry. If W. H. F. has any pressing and particular object in view in making this inquiry, we would endeavour to aid him if he writes and states particulars. Beyond this we must advise him to carefully peruse the pages of WORK, when he will be rewarded by finding a complete and exhaustive treatise of the subject of our head line, which is now being specially written by an experienced London decorator.—F. P.

Imitation Lead Lights.—H. W. H.—These are generally known as "window transparencies," being a class of transparent, oiled papers, and which, when properly affixed to the glass of windows and door panels, form a very durable and decorative substitute for painted and coloured lead light glazing. There are several makes, I append two—W. E. Tuker & Co.'s, "Die ae Note," and M'Caw, Stevenson & Orr's patent "Glacier" decoration. Hinde Bros. (London and Birmingham) are, I believe, the wholesale vendors of the first named; M'Caw & Co. are the patentees and manufacturers of the "Glacier." The latter is, I think, that most used, and an article which I can personally recommend, and can be obtained direct from the makers, Linenhall Works, Belfast, Ireland. Perry & Co., the pen makers, Holborn Viaduct, are still, I believe, the wholesale London agents for "Glacier." Most established stationers are also agents for one or another maker of transparencies, where drawings and designs can usually be seen, and through whom our correspondent could doubtless get all he requires. Directions for use usually accompany the article, but I would advise that the glass should be very carefully cleaned, and the design then arranged so that it can be readily fixed. The glazed or bright side of the transparency is then wetted with water, or the glass can be wetted, placed in position, then all bubbles smoothed out with soft cloth or sponge, working from the centre to the outsides. It must then be left for not less than twelve hours, to allow the water to evaporate and the article to get firmly fixed and hard. Although the process appears very simple, care and patience are necessary to make a good job, and it is advisable to watch that, whilst drying, the transparency does not blister up from the glass. When properly fixed and hard, coat the transparency with best light copal varnish; it will then be thoroughly protected both sides.—F. P.

Covering Plush Frames for Terra-Cotta Plaques, etc.—J. C. (*Aberdeen*).—No preparation of the wooden frame is necessary; all that is wanted is some good strong glue for sticking down the plush. Supposing the frame to be circular or oval, the plush is best cut in a single piece large enough to overlap the wood every way, and it must be nicked or snipped on the inner edges that it may wrap over without creasing. The wood has then to be glued, the plush stretched carefully over it, and well pressed down with a clean cloth or duster. Small square frames are covered in the same way. In covering large square frames it is usual to economise plush by cutting a separate piece for each side, and mitring them at the corners. The joining has to be hidden by a piece of silk cord glued over it. Round and oval frames are sometimes covered in this latter manner with small pieces of plush, the joints being corded; but the best and safest work is made with the single piece. For an answer to his other query (preparing canvas) J. C. is referred to our reply to WAITING (see page 285).—M. M.

Photographic Camera.—T. R. C. (*Ashton-under-Lyne*).—The manufacture of appliances for photography will not be neglected, but their making will be work for the winter rather than for the present summer.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Solidifying Petroleum Oil.—OX GALL (*Manchester*) writes:—"If your correspondent, P. W. S. (*Poplar*), or any other correspondent, will kindly tell me how to solidify petroleum oil, I shall deem it a great favour. I have no objection to stating for what purpose I require the oil solidified.

Water Floats. — REYNARD (*Leeds*) writes:— "Will some of your scientific readers kindly inform me what size piece of circular cork will sustain a man of 12 stone above water? Also what size tin cylinder will do the same?"

Carpet Fitting.—M. G. (*Belfast*) writes:—"If any readers know of a book which would assist in measuring and fitting carpets, etc., would he be good enough to let me know?"

Photo Camera Lens in Magic Lantern.—PALETTE writes:—"I have read that a photo-camera lens can be very successfully used in a magic lantern. I should like a verification (or otherwise) of this statement, with instructions."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

French Polishing.—JACK H. sends the following in reply to T. A. (*Belfast*) (see page 174):—"Denham Bros.' patent 'filler' is said to be a guaranteed cure for the 'sweating' of French polish. It is now in daily use all over the United Kingdom, and is acknowledged to be one of the best inventions ever introduced to the trade. It has long been admitted by all practical men that there is a great necessity of improvement in the old system of polishing, and a demand for a substitute for raw linseed oil, but yet a substitute which will answer the same purpose in bringing up the figure or grain of the wood, without any of the after-injurious effects of oil which, as is well known, is one of the greatest difficulties the trade has to contend with. This difficulty has been entirely and most successfully overcome by the invention under description, the claims of which no person in the trade—in these times when there is a great demand for good work—can afford to disregard or overlook. Firstly, it does away with oiling or 'fatting' over the work previous to polishing, and answers as a 'filler' at the same time, without any extra labour. It is a certain preventive for what is commonly known as 'sweating out of the oil' after an article has been finished two or three months. It is easily worked, and keeps down the grain as no other 'filler' does; saving both labour and material. It is transparent, and does not show white in the grain. It is made in seven different colours, to suit all kinds of wood—namely, white for ash, pitch pine, light oak, satin wood, maple, and all light woods; black for ebonised woods; dark oak for brown or pollard oak; walnut, mahogany, dark mahogany, and rosewood; also birch mahogany, specially prepared, stained ready for all hard woods, such as birch, beech, elm, etc., which are usually stained to imitate mahogany. There is nothing in its composition which will eat or burn away the polish; or which is in any way injurious to health when working it. The 'filler' is specially suitable for bobbin manufacturers, in place of sizing, thus preventing cracking of the varnish, and also keeping down the grain, without any extra labour. It may be had from all wholesale chemists and druggists, oil merchants, French polish and varnish makers, or from the sole patentees and makers, Denham Brothers, Hall Street, Halifax, Yorks.

Joints in Indiarubber.—P. P. (*Withington*) writes in reply to W. P. (*Grangetown*), (see page 190):—"Bicycle tires are made in a mould complete, and are not jointed, as W. P. imagines. They can be mended when broken by putting a piece of hot wire covered with cement into a hole made in both ends, and bringing the rubber together, the joint forming a kind of dowel. Indiarubber is vulcanised with powerful machinery and steam."

Facsimile by Electro Process.—E. L. writes in reply to ELECTROTYPE (see page 190):—"Get some good beeswax, and melt it, then pour it into a shallow metallic dish. When sufficiently hard to prevent the wax sticking to anything brush it over lightly with plumbago, also the article to be reproduced; then press the letter or block into the wax, being sure that it is pressed level all over, then take away the block, and you have the mould. If the mould is satisfactory, put a bright polish on it by using black lead and a very soft brush, and it is then ready for the battery. The battery itself is made with about 4 parts acid to 1 of water, with a silver plate and zinc one facing each other. The tank in which the mould is suspended by a metallic connection is made up of 3 parts water to 1 of sulphuric acid, and a small proportion of sulph. copper. The mould should face a sheet of copper; and, if properly connected, in about twelve hours there will be a copper shell on the mould. To get the shell off, the best way is to pour boiling water on the mould, and the shell will come off by a little gentle easing. After the shell is off it should be tinned with solder by placing it on a hot plate, previously putting some spirits of salts on to make it run, allowing the solder to melt, and when it is melted it should be backed up with metal. Of course, if ELECTROTYPE wishes to do electrotyping for amusement and experiment, the above directions will do very well; but if, on the other hand, he wants it for business purposes, I should strongly advise him to take it to an electrotyper's, and have it done. The cost would be less than 1½d. an inch."

Glaze for Finishing French Polishing.—W. H. B. (*Peterborough*) writes in reply to W. H. B. (*Redditch*) (see page 174):—"I beg to forward receipt for glaze as asked for: Take 1 oz. of gum benzine, ½ gill methylated spirits, thoroughly bruise the gum, mix, and shake the bottle occasionally for three days; strain through fine calico. Also ox gall for brown oak, 4 oz. vandyke brown, 1 pint spirits of ammonia, 1 oz. bichromate potash. By experimenting on a plain piece of wood you will get what shade you require by one or more coats, then brush over with French polish (not varnish) thinly."

Cleaning Oil Paintings.—A. F. (*Falmouth*) writes in reply to L. S. (see page 190):—"Seeing that L. S. wishes to know how to clean an oil painting, I may say that I have done them very satisfactorily in the following way:—Take a raw potato, peel it, and cut it in two, then dip the end in water, and rub it well over the painting; afterwards sponge it with clean water, and then dry it with a cloth. If A. F. tries this method, the end he has in view will be secured.

Trade Notes and Memoranda.

IN a paper on the traffic in London, recently read by Mr. J. S. Jeans, before the Society of Arts, he says that the number of passengers annually carried by railway, omnibus, tramcar, and river steamers, was some 470,000,000, being nearly twelve times the present population of the United Kingdom. Another fact which he mentioned was that, within twelve years, the increase in the number of passengers carried on the six metropolitan railways that deal chiefly with local traffic has been about 72,000,000, or, including season ticket holders, probably about 100,000,000.

IMPORTANT PRIZE COMPETITION.

THE Editor of WORK has the pleasure to offer his readers Prizes to the value of

THREE GUINEAS,

to be distributed for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

FIRST PRIZE ... One Guinea and a Half.
SECOND PRIZE ... One Guinea.
THIRD PRIZE ... Half a Guinea.

Full particulars of the Scheme will be found in WORK No. 17, page 254.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

3 months, free by post	1s. 8d.
6 months, "	3s. 3d.
12 months, "	6s. 6d.

Postal Orders or Post Office Orders payable at the General Post Office, London, to CASSELL and COMPANY, Limited.

TERMS FOR THE INSERTION OF ADVERTISEMENTS IN EACH WEEKLY ISSUE.

	£ s. d.
One Page	12 0 0
Half Page	6 10 0
Quarter Page	3 12 6

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 23.] SATURDAY, AUGUST 24, 1889. [Price One Penny.

THREE USEFUL GARDEN CHAIRS.

BY G. LE BRUN.

A Hammock Chair—A Folding Reclining Chair—A Fixed Reclining Chair.

Although summer is almost over, yet out-door life is still so very pleasant it may be useful to give a brief description of three very simply made articles, that will well repay the trouble of making in the pleasure to be derived from their use in the garden or on the lawn during the fine days that are yet to come. Two (Figs. 1 and 2) are in general use in the eastern States of America, but I have never seen them in this country, although folding chairs of a similar nature are common enough. The material used should be good straight grained ash or oak, free from knots, as the toughness of these woods allows of good strength with a comparatively light scantling. The pieces of a given size can be had cut out at the wood-yard at a slight extra cost, but I think it is desirable, if the worker is not afraid of the hard work of the rip saw, to select a board of the requisite thickness and cut out the various pieces to the sizes required, as there is always so much more satisfaction from the reflection that the whole of the work is your own.

To begin with the hammock chair, as shown in Fig. 1, the pieces required for its construction are as follows:—

Two pieces for sides of back, 2 ft. 4 in.; two pieces for sides of seat, 1 ft. 2 in.; two pieces for arms, 11 in.; two connecting pieces under seat, 9 in.; two front legs, 1 ft. 5 in.; two upright pieces at front of arms, 1 ft.; two pieces for ends of foot-rest, 6 in.; one front piece for foot-rest, 1 ft. 6 in.

All the foregoing pieces are $1\frac{1}{2}$ in. wide and $\frac{7}{8}$ in. thick, and besides them there will also be required three rails, 1 ft. 4 in. in

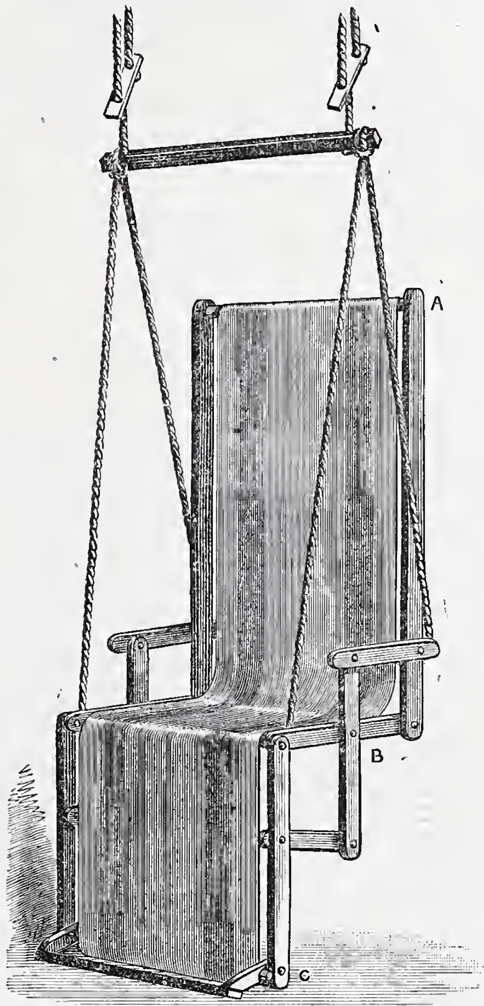

Fig. 1.—Hammock Chair.

length. These rails may be either turned in a lathe or rounded with a plane, whichever way is the most convenient, and should be 1 in. in diameter; they are shouldered at the ends and a square tenon cut on them, in which put two saw cuts for wedging up. These rails are not, when finished, all of the same length, the front one at the edge of the seat being shouldered $1\frac{3}{4}$ in. shorter than the other two, the reason for which will at once be apparent by examining the illustration. The two longer rails are mortised into the side pieces at A and B. A fourth rail is necessary; it is placed at the foot of the legs, going through the pieces that support the foot-rest, and preventing their falling down from the horizontal position by its projecting ends bearing against the foot of the legs, C. This piece is $\frac{7}{8}$ in. in diameter.

The wood for the chair framing (with the exception of the rails described) is planed up all round, and the ends of each piece rounded to a half circle; $\frac{3}{8}$ in. holes are then bored to receive the rivets that hold the chair together, the position of which holes can be ascertained by a reference to the drawing. The rivets used are of copper and have a washer on each end. Insert them from the outside and rivet the ends over the washer on the inside of the framing with a small hammer; put in the rails with glue and wedge up tightly, then the chair is ready for covering. The cloth used for covering may be of any strong material—canvas will do, or a piece of stair carpet can be utilised, if handy.

A hanging bar, 2 ft. 3 in. long and $1\frac{1}{2}$ in. in diameter, is now made from which to suspend the chair, which is hung from it by sash cord, which should be of the best quality procurable, and is attached to the chair framing by boring holes at the positions shown, and, after passing the cord

Fig. 2.—Fixed Reclining Chair.

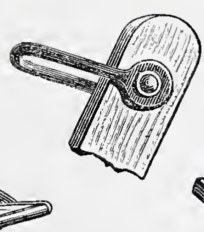

Fig. 4.—Enlarged Sketch of Loops in Fig. 3.

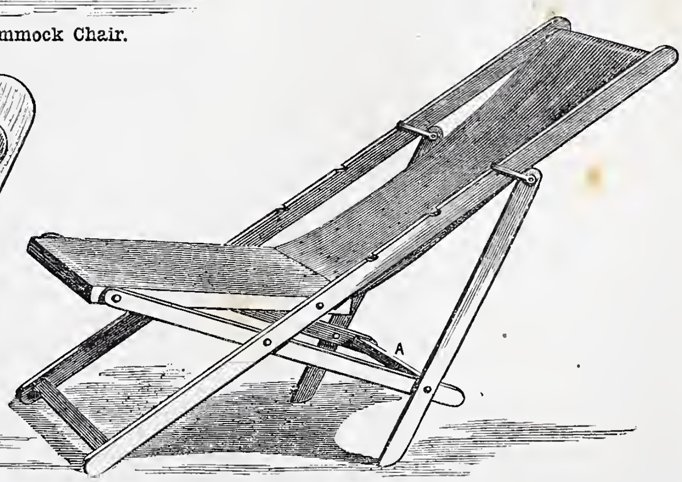

Fig. 3.—Folding Reclining Chair.

through, knotting the ends. The cross-bar may now be hung from the branch of a tree, or any other suitable support, by means of the arrangement shown, in which one end of a cord is attached to a wooden cleat, the other end passing through a hole in it, and then attached to the cross-bar. This method of hanging permits of an easy adjustment when put up on a branch or any support that may not be level. With the hanging of the chair is the end of the labour, and the maker can now enjoy his well earned rest in it while we go on to describe the other piece of garden furniture, which takes the form of a reclining chair, and the labour of making, which is not greater than that involved in the construction of the piece of work just finished.

For this chair then we require :—Two pieces for sides, 4 ft. 2 in. ; two pieces for sides, 3 ft. ; two pieces for seat sides, * 1 ft. 6 in. by 1 in. by 1 in. ; two back legs, 2 ft. ; two seat rails, * 1 ft. 4 in. by 1 in. by 1 in. ; three turned rails, 1 ft. 4 in.

The scantling of these pieces (with the exception of those marked thus *, which are $1\frac{1}{2}$ in. square) is the same as in the previous job, viz., $1\frac{1}{2}$ in. by $\frac{7}{8}$ in. ; they are planed up and rounded at the ends, except the bottom ends of the back legs, the position of the rivet holes being got from the drawing, Fig. 3. The seat is framed together by means of mortising and tenoning, and the turned rails put in in the same manner as those of the hammock chair, the lower rail at the back, A, being $1\frac{3}{4}$ in. shorter than the other two between the tenons. A visit to a blacksmith must be made for the purpose of getting the two loops that connect the top ends of the back legs to the sides of the chair, and allow of the legs being moved backwards or forwards to raise or lower the chair as required. These hoops are made of $\frac{1}{4}$ in. round iron, and are secured to the legs by $\frac{3}{8}$ in. rivets, that pass through holes in the ends. A series of three or four cuts is made on each of the sides of the chair to slip these loops into, which cuts should be about $\frac{1}{2}$ in. deep, and of sufficient width to allow of the loops being easily slipped in and out. An idea of the shape of the loops is given at Fig. 4, the length from the centre of the rivet hole to the inside of the closed end being $2\frac{1}{2}$ in. The chair is covered, in the same manner as the previously described one, with whatever strong material may be handiest, and the work is finished.

The various pieces of these chairs should be polished before being riveted together, as the operation is much easier than that when the parts are in position, and much vexation and trouble will be saved by doing so.

In addition to being useful in a garden, both of the chairs described are of much service on shipboard ; the reclining chair can there be used as a deck chair, and the hammock chair can be slung up, in fair weather, to any suitable part of the ship's rigging ; in fact, an amateur carpenter of my own acquaintance made two of these very articles recently for a lady friend of his who was going to New Zealand in a sailing ship from London, and has just received a letter in which the writer expresses much gratitude for the comfort afforded during the voyage by the use of his very suitable presents.

Both chairs can be set to any required angle, and one can either sit upright, recline, or lie, with much ease and comfort.

There is another and very simple form of chair, of which a drawing is given at Fig. 2. Ash, elm, or any tough light wood will do to make it. The framing, with the exception of the rails, is cut out of $\frac{7}{8}$ in. board, and planed up all round. The following are the lengths of the various pieces required, which are $1\frac{1}{2}$ in. wide :—Two back legs, 4 ft. 9 in. ; two front legs, 2 ft. ; two sides for seat, 1 ft. 6 in. ; and two arms cut to a segment of a circle. Three rails are also required; they can be either turned, or rounded with a plane. The framing is halved and screwed together, and the rails mortised through the sides. The covering of the seat and back may be of canvas, but a piece of light-coloured carpeting is more pleasing to the eye. This chair is a fixture, and cannot fold up. This renders it not quite so portable as the other two described ; but it has the advantage of being easily made, and requires no great skill to put it together, while its appearance, when nicely polished or varnished, is quite as pleasing as either of the others, and it excels them in the matter of rigidity.

SOLDERING IN REPAIRS OF SHEET METAL UTENSILS.

BY R. ALEXANDER.

TEA POT—TIN TEA KETTLE—IRON TEA KETTLE—COPPER TEA KETTLE—SOLDERING SOFT METAL—SOLDERING ZINC—GALVANISED IRON.

I WILL commence this article with a few simple examples of soldering in the way of repairs, none of which will present any great difficulty, and which will require very few tools beyond those already mentioned (p. 257). Let us suppose, for example, that we have the following articles brought us to repair—tin tea pot, tin tea kettle, coffee pot, saucepan, iron tea kettle, copper tea kettle. The first thing is to examine them, and find out what is the matter with them ; on holding the tea pot up to the light and looking in the top a small pin hole is seen in the bottom ; we put it down that that is the faulty place, make a ring round it with a bradawl and put it on one side. Taking up the tin kettle, and treating that in the same way, we are unable to discover any holes in it, and, on farther examination, no sign of a leak is discoverable. So it must be tried with water ; we then find that the water oozes out at the side of the spout ; mark it with the bradawl, and try coffee pot. On treating this in the same manner, nothing seems wrong with it, but as the knob is missing we will put it down that a knob is what it requires ; the saucepan we find to have the same fault as the tea pot, viz., a hole in the bottom ; the iron kettle we find to leak all round the spout, and the copper kettle has a crack about $1\frac{1}{2}$ in. long at the angle where the bottom and sides meet.

Tea Pot.—Now to remedy these defects. Take the tea pot and, with a scraping knife, scrape a clean place round the pin hole about the size of a sixpence. While mentioning the scraping knife, I may as well say that an old razor driven into a file handle makes about the best scraper you can have, though for some things a more pointed one is required, but for all ordinary work the razor will be found sufficient. Have all your soldering tackle handy, iron, solder, spirits, spirit brush, and piece of solder ; heat the iron, hold the tea pot in the left hand, dip the spirit brush in the spirits, rap it against the sides of the jar to remove superfluous liquid, and apply a little to the place you are going to solder. Then take the iron, dip it in the spirits to clean it, apply it to the piece of solder, and try to pick a little up with it ; you will probably find this a little difficult at first, the solder seeming to take a delight in running all over the bench instead of clinging to the iron. The way to do it is this :—Hold the iron in a nearly horizontal position, and, in applying it to the solder, do not dig the point of the iron into it, but lay the side of the iron on it lightly near the point and draw the iron toward you ; then, keeping the iron as near horizontal as possible, bring the point of it with the solder it has picked up to the hole in the bottom of the tea pot. As it touches the leaky place lift the handle of the soldering iron, and the solder will flow off at the point ; move the iron just round the hole and the solder will run all over it. Take the iron away, and allow the metal to cool (blowing on it will accelerate the cooling), and the tea pot is done. Try with water to make sure that it is sound.

Tin Tea Kettle.—The next job is the tin tea kettle. A few words will suffice for this. Dry it thoroughly, scrape it well a little farther each way than the leak extends, hold it in the most suitable position for soldering, which will be on its side, spirit it and solder as just described, laying the angle of the iron in the angle formed by the spout and body. The coffee pot knob is also a very easy job. Simply place the new knob in the hole (after scraping, of course), and with the iron melt a little solder and the end of the knob together, letting the knob rest on the bench whilst soldering, and taking care not to keep the iron on it too long or it will melt the knob away and spoil it ; a little stud is usually punched out and soldered over the place where the knob is fixed to give it a neat appearance.

Iron Tea Kettle.—The iron tea kettle next demands attention. Most wrought iron kettles are tinned outside as well as inside before being japanned. If on scraping the black off this proves to be the case, and it has not been in use very long, the scraping knife will be all that is required to clean it for soldering, but if old and rusty round the spout, say, through having been put by when the leak was discovered, instead of being sent to be repaired at once, then the file will be required ; a 10 in. half-round is about the most useful for these jobbing operations. Carefully clean all round the spout till you are sure there are no dirty places or rust spots. When sufficiently clean, apply the spirits as before mentioned; heat the iron to a good heat, apply the solder by holding a strip of it in one hand and melting a little on with the iron held in the other ; holding the kettle with your body against the bench, draw the iron round the spout and the solder will follow. Let the iron rest on the work, as it must be got hot before the solder will unite to it properly ; a strong job cannot be made unless the parts to be united are as hot as the metal that is to unite them. For example, supposing the kettle we are just supposed to have done had been coated with fur to the depth of half an inch all over the inside, you would have found that you could not have got it hot enough for the solder to flow freely, on account of the wet fur robbing the heat from the iron as fast as it was communicated to it, and although you might have managed to stick a little solder round the spout, it would not have been a good sound job, but if the fur was cleaned out the difference would at once be felt. This remark about fur applies, of course, to patches on bottoms or sides.

The next job on hand is the saucepan. This having only a small hole in the bottom, may be treated the same as the tea pot, especially if a small one and of little value, but a better and a more workmanlike way will be to put a piece on it; people would also rather pay a little more for a patch than if only a "dab" of solder were put on, though a patch soldered on is very little, if any, better than mending it with solder, as far as utility goes, for this reason, that if by any chance the saucepan should be left on the fire without any water, the patch would melt off as easily as the solder. But as a patch looks better and the customer will be better pleased, let us put a patch on by all means. Cut a piece of tin about an inch square, snip off the corners, lay it on the bottom of the saucepan just over the hole, mark round it with the bradawl, scrape clean all the inside of the square thus marked, and $\frac{1}{4}$ of an inch all round the outside of it; or in other words, if the patch is 1 in. square scrape a clean place $1\frac{1}{2}$ in. square. If the saucepan is in good condition and scrapes nice and clean, it will be ready to solder; but in case the bottom is eaten by fire and rust it is difficult to get clean, and after scraping and cleaning it as well as you can, you must "tin" it to make sure of the solder flowing under the patch. To do this, simply rub the soldering iron over it with a little solder, applying spirits to make it tin easily. When this is done, lay the patch on and solder it, drawing the iron first round the edges and then all over it, holding the patch down with something to prevent its shifting, the solder flows underneath, and the patch is what we call "sweated" on. The description of putting on a patch applies equally to other article such as tea kettles, coffee pots, fish kettles, etc. With the exception that a large patch need not be sweated all over, but simply soldered all round the edge of the piece, letting the iron rest mainly on the piece that is put on rather than on the article, this is to draw the metal underneath.

Copper Kettle.—The next and last example of the batch we are at present considering is the copper kettle. This, as we have seen, is supposed to be cracked along the edge of the bottom about $1\frac{1}{4}$ inch. This must be repaired by putting a patch on the bottom and turning it up on the side. Scrape clean a place on the bottom 1 in. wide, and extending a little each side of the crack, scrape up the side $\frac{1}{2}$ an inch in the same manner, tin the places as described previously in speaking of the saucepan; now take a piece of thin copper $1\frac{1}{2}$ in. by 1 in., clean it both sides and tin one side with the soldering iron, it will then be ready to put on. I always fix such a job as this in the vice by the handle, as that leaves the hands at liberty, and place the piece of copper, tinned side down, on the bottom of the kettle, leaving about $\frac{3}{8}$ of an inch overlapping to turn up on the side. Solder the piece on to the bottom, cut the overlapping piece to the same sweep as the sides, and with a light hammer rap it close up to the side, and then solder round that part; clean off any superfluous metal that may have run on to the patch with a file or scraper, and if thought necessary, colour the solder with a little solution of sulphate of copper, more commonly known as blue vitriol or bluestone. Crush a small crystal of the sulphate, dip a small brush (not the spirit brush) in water, and with it touch the powdered sulphate and then draw the brush over the solder; this will give it a copper colour, but, of course, not lasting. The half-dozen jobs that I have described will serve as a model for all of a similar class. In fact, if I were to describe fifty such jobs, they would all amount to the same thing, that to make a good job you must get the place to be repaired or the surfaces to be united perfectly clean and bright, or you cannot solder them properly. If this is carried out and the iron is properly tinned and cleaned, and the solder all right, everything else is sure to be, always supposing the worker to possess the proverbial "grain of common sense."

Soldering Soft Metal.—I will now say a few words on soldering soft metal. This will require a little more skill and practice to master, and I should advise learners to get an old metal tea pot or two and practise on, before attempting to perform on the family plate. One or two things need be observed to ensure success. The metal must be scraped bright, because a tea pot or coffee pot looking clean is no criterion that it is clean enough to solder properly, next a light soldering iron should be used, as you dare not rest the iron on the work as you would in soldering tinware, or the result would be disastrous. So the weight of the iron being all on the wrist, I say use a light one or you will not be able to hold it steady.

Thirdly, the iron must be just the right degree of heat. If it is too hot, the chances are that a hole in the metal will be the result of its application, and if not hot enough the work looks botchy. Try to hit the happy medium, the old tea pots will be good practice. Let us suppose one leaks all round the spout. If it has been in use just lately, the first thing to do is to dry it out thoroughly, or on applying the iron the solder will splutter about and bubble up instead of flowing nicely. Having dried it well, the next thing will be to scrape it, the large blade of a penknife is a very good thing for this, then take some very fine running solder, and have ready some resin and oil for a flux; apply it round the spout with a little brush, heat the iron, apply a little solder to the tea-pot spout, and gently draw it round with the iron, scarcely letting it touch the metal of the tea pot. The heat of the solder will melt the metal as you draw it round; if the iron is fairly hot, do try not to make the solder run round too far, but keep picking more up and reheat the iron when you find it hang. Supposing that you have got safely round the spout, the next thing is to clean off the job so that it can hardly be seen where it has been repaired. A small half-round file about 6-in. long will be the best thing to use. Work round the job lightly, taking care not to file the sides and spout of the tea pot more than you can help, and when you have got it fairly level and smooth go round it with emery cloth or a scraper; the scraper must be round-ended, if pointed like a penknife blade it would make more marks than it took out. After this use a steel or agate burnisher and a capital job is the result. The first try may not be a success; but I have found out by experience that our failures teach us as much as our successes.

A very ticklish kind of work is the repairing of the rims and covers of china tea pots, and hot water jugs. These covers and rims are extremely thin, and made of a very soft and fusible metal, and therefore they require very great care.

The parts to be soldered must be carefully scraped, no streaks of uncleaned metal should be seen, very little flux should be used, and a very steady hand is required. If these directions are attended to, there is little fear of failure or spoiling the work. I have never yet spoilt, or even had an accident with any work of this kind, even in my 'prentice days, and there is no need for my readers to do so if they take pains with their work and use care; but if you attempt to do such work as the last two things I have mentioned, as I have seen some do, with a dirty iron, tin nearly all burnt off, the work half cleaned, and using common solder, it will not be strange if failure is the result.

Soldering Zinc.—This is a difficult metal to solder smoothly and well, even when new and clean; and when old, such as guttering that has been fixed a long time, or old kitchen utensils, it is much worse. In soldering this metal, the strong or raw spirit of salt must be used, and the worker must try and keep the spirit to the part to be soldered, and not let it run all over the work; and after the seam joint, or whatever it may be, is soldered, the spirits should be wiped off as soon as the work is cold, as the spirits have a very corrosive action. Soldering zinc is not a very pleasant job for the olfactory organs, as the smell caused by applying the acid to the zinc is, according to most people's idea, "something awful;" however, use is second nature, and I don't mind it much myself. You will also find that the solder does not flow very well on zinc; this is because a certain amount of it mingles with the solder and deteriorates it, and you will find that it will cling to and get hard on the iron like a lot of dross. The iron will require to be cleaned at intervals if much zinc is being soldered; a light touch up with a file all round, and a rub on the sal-ammoniac with a little solder puts it all right again. Old zinc will require to be got fairly clean with a scraper or file before attempting to solder — use spirits freely.

Zinc is not a soft metal like pewter, but it will melt under the iron if thin and the iron is very hot, so use care in this respect; practice will soon show the right degree of heat to work with. Smooth the soldering where rough with file and scraper. The ordinary plumber's shave hook is a good tool for cleaning off zinc after soldering, especially on long seams such as would occur in joining two sheets together.

Galvanised Iron.—The treatment of this is very similar to that of zinc, strong spirits being used as the flux. I would also advise that anything in zinc or galvanised iron that is to contain any liquid, should be very carefully tried before passing it as done, as though you may fancy that it is all well and truly soldered, yet both zinc and galvanised iron are such treacherous things to solder that it is almost impossible to say with certainty whether it is sound or not, and nothing is more discreditable to a workman than to have his work returned leaky, solely for the sake of a little extra trouble, to say nothing of the inconvenience that might be caused.

The directions given above for the repairs of ordinary metal utensils in common use, will be found sufficient for the renovation of all articles of this description. Although the articles themselves may differ in form, the mode of going to work to mend them is the same in every case. So that although but few articles have been mentioned, the instructions given apply similarly to all that are made of the plain and tinned iron, copper, and soft metal. If any workman can make a good job in one case, he may depend on being able to arrive at the same result in all others of a similar character.

MAKING BOLTS AND SCREWS FOR MODELS.

BY OLLA PODRIDA.

ALTHOUGH such small work may be purchased cheaply, it is nevertheless not always convenient to do so for several reasons which should be obvious. First, there is the delay, which—when the model maker is, as such people generally are, in a fever of impatience—is a very important matter. Then there is the difficulty of obtaining just the right length and size for particular cases, and this may involve alterations, and, consequently, more lost time and patience. All this goes far towards balancing the bother of making such small goods oneself. I know from experience that model bolt-making isn't a very congenial occupation; in fact, it may be considered a necessary evil, but then there is the satisfaction that you are making exactly what you require.

Some years ago, while suffering from a severe attack of model mania, and having a large number of very small screws to make, it occurred to me that some simple means might be devised whereby the labour of turning such small articles might be greatly reduced. An idea suggested itself, and was immediately put into practice with very satisfactory results. The device then employed is now reproduced and illustrated herein. It has at least one merit, that of simplicity both in manufacture and use, and I trust it may be of service to those interested in WORK.

Tool for Making Bolts and Screws for Models.

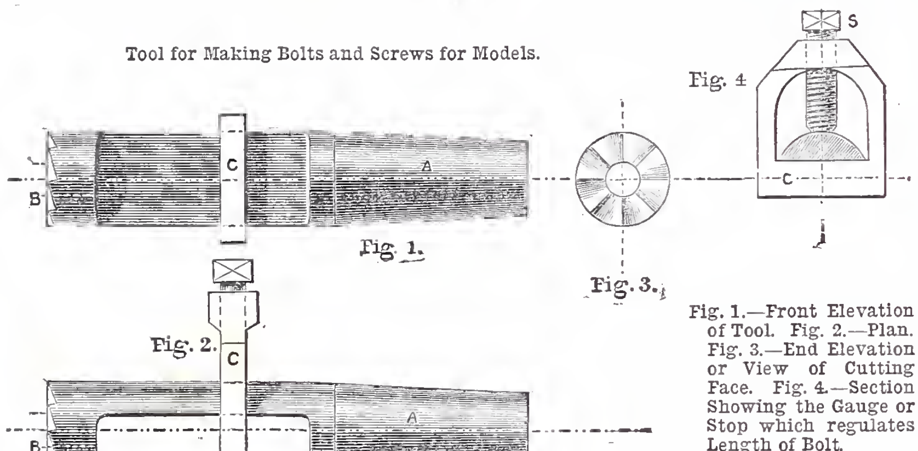

Fig. 1.—Front Elevation of Tool. Fig. 2.—Plan. Fig. 3.—End Elevation or View of Cutting Face. Fig. 4.—Section Showing the Gauge or Stop which regulates Length of Bolt.

Fig. 1 shows a front elevation of the tool; Fig. 2 is a plan; Fig. 3 is an end elevation, or view of the cutting faces; and Fig. 4 is a section shewing the gauge or stop which regulates the length of bolt. The tool is made entirely of steel, and for this purpose a worn-out round file may be economically used up. A separate one is required for each size bolt to be made, but, if desired, this may be avoided by making the body of iron and boring the end out larger, so as to accommodate a series of steel cutters with different size holes as required, these cutters being held by a small set-screw so that they may be changed when desired.

In making a tool of the form given herein, the first thing is to get a piece of steel of suitable size, and soften it for turning. The softening may readily be done in the kitchen fire, by heating it to a blood-red heat, and burying it in fine ashes or quicklime until it cools. It is then centred truly and turned to the required size, the tapered part at A being made to fit the poppet cylinder. The centres should be left in for—at least, in the case of the cutting end—convenience in boring the hole to size of bolt. In the illustration this is given for bolts $\frac{3}{16}$ in. in diameter, and the outside size of tool is $\frac{1}{2}$-in. The hole is best drilled by means of a running drill held in a chuck, the tool being fixed in and advanced by the poppet cylinder. The hole need not be made deeper than just to clear the solid end, say $\frac{3}{8}$ in. deep. A nice smooth hole is required, so as not to injure the body of the bolt. The next thing to be done is the filing away for the flat part to clear the hole, as shewn in Fig. 2 and in section at Fig. 4. This having been done, the cutting faces may next be formed. There are eight of these equally divided. They are formed by filing, and must be finished smoothly. Their formation will be facilitated by making them deeper on the outside, or by slanting the file so that it shall clear the opposite edges at first, and afterwards finishing by short strokes with the point of file. Care must be taken to bring the sharp cutting edges quite true and square to the axis; this, if the end has been nicely faced in the first place, will be comparatively easy.

The tool must now be tempered as follows:—First heat the cutting end to an even blood or cherry red heat, and plunge quickly into lukewarm water. Next brighten the outside of the cutting end by means of a piece of sandstone or brick. Then heat red hot a piece of iron—one of the domestic box iron heaters will suit admirably—and lay the tool upon it, turning it meanwhile to equalise the heat, until it assumes a dark straw colour tinged with blue, when it must be immediately cooled in lukewarm water as before. The tool is now, with the exception of the stop, ready for use. The stop may be made out of a small piece of flat iron, and the hole in centre should only just be large enough to clear over the cutting end. It can by means of the set-screw, S, be fixed in any required position, according to the length of bolt, but, although convenient, it may be dispensed with.

The method of using the tool is as follows:—Wire of suitable size having been obtained, it is held in a chuck so that sufficient projects to enable one bolt to be made and parted off. The wire must be large enough to form the head, and the chuck may be an ordinary "pod" or drill chuck. It should be capable of accommodating sufficient wire for making a number at a time. The tool is, as has already been observed, held in the poppet cylinder, and the poppet head fixed in a convenient position for advance and withdrawal of the tool. The gauge stop having been set, the wire must be pointed and rounded slightly to enable the tool to start fair and give a finish to the point of bolt. The tool is then advanced steadily by hand, and kept well lubricated with soap and water, or oil. When the stop is reached the tool is withdrawn, the head turned up, and the bolt parted off with hand tools and tee-rest. If a hexagonal or square head is desired, the sides can be filed up, and the angles or corners chamfered before parting off. The process of screwing or threading the bolt should follow the turning, and before forming the head, so that in case of stripping of the head a minimum of trouble may be met. The lathe should be run at a smart speed during the operations except for screwing, which must be done by hand, the die or screw plate being held in one hand and the work gently pulled round by the cord with the other.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

VI.—THE SIGN WRITER'S OUTFIT—ITS CARE AND TREATMENT—MATERIALS AND COLOURS.

"A BAD workman always complains of his tools;" so runs the old proverb, but it is nevertheless true, that to do good work we require the best of tools to do it with, and, also, that the result of using bad tools is indifferent and unsatisfactory work. I am, therefore, now going to describe the best and most durable tools required by the sign writer, and also give a few hints and directions as to their proper use and care when lying idle. This latter point must never be neglected, but always attended to immediately the tools are done with, otherwise the pencils will soon become worthless; at least for doing good work, besides causing an unnecessary outlay for new ones. Badly kept tools are also a sure sign of the owner being a slovenly and lazy workman; so I would strongly urge the apprentice or young workman, at the very commencement of his tuition, to take a pride in keeping in workmanlike condition and business order what will through life, perhaps, prove his best friend, his bread winner and his trade mark, viz., his "kit of tools."

I would not advise, under any circumstances, the purchase of cheap and badly made tools; those of the best quality only are always the cheapest in the end, both as regards wear and tear and the turning out of good work. This remark applies specially to camel-hair and sable pencils, and the colours and vehicles used in sign writing.

If the reader will, however, only follow the advice contained in this chapter, on procuring a complete outfit for sign writing, he will, I feel sure, never have to complain of his tools, even though, through his own negligence, he may become but a bad or indifferent workman. The brushes and pencils first demand our attention, so I will dismiss them with a few but weighty words.

The hair pencils used by sign writers are made in various sizes, and the student will do well to obtain a complete set as soon as he can afford it. He had better, however, commence with a few good pencils in preference to a host of common rubbish. I need hardly say that the student must choose his brush or pencil according to the size or nature of the work he has in hand; the small pencils being used for fine and delicate work, and, the larger sizes for large lettering. The

pencils are made in the following sizes, viz.:—

Lark or Miniature.	Goose.	Small Swan.
Crow.	Full Goose.	Middle Swan.
Duck.	Ext. full Goose..	Large Swan.

The most useful sizes will be found illustrated in Fig. 39.

Camel-hair writers are, of course, the cheapest, and for some work they may be used without inconvenience; but when heavy colours are used they are useless, as the colour by its weight causes them to droop or "sagg," so that it is next to impossible to get a sharp, clear outline. Sable pencils are, therefore, the best (although more expensive), the hair being stiffer than camel-hair, whilst at the same time it is just as pliable and considerably more durable. To last even a short time, however, they must always be kept to perfection, and at once cleaned on the completion of a job. This is best done by first rinsing the pencils in some turpentine, then washing with some soap and warm water, and finally dipping the points into some sweet oil, and putting away in a tin case (Figs. 40 and 41). Most workmen merely grease them, for which purpose they have a little compartment in the tin box for holding a small supply of grease, and some keep them always in a little sweet oil at home. It is always best though to thoroughly clean them, as experience will teach. A very good receptacle for the pencils is a long tin box which has contained wax vestas. The sixpenny size is the most useful, and as these can be picked up almost anywhere, the young workman may soon possess as many as he requires. The wooden handles should be removed before putting the pencils away. The writer will eventually require some "riggers," or short hair pencils (Fig. 42), some "liners" (Fig. 43), and some full, short hair or "filling in" brushes (Figs. 44 and 44a), the use of which will be described in a future chapter. The badger-hair softener (Fig. 45) is used for blending two or more colours on any large surface, and the sable blender (Fig. 46) is used for the same purpose in shading letters and blending their colours.

We next come to the wooden palettes, which are held in the left hand, and are used for mixing and working the colours upon. They are made in various shapes and sizes, as shown in Fig. 47. The last (A) is a folding palette for the pocket, etc.

A few tin dippers are very useful appendages to the palette (Fig. 48). They are made with a flange for sliding on to the edge of the palette. Dippers are used for holding small quantities of tube colours, oils and turps, so as to have them close at hand.

A small paint strainer should be possessed by every sign writer, and the most useful one that I know of is illustrated at Fig. 49. It is named Thomasson's Improved Registered Paint Strainer, and is made by Crowden and Garrod, Southwark, S.E. This strainer is designed to meet the wants of the sign writing trade; the triangle stroddle will rest over any sized paint pots, and there is a water dish for keeping the strainer in water when out of use. It is made of stout zinc, with brass wire gauze, and, having used one for some time, I can say that they are durable, easily kept clean, and cheap. The price for the medium size is about 2s. 6d.

One or two palette knives (Fig. 50) will be needed, and their price ranges from a shilling upwards. The dividers (Fig. 51) are used for many purposes, such as measuring out spaces and describing arcs, circles, ovals, and scrolls.

One of the most useful and handy appliances ever brought out for the sign writer is the "jointed" mahl stick, as made by Brodie and Middleton, of Long Acre. It has three or four divisions, and takes to pieces after the manner of a fishing-rod, so that any number can be used, and the stick brought to any desired length according to the nature of the work (see Fig. 52). When taken to pieces it will go in the baskets, box, or pockets. The same firm also make two specialties for the sign writer, one is a candlestick, and the other a complete outfit in a tin box. The candlestick (Fig. 53) is furnished with a shifting reflector, so that the light can be thrown on any particular spot. It is also fitted with a flange for attaching to the palette. This article is very useful when working after sunset awhile in order to complete a job, or for evening practice on the black board.

The guinea sign writer's box (Fig. 54) is made of japanned tin, and it is really a most useful servant to every sign writer. It is fitted in a very complete manner, and contains every requisite that can possibly be required. There are a series of compartments, with tightly fitting lids, to contain the colours, so that there is no danger of their getting accidentally mixed and spoiled, as is often the case when they are carried loosely in a basket. There are also bottles, with screw lids, to contain oils, turpentine, varnishes, and other diluents; spaces for gold leaf, brushes and pencils, and a palette. The spaces for the whole of these articles is so nicely adjusted that there is a maximum of convenience with a minimum of bulk. I need hardly say, how very superior such a "multum in parvo" must be to the cumbrous baskets which writers and grainers ordinarily carry, to say nothing of the superior cleanliness of the japanned box over the old method.

The young workman will also require some sticks of pipe-clay, a chamois leather, a good sponge, cotton wool, and a chalk line and reel, all of which may be obtained from Brodie and Middleton, besides the pencils and the colours; a list of which I now append.

TUBE OIL COLOURS USED BY SIGN WRITERS.

Verona Brown.	Cologne Earth.
Yellow Ochre.	Yellow Lake.
Caledonian Brown.	Purple Lake.
Roman or Golden Ochre.	Indian Lake.
Brown Ochre.	Lake.
Raw Sienna.	Ivory Black.
Burnt Sienna.	Lamp Black.
Prussian Blue.	Blue Black.
Antwerp Blue.	Terravert.
Indigo Blue.	Verdigris.
New Blue.	Flake White.
Pale Ultramarine Blue.	Cassell Earth.
Deep Ultramarine Blue.	Blue Verditer.
Permanent Blue.	Zinc White.
Magenta.	Crimson Lake.
Mauve.	Scarlet Lake.
Olive Green.	Vermilion.
Sap Green.	Mineral Grey.
Emerald Green.	Royal Yellow.
Green Lakes 1, 2, 3, and 4.	Blue Cerulean.
Malachite Green.	French Ultramarine.
Indian Red.	Gamboge.
Light Red.	Oxide of Chromium.
Venetian Red.	Mars Yellow.
Red Lead.	Strontian Yellow.
Bone Brown.	Indian Yellow.
Cappah Brown.	Lemon Yellow.
Vandyke Brown.	Cobalt Blue.
Pale Naples Yellow.	Scarlet Vermilion.
Deep Naples Yellow.	Madder Brown.
Extra deep Naples Yellow.	Mars Orange.
Patent Yellow.	Sepia.
Chromes Nos. 1, 2, 3, and 4.	Pink Madder.
Raw Umber.	Madder Lake.
Burnt Umber.	Rose Madder.

	Mygulph (Copal).
	Sarum or Dryers.

PLOUGHED AND TONGUED JOINTS.

A THIRD FORM OF JOINTING UP.

BY DAVID ADAMSON.

HAVING given a description of the two most usual and useful forms of jointing up boards, as promised in the preceding chapter of this short series, the ploughed and tongued joint may now be briefly considered. It is probably the strongest of the three, but as the dowelled joint is sufficient for ordinary purposes, and is more easily made, tongueing is comparatively seldom resorted to in cabinet work. The reader will please note that only jointing up in order to get required width is referred to. Still, there are occasions when it may be more appropriate than either of the others, as, for example, with pitch pine boards, and if only for the sake of letting the novice know of its existence it must be mentioned. As may almost be inferred from its name, a groove is cut or ploughed along the edge of one or both of the planks to be joined, and the space so made is filled by a thin strip of wood. If both planks have been ploughed this strip is separately made, and half its width inserted in each. When, however, only one has been prepared this way, the other is planed down to leave a projecting ridge, which fits in the ploughed groove. It is almost needless to say that the former is the stronger of the two, and that it is the one almost invariably used in the finest work, *i.e.*, of course, when tongueing is preferred to dowelling. For amateurs, especially, it will be preferable, as only one plane, beyond the ordinary smoothing planes, is required; while in the other form a pair, one for cutting the grooves and the other for the tongue, will be necessary. Let us take the best form first, and see how it may be made properly and efficiently. The edges must be shot perfectly true as for a plain joint, for this is a *sine quâ non* in joints of all kinds. The plane, *i.e.*, the "plough" plane, must then be set so that the iron cuts the groove about the middle of the edge of the plank. I presume it is not necessary to describe here how the plane is to be set, as those who possess a plough will have no difficulty in understanding how to regulate the fence, which, by being pressed or kept in contact with the surface of the wood, causes the iron to cut in the same straight line. It will thus be seen that in working a plough two pressures, as they may be described, are required, one of them downwards and the other sideways during the whole of the forward thrust. One caution may save the novice the annoyance of being taught by experience, to wit, that if the iron is not set to cut exactly in the centre of the wood, the groove must be run equally on both pieces, the distance from the face being taken, with due regard to the grooves corresponding when the edges are brought together. A little thought will show the necessity for this caution, which, having been given, may seem a slight on the novice's common sense; otherwise, were he to make a mistake, for his consolation it may be stated that it would not be the first of the kind. The work with the plough having been completed, the boards are ready for tongueing. That this part of the work may be done in two ways—one of them being wrong, or, if that is too strong an assertion, without much stability in the joint, and the other correct, both theoretically and practically—may seem a superfluous observation. It would be were it not that the weaker method is sometimes practised by those who ought to know better, and the novice especially is warned against it. As has been stated, the tongueing is a strip of wood glued in both the ploughed grooves. Now, if this strip is cut so that the grain is coincident with that of the boards to be connected by it, it is evident that the strength cannot be so great as if the grain were at right angles with that of the board. In other words, the grain of the tongueing must be end on to the bottom of the grooves. This is the key to the proper way of making the tongued and grooved joint, about which, that there may be no possibility of a mistake, Fig. 1 is given, clearly showing the direction of the grain in the tongueing and in the boards to be joined. Possibly the novice may be told by some practical workers that the way the tongueing is done is not of much consequence, and that the insistence on one being better than the other is all moonshine. If so, hear his reasons, for a practical worker's reasons, when he has any and does not work only by routine, are always worth listening to by beginners, even though one may not at once see their force. If the argument in favour of this method of working seems sound, by all means try it, and don't dispose of it simply because some one else has told you that the work must be done in such and such a manner. I merely tell you what I consider the best method, and if there is a better way of getting at the desired result do not hesitate to adopt it. "Prove all things; hold fast to what is good," and always be on the look-out for better methods of work. Finality has hardly been reached yet in joinery, and, so long as new and improved tools and appliances are brought out, never will be. But, perhaps, it may seem much easier to plane up a length of tongueing with the grain than across it. It is; in fact, it would be absurd to expect to plane up a long cross-grain piece. Don't see it? Well, supposing a 6-ft., or even 3-ft., length of tongueing is wanted, where, in the first place, will a board sufficiently wide to get this off it be got in a general way? Boards of this width are not often met with. If they were, any hints on jointing up would scarcely be necessary, for the simple reason that none of this kind of work would be required in cabinet making. Of course, a moment's reflection will show that there is no occasion whatever for the tongueing being all in one piece, so that all that it is necessary to do is to cut pieces of the required width and thickness from the end of any boards. This piece of wood from which the tongueing is got will be prepared by planing before the pieces are cut off, so that the necessity for the awkward job of getting them to the right thickness is afterwards done away with. When prepared, the tongueings are to be fixed in with glue and the boards cramped together; but after what has been said about this part of the operation in connection with dowelling, no further directions can be needed.

But, it may be asked, are these the only methods of jointing up which are employed in carpentering? If so, a wide field is opened up for joinery or carpenters' work, which includes many branches, each having special modes of working. The one with which we have been concerned in these articles relates to the cabinet making only. Were it not so, other forms of jointing might have been mentioned, but the three, viz., plain, dowelled, and tongued joints, which have been dealt with, are those principally in use in all kinds of joinery. Those, therefore, who want to joint up for almost any purpose will know what to do, and, in conclusion, it is hoped that these few hints may have given the novice an insight into operations which can hardly be described in detail, while directions for making up a particular piece of work are being given. In succeeding articles various other joints, including dovetailing, will be explained.

A WHOLE-PLATE CAMERA:
HOW TO MAKE IT.
BY AN OLD HAND.

PHOTOGRAPHY in the present day has become one, if not *the* most popular of our art sciences, affording, as it does, healthy exercise both for mind and body, and opportunity for cultivating those artistic and æsthetic tastes that are innate in most of us. Opportunity is also provided for those of a mechanical bias, for exercising their talents of constructiveness, to aid which will be the special purpose of the following articles. If the instructions given are carefully followed and intelligently worked out, the amateur will not only be able to take a photograph, but have the additional satisfaction of knowing his pictures are veritably his own work, *ab initio*. In the next few papers we propose to put before the reader diagrams of all the necessary apparatus for making a photographic print, with plain instructions for their construction. The article of the first importance is the camera, or camera box as our Transatlantic friends put it, which is in reality a small portable dark chamber, at one end of which is fixed the lens and at the other the sensitive plate. This simple dark box has from time to time been added to and improved, till, from the crude apparatus of its inventor—Baptista Porta—in the second half of the sixteenth century, it has become the elaborate and ingenious contrivance of the present day. It goes without saying that all wood used in the construction of the camera must be of the best quality, and thoroughly well seasoned; the manufacture of this instrument being very high class cabinet work, all the precautions and devices used in cabinet work come into play. In making the camera, wood of close fine grain is to be selected. Mahogany, both Spanish and Honduras, has long been the favourite. Spanish is much heavier and harder than Honduras, and, having a fine grain, is generally preferred for *studio* cameras; but for outdoor work, where weight is a great consideration, the Honduras kind answers every purpose on this account, and being easier to work, it is better for the amateur to use. Very serviceable instruments have been made of teak. Ottewill, an early maker of cameras, used it freely for large-sized apparatus, and I can bear witness they will stand an immense amount of hard work with impunity.

Many other materials have been pressed into service, inclusive of paper, ebonite, and metals, the primary object being to have a tough, rigid, and light material, impervious both to moisture and light.

The camera of which Fig. 1 is a drawing has been selected as comprising all the necessary qualities, with as simple a form as at present devised. It was first introduced by Mr. G. Hare in this special design, but numbers of makers, appreciating the advantages of the pattern, have adopted it, preserving the principle but modifying the form. It will be noticed that the back is made to swing from the bottom, a plan to which some take exception, preferring the centre as the fulcrum; but for all practical purposes it answers very well, and is very convenient in use. A corresponding strut on the opposite side of the camera to that shown keeps the whole firm, the inclination of the back being secured by aid of the milled head screw nut, A, the screw itself being attached to the strip of metal, F, which works on a pin on the side of the baseboard, B. The bellows, C, extends to about 23 in., and closes up to about 3½ in., making it suitable for either long or short focus lenses. In place of the usual plan of raising or lowering the lens, a revolving disc is fitted to the front, working in a rebate, and kept from falling outwards by four small metal plates. The milled head attached to a pinion is for the purpose of shortening or lengthening the bellows. Fig. 2 shows the camera closed for carriage.

We will now proceed to construct a camera, having a supply of well seasoned ½ in. and ¼ in. mahogany. Begin with the baseboard, which it is necessary to make firm and strong, not only as a platform on which to build the body of the camera, but as that part by which it is attached to the tripod, and, of course, subject to greater strain than the rest of it. In the drawing given, Fig. 1A, the baseboard is carefully framed and clamped, in order to prevent the slightest warping, which would seriously interfere with the working of the sliding frame, which regulates the length to which it can be drawn out. In cheap, common cameras the baseboard is merely made of the right dimensions and clamped at each end. Fig. 1A shows the underside of the baseboard, with the framing and small brass screws, about 1 in. apart, which attach the strips shown in diagram Fig. 4, that form guides for the sliding frame, Fig. 2A. The dimensions being given with the diagrams, it is scarcely worth while to repeat them here. Fig. 2A represents the sliding frame, on the upper side, the inside edges of which are bevelled for appearance' sake. Two brass strips, B B, ½ in. wide and $\frac{1}{16}$ in. thick, are screwed to the frame along each outer edge, projecting ⅛ of an inch, and act as runners, so that the racking in or out of the bellows may be smooth and even. The ends of the strips near the hinges, C C, are slightly rounded, and small pieces more of the same are continued over the ends of the hinged bar, D. Fig. 3 shows the underside of the sliding frame and the two brass racks, A A, that when put in place engage with the pinion, F, in Fig. 4, actuated by the milled head at the side, Fig. 4, G. The screw plates, H H, are for the purpose of attaching the camera to the stand; the reason of two being made is that a better balance is obtained by using either one or the other, as the camera is used with long or short extension. Fig. 6 shows the side view of the sliding frame, with the curved joint, to permit easy folding of baseboard when closing the camera, X. The kind of hinge used, Fig. 7, represents the back frame of the camera, A, a metal plate with a slot in the centre, in which a pin attached to the brass strut, Fig. 7A, works. The notch, B, is useful to indicate when the back is a true right angle to the baseboard. The pin resting in this shows that the plate-holder is in its proper place. When a swing back is not required, it saves a considerable amount of trouble in adjustment. The frame, E, Fig. 7, is for the purpose of getting true register with the focussing screen and dark slide; it is sunk a ¼ of an inch below the outside frame, and has strips of black velvet glued on its face. Two small brass plates, C C, retain the slide and framing screen in close contact at the lower part, and two hinged catches, D D, at the top do the same for the upper part, and merely have to be turned back to remove or replace the frames. F F are small notches cut in the frame, bound with brass plates, for use when the dividing screen, Fig. 11, is required. This consists of two strips of wood, B B; on one side of each is a strip of brass, A A, projecting a quarter of an inch beyond the wood, to do duty as buttons. These are connected together by a screen, folded zigzag, made of two thicknesses of black calico, with a core of brown paper pasted together. D D D D are elastic cords on each side of the folds to keep them from bulging when not stretched to their full extent. Fig. 8 is the reversing frame, one of the most useful modern additions, permitting an oblong plate to be used either lengthways or upright without altering the camera. It consists of a light frame made of $\frac{1}{2}$ in. wood, to which the focussing screen is attached by folding hinges. The usual plan is to have the hinges at the top, and lift up the screen to insert the dark slides; but I prefer to reverse this, and have the hinges at the bottom; the focussing glass is more out of the way than with the other arrangement. The position is, however, optional. C C are small brass strips to retain the focussing glass, B, in its place; a shred of cork is placed between the strips and glass to prevent movement. The folding hinges, A A, by projecting a little over the glass, answer the same purpose on the opposite side. Fig. 9 is a side view of the reversing and focussing frame; the projecting fillet, B, is for the purpose of making the frame light-tight. C C, the part of the frame that fits in behind the plates, C C, in Fig. 7. Fig. 10 shows the front of the camera. The frame, C C C, is made of $\frac{1}{2}$ in. wood, E E being $\frac{3}{8}$ in. Two pins, B B B, pass down a groove in the back of the uprights, C C; a small plate attached to the end of the pin fits into the groove formed by brass strips at the bottom, and is pinched tightly by the nut, F. E E is the front, in which a circular hole has been cut with a rebate, in which works the flanged disc, A, Fig. 10. For convenience the rebate may be formed by building up the front of two thicknesses of $\frac{1}{4}$ in. wood, the circular hole in the inner one being a little smaller than the outer. E E is lined at the back with $\frac{1}{4}$ in. wood; a smaller aperture in it than in the front piece forms the rebate, and covers the groove cut in C C, boxing in the pins, B B, and to which the narrow ends of the bellows are fastened with strips of wood, glue, and a few small screws. The bellows, Fig. 12, are fastened to the inside of the frame, Fig. 7, in the same manner, as near to the front as possible. The disc, A, Fig. 10, is provided with apertures for three lenses. This gives an opportunity for using two small lenses for stereo or lantern pictures, or a larger one for the whole size of the plate; also, by using a lens in one of the side apertures, a quarter turn will raise or lower the lens at will, or if the front containing the disc is made to work in grooves in the uprights, C C, a slot and F, a screw, will permit the front to be raised without altering the central lens. Of course caps must be provided for all the lenses, those not in use to be kept covered. The bellows, Fig. 12, is made of leather, over which black lining has been pasted. Each fold is $1\frac{1}{4}$ in. deep. There should be only one corner to join; an inch extra in the width will provide for the overlap. In making the bellows, a piece of leather of sufficient size, or as many as may be necessary, should be pasted firmly down on to the black lining. Cut to shape, then with a chalk pencil rule lines $1\frac{1}{4}$ in. apart across it from end to end; also draw lines from corner to corner, making allowance for the overlap; damp the leathers and fold them fanwise, and well press, so that the creases remain. Let them get nearly dry under pressure, then fold on the lines drawn from corner to corner and diagonals, the leather being outwards; bend them into the proper shape, glue the overlap edge, and put under pressure, folded until dry. It is now ready to be attached to the frame of the camera. All the woodwork of the inside of the camera blackened with lampblack ground up in *thin* shellac varnish, all the visible outside parts nicely French-polished, and the camera is completed. One other important matter is the dark slide, Fig. 13. To make a good folding dark slide almost more skill is required than for any part of the camera

proper; but as the American pattern answers equally well, and is much more easily made, we have selected this as a model, and, personally, prefer it, as being less liable to admit light than where hinges have to be dealt with, or cause imperfections on the plates by the materials used for the hinges—a very common complaint. Fig. 13 represents one of this class of slide. It consists of a frame made of ½ in. wood, B B B, containing two grooves, as shown in section Fig. 16, very carefully mitred at the corners. Fig. 14 will show a side view of the same. The groove at the bottom, Y, is ¼ in. wide, leaving two flanges ⅛ in. each, which will take the position of the focussing screen when in use. Fig. 16 shows a section of the slide; A A are grooves $\frac{1}{12}$th of an inch wide, in which the shutters work, Fig. 13, E. Fig. 15 shows the cap of the frame outside; Fig. 17 a section of the same. It will be seen to be constructed of several pieces, a truer fit being obtained in this way; and it is of vital importance that no light should find entrance. Just below the central bar are two light strips of wood, Fig. 17, E, attached with a strip of any flexible material to the bar above; a small bent wire, F, is passed through the top of the strips, projecting slightly on one side into the groove. The effect of this is, when a shutter is withdrawn, the spring of the wire causes the strip of wood to bar the passage of light from the empty groove, and when it is returned, and the other shutters withdrawn, it closes that side in its turn, thus making an efficient light trap. Inside the grooves, A A, a strip of velvet should be glued, as a further protection from adventitious light. A small L-shaped piece of stout wire, with a thread on one end, should be screwed into the middle bar, Fig. 15, at C, to turn over the end of the caps of the shutters, to prevent them being inadvertently drawn out. A division of wood, Fig. 16, B, ⅛ in. thick, isolates the plates from each other, on which are glued strips of wood $\frac{1}{10}$ in. thick, whereon are fastened two small brass buttons, C C, Fig. 13. Two small pins at the bottom, close to the edge of the shutter groove, D D, provide for the plate being in proper register. The shutter itself may be made of three thicknesses of veneer, one laid opposite way of the grain and sandwiched between the other two to prevent warping, glued and dried under pressure with a capping of wood, as in Fig. 18. The projecting part of the cap is to permit the withdrawal of one shutter without interfering with the other, and is arranged as in Fig. 13. Ebonite may be substituted for veneer, but is rather heavier. The ends of the cap project slightly, in order to cover the groove into which they slide. The measurements given are for a whole-plate camera, as being the most useful of any size. By means of a screen, Fig. 19, made of thin zinc blackened, and one-fourth removed, with small buttons, A, fastened in front of the frame of Fig. 7, any quarter of the plate can be exposed without interfering with the rest. This is useful for lantern slides. To make a quarter-plate camera of this pattern, it is sufficient if the *principal* measurements are one-fourth of those given. Lighter brass work may be used, but ¼ in. wood is sufficiently thin. The circular front is not required, the screw and slot movement being better for raising the front, if a rising front is thought desirable.

In my next paper I shall give an account of the method of making a Tripod Stand, and Stand for Camera in Studio.

BEAKERS, BELL METAL, AND BELTS.

BY GEORGE EDWINSON BONNEY.

BEAKERS—BEER—BEESWAX—BELL METAL BELTS —BENZINE.

Beakers.—These are tumblers made of very thin Bohemian glass for special use in the laboratory, where small quantities of acids and other liquids are employed at high temperatures. Tumblers made of ordinary glass would soon break in pieces, but these thin glass beakers will bear boiling water being poured into them, or will hold acid whilst it is being boiled in them over a gas stove. They are also useful in analysis of solutions, as the clear glass enables the operation of precipitation to be observed whilst the operator holds the beaker away from his face, and thus enables him to avoid breathing the deleterious fumes. Glass beakers are also easily cleaned by rinsing them in clean water. If discoloured, the stains can generally be removed with dilute nitric or hydrochloric acids, or with liquid ammonia. They should always be cleaned and rinsed with clean water after each operation or experiment, and placed upside down on a shelf to drain dry. They are made in sizes to hold from 1 to 40 or more fluid ounces.

Beer.—Stale beer is used as a lubricant for scratch-brushes whilst scratch-brushing electro-plated or electro-gilt articles. Unless this, or a similar lubricant is used, the brass of the brush wire gets worn off as fine dust and becomes embedded in the surface of the plated article, rendering it more or less brassy in appearance. A tea made of marsh mallows, and also weak linseed tea has been recommended to those who may object to the use of stale beer.

Beeswax.—This substance, collected by common bees from flowers, is found to be an excellent material for making moulds on which to electro-deposit copper for electrotypes. Mr. A. Watt says of it: "This is a very useful material for moulding, and may be applied either in the form of virgin or white wax, or the ordinary commercial article—yellow beeswax." Since this substance, however, is very commonly adulterated, it may be useful to know something of its natural characteristics. At the temperature of 32° Fahr. beeswax becomes brittle, at from 80° to 90° it becomes soft and plastic, and it melts at about 155° Fahr. Mr. B. S. Proctor says: "It becomes plastic or kneadable at about 85° Fahr., and its behaviour while worked between the finger and thumb is characteristic. A piece the size of a pea being worked in the hand until tough with the warmth, then placed upon the thumb and forcibly stroked down with the forefinger, curls up, following the finger, and is marked by it with longitudinal streaks." Its ordinary adulterants are resin, farina, mutton suet, and stearine; though more ponderous substances, such as plaster of Paris, have sometimes been detected. White wax is very commonly adulterated with spermaceti, sometimes to the extent of two-thirds of the latter to one of wax. These sophistications, although not necessarily fatal to the preparation of good moulds, are certainly objectionable, inasmuch as it not unfrequently happpens that a wax mould splits or cracks, not alone from cooling too quickly, but owing to the presence of foreign substances which impair its toughness.

Bell Metal.—The bell metal used in gongs is composed of four parts copper to one of tin. This alloy, when first cast, is very brittle, but the casting can be annealed by heating to redness and quenching in cold water. The gong, when turned to form, may then be again heated and allowed to cool slowly, when it recovers its tone and elasticity. Gongs to be plated should be treated as brass, but must not be roughly thrown about, as they are brittle enough to be broken by a sharp blow.

Belts.—Various kinds of belts have been used from time to time for the purpose of driving machinery, but all must yield the palm to leather, for there seems to be "nothing like leather" as a material for driving-belts. As it is most important to have the best belts for driving dynamo machinery, the plater should know something about the choice and care of driving-belts. The best belts of all those I have had to do with are made of raw hide, with seamless joints, manufactured by an American firm, and sold by Messrs, T. C. Andrews and Co., 137, Commercial Street, London, E. The joints are made by cementing the long champfered edges of the leather together under pressure. These are sometimes made stronger with a flat leather lace embedded in the leather. The joints are so neatly made as to present no additional thickness, and very little difference in suppleness, from any other part of the belt. The leather is sent out oiled ready for use, and, therefore the belts will retain their suppleness for many years whilst working in ordinary temperatures. Oiled belts take a better grip on the pulleys than dry belts, and, therefore, need not be run so tight as the latter. This lessens the strain on the grain of the leather and conduces to the long life of the belt. Dry belts are apt to slip on the pulley, and the friction on the leather, caused by slipping, causes it to heat and thus "burns the life" out of the belt. Belts should always present a clammy side to the pulley. In dry situations, such as in an engine-room or hot workshop, the clammy state of the belt should be kept up by giving it a dressing of dubbing and a coat or two of boiled linseed oil at least once a year. Always choose a belt wide enough to do the work without undue tightness. There is economy in using moderately wide belts running slightly slack, as against narrow ones put on as tight as they will bear. Run the flesh side of the leather next the pulley, and the grain side outside, because experience of the both has shown that a belt run this way lasts longer than one run with the grain side next the pulley. It is also the natural bent of the leather. Small belts working light machinery run fairly well with butt joints linked with double tee brass links (Green's patent belt fasteners) inserted in the leather, but these are apt to tear out if the belt has to do heavy work. These joints have the advantage of being easily and quickly made. Sewn lap joints should be used for heavy driving-belts. Laced lap joints with the laps well thinned down and the laceholes punched in diamond-shaped rows do fairly well. All lumps accumulating on the pulleys or the inside faces of the belts should be promptly removed as soon as discovered, as they overstrain the belt and cause jerks in the machinery.

Benzine.—Chemical symbol C_6H_6. This is a thin, limpid, colourless liquid, of agreeable odour found in the light oils obtained by distillation of coal. It boils at a temperature of 176°, and solidifies to a white crystalline mass at 32° Fahr. It is used to free woodcuts and copper plates from printer's ink before they can be copied by the electrotype process.

OUR GUIDE TO GOOD THINGS.

**** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

77.—The "John Bull" Pocket Gauge.

The handy little waistcoat pocket companion which is distinguished by the appellation of "John Bull" Pocket Gauge presents a number of useful features which should commend it to most, if not all, wood and metal workers, and especially to engineers and machinists. It is said to be "the cheapest, best, and most useful ever offered to the trade, serving three times the purposes of any other." That it serves a multiplicity of purposes may be seen by inspection of the annexed illustration, which clearly shows its form and the various purposes to which it may be put. Its price is 2s. 9d., and on receipt of this amount it will be sent post free to any address in the United Kingdom by the manufacturer, Mr. George H. Bruce, mechanician, 10, Helena Street, Smethwick, near Birmingham. It may be useful to our professional readers to add that agents are wanted everywhere for its introduction and sale, and that for terms of agency a stamp should be sent to Mr. Bruce. It is claimed that it can be used as a rule, a straightedge, a centre gauge, two screw-cutting tool gauges, two squares (inside and outside), two hexagons (inside and outside), and five useful drill and wire gauges. It can further be utilised for setting the tools for screw cutting, and as an angle gauge for grinding the points of drills. The drill and wire gauges, as will be seen from Fig. 1, provide for diameters of $\frac{1}{8}$ in., $\frac{5}{32}$ in., $\frac{3}{16}$ in., $\frac{7}{32}$ in., and $\frac{1}{4}$ in. Its utility as a rule, however, is not sufficiently indicated in the illustration, for in the subdivisions of the 2-in. measure, engraved on its lower member, thirty-seconds, sixteenths, eighths, quarters, and halves of inches are shown, whereas on the gauge itself, sixty-fourths of an inch are indicated as well. As a gauge for squares and hexagons, it may be as well to point out that the angle, A B C, affords the gauge for the outside of a hexagon, and the angle, B C D, for the inside hexagon, or rather for a hexagonal hole cut in any material. In like manner, C D E forms the test or gauge for an inside square, and D E F for an outside square. As a straightedge, the bottom of the appliance or edge just below the graduated 2 in. measure is used. The centre gauge and gauges for screw-cutting will be found in the angular indentations on the right and left hand of the drawing. The gauges are made of fine steel, the greatest care being used in their manufacture, and every gauge sent out is guaranteed to be true. They are, at the same time, strong and durable, although light and small, and they have been introduced by the maker to supply the want of such an appliance that has been long felt in every branch of mechanical inquiry.

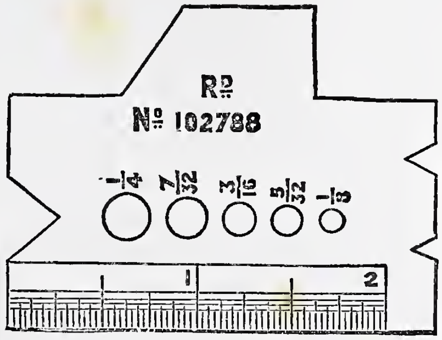

Fig. 1.—The "John Bull" Pocket Gauge.

78.—Patent Potato Raiser.

The Patent Potato Raiser, manufactured by Messrs. Powell Brothers and Whitaker, Wrexham, appears to be a very valuable addition to the agricultural machinery now in use in this country, and although it has not been long in the market it is certainly highly appreciated by farmers who have used it, as affording the means of lifting potatoes from the soil at from one-half to three-fifths the cost incurred by the usual mode of raising the roots by forks, while the potatoes are all cleared and thrown on the surface of the ground without injury in the form of bruises and cuts often caused by bringing the points of the fork into violent contact with them. It may be said that it gained the first prize of the Royal Agricultural Society of England, awarded at Newcastle, October 4th, 1887, when exhibited in competition with other machines of the same class, exhibited by leading manufacturers; the gold medal awarded at the Wirral and Birkenhead Agricultural Show, September 14th and 15th, 1887; and four silver medals in 1888, at the meetings of the Shropshire Agricultural Society, the Cheshire Agricultural Society, the Manchester, Liverpool, and North Lancashire Agricultural Society, and the Altrincham Agricultural Society.

The form and nature of the machine and the mode in which it operates is sufficiently shown in the accompanying illustration (Fig. 2), in which the only thing to which I can take exception is that the seat occupied by the driver apparently proceeds from the left-hand driving wheel, one of those accidents that will sometimes occur in engravings of machinery, but which, in the present case, can be very easily altered in the wood block.

The main part of the machine consists of a heavy strongly-constructed central frame or body, to which all other parts of the machine are attached, from the bars to which the horses that draw it are yoked to the fork wheel and accompanying gear in the rear. Below the body is the axle, on which the driving wheels with their broad tires and projecting points are set, being self-cleansing and adjustable on the axle, so as to suit the width of the ridges, which, as a matter of course, is not in all cases the same. The fork wheel, by which the potatoes are raised from the soil and which enters the soil transversely to the length of the furrow, is flatly conical in shape, so as to admit of the forks being set on it at an angle, thus leaving more soil behind the machine to work with less power than when spread with an ordinary straight wheel, and is less liable to cover the potatoes. It is constructed to work with six, eight, or twelve forks, and is adjustable forwards or back, for heavy or light soil. To the right of the Patent Digger is a revolving wheel or cratch, which turns the potatoes back when thrown against it, thus preventing them from spreading too far, allowing the soil to fall through first, and entirely protecting them against being covered with dust or light earth. This cratch is turned by the force of the soil thrown against it from the fork wheel, which saves the potatoes from being bruised.

The gearing, as the makers explain, is entirely enclosed, and is of improved construction. The speed is gained by spur and bevel wheels, so that the fork spindle is raised above the main axle to give the fork wheel the proper angle, and allows of a large bevel pinion wheel to be keyed firmly on the spindle. The bevel wheel has a bearing on each side, which ensures an easy and perfect running gearing. It is fitted with a pole which entirely prevents the machine from running askew and cutting through the potatoes on one side of the ridge. It is claimed that it is the only machine that can dig one ridge after another without picking all up. A seat, to which I have already alluded, is attached to the pole so that the driver can regulate the depth of the share whilst at work, and to lift it clear from any obstruction without a second lever. It is provided with a simple arrangement to throw it in or out of gear. The machine, it is said, is shorter than any other, can draw out on an ordinary headland, and can raise from three to four acres of potatoes per day. It is made of the best material throughout, and the bearings are fitted with brass bushes and oil cups. Lastly, the share is screwed firmly to the frame, and is without any joint to work loose. The cost of the machine is soon saved on a large farm by the reduction of expenses incurred in raising the tubers by hand.

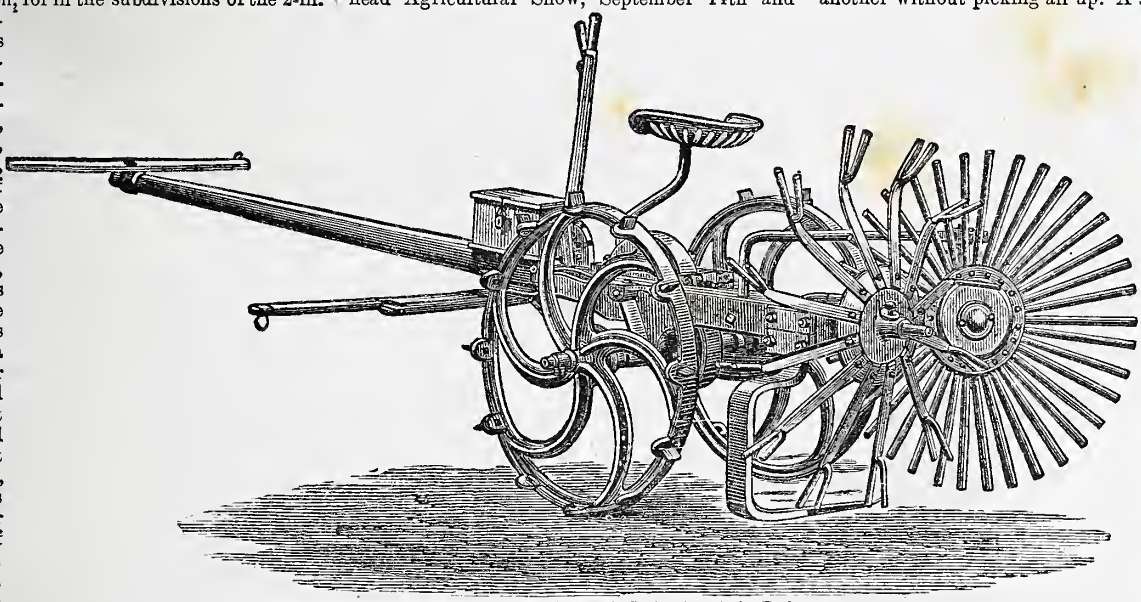

Fig. 2.—Powell Brothers and Whitaker's Patent Potato Raiser.

Whether or no it will ever become popular among English agriculturists remains to be seen; but there is much in it to recommend it to notice.

THE EDITOR.

SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** NOTICE TO CORRESPONDENTS.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

Artistic Domestic Metal Work. — FITTER (*Huddersfield*) writes:—"Would you be so kind as to let me say a few words in 'Shop?' I have taken all the numbers of WORK, and I am well pleased with it, for it is a great blessing to such as me, and I hope it will long live to do its duty to working men in England and elsewhere, as I am sure it will do, if working men will only appreciate it. Will some reader of WORK be so kind as to give a few papers on making what I call artistic domestic metal work, both for ornament and use. I mean such things as fireirons, fenders, coal-boxes, ribs, kettle stands, iron stands, and toasting machines for toasting bread without holding it in the hand. I have a toasting machine which I have made, and if it will be of any use to you I will give you a description of it. It sold for 6s. at a bazaar, so you may guess it is not a plaything. I cannot make a good drawing of it, but I will do the best I can, as I am not a draughtsman."—[Working men, I am glad to say, do appreciate WORK. There are a few who practically tell me that they could manage and edit it far better than I do, but when I remember that there are those who think they could have fought Waterloo much more judiciously than F.M. the Duke of Wellington, and could have knocked Napoleon into a cocked hat into less than half the time the Duke took over it, I rest content under the animadversions on my own shortcomings. You appreciate WORK at precisely its right value. It is not intended absolutely to teach a workman his trade, but to help him to a better comprehension and appreciation of the work he is doing daily. The young workman and the apprentice cannot fail to learn much from it, and all, whether skilled or unskilled, will be helped to the adoption of a hobby, in the prosecution of which he will certainly find amusement and recreation, and perhaps profit as well, in the approaching future; for I have known many a man begin with the practice of an art or craft as a hobby, and end by becoming a proficient in it, and making a good living out of it. By all means send the description and sketch of your toasting machine. WORK is essentially a working man's paper, and as a working man myself—I may say a hard working man—I wish the thoughts of working men, whether on paper or in the more tangible form of things made and done, to find a place in WORK. I am in thorough sympathy with working men, and I covet nothing better than to be in thorough touch with them.—ED.]

II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

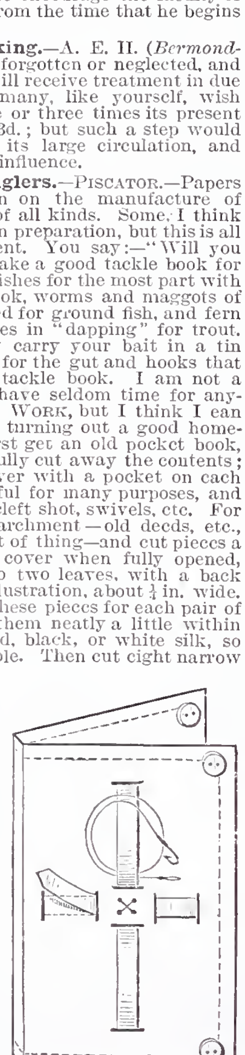
Greenhouse Sashes. —SIGNALMAN (*Southport*).—The best way to find the *exact* sizes of the sashes required for the greenhouse is to erect the framing first and get the sizes from the openings, as any variations in the scantlings of the wood used in the framing will cause an appreciable difference. If, however, the wood is of the sizes given in the description then the sizes of the four side sashes would be—height 3 ft. 8 in., length, 5 ft. 7 in.; the two sashes for the closed end are the same height, and are 3 ft. 7 in. wide; those for the door end are 2 ft. 6 in. If the roof is made as shown in Fig. 9, the sashes are each 5 ft. 10 in. long, and 6 ft. 2 in. wide. The length of the end rafters is 5 ft. 9 in. To get the level of the lower ends draw a square, then draw a line diagonally across it from corner to corner. This gives you the level, which is the angle of 45 degs.; the top ends are square, and dovetailed as described. As to the size of the glass, I would divide the side and roof sashes into five panes, those of the closed end into three, and the door end into two panes respectively. As to the making of the sashes and door, they are mortised and tenoned in the usual manner, detailed instructions for which would occupy several papers. As to the kind of glass, 15 oz. sheet would be sufficient unless you are liable to have heavy hailstorms in your locality, when that in the roof could be 21 oz. The sizes of the triangular sashes in the ends of the house you had better get after the framing is put together. You can then, having got the exact sizes, either draw them down full size on a board, or make a thin wooden mould to fit the openings, from which you can work. All the sashes, with the exception of those of the roof, should be made ¼ in. less than the given sizes. This will save trouble in fitting them, and facilitate their easy removal when taking the house down.—G. L. B.

Stencils.—G. S. (*West Ham*) means the stencil plates used for marking sacks, hop pockets, and such things. I can inform him that I used to cut a great many of them for farmers and hop dealers, and the only tools I used were as follows:—A smooth cast iron plate 12 in. square or larger, a light hammer, three chisels, ⅛ in., $\frac{3}{16}$ in., and ¼ in. in width; a 6 in. half-round file, a 6 in. flat file, and a 4 in. or 5 in. square file. I mark out my letters, taking care to mark the ties that are to be left in; then chop them out, using the narrow chisels for the curves, and the wide for straight lines. I then rap down the burr with a mallet, and file up. The stencils such as used by decorators, &c., are very much thinner, and can be easily cut with a knife. Any ordinary sharp-pointed knife will do, but one with a fixed handle is preferable. Lay the plate on a piece of smooth, hard wood or plate glass; cut slowly, and frequently sharpen your knife. G. S. will see by this that there is no need for any special tools, and anything mentioned here can be got or made at any tool shop, and the price is a mere trifle.—R. A.

Designing.—E. S.—An architect may be a designer, but it by no means follows that designers are architects. You say you are a cabinet maker, serving your time at the trade, and that your "fancy is a little inclined towards designing furniture." Before you can design, you should be able to draw correctly and with ease, and to this end you should attend the school in your neighbourhood where evening lessons are given in drawing, and study to pass the South Kensington examinations and gain your certificates for freehand drawing, geometry, etc. etc. It will be useful to you to obtain and study a work recently published in two volumes, 6s. each, by Messrs. Cassell & Company, Limited, entitled "Hand and Eye Training." In this work it is sought to encourage the faculty of designing in a student from the time that he begins to learn drawing.

Picture Frame Making.—A. E. H. (*Bermondsey*).—No trade will be forgotten or neglected, and picture-frame making will receive treatment in due course. I know that many, like yourself, wish WORK to be made twice or three times its present size, and sold at 2d. or 3d.; but such a step would only tend to diminish its large circulation, and therefore its utility and influence.

Tackle Book for Anglers.—PISCATOR.—Papers will certainly be given on the manufacture of fishing tackle and gear of all kinds. Some, I think I may say, are already in preparation, but this is all I can tell you at present. You say:—"Will you kindly tell me how to make a good tackle book for anglers?" The angler fishes for the most part with a bait impaled on a hook, worms and maggots of various kinds being used for ground fish, and fern webs and bluebottle flies in "dapping" for trout. You must of necessity carry your bait in a tin box or a bottle, and it is for the gut and hooks that you really require the tackle book. I am not a fisherman myself, for I have seldom time for anything else but work and WORK, but I think I can put you in the way of turning out a good home-made tackle book. First get an old pocket book, not too small, and carefully cut away the contents; this will give you a cover with a pocket on each side, which will be useful for many purposes, and the stowage of hooks, cleft shot, swivels, etc. For the leaves get some parchment—old deeds, etc., come handy for this sort of thing—and cut pieces a little smaller than the cover when fully opened, but enough to fold into two leaves, with a back as shown in annexed illustration, about ¼ in. wide. There must be two of these pieces for each pair of leaves. Sew or stitch them neatly a little within the edge, with coloured, black, or white silk, so that the leaves are double. Then cut eight narrow slits through each leaf, as shown, and through the four central slits pass slips of cardboard, or some tougher material, if possible, as drawn, and secure them in the centre by stitching. The ends of slips must be cut to a point, so that each end may be easily passed under the parchment through the slit opposite to that from which it has issued. One slip is shown outside the slit in the illustration to show my meaning clearly. When a slip is released it can be passed through a coil of gut with hooks attached, and then put again through the slit from which it has been withdrawn. A small disc of cork, rather less than ⅛ in. in thickness, should be sewn to the outer corners of each leaf to keep the leaves fairly apart. The leaves should then be sewn into the pocket-book cover along each crease that has been folded to form the back.



Celluloid.—J. P. (*Glasgow*).—The British Xylonite Company, Limited, 124, High Street, Homerton, London, E., are makers of this.—P. W. S.

Safes and Safe Doors. — F. G. (*Brighton*). — Thanks for the extract you forwarded.—ED.

Designs of Drawings.—G. C. (*Drayton Park*).—By all means let me see the designs you wish to submit.—ED.

Glass Printing.—C. D. (*Bethnal Green*).—You cannot patent an idea; but you can patent a process or a machine required to carry one out. You should in your case consult a patent agent.—F. C.

Shell Rabbit. — A. S. (*Euston Road*). — The specimens of shell rabbit that you send have been recently offered for sale in the streets of London at 1d. each, and are curious from their marked resemblance at a little distance to the animal they are intended to imitate. The shell forms the body of the whelk, cleansed, probably by the application of a little hydrochloric acid. The head and fore feet—there is no tail other than that supplied by the lower end of the shell—are made, I should say, of putty, to which white lead has been added in order to make it harden quickly. The material is applied to the point of the shell, and moulded to the shape of a rabbit's head by the fingers, for on one side of the head of one of the specimens sent you can see distinctly the impression left by the ridge-and-furrow skin of the thumb. If you look at the inner side of the top joint of your own thumb you will see what I mean. The ears are first pinched up into one long point, which is divided by a knife, the blade being turned first one way and then the other to make the ears slope outwards. This, as far as I can determine, covers the manufacture of the shell rabbit in every particular. The fore feet are merely two little dabs of the same material rounded off in front; they serve to keep the shell steady, and prevent it from rolling about.

Burnishers for Brass.—A. R. (*Edinburgh*).—A file with the teeth ground out and polished makes as good a burnisher as anything, or good tool steel will answer the purpose equally well. Beer is a good liquor, or water with a little vinegar.—J.

Papier-Mâché.—R. W. (*Manchester*) omits to name the precise purpose for which he wishes to prepare his papier-mâché, which makes it less easy to advise with precision. There are various ways in which paper may be made to resist water and insects. Pasted papier-mâché can, of course, be made bent to any angle. The thorough saturation with linseed oil which it undergoes gives it great water-resisting power, and various coatings may be given it—the solution of gutta-percha in naphtha with a little shellac, recently recommended to BOFIN (page 301), would be a good one. Or, a mixture of paper dust and black japan might be made, which would have the desired qualities, and might be bent whilst yet soft. With regard to procuring papier-mâché pulp in large quantities, R. W. is referred to Messrs. McCallum & Hodgson, Summer Row, Birmingham.—S. W.

Wood Carving in the Round.—MAC O'RONEY (*Nairn*). — Plaster casts will be found the most available patterns from which to carve in the round, as practice for a beginner; and these are to be bought in most towns, though perhaps the largest and best stock in Great Britain is at Brucchiani's, Russell Street, Covent Garden, London. But M. O'R. is strongly advised to practice modelling in clay as a means of making prints and photographs available for his purpose, and still more as a means of embodying any designs of his own, which he may wish eventually to carve in wood. He will shortly be able to learn all about modelling from WORK.—M. M.

Coating Bare Places in Covered Wire.—V. R. (*Liverpool*). — The bare places in your 24 silk-covered wire may be coated with india-rubber cement; but I should prefer covering them with silk. Get some soft silk (floss, tram, or woven silk will be best), never mind the colour, providing it will lie close to the wire. (Sewing silk is too hard and wiry, and will not cover well.) Fix the wire firmly on both sides of the bared spot, and then wind the silk around it, taking the thread of silk direct from the reel, and passing this round and round the wire until covered. Then rub a piece of paraffin wax all over the newly-covered spot for the double purpose of fixing the loose ends, and making sure of the insulation.—G. E. B.

Batteries for Electric Lighting.—NEW BEGINNER (*Manchester*).—Very little in the way of electric lighting can be done by means of primary batteries—that is, electric batteries which have to be charged with acid to produce a current of electricity. The lamp and battery you saw in a shop at Manchester was, probably, a four-cell chromic acid battery supplying current to a five-candle power lamp. The light from this when compared with that from a No. 3 gas burner, or the light of a shilling paraffin lamp, is a mere glimmer. You would require four such lamps to light a moderate-sized room in a private house. Such lamps do fairly well as attractive advertisements for shop windows, or glimmer lamps for small rooms on summer evenings. It will take at least 5-quart Bunsen cells to properly light up a 5 c.p. lamp, and the cells will require fresh charges of acid every nine or ten hours. I will try to go thoroughly into this subject soon, and give the results to the readers of WORK in a separate article.—G. E. B.

Tinning Iron Wire.—H. G. (*Liverpool*).—The proper way to secure an even coating of tin is by drawing the wire as it comes from the tinning bath through a burnished steel die fixed near the bath, and kept warm by an atmospheric gas jet burning beneath it. The die being exactly gauged so that the wire only just passes through, insures an even coating, and being burnished gives it a polish. The winding arrangement should be far enough away to allow the wire to cool after leaving the die, the hole in the dye is rounded off so as not to cut the wire. I expect that H. G. would hardly think it worth his while to go to the expense of a steel die, so I will first suggest something that I think will answer very well, at any rate far better than the corks. Take a 1 in. gas socket and two plugs for same; drill a hole through each side of the socket, say ⅜ of an inch diameter, or larger, file off the rough hurr on the inside, and trim up the outside a bit smooth, in case the wire should rub against it; screw one of the plugs into the socket, about two threads only, then hold the socket in a vice by means of the square on the plug, and pack it tightly with good tow or finely dressed hemp. When packed as tight as you can get it, screw in the other plug a few threads, and the bottom one a little more, then draw your wire through this instead of the corks. You might use two of these arrangements, if so, I should grease all the packing of the first one with tallow. I think this plan will answer every purpose, and shall be glad to know if it is of service to you.—P.S. The top plug is to adjust the pressure on the packing, as you find it necessary.—L. L.

Printing.—T. S. B. (*Shrewsbury*).—Blanket, fine cloth, linen, thin oilcloth, glazed hoard, or paper, may he used for covering the cylinder of a printing machine, and each possesses advantages (or disadvantages) according to the materials to be dealt with and the quality of work to he produced. For rough work, newspapers or broadsides, or where the type is old, it is advisable to use a blanket; but if good work is required, the harder the cylinder is packed the better will he the effect, in the hands of a skilled workman.—J. F. W.

Laying on Picture Frame Gold.—Jumbo (*York*).—Proceed as in answer to B. N. (see page 333), and when thoroughly dry with a camel hair brush, apply good mastic varnish with care, that no dust gets upon it during drying; probably cost 7s. 6d., if you do not waste the gold, and you have all the tools.—G. R.

Gladstone Bags.—Jumbo (*York*).—I have done the same myself, and found best Berlin black evenly laid on with a good painter's sash tool renovate them well; but if you also give it a couple of coats of French polish, and good vegetable black well mixed, this answers admirably.—G. R.

Book-case.—Alpha and P. M. M. (*Epsom*).—You will have noticed that a good form of bookcase was given in No. 15, page 231. Others will follow.

Index to Work.—P. M. M. (*Epsom*).—Indexes will he furnished for Work. I agree with you when you say:—"I think no one intending to buy the Magazine would object to pay for an index if you thought well to issue one."

Photographic Exposure Tables.—W. P. J. (*Aberystwith*).—I shall he very happy to see your tables, as of course till I have had an opportunity of testing them no definite opinion can be expressed. Glad to hear you like Work.

Bookcases.—S. A. (*Homerton*).—In No. 15 of Work you will find some instructions on bookshelves, which will, no doubt, be useful to you. An article in the artistic furniture series of papers will also shortly appear, describing the construction of a bookcase. As the design for this is for an "enclosed bookcase"—*i.e.*, one with cupboards, it is probably just what you want.—D. A.

Bureau Bedstead.—H. G.—An article describing and illustrating the construction of a cupboard bedstead, will appear very shortly. You will find it very useful.—D. A.

Stand for Overmantel.—C. S. (*Brighton*).—The overmantel, when supported in the way you propose for yours, will virtually form the hack or upper portion of a cabinet. An article descriptive of a cabinet is in the list of subjects to be treated in the series "Artistic Furniture," of which the overmantel was the first. Thanks for good wishes.—D. A.

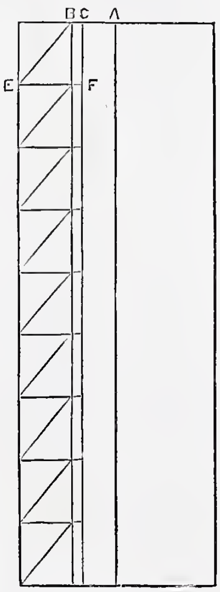
Model Beam Engine.—A. Y. (*Leeds*).—As your engine is only 2 in. stroke by 1½ in. bore, I should not advise you to try to make it condensing. You might do so no doubt, but a little engine of this size ought to run fast, and pumps will not work well unless they go slowly. A turbine runs fast because the water runs through continuously; but in an ordinary pump the water has to be set in motion and brought to rest at every stroke. Take a glass syringe, and, putting the spout in water, draw up the plunger suddenly. You will see the water does not follow immediately, but seems to think about it, and then comes unwillingly, only half filling the barrel. Draw up slowly, and you get the barrel full. Draw up suddenly, and as suddenly press down the piston, and you get no water at all, because the piston comes down before the water has had time to move. You will gain no power by adding a condenser to such a little thing, because all the power gained by the vacuum will be expended in working the air-pump. If you must have a working model condensing engine, have a cylinder 4 in. by 2 in., use a fly-wheel of large diameter, and don't let it run over about sixty revolutions per minute. You could probably make your engine of type metal. I have seen one made so, but I would not expend trouble on such material. I strongly advise you to make a high pressure engine first, of a useful size, and leave the condenser for the present.—F. A. M.

Bamboo Furniture.—E. L. (*Portland Place*).—Yes, articles on this interesting subject have been arranged for, and will appear in due course. Mr. Fred] Westhury, 183, Great Dover Street, holds the largest and best stock of bamhoos suitable for your purpose. You can obtain any quantity from him, but of course you cannot expect wholesale prices for small quantities. Owing to the enormous circulation of Work, we go to press very nearly three weeks before publication.—D. A.

Work Bench.—D. B. (*Perth*).—Yes, the subject will be treated, and in due course. I hope to place before readers of Work designs and instructions for making a bench, both to contain tools and work at. Meanwhile, it may interest you to know that an article describing the construction of a small folding bench is in hand. Your scoldings for destroying the kitchen table may speedily be stopped by your putting a board on top of it, in other words, have a wood cover, and work on it.—D. A.

Polishing Bookcase.—Amateur (*Openshaw*).—You will find it easy to stain your bookcase a mahogany colour; but being inexperienced in staining it is very doubtful if you would be able to match the colour to that of the existing furniture. If you are inclined to try you must first stain and then polish. I hardly think it would be worth your while to French polish, and probably you would get a better result by varnishing. Between staining and polishing or varnishing apply a coat of size. If you decide on French polishing proceed in the usual way.—D. A.

Step Flashing.—A. B. (*Barking*).—To set this out proceed as follows:—Cut your stuff the length required, the width will depend upon how much is to lap on the slates. See sketch, which shows the marking out of a piece 3 ft. long 12 in. wide; draw line, A, down the centre, draw a second line, B, 2½ in. from A, and a third line between the two ½ in. from B. Now obtain the bevel of the roof—that is, the angle formed by the two sides of the roof; take a rule and lay one arm edgeways on the slates, bend the other till it comes parallel with the joints in the brickwork. This will give you the bevel to mark off the flashing with. Before marking these, however, set off lines, E F, from the edge of the stuff to line C, 4 in. apart. The joints in brickwork are 3 in. from top of brick to top of brick; but the flashing laying in a slanting direction, requires to be marked an inch more—that is, supposing the roof is a square mitre, or 90 degrees of angle. Now lay the bevel on line B, and mark off the diagonal lines; now cut the straight lines as far as line C, and the diagonal ones only as far as B. This gives ½ an inch to turn back into the joints. I presume A. B. knows how to fix, and trust this will give him the information he wants. If not clear on the subject, write again.—R. A.



Mahogany Top.—T. R. H. (*Birmingham*).—No doubt the sweating, as it is technically called, of your table is owing to your having used too much oil. You seem to have saturated the wood with this. Only a small quantity of oil is required well rubbed in. In fact as you seem to have an idea that a large quantity is needed perhaps the best way of conveying to you what is wanted is to say that rubbing with an oiled rag is almost sufficient. This, you will see, is very different from a good coat of oil every night for a week, by which one may infer that the wood has been saturated. You must have misunderstood your French polishing friend, as no practical polisher would recommend such a procedure as you have adopted. All you can do now is to let the oil sweat out, and if you keep on rubbing with a dry rag daily you will soon have a good surface, which though not so brilliant as French polish will withstand heat from plates, dishes, etc. The more you rub the better the polish, and you will not require to use wax polish, as by the time your table is done it will be "oil" polished, and quite as brilliant as if you had used wax. Work is seldom oiled before waxing. A simple refrigerator will appear in "Shop" very shortly. Much obliged by your kindly remarks about the articles by Opifex, and your good wishes for Work.—D. A.

Saw Belts Slipping.—"A Reader" (*Skipton*).—As a temporary expedient, a little powdered resin will assist the adhesion of a belt. But belts are very apt to slip on circular saw pulleys, hecause the pulleys being small, the arc of the circle embraced by the belt is small. Hence they require frequent tightening. Do not let the belts become dry, but preserve their suppleness with castor oil. Belts inclined or horizontal drive better than vertical ones. Long belts drive better than short ones, and short ones require to be tighter than long ones. Short belts are a mistake. As a last resource, use a leather-covered pulley, or employ a hinder or tightening pulley to the slack side of the belt.—J.

Dulcimer for Home Use.—"Musician" (*Dublin*).—An experienced hand is preparing an article on Dulcimers for the readers of Work.

Dulcimer.—T. C. B. (*Birmingham*).—Kindly read the above, which answers the questions you are good enough to put.

Prints Transferred to Wood.—J. G. (*Manchester*).—Without precise knowledge of the nature of the process used to produce the prints you mention, I should say, as far as my experience of lithographic and copperplate printing goes, that it would be quite possible to print them upon wood from stone from transfers previously made from copper plates. The wood (sycamore or maple) having been procured of an even thinness throughout, and also planed very smoothly, the scraper of the lithographic press should be set to suit the substance of the wood, and in pulling the impression the putting down and lifting up of the lever should be carefully manipulated to obviate breaking the stone. Articles hearing views of the particular locality are best known at the more frequented seaside resorts, where they furnish an inducement for the unlucky visitor to part with his spare cash in the purchase of them as mementoes or presents for his womankind. Imitations also are sold, which are simply prints mounted upon wood and varnished, and for most purposes they are as good as the real thing. If you do not possess a lithographic press, perhaps you may appreciate the counterfeit as quite within the limit of your powers.—J. H. M.

Cylinder to Geneva Watch, etc.—Watchmaker (*Stoke*).—To put in a cylinder see instructions given to Country Watchjobber, on page 302: tools required, a pair of turns, conical pivot file and burnisher, graver, and gauges, bow and ferrule, wax for ferrules, half resin and half beeswax. To solder, make a close fitting and clean joint, use very little solder, and use powdered borax for flux for all hard soldering joints; boil out or let it stand a time in a solution of sulphuric acid, 1 part to 19 parts of water, then polish off. To make silver solder, melt together 2 parts silver and 1 part brass wire; or a very easy-running solder, but not so strong, may be made from equal parts of silver and tin, melt the silver first. Gold solder, 18 carat gold, 12 parts; silver, 2 parts; brass wire, 1 part; for lower qualities of gold articles use the same standard as the article to be soldered, adding the same proportion of silver and brass. I should strongly recommend all watch and clock jobbers, professional or amateur, to get "Britten's Watch and Clock Maker's Handbook, Dictionary, and Guide," price 5s., containing 384 pages of useful matter relating to nearly everything in the trade, with a host of illustrations of tools, etc.—A. B. C.

Bookbinding.—J. T. H. (*Inverness*).—Papers on bookbinding in the orthodox way will appear shortly, and from these you will learn how to make the nice round back and straight edge that we see on all books, from the professional binder.

Wire-thread Fret Saw.—J. T. H. (*Inverness*).—I can only repeat that the wire-thread fret saw is not yet on sale in this country. As soon as it is so I shall be told of it, and will mention the fact in "Shop."

Bird Stuffing, etc.—W. T. (*Maybole*).—Taxidermy will not be forgotten, but I can say no more than this at present.

Kaleidoscope.—Pica (*Old Brompton*).—The first part of the description of the new kaleidoscope is in my hands, and will soon see the light.

Parkesine.—J. B. (*Oxon*).—Parkesine, xylonite, or celluloid are identical, and are made from nitrocellulose [$C_{12}H_{14}O_4(NO_3)_6$], more commonly known as pyroxiline or "gun cotton," which is cotton or other celluloid substance treated with nitro-sulphuric acid which renders it soluble in various chemical agents, such as alcohol and other hydrocarbons with or without camphor oils, and in some cases, gums and resins. This interesting substance was discovered by Mr. Alexander Parkes, of Birmingham, who, more than forty years ago, being impressed with the necessity for the introduction of a substance to take the place of certain natural productions, such as ivory, tortoiseshell, etc., set himself to discovery such a substitute, and with this end in view, made many thousands of experiments, till at length his ardent search was rewarded by the "epoch-making" discovery that by combining gun cotton with various other substances he could produce such an article as he had heen so long in quest of. In 1855 Parkes took out the first patent, but being at that time engaged with the firm of Elkington, Mason, & Co., he was unable to give his unremitting attention to the subject, and so it was not till the London Exhibition of 1862 that he succeeded in gaining much attention to his product. Though the specimens there exhibited were made in a rough manner by himself without the suitable appliance used in the various trades, he received the silver medal. By the time, however, of the Paris Exhibition, 1867, the matter had made such progress that his exhibit was judged one of the most remarkable specialities shown. Up to this time no name had been given to the new product, and in honour of the invention one of the French papers called it "Parkesine." On his return the Parkesine Company, Limited, was formed, into which the inventor threw his patents and took common lot with the other shareholders. The speculation was not, however, a financial success; and its collapse left poor Parkes minus his outlay of money and his patent rights, and with nothing but the medals he had gained in London and Paris, and the satisfaction of knowing that he had been the discoverer of what is admittedly one of the most important substances applicable to the arts and manufactures ever discovered. A second company followed the first; and this latter was succeeded by the present British Xylonite Company in England, while the Celluloid Company flourishes in America. About ten years ago, Mr. Henry Parkes, who has been associated with his brother in most of the latter's inventions, took out some important patents, and founded at Birmingham the "British Celluloid Company," but I am not informed as to its success or otherwise. Of course, the details of the manufacture vary according to the purpose to which the product is to be applied, and by proper manipulation (mainly by variation of the solvent used and any amount of pressure applied) any required degree of hardness or flexibility can be secured. It can be made, for instance, as hard as ivory, or in so soft a condition as to be capable of being spread in layers over textile fabrics, much in the same way as paint is used. The product is waterproof, acid-proof, and airproof, and may be made, if not fire-proof, at least, non-inflammable. It can be worked in the liquid, plastic, or solid state. It can be pressed and stamped, planed, turned, sawn, carved, woven into fabrics, and, as first seen, applied as a varnish. It can be made transparent or opaque, and of any desired colour. I shall be glad to send any further information at my command on learning your precise requirements; but I have no doubt a letter addressed Messrs. Alexander and Henry Parkes, Inventors of Celluloid, Birmingham, would reach the inventor himself, who would be able to advise you fully.—R. W. S.

Enlarging Camera.—F. C. (*Trefechan*).—I do not know what process you refer to. There are many ways of making crayon enlargements, the easiest of which is to make an enlargement on bromide paper, and work it up with crayons. This process is mostly worked in black or sepia; but if you want to use coloured crayons, then you must develop the image faintly on the paper, so that the black tone may not spoil the colouring. Of course, it requires considerable artistic skill to work up a crayon enlargement and keep the likeness; and, unless you possess such skill, the result of your labours will be disappointment. If you care to try the experiment, you can make an enlargement on Eastman's A paper, develop well out, then soak in castor oil until quite transparent, and colour from behind as in crystoleum. Use oil colours. A very good effect can be got this way with care. The lens you mention would do quite as well for enlarging from $\frac{1}{4}$-plate negatives.—G. Le B.

Advertisement Pages.—GRAHAM (*Perth*).—Kindly see reply to AD FINEM, in No. 16, page 253.

Pump and Pressure Gauge for Model Engine.—W. N. (*Birmingham*).—If the boiler of your engine is only 7 in. long by 3 in. diameter, the feed pump will be very tiny, and will very likely cost you as much trouble as to make the whole engine. You might make it $\frac{1}{4}$ in. diameter and $\frac{1}{4}$ in. stroke. I once had one, that worked, of $\frac{1}{4}$ in. diameter and about $\frac{1}{4}$ in. stroke. It is useless to "fiddle" over such a little thing, nevertheless I send a sketch of mine used with a 1-in. cylinder, 2-in. stroke. Fig. 1: A is the body, screwed and then

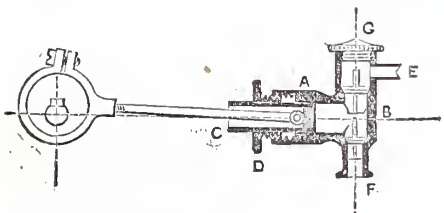


Fig. 1.—Force Pump and Eccentric for Model Engine.

soft soldered into B, the valve-box; C, the plunger, with an eye—the eccentric rod is first fitted, and then the eye is soldered in; D, the gland with milled rim, for screwing up with fingers; E, the delivery pipe, is also screwed and soldered in; F is the suction, and receives an india-rubber tube; G is the cap screwed down on a bit of soft thread: it also acts as a pet cock when slightly released to let out air. The valve-box is drilled first, with three sizes of drills, the middle size being not less than the diameter of plunger; then make the small valve on the end of a bit of brass rod, so that you can push it up the hole and grind it to its seat while the box is running in the lathe. The guide under the valve must fit the hole of F so as to keep it straight, and when ground, it is to be filed with three sides, to form passages for the water. Then turn the little stem above the valve and cut it off. Now fit the upper valve in the same way, making the guide come within $\frac{1}{32}$ in. of the top of the lower valve, so as to limit its lift. It should lift about one-eighth its diameter. Similarly the cap screws down to within about $\frac{1}{32}$ in. of the upper valve. The most important thing in these little pumps, as in large ones, is to leave no pocket for air inside. Put the delivery valve on the highest point, then the air will be driven out first. I have seen many sections of feed-pumps in different papers I feel convinced would give endless trouble, if they worked at all. When you have made this pump, make a $1\frac{1}{2}$-in. cylinder-engine and apply it to that. It will keep it well supplied. You ask, secondly, how to make a steam gauge. Models of the size of yours are not usually furnished with one, and it would be difficult to make one small enough of the ordinary description, and if you could succeed it would probably be worth two or three times as much as the boiler! Fig. 2 shows a kind of steam gauge I made with some bits of $\frac{1}{8}$-in. glass tube, a very little mercury, and a bed-room candle, when a boy of seventeen. A, the tube, held in the candle and gradually bent as seen; the upper end was sealed with a blowpipe made with another bit of tube, partly closed by being held in the flame. The bent end is slightly enlarged to take a short length of india-rubber tubing, which will do to make the connection at low pressures, especially as you can easily renew it if it swells. B is a bit of board to which tube is wired, and on which divisions are marked. A very small quantity of mercury is introduced, as shown; by warming the tube and then holding the mouth in the mercury you can make it suck it in. When the mercury stands at a convenient height, C C, make the mark C on the board after first making sure the tube is cool; then mark at D the end of the hole in the tube. Now C represents atmospheric pressure, say 15 lbs. above vacuum. Halve C, D, and you get E, which will be 30 lbs. from vacuum, or 15 lbs. per square inch. Probably that is as much as your boiler should carry, but you can continue the subdivision, halving E, D at F, and marking there 30 lbs. above the atmosphere, etc., etc.—F. A. M.

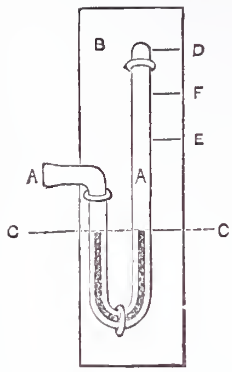

Fig. 2.—Mercurial Steam Gauge for Model Engine.

Damp Floor in Fowl House.—T. G. L.—Fowl houses will be dealt with if opportunity offers, and the subject is in demand. It is a difficult matter to determine, without seeing the place, why the floor of your house is always damp, although the roof is perfectly water-tight. Perhaps as good a plan as any to overcome this drawback would be to dig out the earth to the depth of 12 in. or 18 in., and fill up with brick-bats and coarse gravel, with fine gravel and cinder ashes on the top. This would afford means of drainage if the soil is naturally damp. Give your fowls plenty of old lime if you can get it. Calcined oyster shells, beaten to fragments, and sand, especially sea sand, are also useful.

Basket Making.—J. T. H. (*Inverness*).—Yes, instructions will be given on basket making; but I have not yet succeeded in getting hold of a literary basket maker who can write on his trade.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Insurance of Workman's Tools.—J. K. (*Oxford*) writes:—"I am writing to ask you whether you could tell me (a journeyman cabinet maker), or find out through WORK, if there is an insurance office anywhere to insure tools kept at a workshop. I have tried to insure my tools in other offices, but have failed. I hope this is not out of the range of your column for 'Shop.'"

Tools.—G. P. (*Edgeley*) writes:—"AN AMATEUR would be glad to be advised what tools (carpentering) to get to commence, so as not to get too many, nor go to great expense, and where best can be got at lowest cost—say, for building greenhouse, etc."

Moulders' Pattern Making Tools.—E. R. (*Halifax*) would be glad if some reader would, through the agency of your paper, WORK, give him a list of tools that are used, and the cost of each, in moulders' pattern making.

Walking Stick.—G. W. M. (*Westbourne Park*) writes:—"Can any reader of WORK give me the name of a London turner who would supply me with a lignum vitæ walking stick?"

Blue Prints.—PHOTO (*Chester*) writes:—"I have been much pleased with the instructions for preparing the sensitised paper for taking blue prints, and have succeeded in taking some fine copies. There is, I believe, a process for taking copies of engineering tracings, giving a black line on a white ground, the bath being gallic acid. Would any reader of WORK kindly give me the mixture and the proportion for preparing the sensitised paper for this process?"

Finishing Brass.—S. H. D. (*Newtown*) writes:—"Could any brother reader of this valuable paper inform me as to what method is pursued to put that finish on brasswork so that when it is handled it does not tarnish?"

Removing Ink Stains.—LITTLETON (*Worcester*) writes:—"Will a reader kindly say how best to remove ink stains?"

Trade Notes and Memoranda.

IN 1892—the anniversary of the discovery of America—the United States will hold a World's Exhibition. Workers should prepare.

A DISCOVERY has been made in America, of a chemical compound from which light, heat, and power are obtainable at small cost.

GERMANY is going ahead in a movement to explore the submarine flora and fauna of the ocean. Attention is first to be directed to the east coast of Greenland.

IMPORTANT PRIZE COMPETITION.

THE Editor of WORK has the pleasure to offer his readers Prizes to the value of

THREE GUINEAS,

to be distributed for Competition for Designs for a small Bookcase, to contain the Volumes of

CASSELL'S NATIONAL LIBRARY,

FIRST PRIZE ... One Guinea and a Half.
SECOND PRIZE ... One Guinea.
THIRD PRIZE ... Half a Guinea.

Full particulars of the Scheme will be found in WORK No. 17, page 254.

Full particulars of the Scheme will be found in WORK No. 17, page 254.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

MELLIN'S FOOD

For Infants and Invalids.

NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

VOL. I.—No. 24.] SATURDAY, AUGUST 31, 1889. [PRICE ONE PENNY.

MIRROR FRAME IN CARVED WOOD.

IN THE STYLE OF THE ITALIAN RENAISSANCE OF THE SEVENTEENTH CENTURY.

BY FRED MILLER.

I WILL commence by stating that the accompanying design is a free adaptation of a very good and well-preserved specimen of a seventeenth-century mirror frame, that is well worth the attention of all skilled wood carvers, whether professional or amateur.

Work of this character, it should be said, is difficult, and should only be attempted by those who have passed the initiatory stage. The "carving" must be executed with precision and crispness, and, at the same time, there must be a freedom and springing quality about it, in order to give the sensation of the lines flowing from a common centre and being continuous throughout. Broken-backed curves and disconnected lines ruin the entire effect. If you examine good specimens (and almost all specimens are good) of seventeenth-century Italian carving, you will see what I mean by continuity. One can imagine the craftsman taking a soft, yielding material, and by dexterously guiding his tools, executing the long flowing curves that make up the design in a few sweeps of his gouge. *This* effect we know is obtained by time and labour, and yet when we look at the finished work we should feel that it was wrought in the first freshness of the day, when the nerves are vibrating and the energy is elastic. There should be no feeling of labour about wood carving. Merely the result of infinite pains and a cycle of days depresses one; and though good work requires both patience and time, you should get that nervousness into your carving which makes one feel that the work was wrought in a happy moment, when the interest is undiminished and the hand unwearied.

What has this, I can imagine some one saying, to do with wood carving—this transcendentalism? Everything, I reply: for it is the *spirit* in which you executed your work that gives it its feeling, gives it life. The letter only it is which kills. And so much modern wood carving is wholly deficient in *esprit*. It is commonplace and mechanical in execution if not in design, and depresses rather than exhilarates the beholder. It might have been turned out by a machine instead of executed by the hand of the cunning worker. Therefore, before putting in hand such a work as that figured, charge yourself with feeling, and let the artist triumph over the mechanic.

If the work is for gilding, good pine will do to execute the design in. But if the wood is to show the American walnut, oak or mahogany is better. The thickness of the wood depends upon the amount of "undercutting" you intend to put into your work. This class of design does not look well in too low relief. The effect is largely due to the different planes (or depths) in the work, and the back scrolls that support the front ones should be, say, $1\frac{1}{2}$ in. thick, and allowing for the parts in highest relief the wood ought to be about 3 in. to $3\frac{1}{2}$ in. thick. Two pieces $1\frac{1}{2}$ in. thick when planed might be glued together, the lower piece for the back scrolls and the oval frame itself, and the upper piece for the work in highest relief.

Mirror Frame in Carved Wood. Example of Italian Renaissance, Seventeenth Century.

Make a careful enlargement of the design as far as the main lines go (for it would serve no practical purpose to indicate much undercutting), and paste this down on the wood; be careful to strike the oval correctly. The wood should first of all be pierced, and if your design is accurately enlarged, it might be worth going to the expense (not a considerable one) of having this done by a steam fret cutter. By piercing the design you are helped in the execution of the work, as it gives you a clear idea of the general scheme. The outside or outline of the design should also be cut round; now "ground out" to the depth of the back scrolls. If you have glued two pieces together, this will be to the depth of the upper piece. This gives you a very fair idea of the "masses" of the design. But so far the difficulties have been purely mechanical. The real difficulties begin with the carving itself, and about this little that is helpful can be said in writing. This is so largely a matter of feeling. I have endeavoured to indicate by light and shade the general disposition of the principal curves, and your own intelligence and artistic perception must do the rest.

The scrolls resting on the oval frame should be, say, ½ in. deeper than the frame itself, that is the full depth of the wood through where two pieces are glued together. I said the lower piece should be for the frame and back scrolls. But where the wood is solid the oval frame itself might be 2 in. in depth, the back scrolls 1½ in., and the foremost ones the full depth, 3 in. This gives you three planes, and you can introduce subtler gradations as the work progresses, so that one plane looses itself or sinks into the one below it, for it should not be apparent how many planes there are. The completed work should have subtle qualities if it is to be worthy the notice of the readers of this paper.

A few visits to the South Kensington Museum during the progress of the mirror frame would materially help one, as there is a good collection of wood carving there, and one can always get help and inspiration from looking at good work.

HOME-MADE POLISHING WHEELS, ETC.

BY OPIFEX.

EMERY wheels of various sizes and degrees of cutting power are almost indispensable to a well-stocked workshop, and, as they are rather expensive articles to buy, it may prove a boon to many amateurs to know that it is quite possible to make very serviceable wheels oneself. Besides, there is the pleasure of making them, and the satisfaction which every genuine mechanic (I mean amateur genuine mechanic, not genuine amateur) feels at having supplied his own wants. Many amateurs who live near a good tool shop, and are possessed of plenty of means, have their workshops crammed with everything that the heart of workman can desire, but I doubt if they enjoy their work half so much as he who makes his own tools and appliances. It is much to be able to say of some piece of finished work, "I made it all," but much better to be in a position to say, "I not only made *that*, but the tools with which it was made are my own manufacture also." Now my idea of WORK is that it aims at providing its readers not only with instruction as to "what to make and how to make it," but that it strikes at the root of the matter of success in all mechanical work by showing us how to be thorough-going and therefore independent workers.

It is with the hope that I may help to carry out this latter object that I contribute my "mite" in the shape of some hints upon the making of polishing wheels and artificial whetstones.

I do not pretend that they are as good in every respect as those manufactured by the trade, but they have stood me in good stead in many a job, and I may say that I never knew what comfort, with respect to edged tools, was until I had supplied myself with these home-made articles.

I shall begin with directions for making a coarse-grained wheel for rough work, such as grinding chisels, etc., etc., and here it may be asked, "Why not use an ordinary grindstone?" But that is just my point, and my answer is that I find the artificial stone, driven in a small machine (something like that shown at page 119 of Melhuish's catalogue, only a little heavier, and which carries all my wheels), answers better than any ordinary stone, except, of course, for large tools.

Such a wheel as just mentioned should be about nine inches in diameter, an inch and a half wide, and may be composed of emery or sand.

If of the former, what is known as grinding emery should be used; and here it may be well to point out the different names by which emery powder is known:—1. Corn emery; 2. Coarse grinding emery; 3. Grinding emery; 4. Fine grinding emery; 5. Superfine emery; 6. Coarse flour emery; 7. Flour emery; 8. Fine flour emery; 9. Superfine flour emery.

No. 3 will suit best for our present purpose, but as the grain of this powder is coarse, it will be necessary to add some fine powder in order to supply "body" to the mixture of which the wheel is to be composed; in other words to fill up the chinks which occur between the grains of the coarse powder. The other ingredients required are shellac, resin, and a small quantity of cycle cement. The proportions of these ingredients are as follows:—No. 3 emery powder, 3 lb.; emery flour, washed, 1 lb.; shellac, 4 oz.; resin, 1 oz.; cycle cement, 1 oz.

The flour emery should be washed by mixing well in water, allowing the coarser particles to subside, and pouring off the water. This is necessary because the fine dust would absorb more than its share of the shellac in the after process of melting. The shellac is pulverised as finely as possible in a metal mortar, or, failing this, it may be powdered by tying it up in a closely woven cloth, and beating it on a block with a heavy pestle or mallet. Whichever method is employed it must be reduced to powder which will pass through a fine wire sieve.

The resin and cycle cement are treated in the same way, and if a small quantity of emery powder is mixed with the latter while pounding it will expedite the operation, otherwise it is rather a difficult substance to reduce to powder; but I find it admirable for supplying *toughness*, and much more workable than vulcanised rubber.

When the shellac, etc., have been pulverised and passed through the sieve, all ingredients are well mixed together.

A suitable mould must now be prepared; this should, of course, be of the exact size of the proposed wheel, and I have always used the bottom portion of some tin vessel for the purpose; for the smaller-sized wheels an old lobster tin, etc., but for this large size it is not always easy to find a suitable vessel. I use part of a drum in which soft soap is sold, which is 8½ in. in diameter, but the reader will provide for himself; whatever is used it must be perfectly round, about 1½ in. deep, and as free from dents as possible.

Paint the mould all over the inside with an even coat of blacklead mixed with beer, etc., and when dry it is ready for use.

A considerable degree of heat has now to be applied to the mixture, and great care will be necessary lest the shellac, etc., be burned. A good vessel to use is a small cast-iron frying pan, *not* a thin sheet iron one on any account, or the result will inevitably be failure.

Place the pan upon a hot, clear fire, and stir the contents with an iron spoon, etc., scraping the mixture from the bottom of the pan as it melts, and removing from the fire if it shows any sign of burning. It should not be heated sufficiently to smoke, and the heating should only be continued until the mass has become thoroughly incorporated. Do not expect it to melt in the sense of becoming fluid, but when it has become thoroughly heated, turn out into the mould as quickly as possible, and ram well so that there may be no breaks or flaws. As this mixture keeps its heat for a considerable time, especially in case of a large quantity, it will be safe, in this instance, to cover the bottom and sides of the mould with a thick coat, and when this is well pushed in, fill up with composition from the pan, which should be kept hot during the operation.

When the mould is full, or when the required thickness is obtained, the upper surface should be smoothed over, and the edge made compact, so that when the wheel leaves the mould there may be no flaw or gap at the corners of the cutting face. This smoothing should be done with a broad, pliable knife, or "spatula."

The packing of the mould is one of the most important parts of our subject, as unless the composition is well pushed in there will be flaws on the under side and edges of the wheel, and also the operation has to be so quickly performed, in order that the surface may not have time to cool, so that the second application may merge in the first.

Any one who has watched workmen laying down "val de travers" or any asphalt roadway will have a good idea of the consistency of this emery composition, and also the method of working it, as the substances and their treatment are very much alike. When the mould has become cold, the wheel may be easily turned out, and the next step is to make a hole through the centre for the spindle.

Find the centre on each side with a pair of compasses, and bore with a red-hot piece of round iron, of a suitable size—that is, something smaller than the spindle. Be careful to make the hole at right angles to the sides of the wheel; and when made, but still hot, press the spindle through and screw up.

The wheel may now be run in the lathe at good speed, and trued up with a red-hot iron.

If the mould has been right, and the hole has been carefully bored, the wheel will be fairly true, but it will be necessary to have it perfectly so.

Use a rather thick iron which will retain heat for a considerable time—an old large-sized flat file is what I always use. While red-hot hold it to the sides of the wheel until the surface becomes slightly melted, when, by applying the edge of the tool, any unevenness may be easily removed.

Owing to the speed of the wheel, there is great danger of the hot particles flying into the face of the operator, and this should be guarded against by watching the effect of the hot iron through a piece of glass, which may be held in the left hand or by another person.

The face is then made true by the same means, and our first wheel is made.

Thus far, at the risk of being thought tedious, I have entered into all particulars, however simple, knowing from experience that there are few things requiring more careful manipulation than the subject in hand. Remembering many failures resulting from ignorance of these details, I give them in the hope that any reader who makes the attempt may be spared much trouble and disappointment.

Another good wheel for rough work may be made of sand, two parts, powdered glass, one part; the other ingredients in the same proportion as in the wheel already described.

The sand should be what is known as "silver sand," and must be well washed, thoroughly dried, and allowed to become cold before mixing with the other ingredients.

The glass may be composed of any fragments of broken decanters, dishes, etc., usually to be found about a house. It must be pulverised in a metal mortar, and passed through a fine wire sieve.

In Spon's "Workshop Receipts" the direction is to melt the shellac and stir in the sand, etc., but I do not think this practicable, as the shellac is so small in bulk compared with the other ingredients, that it would be impossible to incorporate, say, two pounds of sand with two ounces of shellac, unless the two substances were thoroughly mixed while cold and in powder.

It must always be borne in mind that we should aim at using a minimum of shellac, resin, etc., otherwise, whilst the forming of the wheel will be comparatively easy, its efficiency will be lessened, as the excess of resinous matter causes the pores of the composition to clog; in fact, this is the great difficulty to be overcome with all wheels of the kind, and the only preventative, even in the case of the best, is to keep up a constant and copious supply of water during use; either running the under side of the wheel in water, like an ordinary grindstone, or by a constant drop from a small cistern of some kind above the wheel.

So far, I have given directions which are only the expanding of receipts obtained from such sources as Spon's books, etc. If there are any other published instructions on this subject, I have never been fortunate enough to come across them; but although this method works well in the case of such rough wheels as above described, I have not found it satisfactory for those of a finer make. My experience of shellac is that it is very difficult to reduce to a very fine powder; and that even when finely pulverised, it is rather unmanageable in combination with such substances as those which form the other ingredients in polishing wheels, etc. When mixed with these ingredients in a dry state, and then heated, it is apt to become absorbed by them, and the mixture therefore refuses to bind; if heated to excess in the least degree, the same result ensues; if insufficiently heated, the gritty and resinous substances fail to become thoroughly amalgamated, and the mixture is honeycombed and crumbles when cold; whilst if the shellac is at all in excess, the wheel, etc., as mentioned before, will clog in use, and is therefore worthless. Encountering these and other difficulties, I was led to adopt another method which proves most satisfactory, and is, as far as I know, unusual. The process is briefly as follows:—In the first place I dissolve the shellac in methylated spirit, forming it into a thick paste, and then, heating the dry emery, etc., I mix the whole, working it thoroughly until all the gritty particles are incorporated in the shellac.

To reduce shellac to a thick paste, put, say, three or four ounces into a small vessel, and pour about a wineglassful of methylated spirit upon it. Boil water in another vessel something larger than that which contains the shellac, and, when boiling, place the latter in it. The shellac will soon melt, and the boiling point of spirit being much lower than that of water, the gum will quickly be reduced to a thin liquid, which, upon cooling, will become a paste.

If, however, it remains liquid when cold—the consistency should be that of thick treacle—place it again in the boiling water until more spirit is evaporated, and by this means the proper consistency may be obtained.

The next step is to prepare the other ingredients. For each ounce of shellac, Spon recommends a piece of resin the size of a walnut. This I think a little in excess, and use twice this quantity to three ounces of shellac.

Powder the resin in a mortar, and then take the same quantity of cycle cement, and melt it in some small metal vessel. When melted, add the resin and a small quantity of the shellac paste. When well mixed, this should be added to the proportion of shellac required for the work in hand, the whole being again melted and thoroughly mixed.

Now heat the emery powder and other grit in some metal vessel. I always use home-made copper bowls for all these operations, and find them more satisfactory than iron pans, ladles, etc., as the heat takes effect so much more quickly, and may be more easily regulated, which is a very important consideration in all these processes. For the method of making these copper bowls, see my "Hints on Hollow Work in Sheet Metal" in No. 18, page 282.

When the emery, etc., is quite hot, apply heat once more to the shellac, and, having placed the powder upon a metal slab, which should also be moderately heated (a piece of sheet iron fixed above a spirit lamp will serve in the absence of a thicker slab, which would retain the heat), with a strong knife or small trowel work up the powder and shellac, when the latter, being partially diluted with spirit, will thus be equally distributed through the mass, and will coat each particle of the powder.

The mixture is next returned to a metal vessel, and subjected to a strong heat, great caution being necessary not to burn it. This will drive off the excess of spirit, and more thoroughly melt the shellac, and when this object is accomplished, turn out the mixture as quickly as possible into the prepared mould and proceed as before directed.

The following are some of the substances which I have found most useful for the finer wheels, etc.:—1. Fine emery, 2 parts; washed flour emery, 1 part. 2. Finest emery, 1 part; washed flour emery, 1 part. 3. Fine emery, 2 parts; very finely powdered glass, 1 part. 4. Washed flour emery, 2 parts; Oakey's Wellington knife polish, 1 part. 5. Fine powdered glass, 1 part; fine powdered pumice (washed), 1 part. In each case shellac, resin, and cycle cement in the proportions before directed.

All of these mixtures when moulded in flat cakes also make excellent artificial whetstones and slips, which will be found most useful for various purposes; and the ease with which they may be grooved, or made to assume any desired shape while hot, renders them peculiarly suited for sharpening carving tools, etc. etc.

I strongly recommend all workmen to adopt my plan of making polishing wheels at home. It is not work that presents any special points of attraction in itself, but it has the eminent merits of being useful and practical although not ornamental.

LOCK REPAIRING AND KEY FITTING.

BY THOMAS WILSON.

REPAIRS OF WORN KEYHOLE—COMMON BACK SPRING LOCK—DESK LOCKS—MORTISE LOCKS—PADLOCKS.

MOST of the locks that are made now are bushed at the keyhole with a small extra plate to avoid wear, but the lock shown in the last paper and a few others are made without a bush, so that occasionally the keyhole is worn away, and the key works loose in the lock. Fig. 3 shows covering plate of lock with worn keyhole. If it is only slightly worn, it can be remedied by making a number of centre punch marks with a centre punch, as shown in Fig. 2; but the keyhole of lock case cannot be done in this way without removing the bridge ward, which is rather a troublesome job. The best way to bush a lock is to cut out a small brass plate with keyhole, and solder or rivet it over worn keyhole, but as this is rather a difficult matter for an amateur, I will describe another plan, which, although it may not look so well, will answer the purpose. Every one is familiar with the iron washers used for putting under the heads and nuts of bolts. Buy two of these at an ironmonger's, of a size to fit over the pin of the key—about $\frac{5}{16}$ in. will be required for a key similar to that shown in the sketch of lock which appeared in the last article—and file one side of them bright; now scrape or file the keyholes of lock bright, and lay the washers on them with the bright parts downwards. Procure a pennyworth of spirits of salts (muriatic or hydrochloric acid), pour it in an old cup or gallipot and put some scraps of zinc in it—if you have not any old zinc get a pennyworth of zinc nails. When it has done boiling, put a little of the spirits on the washers and keyholes, place a small piece of solder on the top of them, and hold them in the flame of the gas or over a clear fire until the solder melts, then lay them on one side to cool. They will now appear as shown in Fig. 4, and after the part marked A is filed away they are completed. The collar of the key will probably require filing back to allow for the extra thickness of the bush. A soldering fluid called "Solderine" is sold by most ironmongers. This preparation is ready for use, and does not require "killing" with zinc before being used. A stick of blowpipe solder can be bought for a penny or two, and the washers at a penny a dozen.

Fig. 1 shows the interior of a common backspring lock. The cheapest way to repair these is to take them off, buy a new one and throw the old one away. A lock of this description can be bought for 4d. or 6d., so that it will be seen it does not pay to repair them.

The old lock should be taken as a pattern when purchasing a new one, so that the new lock may fit in the same place. It is sometimes difficult to get a new one of the same pattern as the old, and then it becomes a question whether it is better to repair the old one or to cut the woodwork for a new one. If it is decided to repair the old it will probably be found that the spring is broken. This can be easily remedied by cutting off a piece of a stout feather spring, and fitting it in the slot of the bolt at B. To get the bolt (A) out, bend back the rim gently at C, afterwards bending it into position when spring is fixed. If a new pin is required, a piece of wire must be used considerably larger than the pipe of key, and filed down so as to form a shoulder as shown at A, Fig. 5. The pin must then be held in the vice at C, and the part marked B rivetted into the lock.

In small locks, such as desk locks, the bolt is sometimes broken. These cannot be repaired, as any extra thickness at the place where it is broken would prevent the bolt from working, but it is comparatively easy to make a new one. The broken pieces should be filed bright on one side, and laid on a piece of brass of the same thickness, and soldered on as described in bushing a lock. Now file away the brass plate around the old bolt, hold it in the gas to melt off the old pieces, and you will have your new bolt. (Fig. 6).

Before finishing with warded locks, it may be as well to say a word about mortise locks. If these are out of order, it will usually be found to be either the spring or the follower that is wrong. To repair or replace these the lock must be taken off, and,

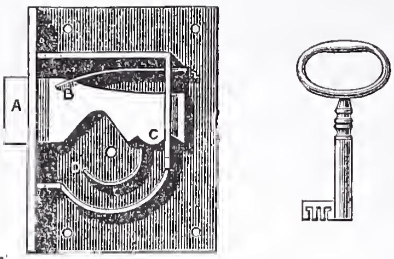

Fig. 1.—Interior of Common Back Spring Lock.

Before taking leave of warded locks, I may mention that when a new key is required it is not always necessary to get a blank and cut the wards. All ironmongers keep a large stock of keys with the wards ready cut, and one can generally be found that will fit the lock with a little alteration. As these are the same price as blanks there is nothing gained by taking a blank if a key can be got instead.

In lever locks, which I shall take occasion to describe in the next paper, keys *must* be cut from blanks. It would be useless to enumerate all the patterns of warded locks in use, as it would fill several numbers of WORK, and would serve no useful purpose, as the directions for cutting the key to rim lock, as described in No. 21 of this Magazine, are really applicable to all warded locks. But should any difficulty arise, I shall be pleased to answer any correspondent who may stand in need of assistance through the medium of "Shop."

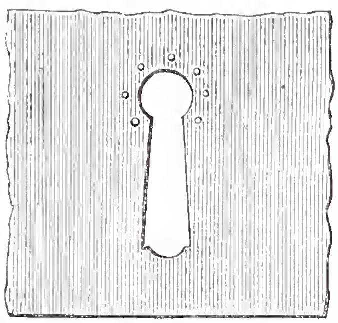

Fig. 2.—Mode of Repairing Worn Keyhole by Enlarging Hole.

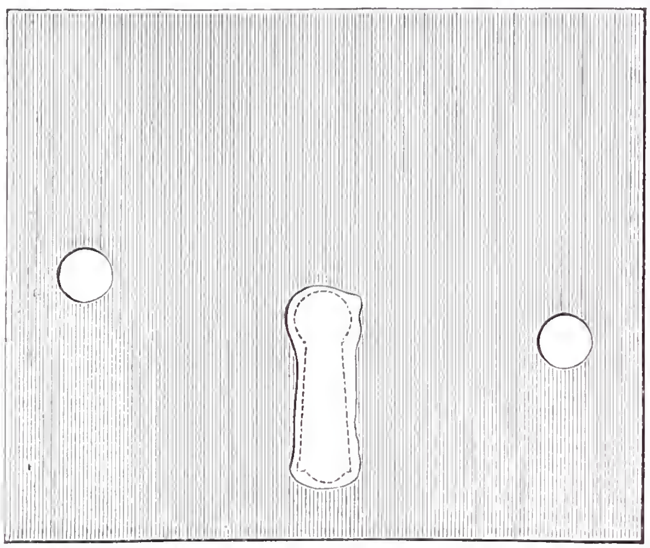

Fig. 3.—Covering Plate of Lock showing Worn Keyhole.

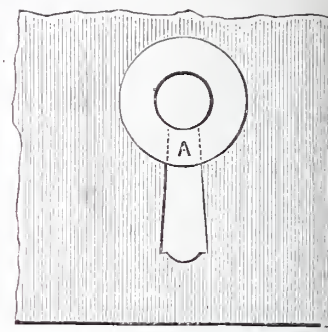

Fig. 4.—Mode of Repairing Worn Keyhole with Iron Washer.

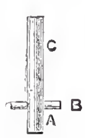

Fig. 5.—Mode of Repairing Pin.

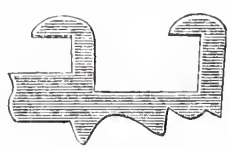

Fig. 6.—Shape of Bolt of Drop Lock.

although this is a simple matter, it may be as well to describe how it is done.

Fig. 7 shows the edge of a door with mortise lock fixed. To take it out remove the knobs and spindle, then take out the screws of face plate A A, under this will be found two other screws. These must be taken out, then if the screw-driver is inserted in the keyhole, and the lock pushed forward, it will come out sufficiently to be grasped by the hand and pulled right out. If the follower is worn out, a new one must be fitted. Those for mortise locks (Fig. 8) and indeed for most rim locks, are not riveted in as described in my last paper, bu work between the two plates of the lock The old one should be taken as a pattern in buying a new one, but it will probably require a little alteration before it will fit. The spring is pretty certain to be a feather spring, and a new one can be bought for a penny, as mentioned in my last paper. The screws of face plate are very short, and liable to be lost; should this be the case the plate can be fixed by ordinary screws, long enough to reach the woodwork.

Keys to padlocks must be fitted by examining the wards, as far as possible through the keyhole, or by blacking the blank as previously described. Warded padlocks, however, can be instantly picked, by holding the lock on one side and raising the tumbler with a pick, when the bolt will drop back by its own weight.

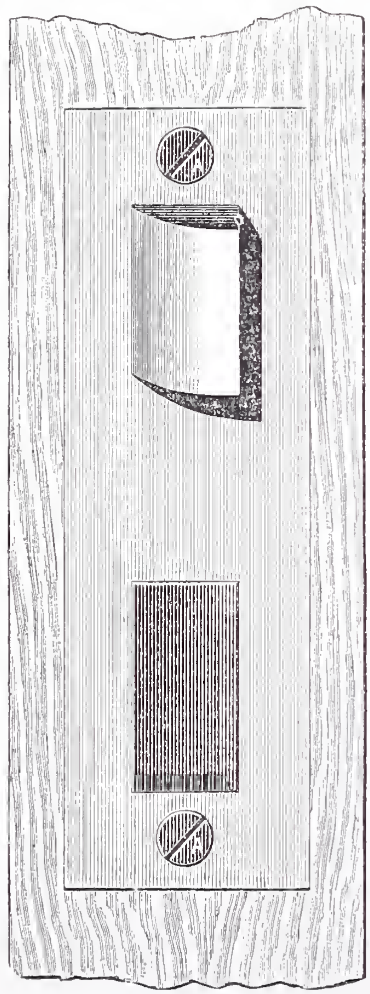

Fig. 7.—Edge of Door with Mortise Lock Fixed.

A FEW WORDS ABOUT SCRAPERS.

BY A CABINET MAKER.

IN a recent article in WORK, called "Friendly Hints to Amateur Wood Workers," by D. Denning, the writer alluded to the use of the scraper. At the time, I must confess the necessity of calling attention to such a well-known tool did not occur to me, or rather it occurred to me as being superfluous. "Surely," thought I, "everyone must know about the scraper without being told," and I wondered why the writer did not tell us about something we did not know of. The utility of mentioning even the ordinary tools of one's own trade, soon however, became evident to me, for a customer, who is hardly an amateur in his own calling, dropped in and referred to WORK, speaking of the article above referred to from an amateur woodworker's point of view. I know he does a little bit in the cabinet making line, and one thing leading to another, he said he would like to know something more about the scraper which he had seen mentioned. He had heard of it before but did not think it much use. Was it really important to use it? How was it made? and a good many other questions besides. Not that I minded being asked them, for the querist is a pleasant young fellow, who does not come bothering about, interrupting and hindering one at his work with all sorts of silly notions, leading one to suppose that he thinks he is conferring an honour or, at the least, condescending very much to ask opinions from a tradesman. Amateurs like that can't be much surprised if they get a rebuff, but if they will be content to ask without pretending to teach, they will not often find that an artisan is afraid to let them into what they call trade secrets. Herein, if I may express an opinion which is not immediately connected with scrapers, this Magazine will do a great deal of good. It concerns itself with both amateurs and professionals, who will by it be more drawn into contact with each other. The result can only be beneficial to both. All this, however, is rather a digression, which I have been drawn into through noticing the stand-offishness of some gentlemen amateurs, and the rather extraordinary way in which they sometimes meet the artisan. Personally, I never object to tell anyone what he wants to know if he will come and say straightforwardly what it is, or if it is any matter I don't feel myself at liberty to speak about I tell him so. When, however, he comes as though he were afraid to ask, and, as it were, tries to worm the desired information out of one, then I "dry up." If he thinks he will be so clever in extracting my supposed trade secrets from me, then I am vain enough to think he shall not. Now, no doubt, some adopt this course through diffidence or fear of intruding, and this feeling of reticence on their part cannot be blamed, as a tradesman's time means money to him. When, however, a good practically-minded amateur is willing to learn, I don't think there are many men who are such churls as to refuse to tell him what they can. There are a few, but there are not many, and in my own experience I have rarely come across one. There is one kind of amateur who won't get to know much; I mean the man who does not care to lie under a supposed obligation, but wishes to pay for lessons. A very praiseworthy wish on his part, but he sometimes spoils the effect when terms come to be spoken of. A case in point occurs to me, and will show very well what is meant. A wood-carver among my acquaintances, one who is always willing to tell anything he can while going on with his work, was asked to give some lessons at the pupil's residence. Said would-be learner was willing to pay—listen, brother craftsmen, and amateurs too, for future guidance—the fabulous sum of sixpence per hour. The offer was, of course, indignantly refused. Committees and such-like self-promoted bodies for the spread of fine art labour have been known to fall into similar mistakes. Now I hope no amateur will take these remarks amiss. I don't think they are couched in offensive language, and I think sensibly-minded men will give me credit for wishing to put them on the right tack for getting over any little difficulty they may encounter in their pastime.

With regard to the scraper, very likely there are others, besides the reader I have referred to, who would like to know something about it. Certainly it is much easier to tell and show anyone how to use it than to explain on paper; still the thing is so simple that no doubt I shall be able to make myself intelligible. It is difficult to know exactly what a man who is quite unacquainted with a tool wishes to be told about it. It all looks so simple to one who has been in the habit of using it, that he is apt to condense his information when asked to explain how it is used, and tell his inquirer to do so in "the usual way." Correct enough, no doubt, but hardly specific enough to enable one who has never seen the tool to use it effectually. Perhaps in this instance I cannot do better than incorporate the questions and answers on the occasion referred to.

To begin with, the scraper is a thin bit of steel of any convenient size, say about 5 in. long by $2\frac{1}{2}$ in. wide. I don't know the exact gauge of the metal, but $\frac{1}{8}$ in. would be too thick. Scrapers are to be bought for a few pence each, but they may very easily be made from a piece of a broken saw. The edges, after the piece has been separated with a cold chisel, must be filed down

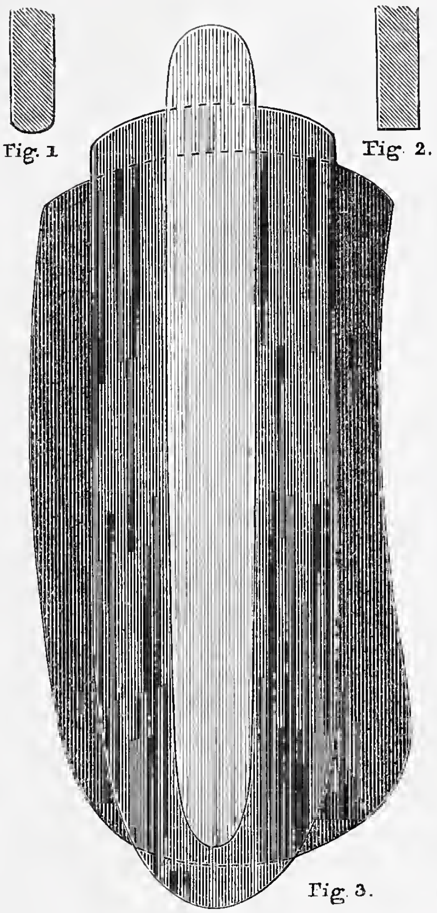

Fig. 1.—Edge wrongly formed. Fig. 2.—Edge rightly formed. Fig. 3.—Outlines of Shaped Scrapers.

straight and square. If it is to be a scraper for flat work, of course it is necessary that one side at least must be perfectly true. This can easily be made by running the file lengthways along the edge, which must afterwards be smoothed down by a rub or two on the oilstone, just enough to remove the file marks. It is necessary to be careful not to round the edges like Fig. 1, but to keep them perfectly square like Fig. 2. Both these illustrations, of course, are given in section on a very much enlarged scale to prevent mistake. The edge, it will be seen, is not a cutting one, but scraping in its action. Such an edge as shown in Fig. 2 will certainly scrape, but the operation would be so very tedious that the tool would be practically worthless. To sharpen it properly is not a difficult operation, but it is one that requires a certain amount of knack, which, however, is soon acquired with a little care and attention. It is not so much sharpening that is required as turning the edge over to form a kind of burr on each face of the steel. A properly-sharpened steel can, apart from its action on the wood, easily be told by holding the plate between a finger and thumb of one hand and moving it with the other, when a very perceptible burr should be felt. A suitable piece of steel does not require much sharpening; a few strokes with the sharpener is all that is necessary. The sharpener may be any hard bit of steel, but perhaps there is nothing to beat the "currier's steel." This is a thin steel rod set in a handle, and, I believe, can be obtained at most tool shops, but instead of it any hard, smooth piece of steel will do almost as well, the rounded back of a gouge for instance. To sharpen the scraper, support it firmly on the bench with the left hand, the edge to be treated being perpendicular. Then draw the sharpener with a smart firm stroke along the edge a few times. Don't rub it up and down irregularly, but take vigorous sweeps with even pressure from top to bottom. If the sharpening is too prolonged, it may have a contrary effect from that intended, as the burr may be scraped away. As I said, to do the sharpening properly requires some knack, though it looks so easy and really is. If the novice can't manage to acquire it after a few trials, he will do well to ask some one to show him how, or better still, let some competent man see how he does it. The chances are that he will detect some fault at once.

When the scraper is properly sharpened, the next thing is to learn how to use it effectively. Scraping is rather laborious work, but when a really finely-finished surface is desired, it is not well to avoid the drudgery. Both hands are used, the thumbs bearing a good deal or most part of the hard work. To show the action of the scraper and the way to hold it is easy enough, but to describe it without fear of being misunderstood is another matter. However, I don't think any one can go far wrong if he will attend to the following directions. I may as well say that it is chiefly on large flat surfaces that the scraper will be found most beneficial. From this it follows that one of the long edges is mostly in requisition. This being so, grasp the scraper in both hands, the thumbs being on the inner or nearer side, and pretty near the centre, and the other fingers so disposed that they have a good grip. Now incline the top edge of the scraper away from you, the lower edge being pressed on the wood. Then scrape, the motion being always a pushing one, with the steel held at an angle to the wood. The sharp edge will scrape off the surface and leave it smoother than any plane almost could do. Of course, discretion must be used not to apply the scraper too much in one part to the exclusion of others. It will be noticed that the pressure of the thumbs causes, or ought to cause, the scraper to bend forward a little in the centre, so that sharp corners are kept from digging accidentally into the wood. It is for this reason that steel $\frac{1}{8}$ in. thick would not do. A certain amount of pliability is essential. As soon as the edges refuse to bite properly it is time to sharpen them again, and if in course of time they get rounded off, a rub with the file or on the oilstone will soon put them all right again.

Scrapers need not be always rectangular, as this shape is only required for flat level surfaces, but their edges may be curved to fit any special surface. For instance, here are three outlines of scrapers in actual use, given in full size (Fig. 3). They are not often required; still they come in handy sometimes, and when a special curve is wanted it can easily be filed down. There is no fixed size for such fancy scrapers, as everything depends on the work they are intended for.

With these remarks the subject must be closed. I don't think any material point which the ingenuity of the worker can't get over has been omitted. If it has, no doubt inquiries will be duly answered in the "Shop" column, and as I see WORK has a very extended circulation in the town where I reside, I don't offer to tell all and sundry who might call on me for lessons on scraping. Hence I merely subscribe myself a "cabinet-maker." As an excuse for the crudeness of my style, I may further say I am "one in the white," *i.e.*, without "polish," but so long as the "stuff" is right, that is only a secondary matter. Good furniture is recognised more by the material than by the polish, which is, like this concluding sentence, only a "finish."

SOME ARGUMENTS IN FAVOUR OF VENEERING.

AN EXAMINATION OF SIR CHARLES EASTLAKE'S OBJECTIONS TO VENEER.

BY DAVID ADAMSON.

ONE objection that often operates against veneer in popular opinion is its alleged want of durability. I say in popular opinion, because those who are most capable of judging, that is the people whose business it is to be in constant contact with furniture, know perfectly well that veneering is not a source of weakness, even if it does not increase the strength, as it is sometimes considered to do.

The question of strength is, however, of secondary importance when compared with durability, and on this score there may possibly be some objections of rather more weight than some of the others which have been alluded to. It must not, however, be inferred from this that furniture when veneered is not quite as reliable for ordinary purposes as when solid. It is only less so when constantly exposed to a moist, warm atmosphere, such as that of some tropical regions during the wet or rainy season. In this country veneers may be used without fear of their not remaining in good condition, always presuming, of course, that the articles of which they form part receive fair usage, and that the veneer itself is properly laid on a suitable foundation; we do not require to make furniture as if it were to be constantly exposed to all the changes of weather. It must be made with due regard to its subsequent use and position, and if this be done, it is a very questionable argument to urge against veneer, or any other method of construction, that it is not adapted for furniture. It would be reasonable to say that veneer is not fit for the external parts of buildings, and it may fairly be supposed that architects when decrying veneer sometimes, overlook the fact that furniture is not exposed to hail, rain, and storm. It is well known that architects are seldom successful designers of furniture, and this may be, altogether apart from their not understanding its construction, to a great extent attributable to the apparent impossibility of freeing their minds from ideas of the larger structures they are commonly called on to devise. I am aware that these remarks may not be altogether palatable to members of the architectural profession, who commonly suppose themselves to be capable of designing, not only furniture, but anything else connected with the house; without, however, in any way wishing to cast reflections on their skill, it must be said that they are not the most competent people to express an opinion on domestic furniture. Some few of them may be acquainted with the subject, more or less, according to the time they have devoted to it, and their opportunities of studying it practically. They then are equal to the furniture designer who is a specialist, in fact they have qualified themselves to design furniture. Among such, the late Bruce Talbert may be instanced, and, to a smaller degree, Sir Charles Eastlake. To both of these, by their work in connection with furniture, much of the improvement which has taken place within recent years, may be ungrudgingly attributed. Eastlake, however, as is shown by more than one remark in his admirable book, "Hints on Household Taste," was only partially acquainted with furniture, or rather (should I say?) with the furniture industry, with its commercial or £. s. d. aspect; without a knowledge of which no man can be thoroughly competent to correctly judge of the capacity of cabinet-makers to design and manufacture sound artistic furniture.

As Eastlake is by many regarded as a thoroughly reliable authority, it may be well to see what he has to say about veneering:—

"Veneering has been so long in vogue, and is apparently so cheap and easy a means of obtaining a valuable result, that it is always difficult to persuade people of its inexpedience. Veneering has been condemned by some writers on the same grounds on which false jewellery should, of course, be condemned. But the two cases are scarcely analogous." Then after referring to the practice of silver-plating, which he states is "too universally recognised to be considered in the light of a deception," he continues, "I do not see exactly how veneering is to be rejected on 'moral' grounds." Further, the impracticability of using walnut wood, by which it may be presumed *burr* walnut is meant, in any other way than in veneers having been admitted, he states that when, "for instance, in piano cases the leaves are so disposed as to reverse their grain symmetrically, the arrangement is not only very beautiful in effect, but at once proclaims the means by which that effect is attained. There are, however, many practical objections to the mode of veneering in present use. To cover inferior wood completely in this fashion, thin and fragile joints must be used, which every cabinet-maker knows are incompatible with perfect construction. The veneer itself is far too slight in substance, and even when laid down with the utmost nicety is liable to blister, especially when used for washing-stands, or in any situation where it is exposed to accidental damp. It is never worth while to buy furniture veneered with mahogany, for a little additional cost may procure the same articles in solid wood." He next refers to a "substantial oak table," which he had made from his own design "at a price which was much less than I should have paid for one veneered with rosewood or walnut." "The most legitimate mode of employing veneer should be in panels of not less than a quarter of an inch in thickness, and, if used for horizontal surfaces, the inferior wood should be allowed to retain a a border of its own in the solid."

I have ventured on this fairly long quotation in order that both sides of the vexed question of veneering may be presented to the reader, and Eastlake's remarks are fairly typical of some of the more commonly urged objections, though it must be admitted he writes in a more unprejudiced manner than some of those who have discussed veneering. Some of his remarks having already been disposed of, others may be taken and examined. In the first place, he refers to it as a cheap and easy means of obtaining a desired result. Now this, I think, most cabinet-makers will dissent from, for they all know that veneering increases the cost of any article, and that it is not what may be considered easy. About the cost I shall have something more to say shortly, but this seems a suitable place to make a few remarks about the "easy" part of the work. I don't mean to say that it is really difficult to an expert artisan, or that the physical toil is great, but for all that, if by easy we are to understand that it can be managed properly without skill and experience, then it must be acknowledged the term is incorrect. To lay veneers thoroughly tests the skill of the worker, and is a constant tax on his general intelligence, so that one who can manage veneering is by no means a mere mechanic. He must have brains and be able to use them as well as his hands. Perhaps the qualifying word "apparently" should be looked on as an admission that this is the case.

The observation about walnut veneers proclaiming the means by which the effect is produced when laid in a particular way, bears out to some extent what has been previously said about veneers not being deceptive. Of course, when laid in the way Sir Charles admires, any one can see that veneers have been used, but in any case the practised observer is very rarely at a loss to tell when wood is veneered. The deception then is only in degree varying according to the perceptive powers of the beholder, and seldom depending only on the way in which the work has been done.

The statement that thin and fragile joints must be used whenever an inferior wood has to be covered with veneers will be news to most practical men, at least to those who have not read "Hints on Household Taste," and one almost wonders how its talented author can have been led into making such an extraordinary assertion. That bad joinery may be concealed by veneer is, no doubt, incontrovertible, but that fragile joints are by any means necessary or usually connected with veneered work is, fortunately, not correct. In practice the jointing used in any piece of furniture is the same whether the surface is veneered or plain. It may be good, bad, or indifferent, according to the worker's skill, but the veneering, *per se*, makes no difference whatever, so that this objection, which might carry weight, may be dismissed.

Were it not that silence about the statement that veneer is too slight in substance, might be construed into an admission that it is so, that expression of opinion would be passed over for what it is worth. Beyond custom there is no arbitrary limit to the thickness of veneer, and without knowing what thickness Sir Charles Eastlake had in mind when writing, it is rather difficult to say that it is too thin. It is sufficient for us to know that veneer as ordinarily cut is quite substantial enough for ordinary usages. Something more will be said later on about thickness of veneers, meanwhile it will be sufficient to state that wood one quarter of an inch in thickness would hardly be regarded as a veneer in the ordinary sense of the word.

That veneered surfaces, to pass on to the next objection, are liable to "blister" is not to be denied, though the liability is not so great as an inexperienced person might suppose on reading the quotation in which it is mentioned. Indeed it is so very small, when veneers are properly laid with the utmost nicety, that it may almost be regarded as non-existent. Blisters generally indicate bad workmanship, and they are so well under control that where they are found it is generally safe to infer that they depend more on careless manipulation and supervision, or subsequent improper usage than on any inherent defect in the form of construction. Occasionally an apparently causeless blister will show, but very rarely. If any rise after the article has left the workshop, it may generally be taken for granted that damp has been the cause. Of course, no one could defend the use of veneered tops for washstands any more than he would advocate the employment of brown paper bags for toilet basins. Marble is so commonly adopted for washstand tops that it seems almost needless to suggest that these are sometimes made of wood. It will be observed that in the quotation from the "Hints" no mention is made of any special part of a washstand, but I infer the top is meant, as no other part is liable to come in contact with any exceptional amount of water. So far as accidental damp is concerned, it may be said that few articles of furniture will stand much of it whether they be veneered or not. If we are to discard veneers for this reason, we must go a little farther and refuse to admit any upholstered piece of furniture into our houses—nay, let us go the whole hog at once, and have nothing about us that will ever wear out or that can, by fair or foul means, accidentally or designedly, be injured. Then, and not till then, may we consistently say that we object to veneer because it might be injured by accidental exposure to damp. We have only got to act up to the idea of getting absolutely imperishable things to land ourselves on the heights of absurdity (wherever these may happen to be situated).

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

CONNECTIONS AND BEARINGS—EXPANSION JOINTS AND BEARINGS.

APART from the joints in each distinct part of a structure, such as cross and main girders, there remain to be considered the connections of these parts with each other, and also their bearings upon each other, and upon other places of support. The bridge flooring itself may be carried by cross girders, by cross girders supporting longitudinal girders or bearers, or by main longitudinal girders only. I shall take for example the most complete form, that in which longitudinal and cross girders both occur in the flooring, the latter being carried by the main girders. The covering of the floor will be separately dealt with subsequently.

In those cases where one girder rests upon the top of another, there is no question of load upon the rivets or bolts used, their duty being then confined to keeping the supported elements in their proper positions, and preventing them from being displaced laterally, or lifted during the passage of a load. In other positions, the load carried by the girder, together with its own weight, will come upon the connecting rivets, and it is always safest so to arrange the attachments, that they shall be in shearing stress, as we are more absolutely certain of their strength in that direction, than when relying upon the resistance of the head which, unless the workmanship is unimpeachable, may be open to some amount of doubt. The cross bearers in light foot bridges are commonly riveted up to the undersides of the main girders, but upon these the load is small, and the margin of strength very ample. On a foot bridge 10 ft. wide, with cross bearers 4 ft. apart, the maximum load would not exceed three tons, and the bearer would be held up by not less than eight rivets, which, allowed to be as little as $\frac{5}{8}$ in. in diameter, would show a *working strength* of more than twelve tons. When, however, we have to deal with the heavy traffic of road and railway bridges, the case is very different.

In studying the connections now under consideration, it must be remembered that at present we are dealing with plate girders only, in which the web, being continuous, can receive the load of the cross girders at any point in the length of the main girders without putting any bending strain upon either top or bottom flange. I call attention to this because a different state of affairs will sometimes occur in lattice girder structures.

In Fig. 11 is shown a method of connecting longitudinal with cross girders, the tops of the girders being made flush to receive the floor covering. A, A are the ends of two longitudinal girders in elevation, being nearly the same depth as the cross girder, B, B, to which they are connected; they are shown deep enough for the bottom flange plate of the longitudinal to run under that of the cross girder, in order to give continuity of structure. It, however, very frequently occurs that the cross girders are much deeper than is necessary for the intermediate longitudinals, as shown at D, D, ends of longitudinals attached to the web of the cross girder, E, E. Additional rivets are here introduced into the junction by means of the brackets, G, G, the ends of which rest upon the angle iron of the bottom flange. In the first figure, the joint is chiefly made by the angle irons, C, C, and in the second by angle irons, F, F, and brackets, G, G; E, E are the flanges of the cross girder. Below is shown a horizontal section of such a joint. H, H are the ends of the longitudinals; I, I, I, I the connecting angle irons; and K, K the cross girder.

It is very desirable in such a combination as the above, to take the load as fully as possible directly from the supported girder to the web of that carrying it, as by so doing the tendency to twist the cross girder on the passage of a load is much reduced, and an undue stress on the horizontal angle irons obviated. Terminating the top flanges of the longitudinals at M assists in this, and secures a flush top to the girders. As shown, the angle irons which connect the flanges to the webs of the longitudinal girders, are turned round at the corners, so as to form a solid continuous frame throughout; but when the girders are of considerable depth, say, 2 ft., the angle irons may be cut through, as shown at N, N, but the corners should be kept solid to protect the ends of the webs from diagonal shearing stresses. In setting out these girders, sufficient depth should always be allowed to admit of a comfortable joint being made, one that can be properly got at by the riveters so as to ensure good workmanship. This is a point that it strongly behoves the manufacturer to examine before commencing the work, for should the room available at these connections be insufficient, a bad and ricketty joint must result; and this being constantly made worse by vibration, the structure must in the end become shaky, and very likely, positively unsafe.

The next connections to be examined are those between the cross girders and the main girders. If it be necessary to place the former beneath the latter, they should be so suspended that shearing stress only is brought upon the rivets; this may be effected most conveniently when the main girder is of box section.

Box girders have two webs connected with the flanges by angle irons, as in single web girders. In order, however, to allow of the attachment of suspending pieces for the cross girders, the angle irons joining the webs to the bottom flange must be put inside the webs, as shown in Fig. 12, where A, A represent the lower parts of the web plates, and B the bottom flange, in vertical section. It is obvious that this form is only suitable for large girders where there is space between the webs to get at the rivets. The cross girder end, C, must also be of a form suitable for the attachment of the straps, D, D, by which it is carried, and of which four will be required, two on each side. The required form may be obtained by stopping off the central web of the cross girder at L, L, and there connecting it by angle irons with a strong diaphragm, and therefrom to the end, making it of box section, as shown at H, H. The side plates are joined to the flanges by angle irons, and stiffened by rigid internal frames, G, to afford a substantial hold for the lower ends, F, F, of the suspending straps; E, E is the bottom flange of the main girder, shown in vertical section on the dotted line, B, B. Referring again to the upper view, the straps, which are made of angle iron or steel, are fastened to the cross girder by the rivets, I, and to the webs of the main girder by the rivets, K. Both in these and the connections previously described, great strength is required on account of the concentrated nature of the loads to which they may be subjected; thus, in a railway bridge, the longitudinal girders and the cross girders receive the concentrated load on the driving wheels of the locomotive, and on ordinary road bridges that occurring in a heavy traction engine, or steam road roller.

When the main girder is single webbed, the cross girders cannot be thus suspended, and in any way that they may be attached to the bottom flanges of main girders, the load must, at length, hang upon rivet heads, if it is only on reaching those that fasten the bottom flange to the main angle irons. It is therefore necessary to fasten the cross girders to the main girder webs above the bottom flange, if we want a thoroughly reliable job; such a joint is shown at Fig. 13, where A, B is a vertical section of the lower part of a single web plate girder; C, the end of a cross girder fastened by rivets at D to the web of the main girder. The bottom flange plate of the cross girder is stopped at F, and the angle irons and web run on as shown, the former being fastened to the bottom flange by rivets, of which one is seen at G. N is one of the ordinary tee iron cranked stiffeners, and I an inside stiffener turned up at the bottom, and fastened to the cross girder by the rivets, E; thus the effect of the stiffener, I, is continued to the bottom flange, B. It is to be remembered, that to get the best result there should be enough rivets at D to take the whole load on the cross girder in shearing stress, and no pressure should come upon the flange, B, nor drag upon the rivets at E; then this connection, when properly fitted, makes a very solid piece of work.

Another arrangement is shown where the end, K, of the cross girder is placed higher up the web, and clear of the bottom flange. It is fastened to the web, N, by the rivets, L, and its position further secured by means of the brackets, M, M, placed above and below. An objection to this is that the bottom flange loses its stiffener on one side. In both these forms of joint, if the cross girders do not fall on the stiffeners, the web of the main girder must be supported by a plate on the other side through which the rivets holding the cross girder will pass, as the webs are generally too thin to be subjected

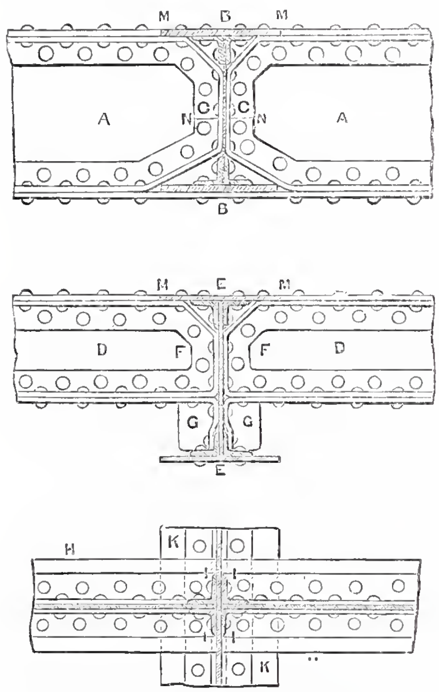

Fig. 11.—Connection of Longitudinal Girder with Cross Girder.

to the possible drag upon the rivets, due to the vibration set up by a heavy passing load, such as 15 tons, moving at a high velocity; and this will constantly occur on railway bridges, and on those carrying a double line of way there will sometimes be this on each end of the cross girder.

The expansion and contraction of the metal that occurs with change of temperature must, of course, be provided for when the work is of any magnitude; this variation of length amounts, in the English climate, to 1 in. in 150 ft. between summer and winter, and is provided for either by sliding or rolling bearings. If this expansion were not met, a great stress, equal to about 6 tons per sectional square inch of the metal endeavouring to expand, would be set up; and to me it seems curious that it has not been customary to provide for the lateral as well as the longitudinal dilatation of the material, for although the lateral movement will be less in distance than the longitudinal, it will be equal to it in intensity. The expansion bearings should evidently be arranged to move in a diagonal direction instead of in one parallel to the length of the main girders.

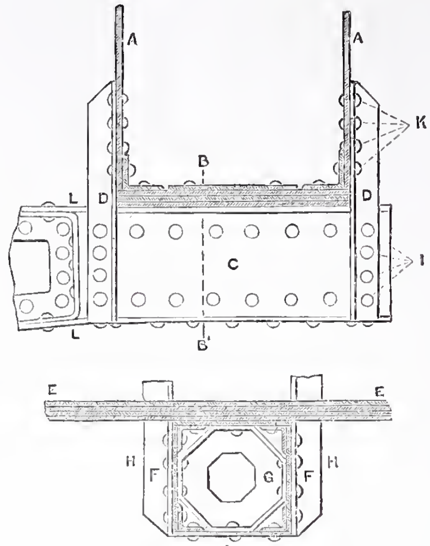

Fig. 12.—Connection of Cross Girder with Box Main Girder.

When the piers supporting the work are in themselves solid and stable enough to withstand the horizontal resistance of the friction of sliding plates, these may be used; but if there is any doubt upon this point, the girders must be put upon rollers. Where a number of consecutive spans follow on, if it is desired to connect them together, expansion joints must be introduced at intervals, and the same course pursued in regard to the flooring.

The expansion joints between the girders may be conveniently made by connecting them together by means of bolts passing through india-rubber washers of sufficient thickness to allow of the necessary expansion; such joints have been made with blade springs instead of the india-rubber washers, but such work is clumsy and would not be found in structures designed by men of experience.

There is another movement in the ends of the main girders that in large spans requires to be provided for, it is that caused by the deflection of the girders under a load which

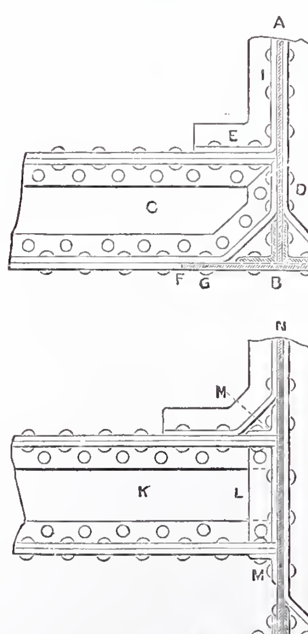

Fig. 13.—Connection of Cross Girder with Single and Main Girders.

will tip up the extreme ends. In short spans this movement is accommodated by bedding the girders on some slightly yielding material, such as felt; but in larger ones, a rocking bearing must be used, so that the load may be distributed equally over the surface of the bearing, otherwise the pressure will all fall on its inner edge. A side view of a rocking bearing upon rollers is shown in Fig. 14; A, A is the bottom end of the main girder, and to it is bolted a casting, B, B, preferably of steel. The upper surface of this casting is planed and fitted to the bottom of the main girder. This is done on an ordinary planing machine, the work being secured to a travelling plate which moves backwards and forwards under the cutting tool. On the under side of the casting is a hollow cylindrical surface, truly worked in a shaping machine, and this is fitted to rock upon a cylindrical saddle, C, forming the top of another casting, D, D. By this arrangement the angular movement of the girder end is accommodated, and the pressure is always uniformly distributed over the lower surface of D, D, which is planed to rest upon another planed surface, such as E, E, or upon rollers, F, F, interposed between them. These rollers are to be accurately turned all of exactly the same diameter,

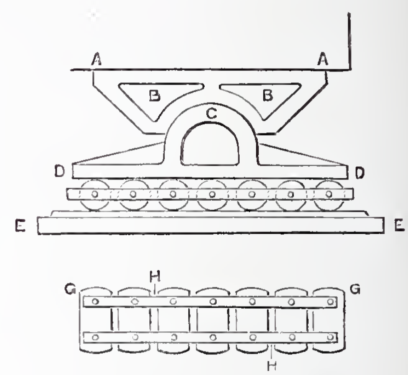

Fig. 14.—Expansion Bearings.

otherwise the bearing upon them would be taken only upon the larger ones. The axis of the saddle, C, must be at right angles to the length of the main girder, or it will jam in rocking, and if the rocker does not act, all the load will, when the bridge deflects, come upon the front roller. The lower or bed plate, E, E, is secured to the pier or abutment by holding-down bolts. If these bed-plates are carried on a transverse girder, they will accompany the girders in the lateral expansion of the bridge, but if firmly fixed to masonry, the girders must slide slightly upon them. At the ends of the rollers are pins which pass through holes in the side bars of a light frame, held together at the ends by distance bars; the rollers are thus placed in their proper relative positions, and prevented from running together while the girders are being adjusted upon them.

The larger the diameter of the rollers the better bearing will they afford, but the more space will they take, and thus increase the total length of the bearing to a perhaps inconvenient degree. To obviate this difficulty, parts of rollers are used, as shown at G, G, their relative positions are secured by the side rods, H, H, at each end, and the arcs are made of sufficient length to amply allow for the movements accruing from change of temperature. Metal, as I have said before, is liable to expansion in hot weather and contraction in cold weather; and this alone accounts for the use of roller bearings.

A Small Sideboard for the Dining-Room with Drawers and Cupboards.

A SMALL SIDEBOARD WITH DRAWERS AND CUPBOARDS.

ITS ARRANGEMENT AND GENERAL DESIGN.

BY ALEXANDER MARTIN.

In a dining-room, the article of furniture which exerts the most influence in the general appearance of the room is, undoubtedly, the sideboard; and it is not, therefore, surprising that cabinet-makers and house furnishers have devoted a very great amount of time and attention to its design and manufacture. For moderate-sized dining-rooms, a 6 ft. or a 6 ft. 6 in. sideboard is considered large enough now, although a few years ago the sizes were generally 7 ft. and 7 ft. 6 in. But if the length of the sideboard top has been curtailed, the height of the back has been increased; and this, along with the fashion of dividing the back into three, five, or more panels, has entirely changed the style of design. The under part must of necessity have the usual drawer and cupboard accommodation, but even this has been changed considerably in the arrangement and decoration.

In a smaller room, however, which can scarcely claim the dignified title of "dining-room," but must be content with the more humble designation of "parlour," there usually is a chiffonier which takes the place of the sideboard, and serves for such, both in its useful and in its ornamental capacities. Now it has been noticed in the furniture trade, that sideboards of a size between the chiffonier and the ordinary sideboard are finding a ready sale; and in order that the many readers of WORK may be kept well to the front in all that is going on in this direction, this paper has been written.

The usual chiffonier measures along the top, 4 ft. or 4 ft. 6 in., while the ordinary sideboard is 6 ft. long; so that a small sideboard with a top 5 ft. long comes in between these sizes; and in a small dining-room or in a moderate-sized parlour, it is much more imposing than a chiffonier, with its usual two cupboard doors, and one drawer under the top. One of the latest styles of these 5 ft. sideboards is that shown in our illustration. It will be seen to consist of, in the lower part, two cupboards and three drawers, with an open space in the centre for a jar or other ornament: and in the upper part there is a shelf extending right across the back, with three bevelled mirrors above it. A novel feature is the roof over the centre plate; it lends importance and dignity to the whole article. If any readers object to the extra work entailed by this arrangement, let them read right on, and they will by-and-by find various suggestions given, and it will be strange if they be not satisfied with one or other of them.

The important matter of what wood our sideboard is to be made of must be decided before much can be done. Oak is the fashionable wood for a dining-room, American walnut coming next in the race for favour; Spanish mahogany will, however, always hold its own as a furniture wood; and it is frequently used for the dining-room by those who want something different from what they see elsewhere. This wood has the additional advantage of attaining a splendid rich tone of colour in the course of a few years. But as it is wholly a matter where taste is allowed full play, there is no need to say more about it here.

As the illustrations of the details of the sideboard will occupy the greater part of two pages of the Magazine, it has been judged better to reserve the whole of them for the next number, in which the different parts and their construction will be fully described.

At present any intending maker will do well to look up some sound well-seasoned wood, either oak or American walnut, or Spanish mahogany, as he may choose. It is desirable also to study carefully and thoughtfully the design of the sideboard given in figure, so that the workman may fix in his mind its general appearance and form, and the relative position of the parts of which it is composed. Time thus spent will be found not to have been thrown away when the work of construction is commenced in earnest.

MAGIC PHOTOGRAPHS: HOW TO MAKE THEM.

BY WALTER E. WOODBURY.

AT the present time there are being sold in Paris a large quantity of so-called magic photographs.

A piece of white paper mounted on pasteboard is all that they appear to consist of, yet by dipping one into water, the portrait of some popular actress or celebrity soon makes its appearance.

I feel sure that a great many readers of WORK, who dabble in photography, will be glad to know that the method of producing these pictures is a very simple one.

Take any negative suitable for the purpose. The quality of the negative is of little importance. Make a print from this negative on a piece of ordinary chloride of silver paper; it can be obtained from any dealer in photographic materials.

Without toning in the gold bath, place direct into the fixing bath composed of a ten per cent. solution of hyposulphite of soda.

This will cause the print to assume a dirty yellow appearance, and it is then necessary to wash carefully in several changes of water until the hyposulphite is entirely eliminated. This is the most important part of the process, as unless every trace of the hyposulphite is removed from the film no invisible image can be made.

A bath is next prepared containing a five per cent. aqueous solution of bichloride of mercury. In this the pictures are placed, and if watched the image will be seen to gradually fade away, until it finally disappears altogether.

When no trace of the image can be detected, the prints are again subjected to a good washing, and afterwards laid across a pole or hung up to dry.

Ordinary cheap photographic mounts, or even pieces of pasteboard, will do to mount these pictures on, but before mounting we have another part to prepare.

In a strong solution of hyposulphite or sulphite of soda dip a few pieces of stout blotting paper, so that it becomes thoroughly impregnated with the soda; then hang up to dry, and cut into small pieces the size of your photo that we have left ready for mounting.

In mounting, one of these pieces of the saturated blotting paper is laid between the mount and the photographic print. It is only necessary to paste round the edges. As these prints have to be dipped in water, however, it is preferable to use a waterproof mount, such as shellac dissolved in alcohol, or india-rubber dissolved in benzole. This will prevent the print from leaving the mount, as it would be apt to do if made to adhere by any substance soluble in water.

When mounted, your magic photographs are finished. To obtain the image, all that is necessary is to dip in water, which apparently acts as a developer, but the following is the actual chemical change that takes place.

The chloride of silver paper is composed of silver and chloride, which form chloride of silver, which, when exposed to the light, assumes a darkened colour due to the "reduction" of the silver. When this is placed in the bichloride of mercury solution, which is a corrosive sublimate, chloride of silver and calomel are formed. Both these substances are colourless, hence the disappearance to the eye of the image. But in the presence of hyposulphite or sulphite, another transformation takes place—the image again becomes dark, and owes its colour to the formation of sulphide of mercury, and probably sulphide of silver also.

Therefore, the real developer is the piece of saturated blotting paper placed between the print and the mount. In its dry state no change takes place, but when the water soaks through the print, attacking the blotting paper and dissolving the sulphite, which immediately acts upon the latent image, development is at once the result.

Prints made after this manner and not mounted can be developed with water, to which a few drops of ammonia have been added, or tobacco smoke even. This latter method of development was the one first used by the Parisians; the pictures were made to fit into the tube of a suitable cigar or cigarette holder, and in smoking the development took place. That this description of the method of making magic photographs may afford some amusement and instruction, if not profit, to some of my readers, is the earnest wish of the writer.

NON-SLIPPING WOOD PAVEMENT FOR ROADS.

BY J. CHARLES KING, AUTHOR OF "ROAD-MAKING AND HIGHWAY LAW," ETC.

IT seems strange that so excellent a paving for roadways as wood is made so as to be a curse as well as a blessing—for its quietness and cleanliness constitute it a blessing to the inhabitants of the houses of the streets in which it is laid, and also to the riders over it. Yet it entails a great amount of suffering to horses that have to travel on it, by its being made so smooth and its joints and surface so slimy, that it is a source of constant accidents to horses, drivers, and vehicles.

This non-gripping surface is moreover rendered more costly by too rapid wear, superinduced by the manner of laying it.

Let me describe the usual plan of procedure in London and other cities, for there is little difference in the way wood-paving is laid. The roadway is cleared of its old paving, and gangs of men are set to work to dig into the hard sub-surface of the road, from which the old paving had been removed. This is done to the depth of from six to twelve inches or more, and the stuff is sifted, the rougher and larger stones are barrowed about without much sense or method, and eventually pitched somewhere on the roadway, raked level, but left loose, remember; then some of the finer siftings are barrowed about and pitched on the top of the loose stones, and raked level and gauged down smooth with templets to the convexity of the intended road. Here at once is a bad foundation, the loose material being unequal in its depth of density—some parts being loose for six inches, others loose for twelve or more inches deep—so that the settlement will be unequal, and the wood-paving above it will in a short time present that billowy appearance of surface which marks the wear of wood-paving.

On this loose surface is laid a coat of lime concrete and gauged level. Now comes the wood blocks, which too often reveal more sap than should be. This is a cause of decay and quick wear under heavy traffic.

There are two systems of fitting the wood blocks together: one close, the other with space between the side fitting.

When laid, the tops of the wood blocks mostly have a coat of gas tar poured over them, which finds its way down between the joints, partially saturating the sides and ends of the blocks. Now comes a dressing of river drift or fine shingle and sand, sometimes mixed with lime and water. This is supposed to afford a bite for the shoes of horses. When done it looks as nice and level as a country taproom floor.

The contractor's unscientific job of mischief is done, and the ratepayers settle by local taxation a costly and deceptive job—too soon to be repeated and again paid for. It would have been less trouble and cost to have done the work properly and the right way, and ensured a more durable wood-paving upon which the slipping of horses would be materially lessened in wet weather.

The senseless digging down and breaking up a hard sub-surface of road was the reverse of what should have been done.

It should have been gauged for convexity and mended where too hollow with concrete and granite, and rammed or rolled level and hard. No other sub-surface is needed. The wood blocks selected from wood free from sap, should be saturated with gas tar—as is usually done with the best work—and the blocks dried and weathered with this coat of tar. Then they should be laid with $\frac{3}{8}$ of an inch space between the sides, and $\frac{3}{8}$ of an inch between the ends forming the joints of the blocks. Into these spaces granite of *not less than a $\frac{1}{2}$-inch polygons* should be rammed tightly, after the manner of caulking a vessel—not with the contractor's unscientific broom—and the wood pavement is complete. No need to sand and lime the joints and surface to make slime, to make the pavement more slippery. These interspaced ridges of granite would be the grip for the horse shoes, and not being concreted together would, as they wore, break and form a grit for the surface to aid the horse's foothold, saving the cost of sanding it constantly, forming so much more slime when worn and churned up with the rain, or water from watercarts to lay the slime dust.

The paving should be watched, and more granite polygons rammed in to any open joints.

Breaking up roadways to cut off gas or water should be prevented. It is a common error to suppose that wood-paving is easier for horse draught of vehicles than granite pitching. It is so only at first; when it becomes unlevel it is much harder for draught than the rough granite pitching. This estimate of draught is with iron tires to the wheels.

OUR GUIDE TO GOOD THINGS.

79.—Watt's Electro-Metallurgy.

At the present time, when so much interest is shown in every description of work in which electricity is pressed into the service of man as an agent or motive power, the volume now under consideration will be welcomed as a serviceable addition to the many technical treatises on subjects in which electric action plays the principal part which have been already issued, or are still issuing from the fruitful press. "Electro-Metallurgy Practically Treated," to give it its full title, is by Mr. Alexander Watt, author of "Electro-Deposition," "The Art of Leather Manufacture," "The Art of Soap-making," etc. It says much for its popularity and utility when it is said that it has reached the ninth edition, having been subjected to considerable enlargement and revision, furnished with additional diagrams and illustrations, and brought down to date by the incorporation of the description of the most recent processes in metallurgy that have been introduced of late years. It forms No. 135 of Weale's Rudimentary Series, and is published at 3s. 6d. by Messrs. Crosby Lockwood & Son, 7, Stationers' Hall Court, Ludgate Hill, London, E.C. The book itself is divided into two parts, of which the first deals with Practical Purposes, and the second with Practical Notes. The first of these is subdivided into several sections, whose subject matter deals separately and in order with the following subjects, namely, the various batteries now in everyday use, the electro-deposition of copper, the electro-deposition of silver, the electro-deposition of gold, and the electro-deposition of brass and bronze, platinum, lead, nickel, tin, zinc, cobalt, and various alloys of metal. The second part comprises a variety of notes and recipes for various processes, and a clear and succinct description of the methods to be followed in effecting a very large number of things which the working electrician is called upon to do every day in connection with the work of electro-deposition. Among these are the whitening of silver articles, the whitening of brass dials, of timepieces, colouring gold articles, coating engraved plates with iron, and much else which it is not possible to dwell on in detail. At the end of the book will be found a copious list of articles required in electro-plating and gilding; a list of requirements for nickel plating on a moderate scale; a comparison of the relative values of Centigrade and Fahrenheit thermometer scales from freezing point to the point at which mercury boils; a table of weights and measures and tables of the electro-chemical relation of elements; the qualities of metals, showing at a view which are the most and least malleable, the most and least ductile, and the most and least tenacious; the conductivity of metals; the relative weights of different metals in cubic inches; the new legal standard wire gauge; the composition of common alloys; the weight, size, and surface of copper and brass tubes 10 feet long; and a table of high temperature, showing the different characteristics of each: thus the characteristic or description of 980° Fahrenheit is a red heat, that of 1,700 an orange red heat, and that of 3,000 a white heat. A good index of eight pages well completes the volume, and adds much to its value.

80.—Humphries & Co.'s Illustrated Catalogue of Photographic Apparatus.

This is an illustrated catalogue and price list of the photographic apparatus and appliances kept in stock, and supplied by Messrs. W. H. Humphries & Co., wholesale, retail, and export manufacturers, 268, Upper Islington Street, London, N. It is sent post free to any applicant on receipt of threepence. The cameras named and priced in Messrs. Humphries & Co.'s catalogue are all of their own design and manufacture. The principal specialty of Messrs. Humphries & Co. seems to be the "Drayton," a new long focus camera, which is shown closed and open in the accompanying illustrations.

The manufacturers claim that—

"The specialities of this camera are its compactness, portability, strength, and rigidity. It is free from loose parts, and can be set up in a few seconds, and comprises the following movements:—long and short focus; rising and falling front, with double swing; falling base board; double swing to back; rack and pinion side swing, and revolving adapter with check action, which cannot overturn, and is warranted not to stick; leather bellows.

"The improvements introduced into this camera are the easy working of all its parts; the special arrangement for revolving the adapter in metal rings instead of wood, which renders it free from climatic changes; and the stop action to the same when in position.

"The revolving adapter being always in position, the camera is ready for use at any moment, and obviates the old method of turning the camera on one side or taking off the reversing back, this being done by simply releasing the spring catch and turning the back round as required.

"There is also an improvement in the vertical swing to back in the means of pivoting, by which wear and tear is lessened, and perfect rigidity is maintained, and in the special arrangement for clamping the front side swing in position and the easy working and manipulation of the same, also in the clamping of the rising and falling front, which enables the operator to do so with one hand while focussing.

"The rack and pinion side swing to the back is an innovation for the sharping of distances.

"In introducing this camera, the chief aim has been to make it as complete as possible, both in construction and workmanship, for all classes of work. Classing together the extra conveniences and improvements in this camera, it will be found to be an instrument simple, compact, light, and capable of standing great wear and tear, perfectly rigid when erected."

The sizes in which the "Drayton" camera is made range from $4\frac{1}{4}$ in. by $3\frac{1}{4}$ in. to 15 in. by 12 in., and the prices from £5 for the smallest size or £5 12s. with extra double dark slide to £14 10s. for the largest size or £16 6s. with extra double dark slides. The cameras can be supplied with less than three dark slides if desired.

In addition to cameras and the different appliances that are needed by the photographer, Messrs. Humphries & Co., keep a large and varied stock of magic lanterns, suitable for all classes of exhibitions. The lenses are said to be remarkably good of their kind, and are fitted with rack and pinion, and with telescopic draw tube, which gives increased focal length. The condensers are composed of two plano-convex lenses of 4 inches in diameter in brass cells, and the lanterns are furnished with 3-wick or 4-wick refulgent lamps as may be desired. Smaller lanterns range in price from £1 10s. to £8, but the triunial lanterns range from £16 to £80.

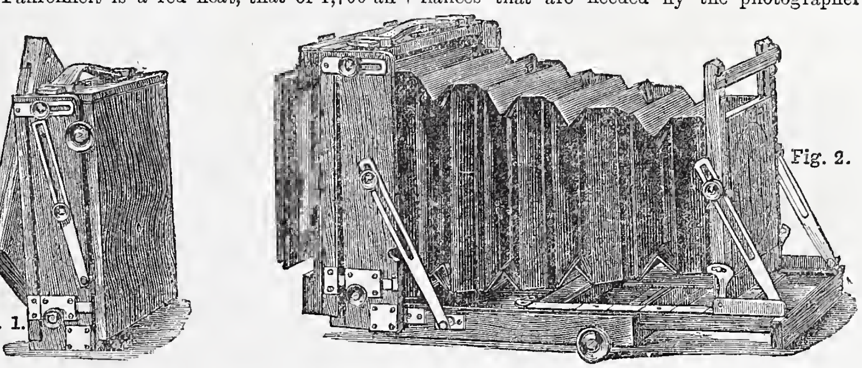

Fig. 1. Fig. 2.

Fig. 1.—Drayton Camera closed, with Revolving Back partly turned round. Fig. 2.—Ditto open.

81.—The Waterbury Watch.

One would imagine that the Waterbury Watch has been so widely and efficiently advertised that everybody must know all about it by this time. The Waterbury Watch (Sales) Company, Limited, 17, Holborn Viaduct, London, E.C., however, seem to think differently, for a specimen watch has been sent with a request for a notice in "Our Guide to Good Things," and perhaps this is so, for whereas as when the Company's leading specialty was first introduced for sale there was, if I remember rightly, only one kind, there are now four, distinguished as the L, E, F and J watches. Of these the E watches are supplied at 10s. 6d. each, the F at 15s., and the J at 17s. 6d. It is claimed for these watches that they are keyless, reliable, durable, and accurate. The long time occupied in winding up will be reckoned an objection, perhaps, by some, but it should be said that in the more expensive watches, *i. e.*, those sold at 17s. 6d., the wind is short and they are jewelled and dust proof. Every watch is guaranteed for two years, and the cost of repairs is but trifling.

The Editor.

SHOP:

A Corner for Those who Want to Talk It.

*** Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Screen Secretary.—G. F. W. (*South Kensington*) writes:—"I have been a subscriber to Work from its commencement, and, I must say, am very much satisfied with every item of its contents. I am a joiner by trade, and some little while ago I was positively longing for some sort of a standard work on the lines of 'artistic furniture,' as described by David Adamson. I am always getting out designs for odd pieces of furniture and ornaments, such as cannot be bought in the ordinary way; but still I wasn't quite satisfied, I wanted to know other people's ideas, and when I saw the first edition of Work I said to myself, 'That is the very thing I want.' I have succeeded in obtaining six subscribers towards it, and shall never lose an opportunity to get some more, because I think that it is something which will become useful to mechanics and amateurs alike, and as such must not be left to go wrong, and so slip through our fingers. Now in Work No. 10 there is a screen secretary by David Adamson. It is a very useful thing. But there is one point which I should like to point out, and try to improve on it, which is this: In Fig. 5, the lid or flap is shown thus, Fig. 1. Now, sir, I

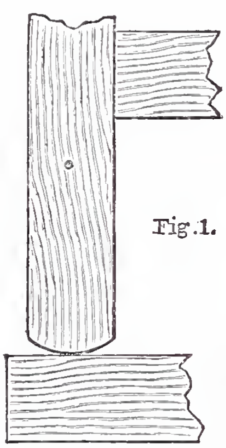

Fig. 1.

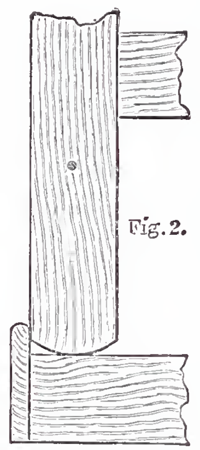

Fig. 2.

think it would be an improvement if it were shown like this, Fig. 2. You see that by planting that bead on that under shelf it completely hides the ugly joint which must otherwise be seen. The bead is at the same time flush with the front edge. because the lid stands back just that thickness."

Hollow Metal Plate Work.—Practical Man (*London, S.W.*) writes in reference to Opifex (see page 282):—"His method of hollowing metal hemispheres, or saucers, etc., I do not agree with. In the first place, stamping half balls cannot be done in one blow. To stamp a half ball would require five or six blows from a drop press (not a fly press); it would not pay a master to do them under five blows. Of course each blow would be a different tool starting from one only a little hollow till it is got to the right shape. Spinning can be done in one operation. The next way is hollowing the way by which all practical men work tin, iron, zinc, copper, brass, nickel and silver. If given to me to get to a required hollow, I would do it by this method which is the easiest, cheapest and quickest, and best. (1) You want a block of oak or any hard wood exceedingly dry, and use it the grain up. Well our blocks are exactly the same as a butcher's block, only they are solid instead of having legs. (2) You want a bullet hammer—a cast iron one will answer well. We have three or four in the factory now in constant use; one with a face about $1\frac{1}{2}$ over on the smallest side would be a convenient size. These can be procured at any tin plate warehouse. (3) The metal: I think tin plate will be the best to start on. If you go to a tin plate warehouse, and ask for a sheet of one cross 20 by 14 charcoal prime. Of course if you ask for this you will get the metal that will work, which will not cost more than 5d. Now for work: get your compasses and score a 5 in. circle, cut this out with a pair of snips; now draw a circle about $2\frac{1}{2}$ in. just to give you a guide to the hammering. Now you will want a little hole or hollow made in the wood block about 3 in. over and $\frac{3}{4}$ in. in the centre or deepest part. Now with the stuff in the left hand, hammer in the right, proceed to hammer on the edge of your metal and on the edge of your hollow in the wood, and gradually go in towards the centre; and the greatest advice any mechanic can give is join your blows, the more you join them the smoother your work will become. This way your work will not require to be annealed. Excuse me for taking so much of your valuable space, wishing Work every success. This is correct you can be sure, as I am a practical man."

II.—Questions Answered by Editor and Staff.

Making Silver-plating Solution. — W. H. (*Pollokshaws*).—When a silver-plating solution is made up as you describe it—namely, by dissolving old silver in nitric acid, throwing down the silver as a chloride with salt, and dissolving the chloride paste in cyanide of potassium—you get chloride of potash in the solution, and this is bad, for it has a tendency to cause the silver to go on loosely, and thus strip under the burnisher. The solution will also give up yielding a good deposit sooner than one made up of cyanide of silver alone. If you must use old silver, adopt the following plan:—Dissolve as you do now, and convert into chloride, and well wash the chloride; then immerse in the wet mass a quantity of scrap zinc, and stir occasionally. After a time the whiteness of the chloride will disappear, and leave nothing but a dirty grey powder. This is finely-divided pure silver. Agitate the wet mass in water with the zinc until all traces of the silver chloride have disappeared; then well wash the grey paste in hot water to dissolve out all the chloride of zinc. Take out the zinc scraps, and add a little sulphuric acid to dissolve any little bits of zinc remaining; stir up a few times, wash until clean as you do now, then dissolve the whole in nitric acid. After this, evaporate off all the acid and convert the solution into pure nitrate of silver crystals. Dissolve these in distilled water, add cyanide of potassium solution until all the silver has been thrown down as silver cyanide; well wash this, and dissolve in cyanide of potassium solution to form the silver plating bath. I prefer buying the silver nitrate to making it myself. To prepare articles for silver plating, well clean them, dip in acid pickle to remove loose specks of dirt, then quick them in a solution of nitrate of mercury, and finally rinse them in clear water. This will be thoroughly dealt with in my "Notes for Electroplaters." If you meet with any special difficulty in preparing the articles, please write and let me know exactly what it is, when I will try to help you out of it.—G. E. B.

Silver Plating. — W. H. B. (*Leicester*). — You cannot use a better solution for silver plating than one made up of the double cyanide of silver and potassium in distilled water. Dissolve the nitrate of silver in distilled water, precipitate the silver as silver cyanide, well wash the precipitate, then dissolve in a solution of cyanide of potassium in distilled water to form the plating bath. If you wish for details of the process, together with weight (per gallon) of ingredients to be employed, please write again and let me know the class of work to be plated. For ordinary trinket work, one Bunsen cell will do fairly well; but a large Daniell or Smee is best for spoon and fork work, since the current is not so intense from these as from the Bunsen. (2) The length of time an article should be kept in the solution depends upon the quantity of silver required, and the volume of current passing through the solution. Now, one ampère of current passing through a silver-plating solution will deposit sixty-one grains of silver in an hour. This current will be obtainable from a large Daniell cell charged with sulphuric acid (one acid to twelve parts water) in the zinc compartment, providing the slinging wires are of No. 16 copper, the connections are clean, and the anode not too far from the work. You must, therefore, calculate the area over which this deposit has to spread, and you will then get a tolerable idea of its thickness. This must guide you in determining whether the coat is thick enough or not. (3) Clean the hoop well as for plating, then wipe dry with a clean soft linen rag. To the inside apply with a soft brush some good copal varnish tinted with red lead or with ultramarine. Allow this to get quite hard in a dry, warm room, or dry it in a lacquering stove before putting it in the plating solution. The "stopping" may be afterwards removed with rags moistened with warm spirits of wine. Many thanks for your kind appreciation of Work, and for your suggestion, *re* banjo. Can't you just write and tell us how you made your banjo?—G. E. B.

Goat Cart.—F. E. B. (*Landport*).—A paper on how to make one is being prepared.

Bird Cage.—Miner (*Dykehead*).—An article on bird cage making is in preparation.

Cornpike.—J. P. (*St. Keyne*).—I do not know the implement termed a cornpike, but suppose it is a kind of fork. If so, it is not the practice to temper tools of this kind. They are made of cast steel, untempered.—J.

Loadstone.—W. L. (*Sheffield*).—Orme, of Barbican, London, can supply you with a piece of natural loadstone. You would only get a small fragment for 5s.—J.

Lantern (*Dartmouth*) asks:—"What advantage is gained by the use of cardboard carriers?" If the slides are properly mounted and marked with white spots or white line on the top front edge and carefully placed in boxes prior to exhibition, a carrier sufficiently long to hold three or four slides, $3\frac{1}{4}$ in. square, one in each lantern, so that when the last slide is placed in the carrier the first is pushed out, is all that is needed. A properly mounted slide has only a paper binding. Slipping and mechanical slides, of course, require exceptional arrangement.—E. D.

Size of Pulleys.—F. A. (*Islington*).—The diameters of the pulleys on the engine shaft and on the driving shaft of the machine, must be inversely as the speeds. Suppose, for instance, you have an engine running at 60 revolutions per minute, and you want to drive a machine at 200 revolutions, the ratio of the diameter of the pulley on the engine shaft to that of the pulley on the machine shaft must be as 200 to 60 — that is, the engine pulley diameter will be $3\frac{1}{3}$ times that of the machine pulley. To state this as a general formula applicable to all kinds of machinery, let D=diameter of driving pulley and N its number of revolutions per minute; and d and n, the diameter and number of revolutions of the driven pulley, then,

$$d = \frac{D \times N}{n}.$$

In the above case let the engine pulley be 50 inches in diameter, then

$$d = \frac{D \times N}{n} = 50 \times \frac{60}{200} = 15 \text{ inches.}$$

This formula will also apply for calculating the diameter of toothed wheels and chain wheels.—F. C.

Yellow Piano Keys.—J. A. (*Salford*) has a piano, the keys of which have turned yellow, and wishes to know how to bleach them. I presume the keys are ivory, and not celluloid. If you will kindly see reply to H. W. (*Sheffield*), on page 317, you will find full details for restoring keys. To bleach try the following:—After taking the polish off with fine glasspaper, take a pennyworth of spirits of salts, and dilute with two-thirds cold water. Now rub over the ivory which is very yellow, and allow it to remain a few moments, and watch the result, not allowing it to remain too long, as it will burn it; when you see an improvement remove the surplus with a cloth damped with methylated spirits and fine paper and polish, in the manner described to H. W. Caution, do not spill the spirits of salts on your clothes.—T. E.

Electrophorus.—R. G. (*Preston*).—Charge the tray of your electrophorus with a mixture of eight parts resin, one part shellac, and one part beeswax or Venice turpentine. Mix well, melt together, and pour into the tray. The cake thus formed will not be so liable to crack as one of pure resin, and may be excited by rubbing with a piece of fur, flannel, or silk. The upper plate or cover may be made of sheet metal or of wood coated with tinfoil. If you make a new one of wood you should well dry the wood by baking in a slow oven before you make it up, but any sheet metal may be used for a cover, and this will not warp. The handle must be of glass or of wood well baked and then soaked in melted paraffin wax. Unless wood is thus treated it absorbs moisture, and becomes a conductor, whereas you want an *insulated* handle. A phial bottle may be used as a handle. Embed the neck in a boss of baked wood fastened to the upper plate. You may varnish the back of the plate, but must not varnish the face nor the tinfoil if you use this.—G. E. B.

Testing Platinum Contacts.—A Reader of Work (*Chepstow*).—When nitric acid is applied to platinum it has no action whatever on the pure metal, but should the speck of platinum be slightly coated with solder (and this may happen accidentally), the acid would leave a black stain on the solder. Nitric acid will stain with a dark spot such alloys as pewter, solder, Britannia metal, and steel. It will also leave a dark stain on iron and on silver. By adding one part of chromic acid to six parts of diluted nitric acid, another testing liquid may be made which will leave a blood-red stain on silver, a brown stain on German silver, a black stain on Britannia metal, but have no effect at all on platinum.—G. E. B.

Telegraph Instruments.—H. D. (*Haverfordwest*) writes:—"I am delighted with Work. It is really an excellent paper for amateurs, and has given me great pleasure to recommend it to all my friends at home and abroad. The articles by Mr. Bonney, especially, are not only practical, but are singularly clear and interesting. Work may not be great in point of circulation or popularity, although that must surely follow when it is more widely known; but in its aims and objects, in its usefulness and comprehensiveness, in the ability and courtesy of editor and staff, the paper is without a rival. Accept, then, my heartiest wishes for its success. I have determined to try and make a telegraph instrument for my own use. Could you tell me where I could get a book upon the telegraph and telegraphy? I should like one that would describe the different kinds of instruments; and shall go in for the study of the subject. But, nevertheless, I shall eagerly wait for a description of the instrument from your able pen."—I thank you for your encouraging words in both of your letters, and your efforts for increasing the circulation of Work. If all our readers worked as you do, our circulation would soon be great indeed. When I can find time to deal with the subject, and can make sure of having the line clear to run my train of thought, I hope to fully illustrate and describe a telegraph instrument such as you can make yourself. Meanwhile, perhaps, you may be assisted in your studies by reading Mr. E. B. Bright's book on "The Electric Telegraph," price 2s. 6d. There are several books published on the subject, such as "Telegraphy," by W. H. Preece, price 3s. 6d.; "Electricity and the Electric Telegraph," by Geo. B. Prescott, 544 illustrations, price 18s. From any of these you will get a tolerably general idea of the various telegraph instruments in use, but they do not give detailed illustrations of the various parts composing a telegraph instrument.—G. E. B.

Subscription to Work.—W. A. D. (Government Land Surveyor, Vredefort, Orange Tree States, South Africa).—The particulars have been sent you by post to save time. Thanks for your letter.

Polishing Fretwork.—N. M. (*Norwich*).—The "easiest and best" way to polish fretwork is to clean and polish the wood before fretting, but as I gather from your inquiry that it is now too late for you to do this with the piece of work you are engaged on, it will be satisfactory for you to know that fretwork is generally polished after it is cut. The polishing is done in the ordinary manner, except that the grain is not filled, for the simple reason that the filling gets in the corners and is difficult to remove—in other words, the filling is more trouble than it is worth. It is not possible to get the best results of which French polish is capable without filling. This can easily be applied to the plain wood, and hence the reason why it is best and easiest to polish before fretting. You are, I presume, acquainted with the process of French polishing, so these remarks are given merely about polishing fretwork. If you polish the wood before cutting, you will understand the work must be touched up afterwards, and that it is necessary to scratch away polish at any joints to be glued together. If you have already done the cutting it may be useful for you to know that the pieces of fret should be polished separately before finally fixing them together. To minimise risk of breaking points let your rubber be small and firm. Don't attempt to polish inside the cuts, and carefully scrape away any polish which may accumulate as the work proceeds at their edges.—D. A.

Polishing.—A. B. (*Lower Edmonton*).—The three varieties of wood mentioned by you require different treatments so far as darkening them is concerned, the stains employed being different for each. These stains you can buy ready made, at a low price, at any oil shop where polishing materials are sold. If the stains as bought are too dark, dilute them with water. Walnut is seldom darkened by staining unless it is ebonised. From your mentioning this wood with the others I think you may have mistaken the slight darkening by oiling for staining, and if I am right in this supposition omit stain and simply use oil in its place. Prepare the wood by cleaning it up thoroughly with glasspaper. Rub in a little raw linseed oil, but do not saturate the wood with it. Allow the work to stand for a time, then fill the grain of the wood by rubbing in either some filling which you may buy, or one composed of whitening made into a paste either with turpentine or with a mixture of linseed oil and polish. Clean off superfluous filling and polish. The polish itself you had better purchase, but if you prefer making your own, dissolve some shellac in methylated spirits, say 6 oz. to 1 pint. Get a piece of soft rag and cotton wool to form a rubber, moisten this with the polish, apply just a touch of oil to the surface of the rubber, and go over the wood to be polished, with an even motion, covering every part equally. When the work has been bodied in with polish finish by spiriting off. This consists of using a rubber with methylated spirits instead of polish, just sufficient to remove the smears left by bodying in. Finishing with glaze is not nearly so difficult, but it is not as durable, and should never be resorted to for first class work. Glaze can be bought so cheaply that it will be hardly worth your while to make your own. If you determine to use it, omit the spiriting off, and go over with a rubber moistened with glaze. Such is a brief outline of the process which will be fully treated in a series of papers on polishing as soon as practicable. Meanwhile I hope the foregoing will be of assistance to you.—D. A.

Polishing Oak Overmantel.—J. K. (*Bethnal Green*).—To darken the job to the extent you name I think you will find that it will only be necessary to oil the wood and use brown polish, but, of course, a good deal depends on the colour of the oak as it is "in the white." Even if it may seem too light at first, remember that oak is a wood which soon darkens. Should a stain of some sort seem desirable use a very weak one of bichromate of potash and water. Put this on with a rag, but don't use too much of it. To avoid risk of spoiling your overmantel by making it too dark, finish up a small piece of wood of the same kind as that used in its construction. If this test piece is too dark, subsequently, you will see that you have used too much staining; while, on the contrary, if too light, more stain will be required. Do not on any account varnish your overmantel, but polish it in the usual way. For further remarks on polishing see above answer to A. B.—D. A.

Bending Rolls.—J. G. (*Wirksworth*).—You should place the centres of your bottom rollers about 9 inches apart, the rollers being 6 inches in diameter. To bend your heaviest iron cold will require a pressure of about two tons on the rolls; the top one being made adjustable.—F. C.

Papier-Mâché to Resist Water and Insects.—R. W. (*Manchester*).—The queries which R. W. repeats have been already answered. In his laudable desire for information, he forgets that with the heavy demands upon "Shop" space time must elapse between the receipt of a question and the publication of a reply to it.—S. W.

Fountain.—J. C. (*Hull*).—An article on the construction of self-acting fountains is in hand, and will be published as soon as possible. It would be impossible to give sufficient details in the columns of "Answers."—C. M. W.

Automatic Carriage Brake.—H. A. H. (*Diall Stenness*).—In my opinion your invention is ingenious and thoroughly practical, and its extreme simplicity precludes its getting out of order, and is a guarantee for durability. There should be no difficulty in getting the invention taken up, but you should obtain protection (it only costs £1) before showing it in the trade.—F. C.

Wheel for Lathe.—A. P. S. (*Heaton Chapel*).—A wheel of 20 in. diameter, and weighing 21 lbs. in weight would be too small and too light for a lathe of 6 in. centres; whether for wood or metal makes no difference. Such a wheel is only fit for a sewing machine or fret saw. For a lathe of 6 in. centres to be driven by a man, you require a wheel of at least 2 ft. diameter, and weighing about 70 lbs. For a boy's lathe, of 4 in. or $3\frac{1}{2}$ in. centres, a wheel of about 22 in. diameter, and 45 to 50 lbs. in weight, would suit well. Two wheels like yours might do pretty well for a $3\frac{1}{2}$ in. lathe.—F. A. M.

Cheval Screen Escritoire.—P. P. (*Blisworth*).—The drawings of the screen escritoire were to scale. Unfortunately I have mislaid the actual size, but if you take the ordinary height of a table for writing, as your ascertained measure, there will be little trouble in finding the rest, especially as the actual dimensions are not important to an inch or so.—J. G. W.

Cabinet in Fretwork.—A SUBSCRIBER FROM THE BEGINNING (*Slough*).—Your pen name is a favourite one I know, but is it not a "leetle" premature to adopt it yet? After No. 1,000 it will be a nice one to swagger; but seriously I am pleased you like WORK, and appreciate the real efforts of the contributors to aid its readers. The partitions of the cabinet should go right through—the depth to be about 4 in.—the width is, of course, the full size, as shown in the working drawing. If fret cut, the drawers may be white with the casing of the whole thing black. For inlaying full instructions were given.—J. G. W.

Cement, etc.—ONE IN THE DARK writes:—"Wanted to know how to make an inexpensive cement or compound, which will possess the following properties:—It must be capable of being used in a body as thick as a man's arm, to set hard in a few hours, with little shrinking, to bear a nail 2 in. long, being driven in when hard, and not to cause cracking or flawing, and to stand a moderate amount of heat without injury. The colour is no object."—To this the reply is:—[A mixture of plaster of Paris, with twice its bulk of plasterer's putty, and water, will set in a few hours; can be moulded, and will bear a moderate amount of heat. If too brittle for driving nail in, add more putty, or use Paris white and thin glue, instead of putty and water.—E.]

Violin Purfling Tools.—G. E. B. (*Hampstead*).—One kind of purfling cutter is sold by Withers & Co., 51, St Martin's Lane, London, for 4s. 6d.; another style is sold by J. Schecrer, Covered Market, Leeds, the price of which is 5s. 6d.—B.

Lithography.—APPRENTICE.—A tint such as you describe often results from using retransfer ink too strong; the remedy is to mix lithographic printing ink with it until the tinting disappears. You must be sure also, that your gum sponge and damping cloth are perfectly free from greasy matter, as want of care in that direction will cause you much annoyance, and contribute to failure.—J. H. M.

Photo-lithography.—PEN AND INK.—It is not competent to fully describe this process in the pages of "Shop," but as you say you are both photographer and lithographer you will, no doubt, be able, from the outline that I here give, to arrive at the necessary information which you lack, concerning the combination of those two arts, but I warn you to summon to your aid all the skill that you are master of. In the first place the lens in common use will not do for the purpose, as the picture it gives suffers a distortion at the edges that in some subjects is very disagreeable; you must, therefore, provide yourself with a lens that is free from this vagary. The detail of the copy to be reproduced must be clearly expressed by stippling or lines, and a glass negative is taken in the ordinary manner. A sensitive paper is used, the coating of which consists of equal parts of bichromate of potash and gelatine, thoroughly dissolved in $7\frac{1}{2}$ times their combined weight of water. The coated paper is dried in the dark room. After a print taken on this paper has undergone exposure, the duration of which experience must decide, it is evenly and entirely coated with transfer ink by pulling through a litho press over a stone that has been previously covered with transfer ink. The print in this state is sponged with gum, and washed repeatedly in warm water, and this operation ought to effect the clearing away of superfluous ink, and develop a transfer that may be dealt with in the usual manner of litho printing.—J. H. M.

Japanese Cabinet.—CLERICUS.—It is the keenest pleasure to hear that any article one has written has been of the least use, and one that, although not absolutely without precedent, can never lose its original pleasure. I like the idea of red enamel for the cabinet, but should use for that no carved work, but gold Japanese paper, or gilded lincrusta for the panels. Liberty, of Regent Street, was selling recently, bundles of odd lengths of the former at 1s. and 1s. 6d. each; these are most useful. There is a gold over red pattern (not gold on a crimson ground, which is quite distinct), that would look extremely well, could you get it. C. Hindley & Sons, Oxford Street, W., also cut lengths of the Japanese-gold paper. For other purposes a new wood carving (Spurr's patent) that is to be shortly introduced in England, will probably satisfy you, as, save the cost, there is nothing to distinguish it from the finest hand-wrought work. If you could get at an oriental warehouse damaged lacquer tea-trays cheaply, they would come in splendidly for the panels of the cabinet.—J. W. G. W.

Enlarging.—W. P. (*Wisbech*).—A camera bellows is one of the things that cannot very well be described at length in "Shop," and would require a paper to itself. The *modus operandi* is somewhat as follows:—Make a box, the outside measurement of which is the same as the inside of the bellows. Procure enough black silesia to go round the box in two thicknesses, and lap, say, about a third over; paste a sheet of strong brown paper between the silesia, and form your bellows, fold by fold, round the box, pressing each fold as it is made, close up to the preceding one; leave on the box till quite dry. This may give you an idea how to go about the thing, or perhaps you can persuade the Editor to give you a paper with diagrams.—G. LE B.

Book Marbling.—T. W. W. (*Mold*).—The process of transferring the pattern from marble paper to the edge of a book is a comparatively easy one, although a considerable amount of dexterity will be required in the manipulation. Have ready at hand the following articles:—Some hydrochloric acid (spirits of salt), a broad camel's-hair brush, some strips of marble paper, a little broader than the edge to be operated upon, a few sheets of scrap white paper and a hammer. Place the book in the lying-press between pressing boards, and screw it up as tightly as possible. Take up some of the acid in the brush, and pass it quickly over the edge, lay on a strip of marble paper, over this place a sheet of paper, and tap gently but firmly with the hammer over the entire edge. Lift off the paper, and the pattern will be found to have been transferred to the book. It requires a good deal of practice, and not a little patience to make a good edge by this method. I hope bookbinder will succeed. The book will require to be flat and very smoothly cut. The marble paper must not be very highly glazed, in fact there is a special paper sold for this purpose. It can be had from Berry & Roberts. I will be pleased to know how you succeed with this.—G. C.

Milling Cutters.—KEYWAY.—You can obtain milling cutters for cutting keyways in shafting at any large tool maker's: send to J. Buck, 56, Holborn Viaduct, for price list. If you mount the cutter between centres of lathe you will have some trouble to fix and adjust the height of shaft. Another way would be to use a slot-drill in the drilling spindle, mounting the work between the centres; but this requires a driller and overhead motion. The size of cutter to use in a small lathe, is very vague—say, 2 in. diameter. The speed the cutter should run, if well oiled, would be about the speed you would use if it were of brass and you were turning it.—F. A. M.

Lettering in Gold.—T. E. T. (*Kingsland*).—I am pleased to see that you have been successful in binding your own books, and am also very pleased to give you the information you ask in regard to lettering in gold. Begin by washing the leather cover with paste water—*i.e.*, water with a little paste mixed in it. If the cover is of calf, rub it well over with paste to fill up the pores previous to washing. When this has become dry give the title and parts to be gilded two coats of glaire—white of eggs beaten until as thin as water—allowing the first to dry before applying the second. When perfectly dry, rub it over with an oily rag kept for the purpose. I don't mean a rag dripping with oil—there must be very little in it. Spread out the gold on the cushion, and cut it to the sizes required. To make the gold adhere until the lettering is finished, rub the parts where the gold is wanted with hog's lard or olive oil. For calf, use the lard; for all other leathers use the oil, and use both sparingly, as leather can be easily stained by these substances. Lift the gold from the cushion with cotton wool, and press it firmly on the book. The tools are heated in a gas stove, and must be warm enough to "bizz" when touched with the wet finger. The hot tool causes the gold to adhere, and whether it is an ornament or a letter it will be firmly impressed upon the book. To letter, you will require guiding lines to keep your letters even. This is done by drawing a fine thread over the gold. When the lettering is completed, the surplus gold is rubbed off with the oily rag mentioned above.—G. C.

Gold Vein in Marble Papers.—DESIROUS (*Dundee*).—This operation is a very difficult one. It requires no small degree of skill and dexterity. I did not think that an amateur or small tradesman would have attempted it, because of the cost and trouble connected therewith. The gold vein does not always adhere even on the London marble papers, for the simple reason that instead of gold powder metal bronze is used. When you ask for gold powder, see that you get it (as they say in advertisements), as herein lies the secret. Metal bronze is too heavy, and requires lithographer's varnish to make it stick. The substance used to make gold powder stick or adhere to the paper is prepared with white of egg and spirits of wine in equal proportion and two parts of water, beating all well, and leaving it to clear. Mix a small portion of the gold powder with the liquid, and use a camel's hair pencil. I hope our friend will succeed. Of course, it is much cheaper to buy the paper already prepared, and far better, for the designs are much prettier than it is possible to make them in a small way.—G. C.

Ticket Writer's Ink.—H. T. J. (*Newport, Mon.*). —The colours should be bought in a dry state. Always use the best, such as lamp black, vermilion, royal green, and ultramarine. Mix your colours with a thick solution of gum arabic, and grind them well with a palette knife on a piece of glass or marble. To make colours lighter add flake white until of the required tints. There are other recipes. —H. S. B.

Watch and Clock Oil.—AMATEUR REPAIRER (*Kent*) cannot possibly do better than use Ezra Kelley's oils for watch or clock, at least, that is the conclusion I have come to after eighteen years at the bench. For coarse, heavy watches I sometimes use Windle's chronometer oil. To cement stones use very best and new plaster of Paris, mixed with water. With clear settings a little coaguline is a good cement.—A. B. C.

Instrument for Enlarging Drawings. — INVENTION (*Liverpool*).—The "instrument" you refer to is doubtless that known as a pantagraph. If this is not the thing you saw, a pantagraph will serve the same purpose, as it is commonly used for enlarging drawings. I do not, of course, know in which shop you saw it; but if you are a "down town" man very likely it was at Matheson's tool place. You will also be able to get one at several shops in Whitechapel. As the Dinglet omnibus passes his door, perhaps you will find Jeffery, the artists' colourman, at the top of Renshaw Street, the most convenient for you; but you can hardly walk along the streets without noticing the pantagraph in many shop windows. The construction of a pantagraph will be explained in WORK in due course.—D. D.

Colouring Oak Overmantel.—J. K. (*Bethnal Green*).—A good deal will depend on the natural colour of the wood as to the amount of stain required to darken your overmantel to the tint required. You can best ascertain by experimenting on small pieces of waste, and you will probably find that by oiling before polishing and using ordinary, not white, French polish, you will not require any stain. If you should find this necessary you can buy a small quantity at many shops in your neighbourhood, or make some by dissolving a little bichromate of potash in water. To prevent the oak being stained too dark, be sure and add plenty of water; but if you try the result on waste, as suggested above, you are not likely to spoil the job. Of course, you know the stain must be put on before the polish.—D. A.

Carpenter's Bench.—J. F. R. (*Nottingham*).—Your want has been partly anticipated, as an article describing a small bench is now in hand and will shortly appear. I have said "partly anticipated," as the bench described is of rather an unusual kind, and while it will be useful to a very large number of readers it may not be just what you want. If so, I may say that the construction of an ordinary bench will be given ere long; and surely you do not need to be told that in order to render your bench easily removable you can put the parts together with screws. Criticism, as you suggest, is not objectionable when fairly given; and opinions are often valuable, though many of them may suggest alterations which are impracticable. Still, they all receive attention. With regard to advertisement pages and wrapper, it must suffice to refer you to remarks which have already appeared thereon in "Shop." Your good wishes are appreciated.—D. A.

Rough Frame. — G. S. B. (*Rotherhithe*). — The rough gilded frame, I confess, is beyond me. I hear it is done in the usual way, but fear that will be little assistance to you. It seems rather more than an amateur can attempt.—E. B. S.

Cheval Screen Hinges.—C. M. J. (*Limavady*). —The long elbow hinges I got at a country ironmonger's, whose name and address I forget, but Churchill or Melhuish would be sure to be able to supply them.—E. B. S.

Books on Estimating and Measuring.— L. G. (*Cambridge Road*).—The following are good books for measuring work connected with the building trades:—"Laxton's Builders' Price Book," 4s. (G. Wilson); "Laxton's Builders' Tables," 5s. (Spon); "Horton's Complete Measurer," 4s. (Lockwood).—J. H.

Heating Greenhouses with Oil.—SIGNALMAN (*Lancashire*).—My experience with heating apparatuses generally leads me to give the preference to a stove outside the house and hot water pipes within it. If the wick of the oil lamp rises—and sometimes it will rise — above its proper height, the result is the discharge of copious showers of soot, which will spoil everything, or almost everything, in the house. There are many oil heaters, but I give my preference to the "Tower" heater, of which you may ascertain all particulars by writing to Mr. John Waller, Arabin Road, Brockley, London, S.E. The hand-light to which you refer is an invention of my own, not of Mr. Le Brun. It is not yet patented, and, therefore, I cannot describe it at present. It is unfortunate that your soil is so sandy, but the remedy—namely, the admixture of plenty of good loam and humus, or leaf mould—would be worse than the ailment, on account of the expense. I should recommend you to try to do more with greenhouse work and growing in tubs and boxes. I have a fine display of geraniums in fancy boxes on walls, and grow cucumbers and marrows in tubs, training the former over the roof of the greenhouse, and the latter on trellis work and along the top of a wall. Results from work of this kind will compensate for the hungriness of the soil, in which, by the way, you ought to be able to get first-class carrots.

Garden Frame.—J. H. H. (*Sydenham*). — Sash lights are not suitable for garden frames. You should make your own frames, and this, I think, you may do from Mr. G. Le Brun's instructions for making lights for the roof of his "Tenant's Greenhouse." If you want more detailed information, write and say so, and you shall have it.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Billiard Slates. — CEMENT (*Cork*) writes:— "Would some kind reader give me a recipe for a cement for the filling up of chipped billiard slates? I have used resin and beeswax, and find in the ironing it is inclined to stick to the cloth."

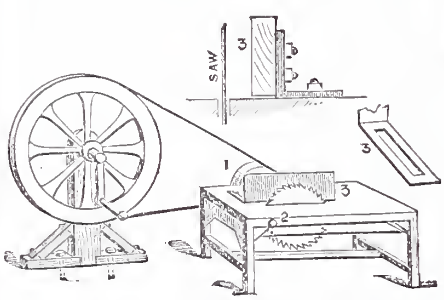
Lathe Work.—A READER OF WORK (*London, N.W.*) writes: — "Would any brother-reader of WORK that's well up in lathe work kindly tell me how to adjust compound rest on lathe, to give the right taper for male and female tapers, also the right place to drop nut into lathe screw in cutting odd threads per inch as 7, and broken threads as 4½ in. saddle taken back by hand at every cut for starting again, lathe screw ¼ pitch?"

Screwing Machine.— INQUIRER asks:— "Will some reader kindly tell me the names and addresses of the latest screwing machine manufacturers?"

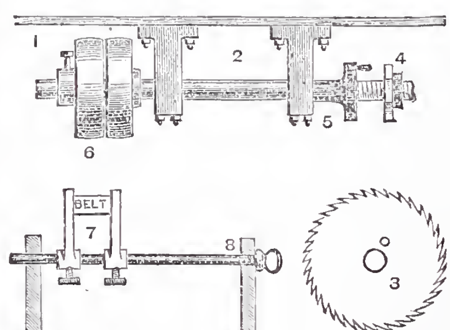
Blacking Hooks and Eyes.— H. R. (*London*) writes:—"Should be thankful to any of your numerous correspondents who could acquaint me with the process of blacking hooks and eyes, and the like."

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Hand Saw Bench.—B. F. (*Liverpool*) writes in reply to G. H. L. (*Hull*) (see page 222):—"I send sketch of hand-saw bench as required. It does not want much explanation. He will find it hard work; the heavier the driving wheel is the lighter it will be to turn saw when it gets on a swing; the smaller



1, Fast and Loose Pulley. 2, Knob for Moving the Strap Back and Forward. 3, Fence to be Moved as required for the Cut.



1, Collar. 2, Spindle. 3, Saw. 4, Nut to Tighten Saw. 5, Place for Washer. 6, Pulley. 7, Belt. 8, Fork to Move the Belt.

the pulleys are the greater the speed on saw, but the larger they are the less power. I should say about 8 or 10 in. diameter, the driving wheel not less than 5 ft. There is another way, by having an extra driving shaft; but the above I fitted up and worked to cross cut firewood; it worked well, but required a strong man to turn it, and keep up the speed, cross cut planks, etc., also ripping 2½ in. boards."

Tobacco Pipe Making. — A PIPE MANUFACTURER writes in answer to SMOKE (see page 222):— "I wish to inform him that there is no book published on the above trade, that I am aware of; but if SMOKE wants to know anything concerning the same, I have an essay on pipe making which treats on all subjects, from the clay to the churchwarden or imitation meerschaum, etc, and which I will submit to the Editor if I may do so."—[I shall be glad to see the article on approval, to which you refer.—ED.]

Trade Notes and Memoranda.

OUR contemporary, *The Engineer*, recently gave illustrations of an automatic pill-picking machine, the joint invention of a practical chemist and of a practical mechanic. The machine can be set to reject any pills which are in the least degree above or below the standard size, or which are not perfectly round, while for commoner qualities of goods it can be arranged to reject only those pills which are conspicuously defective in either of these respects. The machine is already in extensive use.

AN immense engine for rolling steel rails is being erected at the works of Palmer's Shipbuilding Yard, Jarrow. It will be capable of exerting 10,000 h.p. The crank shaft is 21 in. in diameter, and the forging for the shaft weighed over 40 tons. The weight of the entire engine is over 300 tons.

M. BOLLINCKX is casting the valves of Rider engines with chilled faces. The chill penetrates to a depth of ⅛ in. to ½ in. As the surfaces cannot be cut with a tool, they are ground with emery rollers. It is claimed that these surfaces are not only durable, but that they do not wear the surfaces upon which they work, and that the coefficient of friction is very small.

WHAT will be the longest tram-line in the world is being constructed in the Argentine Republic. It will connect Buenos Ayres with the outlying towns, and will be worked by horses. There will be five sleeping cars, 18 ft. long, each with six beds, which in the daytime are rolled back to form seats; and in addition thereto, four two-storeyed carriages, twenty platform carriages, six ice waggons, four cattle trucks, and two hundred goods vans.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

SPECIAL NOTICE.

MELHUISH'S New Pattern

Combined CARVING and WORK BENCH —— CABINET, £8 14 0. ——

Made from American Bass Wood, Stained and Polished, and can be made to Harmonise with any Furniture.

Fitted with the following List of Warranted Tools, precisely the same as we supply to Practical Workmen:

	s.	d.		s.	d.
1 Duplex Iron Plane	1	3	1 Joiner's Hammer	1	2
1 Straightedge, 3 ft. 6 in. ...	1	6	1 Melhuish's Handsaw ...	3	6
1 Bright Hammer	1	6	1 Box Drawing Knife... ...	1	9
1 2 ft. 2-fold Rule	1	0	1 Brace, and Set of 24 well-assorted Bright Boring Bits	6	9
3 Twist Gimlets	0	10	1 Pair Pincers	1	3
3 Patent Bradawls	0	8	1 Spokeshave	0	9
1 Screwdriver each, 10d., 1/6	2	4	1 Beechwood Gauge	1	3
1 Cabinet Scraper	0	5	2 Rasps, handled	1	10
6 Assorted Firmer Chisels...	4	2	1 Pencil	0	1
3 Assorted Firmer Gouges...	2	1	And our Patent Combined Tool, Joinery, and Wood-Carving Work Bench Cabinet, with Vertical Bench Stop and Patent Vice, &c., complete	£5 10	0
1 6 in. Combination Square	2	4			
1 Bright Bench Holdfast ...	5	6			
1 Boxed Oilstone	3	0			
1 Can Liquid Glue	1	6			
1 Beech Mallet	1	6			
1 Beech Mitre Block	1	3			
1 Frame Bow Saw	3	6			
1 9 in. Tenon Saw	3	0			
1 $2\frac{1}{4}$ in. Jack Plane	5	0	Total	£8 14	0
1 2 in. Smooth Plane	3	4

GESSO WORK.

A NEW MODE OF DECORATION IN LOW RELIEF.

BY E. C.

A fresh kind of art work is interesting since the love of novelty and of research is inherent in most natures. Artists, and workmen of the more intelligent sort, enjoy finding out what effects they can secure with any new materials or tools they may have at command. Amateurs especially delight in the latest inventions, and many even cannot resist the temptation of trying each novelty in the way of minor arts as it is brought out, thus making it a foregone conclusion that they will be proficient in none until they cease to play the part of "rolling stones." Still, I do not consider such flitting from one occupation to another as altogether deserving of the scathing condemnation bestowed sometimes upon it. If only at last the butterflies will settle down in earnest to a congenial pursuit when they discover it, they will be none the worse for the smattering of knowledge they have gained. It is not always the case that we can find at once our own nook in the midst of the labourers; having done so, let us fill it to the best of our ability.

As I have been asked to write for this Magazine a paper on "Gesso Work," I am pleased to do so, because I am sure that the art as applied to decoration has a future before it, and those who become by practice competent to execute thoroughly good specimens, will have a pretty safe chance of earning something better than a mere livelihood.

Now I cannot claim for gesso work the charm of novelty since it is ages old, but it is tolerably new to us (last year, I think, the first examples were exhibited in England) as regards its adaptability to furniture and house decoration. Here is the opportunity for those who enter the lists to make their mark; and women may succeed quite as well as men.

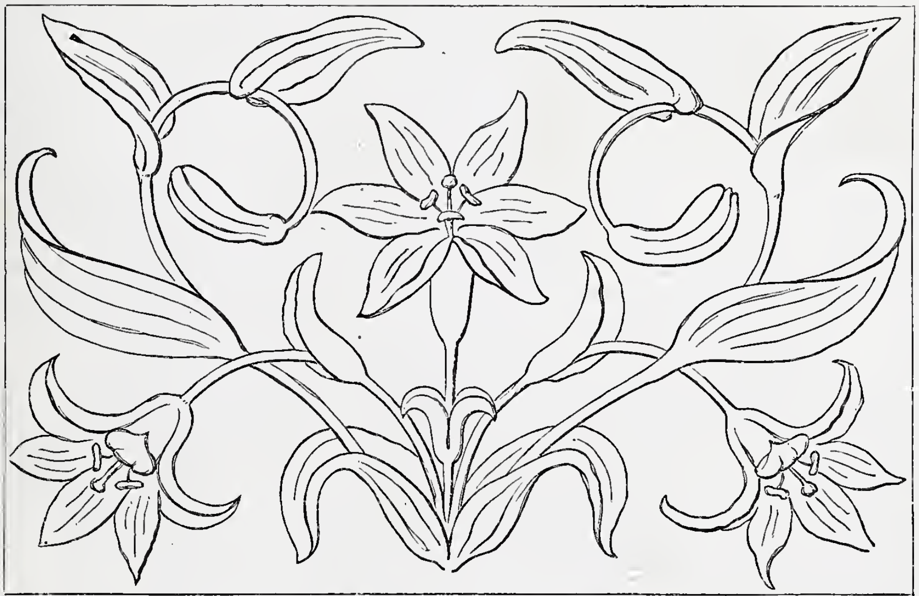

Fig. 1.—Panel for Piano Front in Gesso Work.

Gesso is composed of the finest plaster of Paris and glue. The mixture, which should be of the same consistency as cream, is laid on the surface of sized or lacquered wood with a brush. Two or more coats may be applied to bring the decoration into higher relief, and whilst still soft the composition can be modelled with the brush. It can also be left flat, when it forms a good white ground for painting on. A composition for gesso work has just now been brought out by the Society of Artists, 53, New Bond Street, W. This is prepared so that it will not harden too quickly to allow of its being carefully modelled. It takes about half an hour to dry. Gesso is difficult and troublesome to prepare at home, and it takes up a considerable amount of time, so it is far better for learners, at least, to use the ready prepared composition. Hogs' hair and camel hair brushes are used for the work, and often the gesso is laid on with the palette knife where a high relief is desired.

To gain some conception of the appearance of a piece of gesso work when completed, we can imagine a plaster cast, such as is employed for teaching drawing in schools of art, decorated with silver and gold, and tinted with metallic colours. The effect, when the work is well executed, is rich and harmonious. It is quite possible, of course, that instead of being harmonious it may be garish and vulgar; but this is the case with all work if artistic feeling is not brought to bear upon it; the worker alone is to blame if a pleasing harmony is not secured.

I will describe a few of the different methods of gessoing that will be of practical use to those attempting it for the first

Fig. 2.—Decorative Frieze for Drawing-Room in Gesso Work.

time. Take a panel of wood, and lacquer it green. The term lacquer is rather freely applied in our day. Metallic colours, when sized and varnished, are called lacquers. On the green ground model the design in gesso; let it dry, then silver it, adding touches of gold to bring out the pattern. Or the design may first be sketched on the panel, the gesso laid and modelled, then the background laid in, and, lastly, the gesso silvered and gilded. This is one of the simplest styles of panel that can be executed.

Workers will find that they can get good ideas for designs from some of the best Japanese papers. Large scrolls, arranged on decorated backgrounds, are effective. Beginners should avoid falling into the common error of designing in a finicking manner. Let the treatment of the subject be broad, and free, and strong. Gesso is not fitted to the carrying out of minute details. Still, the decoration can be far more elaborate than that which I have suggested for a first trial. Here is another hint to be followed when a little experience has been gained.

Get a panel of wood, and cover it all over with gesso. Rapidly sketch the design. Now model on the background a set pattern in low relief, after the style of old illuminations or pictures of saints. Next fill in the design with gesso in higher relief and let the whole set. The gesso composition will take the colours more easily if it is sized, but this is not indispensable always. Silver the background, gild the set pattern, and tint the design, which is in high relief, with emerald or serge blue, relieving it with copper gold in parts. If it is desired to get a bright effect, size and varnish the panel; if not, the gold alone can be sized; this renders it more permanent. Nothing more is required in the way of finishing, so it will be understood how easily and quickly gesso work can be accomplished—a great desideratum in these days of hurry and bustle.

Metallic colours are sold, ready prepared, in small tins at 1s. each. A number of extremely beautiful tints are made. Amongst them may be found an exquisite salmon hue, serge and forget-me-not blue, lilac, emerald and bronze green, reds, and a peculiar parrot green. Then there are silver, gold, and copper gold; the latter is particularly effective on a gesso design that has a silvered background. In using the colours, pour off some of the liquid, turn out on to the palette as much of the colour as is likely to be required, then put the rest of the liquid back into the tin; this keeps the colour in good condition.

The white powder and the composition must be well mixed; if too much of the latter is added to the powder a high relief cannot be secured. The brushes and palette are cleaned with turpentine.

The worker has it in his power to obtain charming effects by shading his backgrounds from silver to blue, or by graduating the tints from light blue to dark blue, or from salmon to bronze. A background again may be entirely gilded, or silvered, or coloured any desired shade. When the gilding or silvering is chosen, the ground may be the plain wood or the gessoed wood. It is unnecessary to gesso the panel for gilding or silvering unless a decorated background is wanted; in the latter case the decoration is first moulded, or incised, on the gesso ground, and the whole is then coated with gold or silver.

The design in its turn may be silvered, copper gilded, or gilded. The indentations may be accentuated with colour. Yet again the design may be tinted with one or more colours relieved, or not, according to the artist's fancy, with gold or silver, or copper gold.

It can be seen from the above that a gesso worker is able to produce greatly varied effects, and the decoration, consequently, is well worthy of study. The objection of its costliness will keep it from becoming common, but there are many who will be disposed the more on this account to pay a good price for artistically executed specimens.

The amateur worker is likely to fall into the error of attempting to secure too high a relief. This he should guard against. For a frieze a high relief is desirable; for a panel intended for piano, low relief may be infinitely preferable. Some artists do not model the gesso at all, but lacquer, silver, or gild it flat; others, in certain portions of their decorations, introduce cotton wool, sometimes for the purpose of securing higher relief, and sometimes to obtain a particular effect. For example, Mr. Walter Crane employs cotton wool in his frieze panel, "St. George and the Dragon," in representing the texture of the dragon's wings with excellent result. The wool is dipped into the preparation and laid on the work, slightly modelled or not as the case may require.

One more suggestion to the worker. Try the effect of a gesso design, lacquered or silvered, or both, on a stained or polished wood panel. Those who are clever at drawing or modelling figures have great facilities here for showing their skill, and the draperies afford opportunities of composing rich harmonies of colour.

Pieces of furniture, caskets, ornaments, flower boxes, photo frames, are some of the articles that can be beautified with gesso work. I could add a long list were it not wearisome to read such, but hundreds of things will suggest themselves to readers as appropriate for gesso decoration.

Before executing the illustrated frieze, it is necessary to know the scheme of colour of which it will form a part. As this, however, is an impossibility for me, I will describe how it can be carried out, and workers must substitute other colours for those I mention should they not harmonise with the scheme proposed for the room decoration. We will suppose, for the sake of making the directions as clear as possible, that the scheme of colour chosen is tawny orange, with two shades of blue, the woodwork is painted white, the walls covered with white and gold Japanese paper. The frieze should be treated after this manner. First gesso the ground entirely over, then model the design and bring the grotesque creatures into much higher relief than the foliage. Use the palette knife freely in laying on the gesso, as it saves time. When all the frieze is so far prepared, set to work to colour it. A coat of size will be advantageous, as the gesso will then take the colours easily. There are several ways in which the frieze might be tinted. I should colour the creatures serge blue and gold, the foliage gold and copper gold; then silver the background. Or the ground might be forget-me-not, foliage gold and copper gold, and creatures silvered. The draperies employed with this scheme should be tawny gold plush, the carpet two shades of blue (Wilton), the chair coverings silvery grey, ground with blue and gold in the design. A few touches of red will be required to complete the harmony.

As gesso work is by no means an inexpensive decoration, I strongly advise those who wish to turn the art to practical account only to execute one portion of the frieze (it should include the entire design), as a completed sample is all that is necessary to submit to decorators.

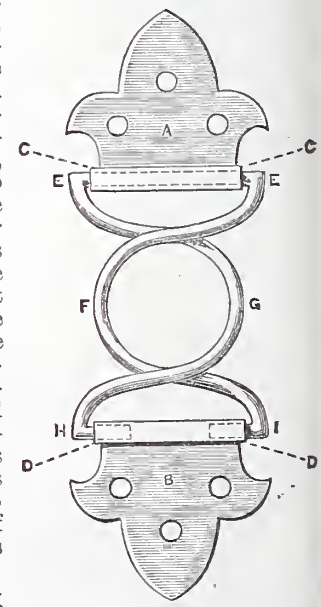
The "Lily" Panel is very simple, and most suitable for a beginner to try his hand upon. The design should not be in at all high relief, although well raised and well modelled. The lily may be painted white and the foliage green on a gold background, or the flower may be silvered, the foliage gilded, and the background tinted emerald or blue. But here again, if it is being done to fill a particular position, the surroundings must be taken into consideration. For my part I prefer the second suggestion for colouring the panel, as gesso work should be as conventional as possible to be truly decorative. Naturalistic effects are not desirable.

A NEW FASTENING FOR LETTER-CASES, ALBUMS, ETC.

BY INVENTOR.

In the district where the writer lives there is a constant demand for novelties in the way of "fancy cases," and it has been part of his vocation to supply models of these to manufacturers. In very many instances a new fastening is asked for, but to invent anything novel in this direction being a great tax upon the brain, it is seldom obtained.

In the course, however, of trying to devise a new means of readily fastening and unfastening a needle-case, the writer invented the clasp shown in the annexed illustration, and, though too large for the purpose for which it was required, he thought it would be very suitable for letter-cases, albums, and other articles, and as such it is presented to the notice of the readers of Work.



New Fastening for Albums, etc.

The construction of this clasp is simple enough, and the model was made by a person possessed of only the ordinary tools which a workman might be supposed to have in his own house. The top part, A, and the lower part, B, were cut out of sheet brass, each long enough to allow of the rolling over of their straight side into a tube, as shown at C C and D D.

Before forming these tubular portions of the clasp it was necessary to bend a piece of wire in the manner shown at I F E E G H. The tube, C C, was then folded over the part of the wire marked E E, and the tube, D D, formed in a similar manner to receive the ends, H I, of the wire.

By an inspection of the illustration it will be perceived that the clasp is there shown as fastened, and it is equally apparent that a slight pressure of the thumb and finger upon F, G, will cause the ends, H, I, of the wire to be withdrawn from the tube, D, D, and the clasp will be unfastened.

This clasp has the advantage of not by its form showing to every one the mode of unfastening it. In fact, to all who have seen it for the first time it appears to be not only a clasp, but an ingenious puzzle.

PAPIER-MÂCHÉ.

HOW TO MOULD, AND HOW TO ORNAMENT IT.

BY SYLVANUS WARD.

DECORATION (*concluded*)—SKY AND WATER EFFECTS IN BRONZE WORK—FANTASTIC CHINESE ROCKS AND RUGGED GROUND IN BRONZE—INTERIORS IN BRONZE—PAINTING IN POWDER COLOURS — PAINTED ORNAMENT RELIEVED WITH GOLD AND BRONZE—SPANGLING—PAINTING, GRAINING, AND MARBLING—FINISHING.

Bronze Work (*continued*).—There is another way in which bronze powder may be applied—by a stencilling process which is the converse of that already described. To effect this, the ornament is not, as in the former case, cut through the stencil plate, but is left remaining, whilst the other parts are cut away. The plate thus formed is laid on the work, and the bronze powder is dusted upon those parts which are not protected by it, and shaded off till it dies away in the general ground. In this work a white bronze is used, and afterwards stained with some transparent colour. The ornament is thus left black; and purple, which harmonises well with black, is a good colour with which to stain the bronze. The result is a rich velvety effect.

Fig. 44 shows the principle on which a stencil plate for this kind of dusting-in should be cut, which, it will be observed, is very much that of fretwork. The form given may either serve as a "repeat" in a running pattern, or as a quarter of a quatrefoil. The dots would be pierced, and would show on the work as solid bronze.

Sky and Water Effects in Bronze.—By bronze work something of the glowing effect of evening skies is to be attained in a much more rapid manner than by colours. In that part of the work where the light is supposed to be most brilliant—that is to say, in the lower part of the sky—the bronze powder is first dusted-in pretty solidly. In depicting such skies, the sun himself is not usually shown; but if he does appear, he must be put in quite solid—indeed, gold powder is best for the luminary, put in with a "stump." The brilliant variations of hue seen in sunset or sunrise skies are readily reached by using different bronzes, the brightest touches on the sunlit clouds being put in last of all with gold powder and a "stump."

It may, perhaps, be well to explain the "stump" used for this work, which has nothing in common with the little roll of wash-leather used by the ordinary draughtsman, and called by the same name. The japanner's stump is a small camel-hair pencil (say, of the same size as that previously mentioned as a "sprigger") which has been cut off almost close to the quill—as near, perhaps, as the tenth of an inch—and which has then been rubbed down to a rounded, or rather convex, shape on a pumice stone. It will be found useful for many purposes in bronze work, besides those of which we have spoken of.

By using a white bronze an approximation to the effect of water may be produced in much the same way, and the resemblance increased by adding a bluish shade with transparent varnish colour.

Fantastic Chinese Rocks and Rugged Ground in Bronze.—Fantastic rocks of the type shown in Fig. 45—forms derived, like the art itself, from the far East—have been of frequent occurrence in japanned work, and they are produced by first pencilling-in with gold size, and then dusting with bronze. Sharpness and decision are afterwards given to the masses by touches here and there of pencil bronze. In Fig. 45 the dark strokes denote this pencil bronze work; and as the example before us is necessarily on a *white* instead of a *black* ground, the greatest depth of shade in it represents what would be the lightest part of the actual bronzed work. This will equally apply to Fig. 46. Throughout these articles the fact that papier-mâché gives a *black* ground, whereas the printer's paper gives a *white* one, has been a serious bar in the way of efficient illustration.

Rugged or broken ground (Fig. 46) is worked in bronze by first sizing over the space with gold size; then a piece of paper is taken, and cut to an irregular outline, something after the fashion of Fig. 47, for use as a stencil plate. This is first laid at the bottom of the work, and bronze is dusted on, thickly just at the edge of the paper, but it is allowed to die away beyond. Then the stencil plate is moved a little higher, and the process repeated; and this is done again and again till the required space has been covered. The desired effect is thus easily attained, and a few bold strokes with pencil bronze showing as blades of grass on the summits of some of the irregularities, etc., gives an amount of conventional completeness to the representation. This, like the rocks, is Chinese in its origin; the Willow-Pattern Plate shows vestiges of it.

Interiors in Bronze.—Interior views of buildings, and more especially of such buildings as Gothic cathedrals, are capable of being made highly effective in bronze work. The proper mode of procedure is first to lay in the light side of the interior pretty solidly with bronze powder in the usual way, and to shade off to the darker side. If the pillars stand out in light, they should be stumped with gold powder or pale bronze. At this stage a thorough drying in the stove is desirable.

The details will now have to be sketched out with approximate accuracy, and, as in work of this sort straight lines are sure to abound, the straightedge will of course be freely used. The blacklead pencil will be found to mark well on the bronze, which has that sort of roughness commonly spoken of by workers as a "tooth." And now, where rays of sunlight streaming in through the windows make brilliant patches on pillars, walls, etc., such patches should be laid in with gold size and gilt with pale gold. If, as is most likely the case, our interior is that of some Gothic minster, one of its most striking features will doubtless be a stained-glass window. This, with the means at our command, can be rendered highly effective. The lights—the glass portions, that is—of the window we lay in with gold size and cover with silver leaf, which will enable us by-and-by to colour them most brilliantly.

Our window, being that feature of the composition which most catches the eye, will be the one on which to work first, the other parts being afterwards brought up to and made to harmonise with it. The mullions and tracery should first be put in to serve as frames for our representations of stained glass. These, which will show quite dark, must be put in with black paint, in which is a mere touch of bronze powder, just sufficient to preserve its affinity with the surrounding bronze work. The figures or other designs of the stained glass can then be painted in with transparent colours on the silver leaf. The scale will, of course, rarely be one to allow more than mere indications of such designs to be brought in; but slight as they may be, the effect produced will be one of much richness and beauty.

Figures in rich vestments are sometimes introduced, and these can also be laid in with silver leaf, and stained with transparent colours as above; but these can never be made to arrest and delight the eye like a window.

But to return: our glass being stained, the parts of the structure immediately surrounding our window will next have to be worked upon with a mixture of bronze and some little transparent colour. The parts in light are then proceeded with, bronze paint being used—that is, bronze powder mixed with copal varnish, and applied just as paint might be. In some of the light parts (such as those pillars which are to the front, and being in light show most prominently) the bronze will have to be laid in quite solid, in order that it may as nearly come up to those parts which are gilded as is demanded by artistic effect. On the more receding pillars, etc., the bronze will have to be so reduced as to allow them to recede into their proper places; either using less bronze, or mixing the bronze with transparent colour, will enable the decorator to effect this.

Painting in Powder Colours.—Our remarks on bronze work may properly be followed by some information as to the methods of using colours which, like the bronze, are in a powdered state. Papier-mâché decorators have chiefly used powder colours for two purposes:—Firstly, for groups of flowers, in which the effect has been almost wholly dependent on this process; and, secondly, for views of interiors, in which this process has served as little more than a preparation and background on which the finished result has been attained by other means.

As an illustration of flower painting in powder, let us suppose that the object to be represented is a red rose. There are three ways in which we may set to work:—

1st. The block form of the flower is laid in with tube oil colour (flake white) to which a little varnish has been added to make it dry more quickly. On the ground thus formed a single petal is pencilled-in, and powdered colour is dusted upon it—it being applied most thickly in those parts where most colour would appear in the natural petal. This has to be dried. A second petal is then coloured in the same manner, and also dried; and so on till the rose is completed. This was the older process. It was necessarily a slow and laborious one, but no other process equals it in softness and beauty of effect.

2nd. With tube colour (flake white) mixed as before, the whole rose is painted in so as to have somewhat the appearance of a white rose, and upon this powdered lake is dusted. The parts most strongly painted in white will appear to come forward, and the others to recede. The finishing is done with brush and tube colour.

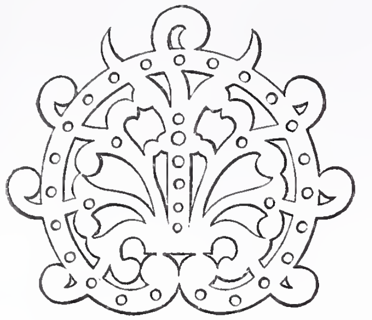


Fig. 44.—Bronze Work: Ground Stencilling.

3rd. The rose is solidly blocked in throughout with the white paint, and on this the dust is then placed and shaded down with the brush. A dead representation of the flower is thus obtained.

Powder colours give a softness of effect not attainable by any other process of painting, and they can be used expeditiously.

With regard to the application of this process to interiors, not many words of explanation will be necessary. The whole has to be painted in with the tube flake white mixed as above, and powdered colours are dusted on. It is afterwards finished when dry with moist colours. Silver leaf is sometimes introduced in interiors thus painted, as it is in those done in bronze. Indeed, dusting-in with bronze and colour may be said to be really one and the same process, the material only being varied.

Painted Ornament Relieved with Gold and Bronze. — A method of decoration sometimes adopted on large articles is to paint the ornament in colour—usually a brown (burnt umber) or a bronzy green—and to give brightness and variety by relieving it in parts with gilding and bronze. Fig. 48 may serve as an illustration of this kind of ornament. In this figure the simple tint represents the green or brown ornament, and the shaded parts those which are bronzed. On these latter, after the colour painting, the bronze powder is dusted in the usual manner, and a drying in the stove or otherwise is necessary. The ornament is then almost wholly outlined and lighted up with gold, as shown in Fig. 48, where gilding is represented by black. A considerable amount of gold sprigging around or in connection with the ornament is often added with good effect. This is also exemplified in the illustration.

Spangling.—Among the showy methods of decoration used on papier-mâché is the employment of gold spangles. These the decorator readily makes for himself by following the ensuing directions :—

Take a glass bottle, and, having made sure that its outside is thoroughly clean, gild it wholly or in part, according to the quantity of spangles required. The gilding will be done with leaf gold and isinglass size, in the manner recommended for bright gilding on papier-mâché. After burnishing as directed in connection with that process, varnish the gold all over with copal varnish, and dry in a stove or warm room. When the varnish is quite set, fill the bottle with cold water, and let it stand for a night in a cool place. By this the varnish will be rendered brittle ; the bottle should then be held aslant and scraped upwards with a knife, which will cause the varnish to fly off in small flakes, bringing the gold with it. The spangles thus formed will be of a brilliancy not to be surpassed ; and should they be too large for use, they may be reduced in size by rolling and crushing under the thumb in a piece of paper. There are many purposes, apart from the decoration of papier-mâché, to which such spangles may be applied.

On papier-mâché they are thus used :—The space to be spangled is gone over with copal varnish, to which a little oil has been added, and this should be laid on carefully and evenly. Spangles, in order that they may adhere properly, demand, it should be remembered, a much more moist surface than is required by gold leaf ; the ground must, therefore, be only partially dried ; and when it is ready, they are to be dusted freely on with a camel-hair brush. The dry brush will readily remove those which do not stick, which will be none the worse for future use. Nothing more is required except drying in the stove or otherwise.

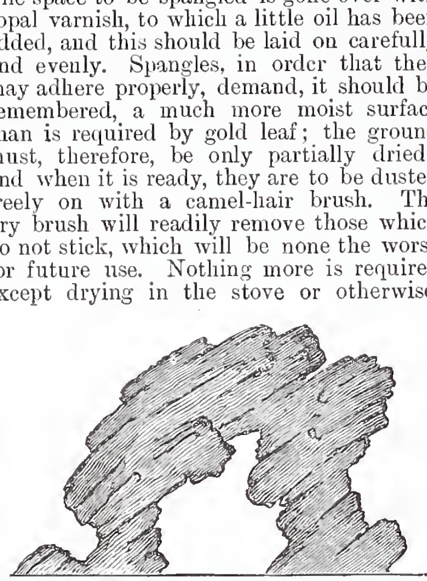

Fig. 45.—Fantastic Chinese Rocks in Bronze.

Fig. 46.—Rugged Ground in Bronze.

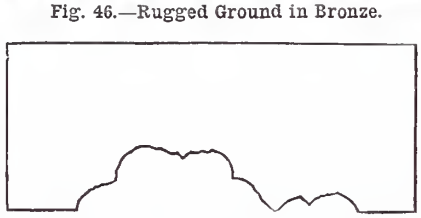

Fig. 47.—Stencil Plate for Working Rugged Ground.

Spangles thus used have a rich sparkling effect.

Painting, Graining, Marbling, etc.—For painting in the ordinary manner with ordinary colours, papier-mâché forms an admirable ground, though those brighter and more showy methods of decoration which we have described, and to which it lends itself so readily, have ever been more in favour for ornamenting it. This is not the place in which to give any treatise on ordinary painting, and there are no special points in regard to its relation to our material to be noticed. Nor need much be said here with respect to graining or marbling, both of which have been practised on papier-mâché. In the matter of marbling it may, however, be observed that the spangles named above will be found useful, sparingly used, in giving imitations of lapis lazuli, as furnishing the sparkle of the natural stone. Malachite, like the foregoing, has been a favourite stone for imitation on papier-mâché, and in passing we may mention that the dark rings which distinguish it may most readily be produced by applying the finger end and turning it round ; withdrawing it abruptly will then form the dark spot which occupies the centre of the ring.

Associated with graining is a way of imitating inlaid woods which first came under the writer's notice in connection with papier-mâché work, though he has since seen it applied to other purposes ; this also may be worth a passing word. The space is first grained all over with graining of one kind —say, maple—and, when this is dry, those portions of it which are to appear as inlaid are painted over with a kind of paint made with finely-powdered rotten-stone mixed with treacle or sugar. On this, when dry, a second entire coat of graining is given to the space —say, this time, of walnut. If, when this is set, the article is damped, the saccharine paint will come off and bring with it that coat of graining which lies above it. The result will be that the space will appear as of walnut, with inlaid ornaments in maple.

Finishing.—Whatever mode of decorating the papier-mâché may be adopted—whether pearl-inlaying, gilding, bronzing, painting, or a combination of any or all of these—the decorations will finally, with a single exception, have to be covered and protected with a coat of varnish. The solitary exception is when the decoration consists of broad surfaces of natural pearl not painted or otherwise embellished. These need no varnish, and indeed, if put over them, the varnish will be liable to peel off under changes of weather ; it is the painting, etc., upon the pearl which binds varnish firmly to it.

If the decoration extends over much of the surface of the papier-mâché the better plan is to take a broad brush and lay an even coat of varnish over the whole. If, however, the decoration is confined to detached portions, it is best to pencil the varnish over the ornaments only, leaving the ground untouched. And for this reason the black japan varnish of the ground takes a finer polish than is to be got on copal, and therefore the more of it that can be left uncovered the better.

When the varnish is thoroughly dry, it has to be polished. First, to remove any slight irregularities, it is lightly gone over with a bob and wet rotten-stone ; and after this has been swilled or wiped off with a clean wet rag, with powdered dry, hard rotten stone ; then with whiting powdered very fine and sifted through muslin. The dr

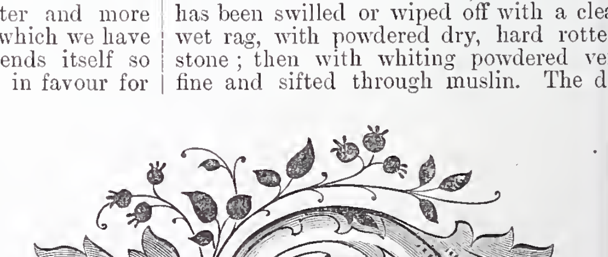

Fig. 48.—Painted Ornament Relieved with Gold and Bronze.

tten-stone and whiting should be carefully eaned away with a silk duster. Lastly, brilliancy not to be attained by any other eans is given by friction with the palm of ie hand lubricated with a spot or two of veet oil. A woman's hand only is capable doing this properly, and a hand of which ie fingers can be bent well back.

The perfect brilliancy of surface reached y these means on well-finished papier-iâché is one of the distinctive beauties of ie material; and when the article is in ousehold use, this brilliancy should be preerved by wiping or dusting it only with a oft old silk handkerchief.

POLARISATION OF LIGHT AND POLARISCOPES.

BY O. BECKERLEGGE.

POLARISATION OF LIGHT EXPLAINED.

HE subject which I have set before me to iscuss for the readers of WORK is one eset with unusual difficulties. First of all, n the part of the reader, a great deal of reliminary knowledge is required in reerence to the theory and physical properties

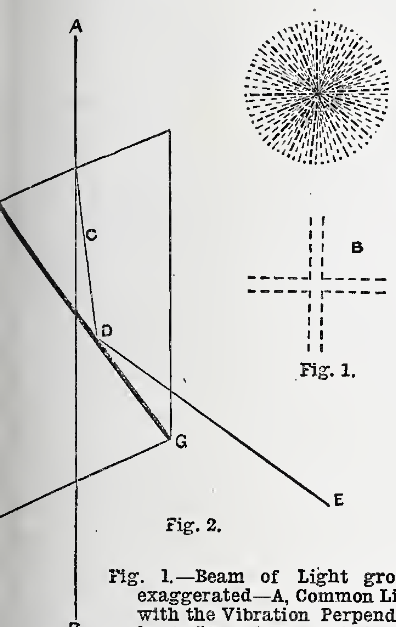

Fig. 2.

Fig. 1.

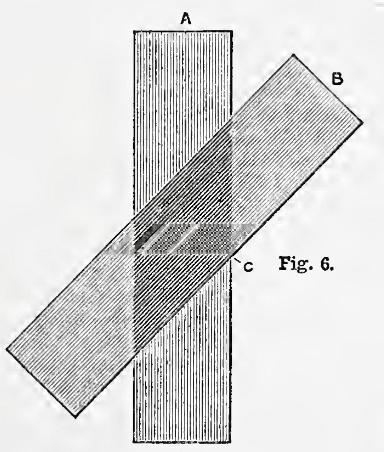

Fig. 6.

f light. On the other hand, there are but ew—the present writer included—who eem able to grasp the subject so as to ay it before the reader in a manner easy to e understood. It is a difficult subject. But it should be remembered that the scienific or philosophical instrument maker, as a ule, is not held responsible for the theory r its explanation, only so far as demonstraion and the application of his instrument o the theory may be concerned. I, thereore, shall have no more to do with the heory than will be necessary to obtain an ntelligent view of our work, my object eing principally practical—to furnish hose who wish to study more advanced reatises on the subject with the means of emonstrating by the use of instruments, nd especially in conjunction with the nicroscope.

By polarised light, we understand light hat has undergone some change by which it resents two distinct and opposite conditions

Fig. 2.—Rhomb of Iceland Spar made into a Nicol Prism—A, Direction of Ray of Light; B, Extraordinary Ray; C, Ordinary Ray refracted at D to E by Canada Balsam at Juncture F G. Fig. 3.—Diagram of Plates of Glass at Angle of 26°. Fig. 4.—A, Analyser; B, Section of Polariser; C, Thin Plates of Glass; D, Ledge to Support Glass. Fig. 5.—Two Plates of Tourmaline, showing the Light intercepted at C. Fig. 6.—The same, showing the Light Fading when partly turned. Fig. 7.—The Vibration of Ether grossly exaggerated—A B, The Length of the Wave; B C, the Amplitude.

or sides, the term being a figurative one, borrowed from the opposite ends or poles of a magnet.

It will be admitted that light is the result of an imponderable medium known as ether, thrown into a state of vibration. This medium pervades all space, and envelops every atom of matter. In the transmission of a beam of light, there is no forward motion of ether, but simply a progressive wave.

For example, in looking over a corn-field a wave will often seem to pass over it, occasioned by the breeze. A row of corn is slightly depressed for an instant, but as soon as the pressure of wind is gone it regains its upright position. The falling and rising succeed each other with great rapidity, and the eye takes cognisance of a forward motion, not of the corn but of the wave—the corn has simply moved in a perpendicular manner.

Another, and a familiar, illustration is the series of rings on water caused by throwing a stone into it. Now, it will be seen that if a straw is lying on the water it will simply rise and fall with each succeeding wave, but will make no forward motion, as it would if the water advanced. Light then is the result of the undulations or vibrations of ether. When these vibrations are conveyed to the brain through special nerves, we see. In ordinary light the vibrations take place in all planes perpendicular to the ray, Fig. 1, A. It may be further added that intensity of light is as the amplitude of the wave, or distance from the crest of one wave to the sinus or hollow of the next, A C, Fig. 7. The colour of the light depends on the number of vibrations. All are aware that in a ray of white light there are combined the three primary colours—red, yellow, and blue—and that they vibrate at different rates. Imagine a ray of light approaching the eye, if one may so say, end on, with the vibrations perpendicular to its path; this is common light. Let us now, by some means, split the ray into two, and cause one ray to vibrate perpendicular to the other. We shall find that whilst to the unaided eye there is no difference whatever, yet, when viewed under certain circumstances, there is a marked difference, Fig. 1, A B.

There are various means by which a ray of light may be brought into this condition. The means most generally employed are by refraction and reflection. Almost all crystals of the rhombohedron class will polarise, whilst those crystals belonging to the cube system, such as common salt, will not. Of all crystals belonging to the former system, Iceland spar, a transparent form of carbonate of lime, is the best, Fig. 2. If a black line is viewed through it, it is doubled; viewed in a careless manner, they seem to be just alike, but in reality they are very different and obey different laws. Thus, one is called the ordinary, and the other the extraordinary ray. Now, if the crystal is turned on its axis, the lines will come together until there is but one visible; continuing to turn they will again divide, until crossing the crystal at an angle they reach their widest divergency. Now let us substitute a black spot for a line, and we shall find something more has transpired than we were aware of, for now, instead of the spots receding and coming together, we find that one spot is stationary, whilst the other travels round it. Of course, the difference between this phenomena and the last, is only the difference between a point and a continuous line; the line simply revealing the horizontal but not the perpendicular displacement. But another difference may be observed. If we view the divided lines through another piece of spar, we shall find that in causing one piece to rotate, one of the lines will disappear at each quarter of a revolution. But the same appearance and disappearance may be observed in a very striking manner by viewing the lines through a bundle of thin glasses, Fig. 3.

This latter fact leads us on to another subject. Although Iceland spar is for many reasons preferred, yet other substances have the power of polarising transmitted light. Let us make two tubes like Fig. 4, with the ends cut off at an angle of 26°. In each tube must be placed a number of plates of glass. Common window glass will answer our purpose if we make the tubes large; but if we purpose using small tubes—say with a microscope—then the thick glass will not afford much light. In practice, I have found the thin glass used as micro covers by far the best. Now if we look through the tube B, we shall find no change visible in the light transmitted, yet a change has been effected of the most striking kind. This piece we call the polariser, and the light is polarised, although so far we can see no difference. Let us now look at the transmitted light through the second tube, A, which we call the analyser. Let the angle of the tubes lie in the same plane, still no alteration takes place. If now we turn one tube round so that the angles shall be perpendicular to each other, A, B, Fig. 4 —that is to say, let the tube be turned one quarter round—we shall find that the light has gradually disappeared, until, if there be several films of glass, the light is extinguished. Continuing to turn the tube the light will again be transmitted, gaining in intensity until the tube is turned half-way round. Passing on to three-quarters the light is again quenched, but gradually restored as we gain the starting point. We now arrive at a very important point, which is this—that the ray of light transmitted has two distinct sides or poles, and that in one position the films of glass offer no resistance to the ray, whilst in another position, a perfectly transparent medium refuses to allow the ray to pass. It is evident, therefore, that the ray of light is not in an ordinary condition, as the glass offers no impediment to ordinary light.

We are now led to make this inquiry: What is the optical condition of the medium through which the ray passes? The answer is this—that the ether surrounding the atoms of which the crystal is built up is in unequal tension in opposite directions, and vibrates at different rates. A sheet or film of ice is a familiar illustration. In the act of crystallising, the molecules arranging themselves according to a definite plan, render the ether less at liberty to vibrate in one direction than another. Between the horizontal and perpendicular there is an unequal tension. It will now be easily understood that a ray of polarised light—that is to say, a ray which has been split into two, and one half stands at right angles to the other—if it is transmitted through such a medium, will meet with difficulty in one direction, consequently the ray in that direction will be retarded. When tourmaline is cut in thin slices it will transmit a ray of light, but if cut in a certain direction it will allow the light to pass only in one plane, the ether being at liberty to vibrate in that direction only. Now let us suppose ourselves to be looking at a ray of light coming towards us, with the vibrations at right angles to each other, or polarised, B, Fig. 1. If the ray be viewed through a slice of tourmaline, those rays which are in the same plane with the line of transmission will freely pass, but those which are at right angles to that line will be retarded. If we cause the plate to revolve, there will be neither diminution nor increase of light, for as it gradually stops out the perpendicular rays, it will also gradually admit the horizontal.

Let us now place a second slice of tourmaline over the first with the plane of transmission coincident with the first; no change will be perceived, beyond a slight decrease in transmitted light occasioned by a portion being absorbed. If we now turn one plate round, Fig. 6, the light will grow fainter until the plates stand at right angles to each other, when there will be an utter extinction. Why? For this reason: The light being polarised, is transmitted in two planes perpendicular to each other. Thus the first film allowed but one set of vibrations to pass. The second being placed at right angles to it, cut this off, as the first cut off the other, the result being that no light at all is transmitted, and the centre of the crossed films is black, Fig. 5. Proceeding to turn the film round still further, the light increases until they are coincident. We have thus in a revolution two positions of transmitted light, and two positions of darkness. Instead of the films of tourmaline, we may use a Nicol prism, called after its inventor, which is a rhomb of Iceland spar, cut as indicated by the thick line F G, Fig. 2. The surfaces are polished and cemented together by Canada balsam. Now, as the refractory angle of Canada balsam is different to that of the spar, and as the ordinary ray is refracted at a different angle to the extraordinary ray, we can throw the ordinary ray outside the prism altogether, and so have the polarised ray only in the field of view; A B is the extraordinary ray; C D is the ordinary ray obeying the ordinary law of refraction; at D the ray impinges on the cement, which having a greater refracting angle turns it to E, and thus it fails to reach the eye. Let us now take two such prisms, the polariser and the analyser, or two bundles of glass, and place them at right angles, and so cut off all light. If now we pass a thin film of certain crystalline material between the polariser and analyser, we shall find that light is again transmitted. Indeed, it seems, as one has remarked, as if the film pushes away the darkness. Thin films of mica have this property, but that which is most commonly used in microscopic work is selenite, a transparent form of sulphate of lime. But many other crystals will do the same. In viewing thin sections of crystalline rocks, the writer has often seen the same phenomena. Certain crystals in the rock having this property lying at a definite angle transmit the light; whilst other crystals equally transparent to ordinary light refuse to transmit any whilst the analyser stands in that position; but when the analyser is turned round, the first crystals become dark, whilst others transmit the ray. We have again to inquire, how is this? Certain crystals are so built up that the ether can vibrate but in two directions perpendicular to each other. Now, it will be readily seen that if such a crystal be placed obliquely between, say, two tourmaline films, it will pick up some rays belonging to each side and transmit them; whilst if the planes of transmission stand coincident with the plane of transmission of either plate of tourmaline, no light can be transmitted.

Thus we see that so far we have come in contact with three systems of transparent crystalline substances; one, as common glass that vibrates in all directions; a second, as tourmaline, that vibrates but in one direction; and a third, as selenite, that vibrates in two directions perpendicular to each other. There is a further phenomenon yet to be explained, if possible. In using thin films of mica or selenite, we not only discover the phenomena just now referred to, but another and beautiful one—that of colour. Dependent on the thinness of the plate, so will be the colour, which will be of the richest hue; further on, turning the analyser or polariser, we find the colour fade, but instantly change to its complementary. It is understood that all light *under similar conditions* travels at the same rate, but that the length of wave, that is, the distance between the crests of the waves, A, B, Fig. 7, is different for each colour. Let us make a mental picture of two differently coloured rays of light, and we shall find that though they pass through the *same space* in the *same time*, yet the length of their wave is different.

"The shortest waves of the visible spectrum are those of the extreme violet; the longest, those of the extreme red; while the other colours are of intermediate pitch, or wave-length. The length of a wave of the extreme red is such that it would require 36,918 placed end to end to cover one inch, while 64,631 of the extreme violet waves would be required to span the same distance." *

We see from this, then, that there is a difference between the length of wave in the violet and red amounting to nearly one-half.

Taking an inch as a unit, then the distance between two waves of red light would be $\frac{1}{36918}$, and between two waves of violet, $\frac{1}{64631}$ of an inch. We have already endeavoured to explain the fact that certain crystals retard a ray of light in proportion to the angle at which it is transmitted and the thickness of the plate. Now, let us imagine a

* Tyndall, on light.

ay of light traversing a crystal in such a lirection that no obstacle is presented, then t is evident that all the vibrations will be ransmitted, and white light will be the esult; but let us now turn the crystal so hat the power of transmission shall be coincident with certain rates of vibrations nly; the result will be that the colour nswering to those vibrations will be transmitted. If the light is retarded so that only vibrations the 36,918th part of an inch in length can pass, then the light will be red, and so on for every separate colour. On turning the analyser the complementary colour is transmitted, or that portion which has been quenched, which, united to the first, constitutes white light; so that, in revolving the polariser or analyser, the whole of the light is transmitted, but in two amounts—the balance due on the first is transmitted on the second.

In splitting off a film of selenite, somewhat as an amateur would do, a variety of colours will be visible, arising from the fact that the film is of unequal thickness. Sometimes they are so purposely arranged, that they shall make a kind of picture, say, of a flower—the leaves and flower alternating in colour as the analyser may be turned.

I think little more need be said on this part of my subject to help one to an intelligent comprehension of the use of the instrument I purpose describing. For more exhaustive details I must refer the reader to such masters as Tyndall, Spottiswoode, etc.

A SMALL SIDEBOARD WITH DRAWERS AND CUPBOARDS.

ITS ARRANGEMENT AND GENERAL DESIGN.

BY ALEXANDER MARTIN.

Construction and Details.

Before doing anything to the actual making of the sideboard, the design should be drawn out full size on a board, from which drawing all the sizes—lengths, breadths, and thicknesses—of the different pieces of wood may be obtained. This is the plan adopted in large establishments, and it is found to be the most convenient in every way; it saves time, and everything may be seen at a glance where it has to go, and how it is related to its immediate surroundings, so that nothing need be done haphazard or by guess. There is, therefore, far less chance of a mistake being made which may cost hours of work to put right; not to mention the waste of materials at the same time. In describing the drawings required to be put on a board, it may be advisable to state, first of all, that an end elevation of the sideboard shown in Fig. 1 (p. 377) is given in Fig. 2. This end elevation is drawn to a scale of 1 in. to 1 ft., or one-twelfth real size. All the other figures are drawn exactly one-half full size, so that to get the real size of any moulding, simply double the measurement it has on the paper. The detail drawings, from Figs. 3 to 15, are arranged—as regards numerical order—in the way the different parts would come under notice, when one begins at the top pediment and carefully examines the design downwards until he reaches the turned feet in Fig. 15, Fig. 3 having been the section of the moulding used in the pediment.

The size of the top measures 5 ft. × 1 ft. 10 in. Draw on the board then, as the first operation in the horizontal section through the cupboards, the half of this top—2 ft. 6 in. × 1 ft. 10 in. It is unnecessary to draw more than the one-half, as the other half is exactly similar. Next draw in the positions of the posts under the top. As the top projects $1\frac{1}{2}$ in., the posts must be kept that distance in on front and ends, but not at back, as the top does not project there. These posts are $1\frac{3}{4}$ in. square, and the two front ones have three beads scratched on their face, as shown in Fig. 13, where is also seen a section of the door stiles, rebated for the planted moulding, which again forms the rebate for the carved panel. This door measures 15 in. across to the division or centre gable, $\frac{3}{4}$ in. thick, and beaded as shown in Fig. 14. The position of the division between the two top drawers should be indicated, and it is also beaded on face as in Fig. 14. The outside gables are framed up with two rails and a panel, the latter being $\frac{1}{2}$ in. thick, and grooved into rails and posts as shown in Fig. 13. The back to the cupboards may be plain pine, *i.e.*, not framed up; but the back to the centre open space must, of course, be made of the wood the sideboard is made of. That completes the horizontal section through the cupboards.

A horizontal section of the back should now be drawn; and in order to save confusion, it is better to draw it on a different part of the board, or on another board altogether. Keep the outside posts of the back right above those underneath. The posts in the top part are $1\frac{1}{4}$ in. square, and have three beads scratched on their faces. They are also rebated for the side glasses, and the panels underneath them. In Fig. 6 is shown a section of one of the centre posts, showing it rebated for the side glass, and also showing the framing and planted moulding round the centre mirror. This mirror is 24 in. wide, so the daylight size inside the moulding should not be more than $23\frac{5}{8}$ in.; this allows for the necessary cover over the edge of the glass. Placing this size on the board in the centre of the space at command, the remaining space at each side will regulate the width of the side mirrors. The panels under the shelf are exactly similar to the glasses above, except that the side panels have a moulding similar to that put round the centre glass planted round them. The shelf is shaped on the front as indicated in Fig. 1, and is 9 in. wide at its broadest part and $5\frac{1}{2}$ in. at its narrowest, which is at its extreme end, where it is supported by brackets $\frac{3}{4}$ in. thick, see Fig. 2. The edge of the shelf is moulded, as shown in outline at the top of Fig. 10, where also will be seen the distance from the edge which the turned pillars are to keep. These pillars supporting the roof are placed right in front of the centre posts of the back.

Now upright sections are required. Begin with the top of the under carcase. It is 3 ft. 2 in. from the floor, and is moulded as in Fig. 11. This whole figure should be drawn exactly as it is, but double the size, of course, on the board. Under the top is a large moulding; then the drawer and its fore edge; then the door top rail, which is much wider than the door stile is, in order to receive the pediment which is glued on its face. The thickness of this pediment is shown to be sufficient to make it project slightly beyond the panel moulding. It has a hollow run out of it near its bottom edge, and the height of it at each end is indicated by a line across it about midway up. The centre is carved after the style of the carving in the pediment. Now, working from the floor up, the front part stands $2\frac{3}{4}$ in. clear of the floor, and turned feet are put on separately. These feet are drawn in Fig. 15. The bottom rail is placed 5 in. from the floor to its under edge, and it has three beads scratched on it, as shown in Fig. 12. In that same figure is given a section of the bottom rail of the door—broad as the top one was, and for the same reason—to receive the moulding and shaping on its face. For the carcase back there is a broad rail at the back of the depth of the drawer fronts, and also another back rail of same size as the bottom rail at front, and in the same position. Both rails may, of course, be pine, as they are not seen at all. Just indicate the position of the bearers for the centre drawer, which is lower than the other two, and this section will be finished.

An upright section is also required through the centre and through the side glasses; draw the centre one first. The shelf, 9 in. broad, is $9\frac{1}{2}$ in. high, and the glass is 22 in. high—that means a daylight opening of $21\frac{5}{8}$ in. The framing round glass and panels below shelf is similar to that already drawn in the horizontal section of the back. Note to make the rail behind shelf broad enough to show the proper margin above and below the shelf when it is put in position. The cornice is made separately, and rests on top of back framing and the two turned pillars in front. A section of it is given in Fig. 4, showing it built up of three pieces. The shaped pediment, $\frac{3}{4}$ in. thick, rises above that again, and has a moulding planted on it, a section of the moulding being given in Fig. 3. The upright section through the side glasses is exactly the same as that already drawn until the shelf is reached. Above the shelf the rail projects $1\frac{3}{4}$ in.; it has a plain margin of 1 in. wide, then a bead is run. On the top edge is formed a hollow and a rebate for the glass similar to that in the top rail which is above the glass. The side glasses are 10 in. high—$9\frac{5}{8}$ in. daylight size—and the rail above is shown in section in Fig. 5, the shaped bracket, $\frac{3}{4}$ in. thick, being above that again.

If any one think these directions and explanations are too fully given, it must be remembered that the drawings must be accurate, or they are useless, and these remarks so fully explain the design that the less remains to be said.

A list of the different pieces of wood required should now be made after this fashion:—

No. of Pieces.	Description.	Wood.	Length.		Breadth.		Thickness.
			Ft.	*In.*	*Ft.*	*In.*	*In.*
1	Top	Mahogany	5	0	1	10	$\frac{3}{4}$
2	Posts, front	„	2	$10\frac{1}{2}$	0	$1\frac{3}{4}$	$1\frac{3}{4}$
2	„ back	„	3	$1\frac{1}{4}$	0	$1\frac{3}{4}$	$1\frac{3}{4}$

The first column is for the number of pieces required; the second for the name of the pieces; the third for the wood—mahogany, oak, pine, cedar, etc.; and the others for the sizes. From this list every piece of wood required may be sought out and cut. The different pieces requiring jointing—as, for instance, the top and gables—should be shot and glued up. The outside gables are framed up, the panels being grooved in, and the posts mortised for front and back rails and fore edges. The inner gables are prepared to receive the bearers of the centre drawer, and are themselves pinned into the bottom rails and drawer fore edges. The bottom—which is in three pieces—is now put up from below; the centre piece of the bottom, being seen, must be of show wood; the other two pieces may be of pine. The mahogany and pine should be half checked underneath the inner gables and screwed to them, as shown in Fig. 19. Here

notice that the right-hand bottom is the mahogany one, and the left-hand one the pine one. If they be reversed, the edge of the white wood bottom might be seen if the joint were the least bit open; the other way it cannot. The bottom is blocked at front, back, and ends, where it had better also be secured to the end rails. The earcase backs may now be put on: mahogany again at the eentre; pine at the sides. The drawer bearers and guides are put in their places, and the drawers made. The doors may now be framed up and moulding planted, as indieated in the sections in Figs. 11, 12, and 13. The pediment and lower base moulding and shaping to panel add some little work to the door; but it is time well spent, as it forms quite a feature in the design. If, however, it be thought that there is enough work without this extra amount, it is easy to make the top and bottom rails of same width as the stiles are, making the carved panel, of course, a little bit longer. This carved panel is the principal part of the decoration of the door, but the extra mouldings and shapings above and below it have a great influence in effectively placing it before the eye. The brackets under centre drawer, and also those under bottom rail, are $\frac{3}{4}$ in. thick, and have the little scroll carved on them to carry out the line of shaping to a suitable termination, at the same time decorating the bracket. The turned feet, it has already been mentioned, are put on separately to the post. This is to save wood, as the feet are thicker in diameter than the post (see Fig. 15); and mark that the corners of the square posts are rounded away where the turning commences. For the carver's guidance, the door panel is drawn in Fig. 18, the reverse side being, of course, similar to that shown. The dotted line indicates the margin that is covered by the panel moulding when the panel is beaded into the door.

The upper part has not nearly so much work in it. The four posts are mortised for the cross rails, and rebated for the panels and glasses, and moulded on faces, as already described and shown in Fig. 6. The top rail is an important feature in the back, having part of the moulding "dentilled," as shown in Fig. 5. This "dentilling" may readily be done with a chisel, and eonsists in cutting a channel through the convex moulding to the depth shown by the dotted line in section in Fig. 5. It forms a capital enrichment obtained by means of a very little work. Above this rail is fitted a shaped and carved bracket, which is blocked into its place. A sketch of the earving is given in Fig. 17. The frame for the centre glass is mortised together, and dowelled between the posts. Notice that the frame goes from top to bottom, the shelf being placed against it. The rail behind the shelf is made broad enough to show the proper amount of margin both above and below it. The end posts have a turned knob at top, which is turned like that shown in Fig. 8. This figure illustrates the turned finial in centre of pediment, and is much larger than the other knobs should be; they should only measure about $2\frac{1}{2}$ in. high and 2 in. over their widest parts, in place of 6 in. high and $4\frac{1}{2}$ in. wide. The two centre posts are taken only to the underside of the cornice, it being made separately, as previously mentioned. The foundation of the cornice is a solid roof, over which the other members are placed, as shown in Fig. 4. This solid roof had better have cross ends put on it, mitred at front corners, so that end wood may not be seen in any part of the cornice. The pediment is fixed above top moulding of cornice, and is carved at sides, as shown in Fig. 16; and in the centre, under the turned vase, it has three flutes cut. This turned vase, finishing the centre of the pediment, is earved too, as shown in Fig. 8. The pediment being only $\frac{3}{4}$ in. thick, and with the addition of the moulding $1\frac{3}{4}$ in., it will be seen that this vase cannot sit on that narrow surface. It should be placed 1 in. back from the face of the moulding—*i.e.*, having its front surface exactly in a line with the surface of the pediment; and another piece of wood may be put in behind the pediment to receive the vase. This cornice rests on the back, and is supported by turned pillars at front. The shelf is screwed from behind, as also are the brackets at its ends. There should be a dowel in the bottom edge of the brackets near their outermost corner, to enter the top of the sideboard, in order to keep them securely in their proper positions. The pillars supporting this shelf are shown in detail in Fig. 10, and the larger pillars supporting the cornice in Fig. 11. In this latter instance, the long, straight shaft of the pillar is broken off to save space, but all the rest of it is shown. Notice that, as the shelf is rather thin to receive a pin from both top and bottom sides, as these pillars require, it is better to make the pin of one pillar stouter than usual, so that it may be bored to receive the pin of the other. This is indicated by dotted lines at the topmost end of Fig. 10. Blind backs must be provided to protect the backs of the mirrors. These are usually not more than $\frac{1}{4}$ in. thick, and are screwed to the back of the framing. (See Figs. 5 and 6.)

It is advisable, when all is finished, to take as much of it apart as possible, in order that the polishing may be the more expeditiously performed. The doors should be taken off, the panels taken out, the pillars, shelf, and cornice removed, and the brackets and pediment unfastened. If made of mahogany, it should be polished in its natural colour, allowing it to darken through exposure to the atmosphere. If, however, that be thought too slow a process, it may be stained dark at once. The same remark—about staining—applies to oak, if that be the wood used; and it may darken through age, but very slowly indeed. Walnut needs no staining, but the inside of the job will need it, at any rate where white wood has been used, whether oak, mahogany, or walnut be the chief wood.

The glass should, of course, have bevelled edges; there is scarcely any other used in furniture now. The handles should be nice brass mediæval ones; they are to be had readily. Handles are sometimes put on the eupboard doors, but they are not considered indispensable.

The interior fittings have been purposely left unmentioned till now, because they depend so much on individual requirements. One might want quite a different kind of accommodation from another. For instance one tray might be wanted in a cupboard, where there would be room for four; or a shelf in each cupboard might be deemed ample. By most people, however, a cellaret drawer would be considered necessary. This is usually put in the right-hand cupboard, and consists of a deep drawer—about 6 in. deep inside—with cross divisions in it, dividing the space into so many divisions, each to contain a bottle. This drawer, in good work, is lined with lead or zinc; but often it is only lined with green baize, and if the bottles be only moderately carefully handled, this should be quite enough. A shelf may eonveniently be put in above this drawer, just so high as to leave sufficient room for the bottles to stand in the cellaret drawer. In the other, or left-hand, cupboard, a shelf placed about half-way up is perhaps sufficient; or a tray might be put in close to the top of the cupboard, and the rest of the space left elear. Whichever drawer or tray may be intended for holding spoons, knives, and forks, etc., it is a good plan to line it with baize.

Now that this sideboard has been described from beginning to end, it may be well to make several suggestions, in order that it may suit the greatest possible number of our readers. You know we want to please, not a few, but a great many; and the more successful we can be in this way, the more satisfied shall we feel with the results of our labours. Beginning, then, with the lower part, if a thrifty housewife, on being shown this design by her lord and master, take exception to the open base, as being likely to allow dust, etc., to gather underneath, it may be made a close one very easily. In that case, the base, moulding on top edge included, should not exceed 5 in. in height, and in this way the eupboard will be $2\frac{1}{4}$ in. higher—that being occasioned by the bottom being placed lower down and in a line with the top of the close base. The open centre might also be wished closed with a door, either retaining the drawer as shown between the cupboards, or making the door the same height as the others are. It might also be of the same design, with different carving in the panel; or it would be better to make it quite different, as then it would make the side panels more distinct. This latter plan could be carried out by forming four panels in the door, the outer framing showing a margin of $1\frac{1}{2}$ in., and the inner framing of $1\frac{1}{4}$ in., with mouldings mitred round panels as on other doors. These panels should also be fielded on their face side, and may either be plain or carved. In the writer's opinion, plain panels would, in this instance, be preferable.

In the upper part several alterations may readily be suggested. The projecting cornice may be removed altogether, and the mouldings and pediment be made flat against the wall. This is the usual method of making a sideboard back, and might be preferred by many. Then the shelf might not run from end to end, but might be underneath the side mirrors only, in which case they had better be shaped so that they are of the same width at each end—not broader at one than at the other, as they are in the present instance—and be supported by two brackets each, or by two pillars each; either way will do. The centre mirror might then be made to come right down, instead of having a plain wood panel there, with no apparent reason for its existence. This plan of having the glass in the centre extending from the top of the sideboard upwards is undoubtedly by far the commoner method, perhaps because it reflects anything placed in the centre of the top in such a magnificent style.

No one will deny that matters of taste, or liking, vary very much indeed. Every man is entitled to his own opinion as to the amount of beauty possessed by any one or any thing—including sideboards; and hence, though each reader may form his own opinion of the merit pertaining to the various suggestions I have brought before him, I feel sure he will, in eommon fairness, allow me to state that, taking all things into consideration, the design, as illustrated, appears to me to be the most attractive and useful of all.

OUR GUIDE TO GOOD THINGS.

**** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

82.—Rowe and Smith's Patent Automatic Indicator.

It has frequently happened that passengers have met with accidents, often of a most serious nature, through leaning on or against the door of a railway carriage, which has been pushed to or has swung to, but whose handle has not been turned so as to prevent its opening by pressure from within. In such cases there is only one handle to the door, and that is on the outside, and this state of things prevails in railway carriages generally, although occasionally, and notably on the Metropolitan District Railway, there are handles within the carriage as well as without, from whose position it may be known whether the door is properly closed or not. However, as it has just been said, in the great majority of railway carriages there is only one handle, and as that is hidden from the view of those within it is absolutely impossible to determine whether the door is latched or not without trying it. This fact, and the mishaps occasioned through it, induced Messrs. Rowe and Smith, 3, Hawthorn Place, New Wortley, Leeds, to think out a plan whereby the state of the door might be always indicated, and the result of their joint labour was the production of the Patent Automatic Indicator, which is shown in position on the door—or, rather, the framing of the door—of the carriage in Fig. 1, the two conditions of the indicator itself and the means by which it is actuated being exhibited in Figs. 2 and 3.

The following is the description of the apparatus as given by the inventors and patentees:—

"The indicator consists of a rod working in the groove of a casting which is affixed, not to the carriage door, but to the framework (*lintel*), into which the iron tongue of the lock, bolt, or catch engages when the door is fastened. Attached to the upper end is the indicating slide, on which are the words 'Open' and 'Shut' *or their equivalents.* The rod, A, is acted upon by the tongue, catch, lever, or bolt, C, of the handle or lock, and when the handle is completely turned, the door being closed, exhibits the sentence, 'THIS DOOR IS SHUT,' as in Fig. 2. Directly the handle is turned to open the door, a spiral spring causes the rod, A, to return to its normal position, and the warning, 'THIS DOOR IS OPEN,' appears as in Fig. 3. Should the door be closed, but the handle not turned, this warning still remains, thereby cautioning the passengers against leaning on the door, and continues to be exhibited until the handle is completely turned and the door secure. As the rod which works the indicating slide is fixed in the socket, it can be clearly seen that it can only work when the tongue, catch, lever, or bolt, C, enters or leaves the socket, and that, consequently, no matter how apparently secure a door may be, unless the tongue, C, of the handle is properly and fully inserted, the indicator invariably shows the warning, 'THIS DOOR IS OPEN,' the word 'Open' being in white letters on a red ground; the colour of the slide itself indicates danger."

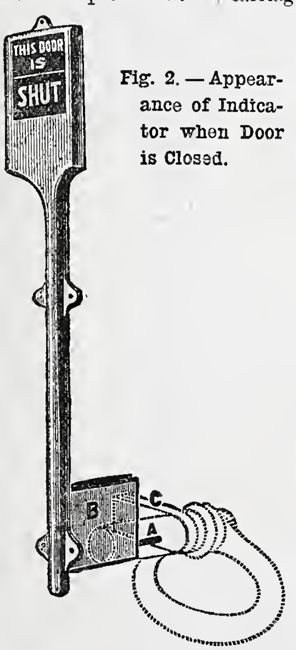

Fig. 2.—Appearance of Indicator when Door is Closed.

There are many points in favour of the adoption of this invention by railway companies. Firstly, there would be no longer any cause of complaint that there is nothing within railway

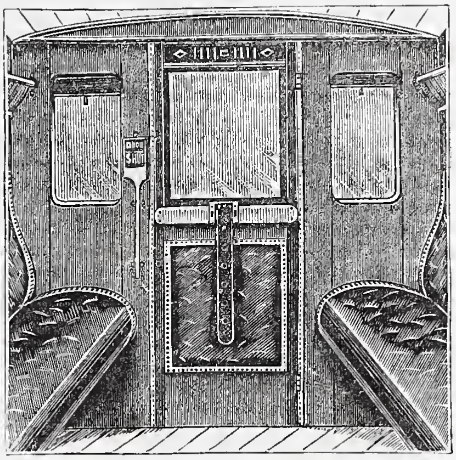

Fig. 1.—Rowe and Smith's Patent Automatic Indicator.

carriages, or coaches as they are called by all railway officials, to show in what position the handle on the outside may be, and the position of the indicator on the framing of the door inside the carriage renders the announcement that it conveys so conspicuous to all within the carriage, that any may see at a glance whether the door is properly closed or not, without having to open the window and feel for the handle outside, as at present, to find out the actual state of affairs. Secondly, it is simple in construction, and, therefore, not liable to be thrown out of working order, and it is easily affixed to any existing carriage; and, thirdly, if any one met with an accident by falling out of any carriage or compartment of a carriage to which the indicator had been affixed, blame would attach to the person thus falling out, and the Company would be relieved of all responsibility and claims for compensation, inasmuch as on their part all would have been done to prevent accident that could be done or could be reasonably expected by the travelling public as a safeguard. And this last point would be manifestly in favour of the railway companies, and should operate upon them as a powerful inducement to have all their coaches fitted with the indicator.

83.—Pitman's Carving Tools.

Mr. P. Pitman, Aubrey Road, Mauldeth Road, Withington, near Manchester, has sent me for inspection and testing a very handy little set of eight wood-carving tools, which he supplies for 7s., with strop and stone for sharpening the tools, specimens of carving, patterns and instructions, and some wood to practice on, so that any would-be beginner has it in his power to provide himself with a sufficient outfit and materials, and can commence operations at once at no greater outlay than the sum named. The set, as it has been said, comprises eight tools, of which three are chisels $\frac{5}{16}$ in., $\frac{1}{4}$ in., and $\frac{3}{16}$ in. in width; two gouges, $\frac{5}{16}$ in. and $\frac{3}{16}$ in. in width; two skew tools—one a chisel and the other a gouge—and one small V-tool or veining tool. The tools are of good quality, and will be found to be enough to make a beginning with, although when the wood carver begins to make progress he will find that a very much larger set is not only desirable, but absolutely necessary. For this Mr. Pitman makes provision by supplying a complete set of tools at 7d. per tool, if I read his letter rightly. The specimens of carvings sent with the tools are intended, as he says, to show the different stages of carving from commencement to finish. He has not sent me these on the plea that they are bulky in the first place; and, in the second place, would be uninteresting to me. With regard to the latter assertion I can only say that they would by no means have been without interest, and that a look at them would have enabled me to judge how far they would be useful to beginners, and to have given an opinion with regard to them.

Mr. Pitman also sends some instructions for the use of the tools. He does not say whether or not they are the instructions sent to beginners; if so, they are useful as far as they go, but do not amount to much. They are as follows:—"I give below a few instructions, which the pupil will do well to follow. The tools as they leave the workshop are not so sharp as they can be made, but the pupil must learn to sharpen the tools to suit the different woods with which he has to work. Place the tools on bench in order, and with the handles towards you. Keep the tools very short (*sic.; query* sharp). Learn to work with left hand in sharpening on the strop; the tool is pressed only on being drawn towards you. Amongst the tools will be found a V-tool, which is difficult both to sharpen and to use, so that beginners had better master all the other tools before trying their hand on the delicate V-tool. Practise on a piece of soft pine (like best pattern makers'), and work the tools with a wedge-like action—that is, cut all round your wood so that it falls away in chips, and do not *lever* it up or *break* it off, or you will ruin the tools. First try the chisel, and then learn the tools in order, the easiest first (*i.e.*, chisel), then gouge, skew tool, and V-tool. All questions sent to us are answered free."

There are three patterns of handles sent with the tools, one in beech, another in mahogany, and a third in rosewood. I prefer the rosewood handle myself, as the section lengthways may be described as an elongated oval, with the ends squared off and widest at about one-third of its length from the bottom. This form of handle is the most comfortable to hold, and affords the firmest grasp of the tool. Readers will kindly bear in mind that I consider the tools well worth the money asked for them, and the instructions useful as far as they go. I can say nothing about the specimens of carving sent out and the wood supplied for practice, as I have seen neither the one nor the other. It would be well if something were said in the instructions about the character and form of the wood-carver's bench and the means of fastening the wood down to it, for, in carving, it is half the battle to have the wood on which you are operating immovably fixed to a rigid bench.

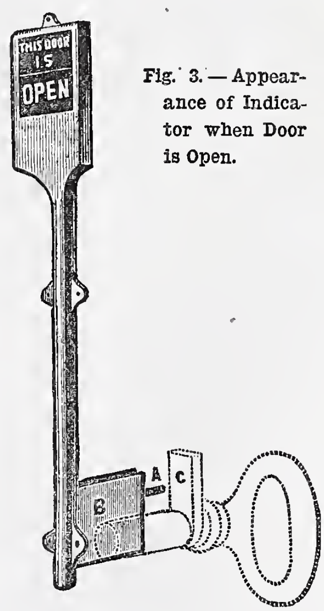

Fig. 3.—Appearance of Indicator when Door is Open.

The moderate price of the tools, etc., supplied by Mr. Pitman brings it within the reach of all who have an inclination to take up wood carving as a hobby to provide themselves with the necessary appliances in this respect. Few branches of the wood-workers' art are so attractive.

THE EDITOR.

A Corner for Those who Want to Talk It.

*** Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Subjects for Work.—H. G. (*Oxford*) writes:—"I must pay my humble tribute to the merits of Work. I have read it from the commencement, and feel that it is filling a long-felt want. I wish you every success, as you most certainly deserve. I have derived help from your many valuable suggestions on different subjects, which I have greedily devoured, which has spurred me on to more perfection in my work, and I am certain others that you 'wot not of' must be in the same position as myself—viz., compelled to recognise you as our benefactor. I have induced several of my friends to take in Work, and they one and all state that it is the best pennyworth they ever invested in. I think that every reader of Work ought to at least induce one, if not more, of his or her (as I hope you have many lady readers) friends to become subscribers to your work. I shall continue to do so. There are one or two things I have been on the point of writing about several times, but have put off again and again, hoping to see someone else write about the same subjects. In the first place I must tell you that I am a man who is obliged to get his living at work which I had no opportunity of learning anything about, but have had to form my own notions and judgment as to how things should be done, and have done it, and am afraid I do not do them the easiest or quickest way. I refer to tin and iron plate working, and general repairs in connection with that trade. I was very pleased the other week to see that you have a series of papers on the above subject nearly ready for publication, and shall anxiously await their advent. I hope the tools of a tinman, etc., will be specified. The other subject I wish to write about is 'Grinding,' how to grind razors, scissors, knives, etc. I do a good many, but never having learnt how, I feel at a disadvantage in not knowing the best way, so should feel very much obliged if you would allow one of your readers, through 'Shop,' to state what kind of stone or emery wheel would be suitable for different classes of work (I only use a 3-in. emery wheel, coarse, for everything, and am afraid I am wrong, as work does not look nice when done), and how to hold them on the wheel, and what kind of machine would be best (I have a small lathe with a wheel fixed on spindle). I think, Sir, this would be a topic of interest to some of your other numerous readers, so am inclined to think that it would not be lost to all the rest, and only a benefit to the one, but a good many would share in the benefit. How to make and mend umbrellas is a subject on which I should like to see a paper."—[You will have seen that papers on the tin plate worker's art have been commenced. The other subjects you mention will be treated in due course—even umbrella mending if any reader can write on it.—Ed.]

Circular Saw Rigs. — J. (*Twerton-on-Avon*) writes in reply to G. E. (see p. 284):—"Replying again to the criticisms of G. E., *re* my reply on p. 172, surely any amateur can use a collar plate to tap a thread. Certainly there is not so much difficulty in cutting a thread thus as there is in striking threads in wooden chucks, yet plenty of amateurs can do that. Again, the recess behind the screw is not necessarily 'turned out.' It may be cast in with the rough hole for the threads; but if turned, it is not 'superfluous,' or troublesome work, 'with small results.' G. E. has apparently a poor notion of amateur skill. Further, if G. E. objects to 'cutting a thread in a saw spindle,' it does not follow that others have the same objection. Neither is the spindle made in brass 'too soft to be of much practical service.' What of the numberless brass chucks in use? Besides, one would not use soft brass or yellow metal, but rather engineer's machinery brass or gun metal; and there are plenty of such chucks which have been in constant use for many years, perhaps eighteen or twenty. And what is the essential difference between cutting and fitting a chuck and a saw spindle? There is none. As to wood for spindles. If a piece of hard wood will not keep true for several years—and that depends chiefly on previous seasoning—it can be trued up like a wooden face plate, or can be renewed; and I know a turner who has such wooden spindles in constant use, and has had them in use for several years. Then my critic says, 'The amount of steadiness given to the chuck depends on whether the face is true and ground flat.' Precisely so, as in the case of any other chuck. But as I have already said, the spindle may be assisted by centring in the poppet. Finally, as to the table, that is matter of choice. I gave tables both simple and elaborate to suit all readers."

"Guide to Good Things."—E. G. C. (*Bristol*) writes:—"It was in my mind, and I imagine in the minds of others, that 'Our Guide to Good Things' was a paid-for advertisement. Now that you have affirmed otherwise, you have established confidence between Work and its readers, and conferred benefits on all concerned. With such editing there is no fear that Work will flag in interest or circulation. Its readers will all think of it as 'a friend in need,' when its editor thus dares to make it 'a friend indeed.' Sir, I thank you."

II.—Questions Answered by Editor and Staff.

Lathe Driven by Single Belt.—J. F. P. (*Darlaston*).—You ask if we have ever seen a lathe driven by a single belt from the top shafting which can be started, stopped, or reversed, without interfering with the belt at all, or with the engine which drives it. The answer is that lathes driven by power are almost always driven that way; there is never a second belt coming down on to the cone pulley on the mandrel; the reversing is managed by a counter-shaft and two belts above, which counter-shaft receives motion from the main shafting in one direction or the other, according as it is driven by the open or crossed one of the two belts. Get some mechanical friend to show you the arrangement—there must be plenty of power-driven lathes in your town. Perhaps, however, you mean that there must not be the usual counter-shaft with striking gear, but that the "one belt" comes straight from the main shafting down to the pulley on the lathe mandrel. Then I must answer that I never saw such an arrangement, though I imagine how it could be done. By means of frictional gearing it would be neater, perhaps, yet there are many who would object to add any unnecessary complication to the mandrel and headstock.—F. A. M.

Castings of Lathe. — Lathe. — You ask where you can procure castings for a lathe of $1\frac{1}{4}$ in. or $1\frac{1}{2}$ in. centres on which you can turn the inside work of the Egyptian trellis in No. 7, and stanchions for model yachts. Pray don't have such a small thing. I know of no lathes so small except for watchmakers. Don't have anything less than $3\frac{1}{2}$ in. centres. That size will be equally suitable for the work you wish to do, and infinitely more generally useful. You can buy castings of $3\frac{1}{2}$ in. and 3 in. lathes from almost any lathe maker. Go to your nearest ironmonger, and ask him to show you his price list. Possibly you can buy a finished lathe, second hand, for the same price you would have to pay for the castings, and if you are not a good workman having access to a good lathe this would be your best plan.—F. A. M.

Stereo Flong.—A Stereotyper's Apprentice.—Either a mangle or brush or both combined is proceeded with as follows:—Make a paste of 1 lb. of flour, $\frac{1}{2}$ lb. of whiting, 2 oz. of melted glue, and a very little alum. Mix with water so as to make a paste of the consistence of cream, and pass it through a strainer. Take a sheet of blotting paper and paste it thinly and evenly all over; cover this with a sheet of tissue paper, taking care to rub it all over with the hand in such a way as to prevent its creasing. Then add two more sheets of tissue pasted in the same way. Turn the flong over and paste a sheet of wrapper or sugar paper on the blotting. Then roll it flat with an iron roller or a wooden ruler, and let it stand for a few minutes, when it will be ready for use. The fault you complain of is probably owing to the use of too much paste, or to its being unevenly laid upon the paper, or to the paste being badly made. Prepared paste for the purpose is supplied by Messrs. Harrild & Sons, Fleet Works, London; and by Messrs. Richardson, Racquet Foundry, St. Bride Street, London.—J. F. W.

Magnet.—C. E. P. E. (*Ebbw Vale, Mon.*).—A permanent magnet should at least hold up its own weight of iron. It has been found possible to greatly exceed this by carefully selecting, hardening, and magnetising the steel bars, of which magnets are made. The capability of a magnet to receive and retain magnetism depends very much on the quality of the steel and its hardness. It will lose a very large portion of its magnetism if allowed to lie about in any position, or if exposed to extremes of heat and cold, or if jolted or jarred. To preserve a bar magnet, it should be kept free from bad treatment, and be kept lying in a position coincident with the direction of the earth's magnetic current. Two bar magnets may be made to preserve each other's magnetism by placing their opposite poles together, and placing a keeper of soft iron across both ends.—G. E. B.

Leclanché Battery Gone Wrong.—G. E. H. (*Oldham*).—The spasmodic action of your battery cells is probably due to hard work. A Leclanché cell will not furnish a constant current for any great length of time. It will ring a bell for a few minutes, and then it must have a rest to recuperate itself. If you give it a long spell of work, it will take a long spell of rest (perhaps a day or two, as yours does) before it will be ready to work again. This sluggish recovery is made worse by having the porous cells quite sealed over, because then the gases set free at the carbon plates cannot readily escape from the cells as they should. See to it that there are clear ventilation holes in the pitch seals of the cells. Perhaps the fault is not in the battery, but in the bell or in the pusher. The set of these will vary sometimes with the state and temperature of the weather, if not properly made, and will then require to be adjusted afresh. It is also possible there may be leakage of current between the lines on the battery side of the bell. It is impossible to reply to your letter the same week in which you write it.—G. E. B.

Ayrton's Practical Magnetism. — A. B. (*Middlesborough*).—This work is not yet published by Messrs. Cassell & Company, Limited.—F. J. C.

Books on Mill Work. — Lover of Work (*Shepton Mallet*). — Several good works on mill work are published by Messrs. Spon & Co., 125, Strand, London, but there seems to be no book specially on corn and grist mills.

Electric Bell Parts, Tools, etc. — Platinum (*London, N.W.*).—As you are living in London you can easily make up an electric bell, without the use of a lathe, by buying the various parts, such as magnet cores, bobbins, pillars, screws, and gong at a shop where they sell such things. Messrs. Dale & Co. (who advertise in this paper) will be happy to supply you with any parts you cannot conveniently make for yourself. It is not necessary to increase the size of the metal frame for each increase in size of the gong; but it is only reasonable to have this proportionate to the other parts. Respecting tools required to make an electric bell, these and their size will be naturally suggested by the kind of work to be done. For instance, if you have a $\frac{1}{4}$ in. hole to drill and tap, and a $\frac{1}{4}$ in. screw to cut to fit it, you must have a corresponding sized drill, stock dies, and screwing taps, making allowance always for the cut of screwing tackle. Some day I hope to go thoroughly into the subject of electric bell making, and then I will do as you suggest about a list of tools.—G. E. B.

Brazing Band Saw.—G. (*Salop*).—I have not had any practical experience in brazing band saws, but have seen the operation described. It may be done with a blowpipe or by means of a pair of tongs made white hot. First warm the two broken ends and scarf them down with a file until the lap does not exceed in thickness the other part of the saw. Get some brazing spelter, or some very soft yellow brass, or some tinned brass pins, and reduce a small quantity to filings. Then procure some borax, and grind a little on a slate to a smooth paste with clean water. Mix some of the brass filings with the borax paste in sufficient quantity to form the joint, and place this on the scarfed ends of the saw. Bring the teeth together in their proper places, and bind the joint firmly with iron binding wire. Clamp a pair of warmed tongs or pliers so as to bring pressure to bear on the joint to keep it from shifting when the brass runs with the heat, and then proceed to heat up the joint either with a blowpipe flame above and a piece of charcoal below the joint, or by means of a pair of heavy tongs made white hot. If the latter, clip the joint firmly until the filings melt into it, then release them, and grip the joint with a pair of warmed tongs for a few moments. If the blowpipe flame is used, the source of heat should be from a broad wick oil lamp in preference to gas flame, because the flame from coal gas ejected on steel is said to make it brittle. In either case make the joint sure by gripping it with a pair of warm tongs as soon as the filings run into the joint. When the joint is cool strip off the binding wire, and make all smooth with a file. Perhaps J. H. or A. R. (*Scorrier*) will oblige with their opinion on the proper method to be employed.—G. E. B.

Electric Bell Battery.—Amateur in a Fix (*Nottingham*). — The "white substance much like white lead" that seems to eat away the leaden head on the carbon plates of your cells is an oxychloride of lead, caused by the chloride of ammonia from the cell below creeping up through the pores of the carbon plate and dissolving away the lead. As this white substance first forms on the lead next the carbon plate it soon shuts the head off from being in direct contact with the carbon; the current then fails, and the bell ceases to ring. To remedy this you must take out the plates, melt the lead heads off, soak the carbons for several hours in hot water (changing the water during the last hour) to dissolve out the ammonia and lead salts, then well dry the plates in a hot oven. Whilst still hot, dip the ends intended to have the lead head in melted paraffin wax, and hold them in it until the wax has gone well into the carbon. When the plates are cool, drill one or two holes through each to form a holding for the lead, and then cast the heads afresh. The paraffin wax (solid paraffin, obtainable through any druggist) will fill up the pores of the carbon, and prevent the salts from creeping up under the lead cap. Whilst the lead cap is still hot, give it a coat of Brunswick black or other black varnish, and let this coat overlap on the carbon about $\frac{1}{4}$ in. This will protect the outside from the action of ammonia fumes. Retort carbon is the carbon scurf got off from the retort furnaces of gas works, and is a much denser, close-grained article than the carbon represented by the cokes used in a blacksmith's forge. These last are useless for battery plates. Porous cells of earthenware are more durable and look better than those made of canvas, but canvas bags make very useful cells; and, possibly, the reason you find them work best, is because they offer less resistance to the current than those made of earthenware. Thank you for your kind appreciation of Work. Try to increase its circulation by making it known to your friends.—G. E. B.

Walnut Stain.—Centrebit (*Tullow*).—Vandyke brown, mixed with a little liquid ammonia and then diluted with water to the necessary liquidity and strength, or rather weakness, makes an excellent walnut stain of any intensity. Whether it will be the best for your particular purpose or not I cannot say, as you do not mention the kind of timber you wish to stain. Other inquirers please note, and do not be afraid of giving too many particulars.—D. A.

Cement Floor Laying.—R. S. (*Edinburgh*).—The foundation should be rammed solid; if any filling up is required, it should be done with hard dry material, and no lime rubbish should be in it, as this has a tendency to swell, and lift the floor; a covering of broken stones to pass through a 2-in. ring not less than 3 in. thick should be laid over the floor, leaving 2 in. or more, if required, for the concrete. The concrete is mixed with 5½ cwt. of Portland cement to 1 ton of crushed bricks, limestone, or slag, that will pass through a ½-in. mesh. It must be well mixed, wetted, and turned over twice, then laid on the broken stones, and levelled by means of a straightedge from pegs, or a board laid level at each side. It must also be well beaten down with a hand beater about 15 in. by 10 in. with a handle on the back, till quite level and fluid on the top; it is then left for a few hours till nearly stiff, when it is smoothed over with a plasterer's trowel. If laid outside as footpaths, it should be in squares not more than 6 ft., or it will crack; the harder and more solid the foundation is the less likely it is to crack. The quantity named will lay about 14 or 15 super. yards.—E.

Preparing Vellum.—PUZZLED.—To describe this practically demands rather an illustrated article than the space available in this column; but your queries shall, as far as possible, be answered. (1) The skins used are those of calves, kids, and still-born lambs. (2) These are unhaired either by steeping with lime, by sweating—*i.e.*, by hanging in a smoke house heated by a smouldering fire till fermentation sets in; or by soaking with dilute acids. As you seek a cleanly method you may, perhaps, prefer the last. The hair, etc., is scraped off with a two-handed unhairing knife. After this the skin is stretched in a "herse" (merely a square frame of four sticks joined at corners); strings from the edges of the skin to this frame allow of its being made quite tight, and it is well scraped with a half-moon knife to clear away all fleshy particles, dirt, etc. Next it is ground. The grain side is merely ground over with a flat pumice-stone, but the flesh side is rubbed over with powdered chalk before grinding. The half-moon knife is now passed over the skin to drain it; this makes it look whiter. Fine chalk is then rubbed over both sides, and it is put to dry. It has next to be pared down to a proper thickness—probably about one-half—with a sharp circular knife, and then pumiced smooth where required. Lastly, it is glazed with albumen—white of egg. (3) Tools such as the unhairing knife, half-moon knife, etc., you can doubtless get at any good tool shop, such as Buck's, Holborn Viaduct.—S. W.

Music Stand.—J. H. F. C. (*Bermondsey*).—I am glad my music stand has been approved by J. H. F. C. In reference to its cost, I think the material was purchased for about 5s. as follows:—Mahogany, 1s. 6d.; brass tubing, 2s. 3d.; wood for bosses, 3d.; scrolls for feet, 1s. 6d.; wire for rods, 2½d. In reply to his second question, I could not undertake to make another in the way of trade. As a minister my time is pretty well occupied, and I only turn to mechanics or science by way of recreation and for the love thereof. I do not know, but I hardly think a man could afford to make it for much less than 12s. 6d. or 15s.; as a matter of fact I know there are stands sold for 21s. not nearly so handsome, useful, or substantial. But why does not J. H. F. C. make one? There is nothing in it except the turned work that a man with one eye and two hands, backed by will power, could not accomplish without any mechanical training whatever. I have found it possible by patient care to do what has passed muster for professional work.—O. B.

Furniture Polish Cleanser and Reviver.—C. H. W. (*Hastings*).—I cannot understand how you find any difficulty in preparing this, and the only explanation that occurs to me to account for the substances not mixing properly is owing to some ingredient in the polish. I daresay you are aware that other substances besides shellac and spirit are sometimes used in making French polish, and it is just possible that one of these may be the cause of failure. Suppose you try a smaller proportion of polish, which I presume you have bought ready made. Though it will not form so good a mixture, you might use methylated spirit and omit the polish altogether. I may say it is not necessary to enclose a stamp, as all inquiries are answered in these columns gratuitously, though none can be sent direct by post. Neither you nor any other correspondent who can be helped in any matter coming within the scope of WORK need think you are "troubling" us.—D. A.

Shorthand.—CUPID (*Castlejohn*).—Shorthand will not be treated in WORK. Full instructions, however, for learning this useful branch of education are contained in Cassell's "Popular Educator," a new edition of which is now being issued.

Bell Hanging.—J. S.—I am not acquainted with any book on bell-hanging in the old style—that is to say, by cranks, wires, and springs; but the subject will be treated in due time in a paper or two by a contributor who is accustomed to the work.

Tables, etc., for the Construction of Measures.—J. S.—I will obtain the American book of which you speak, and see what can be done towards the construction of tables showing the contents of vessels in imperial gallons, according to depth and diameter. I am obliged to you for your letter, and regret that when giving your name you should have omitted your address. Kindly let me have it, as it may be of advantage to be able to communicate with you.

Wooden Teeth in Iron Cog.—X. Y. Z. (*Orkney*).—You should have informed me by means of a sketch of the shape of the teeth of the iron wheel into which your wooden teeth have to gear. Had you done so I would have drawn at once the correct shape of the wooden teeth required. In the absence of this very essential information, I must take a somewhat circuitous course in order to show you how you can obtain the correct shape for yourself. I must assume, as is the case nine times out of ten, that the teeth you require are of cycloidal form, in which case you will proceed as follows:—Get a sheet of white paper and lay it against the face of the wheel into which your new teeth have to gear, and so take a rubbing of the tooth forms. Fasten this sheet of paper to a board with drawing pins; obtain and strike thereon the correct pitch circle for the wheel; make a templet, as shown in Fig. 1,

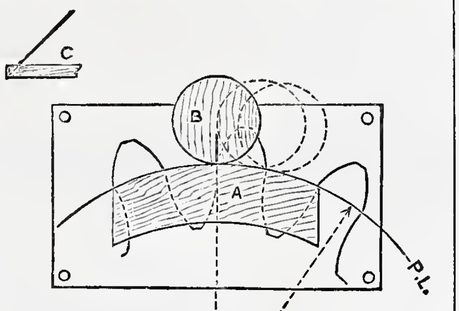

Fig. 1.

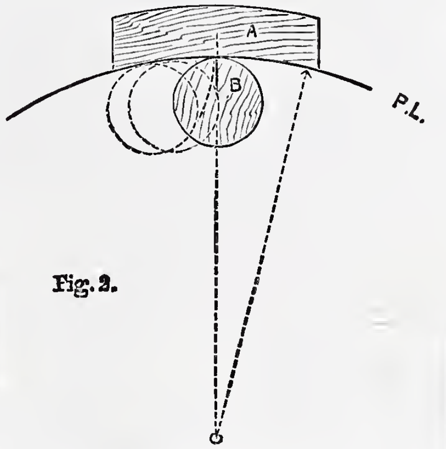

Fig. 2.

A, having convex and concave edges, each cut to the radius of the pitch circle. Place, say, first of all, the convex edge against the pitch line, as shown in Fig. 1. Prepare sundry circles cut from cardboard or wood, and of different diameters, ranging from perhaps 1 in. to 5 in., dependent entirely on diameter and pitch of wheel. Into the edge of each stick a needle diagonally (Fig. 1, C). Take one of the circles at random, placing the needle point against the pitch line and coincident with one of the tooth edges already taken by the rubbing, and roll the circle (Fig. 1, B) along the convex edge of the template, A, and note whether the needle point traces over the tooth curvature obtained by the rubbing. Probably you may have to try half a dozen different circles of different sizes before you obtain that one whose needle point will trace the exact curvature of the teeth of the old wheel; but when you have obtained it, that is the circle which, when rolled on a concave templet, cut to the curvature of the pitch circle of your wheel with the wooden teeth, will give the correct shape of the flanks of the wooden teeth—that is, of those portions lying below pitch line. Having thus at once found the proper curvature for the tooth flank, you can adapt a radius thereto by which to strike the planks of all the teeth in the wheel. To obtain the shape of the tooth faces—that is, of those portions lying above pitch line—you must place the concave edge of the templet, A, in Fig. 1, against the pitch line of the wheel of which you have taken a rubbing, and obtain the curvature of the tooth planks by means of a suitable rolling circle, precisely as you obtained the curvature of the faces, as shown in Fig. 1. Then the same rolling circle by which that curvature is obtained will, when rolled on the convex edge of the templet, A, in Fig. 2, give the shape of your wooden teeth above pitch line. There are other methods, more or less elaborate, by which tooth forms may be obtained, but there are none so suitable for workshop use, or so readily put in practice, as that which I have here given. It is founded on the mathematical principle of the cycloid curve, and the only departure from strict precision is the adaptation of a radius to the true cycloid curve obtained by the rolling of the circle on its base line. A cycloid curve cannot be struck mathematically true with compasses; but, excepting in the case of wheels of large pitch, the difference is quite inappreciable, and is not, in fact, so great as the slight inaccuracies inseparable from ordinary workmanship.—J.

Printing on Tin.—T. R. Y. (*Ramsbottom*) wants to know how to print upon tin and other hard substances, and asks me to mention some book on the subject. Books there are none, and every process for the decoration of metals has been patented, so I think T. R. Y. will get most information from the specifications themselves. These may be had from the Patent Office, 25, Southampton Buildings, Chancery Lane, London, W.C. Under the heading of "Letterpress and Similar Printing" are published abridgments of specifications of patents, which will guide the searcher to the full specifications as follows:—Part 1A, A.D. 1858 to 1866, 2nd edition, 2s. 9d. post free; Part 2, A.D. 1867 to 1876, 2s. 7½d. post free. These may also be seen at the Mechanics' Institute, Bolton, near which I think your town is situated. They can also be seen, free of all charge, at the Free Reference Library, Manchester.—N. M.

Hydroquinone Developer.—J. B. (*Brixton*).—I have read of such a deposit as you name being formed, but in my own experience it has rarely occurred. I do not keep notes of my developments, but I am under the impression that the grey deposit has only occurred with plates which have been under exposed and, consequently, forced in development, besides having been a long time in the developer. Mind, I only throw this out as a hint, as I am unable from my own knowledge to explain the defect you allude to, which, I take it, is somewhat analogous to the fog of ammonia. Perhaps if you were to try a different sample of the hydroquinone you might get better results, though, as you say the printing is not affected by the deposit, I hardly think there can be much wrong. You must be from what you say expert in the use of oxalate developer, so why change? It is a very good one, and as you have mastered it you will not find any others as easy till you have thoroughly familiarised yourself with their peculiarities. Thanks for good wishes.—L. I. P.

Polishing Rosewood Box.—J. S. (*Bradford*).—Without knowing exactly what materials you have used and how you have manipulated them when French polishing your rosewood box, it is impossible for any one to say positively why the polish always looks dull and greasy. I think, however, it is very probably owing to too much oil having been used either during the "oiling" or subsequent "bodying in" with polish. Rosewood, you no doubt know, is naturally an oily wood. If you will write again, detailing your process and describing more fully the appearance of the box, I will do my best to point out the cause of failure. The fault may possibly only be due to the natural "sweating" which is apt to occur on all newly polished work where oil has been used. Yes, the papers you refer to will appear as soon as practicable. They are in hand; but arrangements are made far in advance, and you know everything cannot be first. Meanwhile, any assistance I can render you in "Shop" is at your service.—D. A.

Door-Mat Method.—POWELL (*Londonderry*).—On reading your inquiry, another one, viz.:—
"Where can all this difference be
'Twixt tweedledum and tweedledee?"
occurs to me. If, as I gather, you are intending to make alterations, I am afraid you will find either of those you suggest to be more trouble than they are worth; but on this point you must be guided by circumstances. I would suggest that an easier way to manage is to cut the door at the bottom, so that it will clear a mat laid on the present floor and just under the door. Fill up the space or opening that has been made by cutting the door, by fastening a piece of wood to the floor. If practicable this will be the easiest way, and will save you the trouble of lowering the whole of your hall flooring. As for appearance of the two methods you ask about, it may be said that there is not much choice; and whichever you adopt, you are violating no canon of taste. This may not be so satisfactory to you as if I were to say that one plan is better than another; but were I to do this it would be only misleading you, as I should be entirely guided by many things which, without seeing your hall, I cannot know to offer a definite opinion.—D. A.

Window Blind in Turned Lattice Work.—C. E. P. E. (*Ebbw Vale*).—You write:—"Could you give me a rough sketch for a window blind of the ordinary size in turned lattice work? I only want the arrangement of the pieces, not to any particular pattern in turning, as I have a number of patterns in three panels." From this I gather that you want suggestions for the kind of blind known as a half blind—a blind that goes across the lower part of a sitting-room window on the ground floor to break the view of the interior to passers-by. You will find, I think, suitable arrangements in No. 7, page 98, and No. 18, page 281, for a half blind. A central panel within a border is the most fitting arrangement for a small window, but for a large window the central panel may be divided into three parts, or into a number of small panels like squares in a chess-board, the panels containing a different arrangement of pieces, so as to present a chequered appearance. Before beginning work you should construct a full size working drawing, and you can then arrange the border and panels to receive the decorative turned work in due proportions. I can only reply to you indefinitely as above, because you do not tell me the size of the blind you wish to make. Had you done so, I could have said something with regard to proportions of the various parts—border and panels; but it is no use assuming a size and replying hypothetically.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Boot and Shoe Making.—NITRAM (*Boscombe*) writes in reply to FARNWORTH (see page 284):—"Go to any shoemaker's grindery store or leather shop, and purchase the following articles, which will do to finish the edges of your boots: one black heel-ball, one white heel-ball, small bottle of ink, sheet of 1½ glass paper, ditto emery paper or cloth, shoemaker's knife (thin blade), shoemaker's rasp, ditto man's forepart iron with one bevel, ditto plough, ditto paring up hammer, and ditto scraper, and get the man in the shop to sharpen this last article for you if you have never done so before. If you have to finish the heels you will have to get at least a heel iron, or, as I have heard some northern Crispins call it, 'a brazer.' If you do not know how to use the above articles, I shall be but too pleased to give any information on the subject at any time, with sketches if required."

Saws Running out of Truth.—A. R. (*Scorrier Saw Mills*) writes in reply to ALPHA (*Grangemouth*) (see page 286):—"Your swage saw should be 19th gauge tight at point of teeth, and 10th gauge at centre, bevelled from about ½ in. outside of collar washer. The saw must be kept perfectly round, and the set very even; ⅝-in. boards are rather thick to be sawn off with swage saw, though we often cut ⅝-in. and even ¾-in. with swage. A swage saw is not adapted for cutting off boards above ⅝ in. or ½ in. If the deal is not even on side next to fence, the first board will be thick, but if the saw is in good trim, the next will be its required thickness. Care must be taken not to overfeed the saw, and to spread the board a little as soon as it passes back of saw. You must remember that more care is to be taken in the working and sharpening of the swage than with a saw that is of even thickness to get good work done. In fact, I know many sawyers that cannot work a swage saw so as to give satisfaction."

Gripping with the Vice.—SYER & Co. write in reply to CROSS-CUT (see page 222):—"One of our patent instantaneous grip joiner's vices would answer the purpose, as you can use 12 in., and instantly change to $\frac{1}{16}$th."

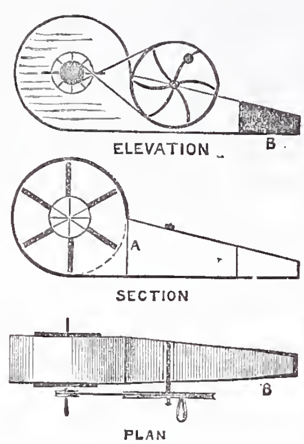
Colouring Photographs.—W. L. S. (*Walton-on-the-Naze*) writes in reply to EXPECTANT (see page 174):—"I have not had the chance to reply to the query of EXPECTANT (*Hull*), and I hope I am not too late. I shake hands with him in his profession, as I am presuming enough to style myself an amateur artist. Photos can successfully be coloured. A photo was shown me by a friend a few days ago of a group of lads four in number; it was a fairly sharp one, but a young gentleman of the number had a shadow somehow cast on his face, so as to give an expression about his eyes looking rather full, also of having one corner of his mouth drawn down. I was asked if I could remedy same, and tint the features, and button flowers, etc. I did so, my success giving satisfaction in such a degree as to have a set of half a dozen to manipulate with. I had but coloured one before, then I experienced some considerable difficulty in so doing. I reverted to a plan which I use when colouring cloth tracings, *i.e.*, rubbing my brush lightly on a piece of common yellow or mottled soap, the latter is the best, and then in the colour, and it will then flow freely and work easily on the photo. I should be greatly obliged if you, sir, would print my name and address with this small piece of advice, if you do not think it too useless, to enable EXPECTANT to communicate with me through your interesting and extremely valuable paper, especially 'Shop.' On oil or water colour sketches my experience is only of six months' standing, and self gained; but painting, as well as crystoleum painting, is a great favourite of mine, and a thing which I am pretty successful with, at least in my opinion and a few outsiders."

Blueing Steel.—W. P. (*Wisbech*) writes in reply to PALL MALL (see page 222):—"This is done in the tempering. It is by means of the colour that the temper of the steel is known. The colours run dark straw, light straw, crimson, dark blue, and light blue, after which the steel becomes quite soft, and requires hardening before anything can be done with it. The blue colour is almost too soft to cut wood, though quite hard enough for swords and daggers."

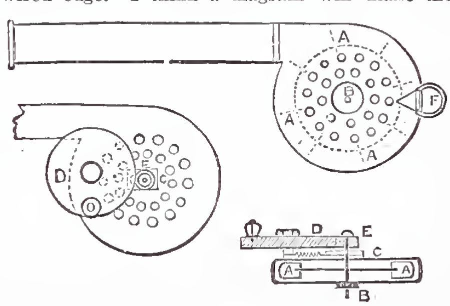
Flour Paste Souring.—X. M. T. C. C. (*Belfast*) writes in answer to J. R. (*Skerries*) (see page 238):—"To keep flour paste from getting sour, he might dissolve ½ oz. of alum to 1 lb. flour, which will make it keep for about a week. This is the only thing I know that will keep paste from souring."

Canvas for Painting.—H. R. M. (*Dover*) writes in reply to WAITING (see page 236):—"*Re* canvas for painting, I often experienced the same difficulties, which I at last got over by mixing a little flake white or even ordinary whiting with the size to the consistency of paint, and giving two or three coats according to texture of canvas, and allowing each coat to dry; well rub down with sand paper. It will then be smooth enough for painting."

Machine for Current of Air.—SCLATTIE (*Kemnay*) writes in reply to BELLOWS (*Gloucester*) (see page 190):—"With reference to how a machine can be made to give constant current of air, with rotary action, I submit the following sketch. Excuse the look of it, as it was done on the spur of the moment, after reading the number in which the question appeared. The machine is very handy to any one who would like to do any smith work at home, as with it light iron can be wrought, and even welded. The sketch, which is drawn to the scale of one-eighth to the inch, will explain itself, as far as size and general appearance go. Of the material, the sides may be of ½ in. deal to within 3 in. of nozzle, with a saw key run in where they bend. The top and bottom and round the blast should be of the thinnest of sheet iron; even tin would do, except at the nozzle, where it would require to be a little stronger. The journals and spindles are nothing but what a handy man might make himself. The pulleys the same."



Bellows with Rotary Motion.—G. E. S. (*Tonbridge*) writes in reply to BELLOWS (see page 190):—"I have one in my possession which works satisfactorily (but the worse for age in appearance only), and will try to describe it. It is made of tin plate, and measures 17 in. over all. The fan chamber is 6½ in. in diameter; the directing tube is 2 in. square where it joins the fan chamber, but changes to a circular shape about half way to the nozzle, the diameter of which is 1¾ in. Each side of fan chamber is perforated with two concentric rows of holes of ⅜ in. diameter, as near the centre as is compatible without weakening the plate. The inner circle of mine has eight holes, and the outer fourteen. The nozzle has a wired edge. I think a diagram will make the



driving arrangement more lucid than further description. The rim of the fan chamber is 1¾ in. wide; the sides are cut in one piece as far as the seam shown, and hollowed out a little. When fixed to the rim they make the chamber about 2 in. wide at the rim, and about 3 in. at the centre, on account of the hollowing out. A circular plate is notched to receive the vanes as at A, a brass bush is soldered on to take the spindle at B, a small bridge is made with a plot in the top for the spindle to be drawn into contact with the wooden driving wheel, D, which has a few fine grooves turned in its edge to better engage it with the small wheel at E, which is covered with leather, and is kept in contact with the driving wheel by a strong, cheap spring fastened to the spindle of wheel D, and also passing under the bridge to the spindle of wheel E. The loop, F, is for hanging up by when out of use."

Tuition in Carpentry.—A. L. O. (*Hammersmith*) writes in reply to AMATEUR (*Bayswater*) (see page 302):—"The gentleman (Mr. Robertson) whose circular I enclose can give the inquirer just the instruction he requires in his beautifully appointed workshop, 14, Augustus Road, Shepherd's Bush. I have only had twenty lessons from him, yet so extremely intelligent and intelligible are his methods of teaching that I have obtained a first-class certificate from Professor Unwin, of the City Guilds Institute, and have made a miniature bookcase 2 ft. 7 in. by 2 ft. for a collection of the various kinds of woods. AMATEUR could not do better, and moreover it is not very far from Bayswater."

Trade Notes and Memoranda.

PROFESSOR THURSTON expresses his opinion that the steam engine, so far from being superseded in the immediate future, is capable of vast improvement. He predicts that the next generation will see it consuming 1lb. of fuel per hour for a single horse power, that ships of 20,000 tons will be driven at the rate of forty miles per hour, and that the American Continent may be spanned by flying trains in two days. Professor Thurston is no visionary, but a hard, matter-of-fact engineer and mathematician; and when we remember, too, that the mechanical triumphs which now bless the world were deemed wild and impossible of achievement a generation ago, we look ahead with confidence to the realisation of the Professor's predictions.

WHAT strikes the average American as one of the silliest of regulations at the Paris Exhibition is that which makes it an offence to make rough sketches of machines. Nearly all exhibitors, with the exception of those from England and the United States, take special pains not to show anything but the bare outside of their machinery, and to show that at as great distance as possible. Then the luckless fellow who tries his hand at sketching is warned of the consequences, his sketch destroyed, and, if at all persistent in his search after knowledge, he is marched to the police department, and perhaps off the ground. This for the first attempt. We are not sure what the punishment for the second attempt would be. There probably never was another exhibition of machinery in which so much effort was put forth, both to make a show and to avoid giving information.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

A COMBINATION BEDROOM SUITE.

BY J. SCOTT.

'Cleanliness is next to godliness." This s an acknowledged fact; but it is curious o note the relative proportion one bears o the other in the estimation of certain peoples. The Arab, for nstance, is noted for his godliness, and is equally noted for his dirtiness. Whether this is to be ac-counted for by the ab-sence of the—to us—necessary utensils in his possession, I will not venture to say. Certain it is that we have advantages over the Arab and his brethren, and this, I suppose, is one particular reason why we can boast that we are a cleanly as well as a godly people.

Fig. 1.—Section of Glass Door.

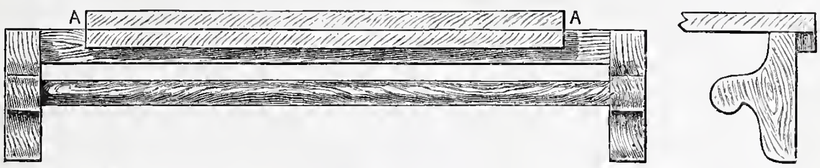

Fig. 2.—Towel Rail: Front Elevation (A, A, Flap) and Side Elevation. (Scale, 2 in. to 1 ft.)

The advantages above mentioned it is needless to speak of; my object in mentioning them was to show that there is at least one among us—and that is myself—who is not satisfied with even the present obtainable conveniences, for the reason that, being a bachelor, and having but one room, I have not sufficient space for a complete bedroom outfit.

As will be seen by a glance at my drawings, my aim is to combine all the uses of an ordinary bedroom suite in a

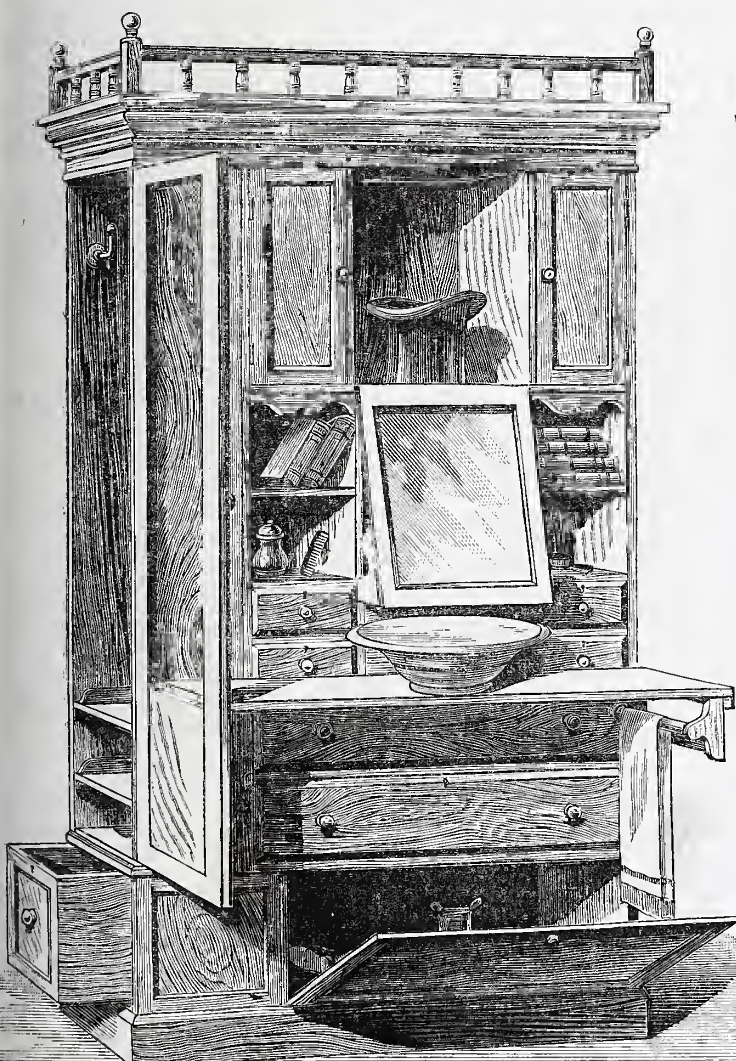

Fig. 3.—Suite Open.

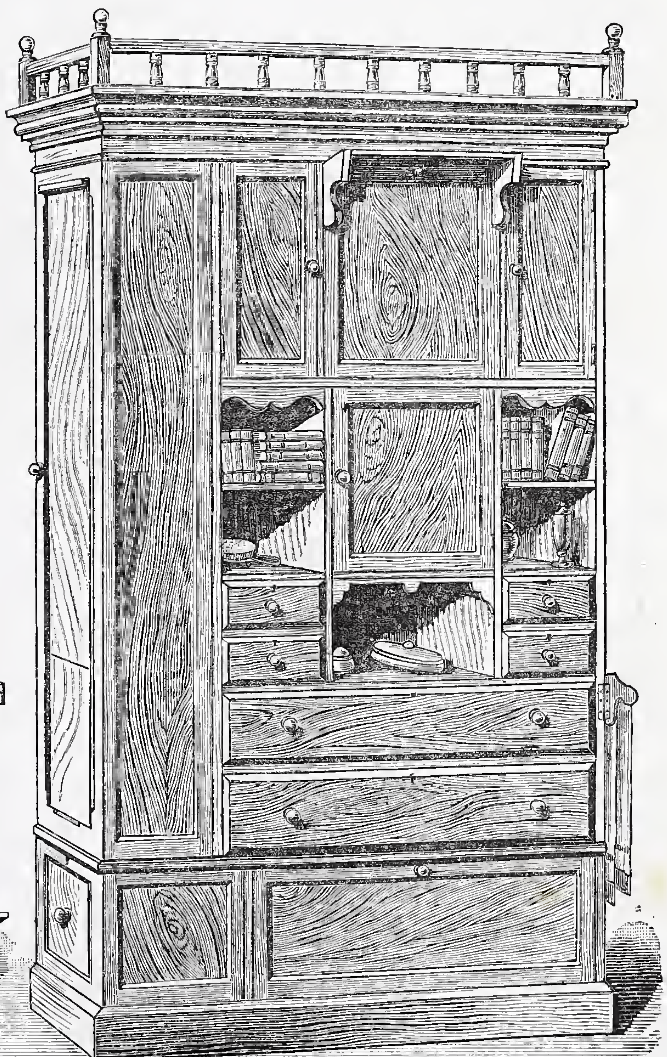

Fig. 4.—Suite Closed.

A Combination Bedroom Suite.

single article of furniture; and I think I may safely say that I have succeeded in doing so.

Presuming that I am addressing the amateur reader, I will now proceed with measurements. As I have drawn Figs. 3 and 4 to ¾ in. scale, professional workmen will know that that is sufficient for them. The job, when closed, occupies the space of twenty inches from the wall, and is 3 ft. 7 in. wide. Even in a very small room this will not be found inconvenient. When required for the purposes of a washstand, the long door on the left-hand side is opened, and the flap, which is part of the door panel, is let down; the towel rail is then brought round, and forms a support for the flap. Along the top of the flap is glued a strip of wood, which prevents it from slipping off the towel rail. The advantage of having the door and drawer to open at the side will be readily seen. Required as a dressing table, the door of the centre cupboard at the top is let down; and being fitted with a glass inside, and having a shaped piece of wood outside, to keep it at a slight angle, it forms a handy toilet mirror.

In making, care should be taken to get the pieces firmly joined together; and I should advise the amateur to get it cut out and fitted together before gluing, as it can undergo any necessary alterations, and can be glued up afterwards.

It is not my purpose in this paper to give any instructions on joinery, as I suppose that the reader has a sufficient knowledge of that craft. The wood should be ½ in. thick. Beginning with the plinth, *i.e.*, the bottom part, get two pieces of wood, each 3 ft. 7 in. long, and two pieces each 20 in. and 4 in. in depth; firmly join them together, and fix two or three thicker pieces in the space between at half an inch from the top to support the whole weight of the job. Very great care must be taken with this part, as the slightest mismeasurement will throw the whole job out of the square; or else prevent it from fitting exactly. It matters little whether the supports mentioned above are joined in lengthways or crossways, providing they are properly fixed. The edge all round the plinth should be canted slightly, as is shown in Figs. 3 and 4.

Proceeding with the side drawer and bottom cupboard, the top and bottom boards should be 3 ft. 6 in. long, and 19 in. wide; the two pieces forming the sides of the cupboard 12½ in. by 19 in.; and the piece in front, forming the side of the drawer, 12 in. by 12½ in.; whilst the back board is 3 ft. 7 in. by 12½ in. The drawer and cupboard door can then be made accordingly. A moulding should then be glued round the top, leaving half its depth free to receive the top carcase. When all is cut out, the bottom carcase should be glued into the plinth, thus hiding the thickness of the bottom board.

We now come to the top carcase. The back should be made up of boards firmly joined together; these separately may be of any width, providing that collectively they are 42 in. in width. A bottom and a top board, 19 in. by 33 in., should be fitted to the back board. Then a board, 58 in. long and 19 in. wide, should be fixed at the right-hand side, between the top and bottom; whilst another of the same dimensions is put between them at 32 in. distance from it towards the left-hand side. Next, the board forming the side of the long cupboard should be placed in its position. This board is 9 in. by 58 in.

We now have our top carcase ready to have its inside fed. We have four boards, each 32 in. by 18½ in., to fix. One at 7 in. from the bottom, another 6 in. above it, the next 9 in. above that, and the last 16 in. above that. These boards would be sufficiently firm, I think, if they were nailed or screwed in. The width of the top centre cupboard is 14 in.; the height 18 in. The two side cupboards are the same height, and 8 in. wide. The smaller cupboard underneath is 13 in. by 16 in. The jewel drawers should each be 4 in. deep.

I think I have now given sufficient measurements concerning the top carcase; the main thing is to get the big boards exactly fitted, the smaller ones can then be worked accordingly. If it is exactly joined and fitted it will now fit perfectly into the bottom carcase. These should not be glued together, as, in case of removal, it will be found convenient to have the job in two or three separate pieces.

The cornice is the next part to deal with. After having procured the moulding, mitre it up on three sides, to fit partly over the frieze, to which it should be glued. Proceed with the frieze in the same manner as with the plinth, using the same measurements, with the exception that the frieze is 2½ in. deep, taking care to get the inside cross pieces exact. A small beading might be glued round the bottom edge of the frieze.

If the Early English simplicity of the spindle rail on top is not admired by the maker, a pediment can easily be cut out to suit his taste, and should be glued along the moulding.

Having got the skeleton of our job together, the drawers and doors will next occupy attention. I need not say much of the drawers; they should have a beading glued round their fronts; otherwise, if they are bevelled, they will prevent the towel rail from carrying out its purpose.

Make all the door stiles 2 in. wide.

The full length of the side cupboard door should be 58 in.; the width 18 in. The movable panel must be 42½ in. long. This extra ½ in. allows for the strip of wood to be glued along the top, as before spoken of. The fixing of the towel rail (Fig. 2) should be left until the last, as it can then be screwed on at its proper height. It must be hinged on only to the front.

We will now look at the door containing the glass. I think an ordinary picture frame will explain the method to be adopted. Fig. 1 will give a sufficient idea of it. The glass, A, is fastened on B, the panel is then put in, and a moulding, C, is glued round the edges.

I have placed the cupboard on the left-hand side, so as to allow of a free movement of the arm of the person making use of the article as a washstand. If required, a cupboard could also be placed at the right-hand side; and I would be pleased to answer any inquiries concerning it through "Shop." Brass handles, or knobs, can be used. A handle must be placed somewhere along the flap, as shown, to keep it in its position as a panel of the door.

The two trays shown in the long cupboard should be made to slide in and out freely; and should each consist of a bottom piece 18 in. by 8½ in., with back and sides of 1½ in. depth.

Four pieces of wood should be screwed into the cupboard, two on each side, to allow for the introduction of the trays.

For finishing off the job I should advise it to be painted in some kind of enamel; there is at present in the market a very pretty and, I think, good enamel suitable for such purposes. Of course the inside parts can be stained. I think that if it were painted in some light colour it would relieve the heavy square appearance which seems to pervade it.

If my instructions are carried out, a firm and substantial article of furniture will be the result.

If any one should deem it worth a trial to make one of these wardrobes, I should be very pleased to hear of his success, through the ever-interesting columns of "Shop."

Such a job as is here described would, I think, be a very saleable article, especially at the present time, for the furnishing of small rooms at the seaside, etc., where space is important; and would, I think, repay the time and cost if one or two were made by a professional workman.

It will very likely be said by some of my professional readers that it is possible to purchase a complete bedroom suite almost as cheaply as it would cost to make one of these robes; but they must remember that space, and the convenience of putting it to the several uses named, was my motive for designing it.

Of course the back boards could be made of thinner stuff, and where the drawers fit in, a narrow framing would answer the purpose; but I should advise it to be made solid throughout, and of the same thickness.

It is quite unnecessary to have the backs, sides, and bottoms of the drawers as thick as the fronts—these could be made of much thinner stuff.

The method also that I have given of making the plinth and cornice varies also from the usual method, but made after the style that I have described they would be very firm.

I give no instructions as to panelling the doors and drawer fronts; I suppose this to be understood.

It will be observed that I have given all my measurements so as to allow for each board to be joined to its fellows in a strong manner. If it is the intention of the maker merely to nail the job together, he must first study my measurements, so as to reduce some of them accordingly.

POLARISATION OF LIGHT AND POLARISCOPES.

BY O. BECKERLEGGE.

THE CONSTRUCTION OF THE POLARISER.

IN constructing instruments, we may avail ourselves of more than one method, or material, without vitiating the results. For example, we may use reflected light for our analyser, and for the reflector we may avail ourselves of glass, crystals, polished wood—preferably mahogany—or the clear, blue sky; indeed, anything that will reflect light except metals. With any of these, we may use a Nicol prism for the analyser, or films or plates of glass, the result in the main being the same. On the other hand, we may use a Nicol prism for the polariser, and a reflector for the analyser. This latter arrangement, however, would present so many mechanical difficulties if applied to microscopic work, as to render it practically impossible; though for simple demonstration it might be used well enough.

In 1808, M. Malus, a young man of philosophical mind, experimenting with a piece of Iceland spar, directed it towards a beam of light reflected from the windows of the Luxembourg Palace, and, to his surprise found it to be polarised. Further experiment not only determined the polarising angle fo glass, but showed that each reflecting substance had its own particular polarising angle. In describing methods I shall have nothing whatever to say in reference to constructing a Nicol prism, beyond the fact that a rhomb of Iceland spar is cut in two in the direction already indicated. This must be done by a lapidary's slitting disc, or wheel. The surfaces are then ground perfectly flat, polished, and cemented together with Canada balsam. I confess that in my hands the polishing has been a failure. Others with more mechanical skill may certainly do it; but I would not advise an amateur who is fortunate enough to possess a piece of spar pure enough to make a prism to attempt making one. I believe small prisms can be purchased unmounted for about 10s. per pair. At the same time, it must be fairly understood that a pair of Nicol prisms will give better results than the mode I am about to describe. But there are other considerations. If one goes the right way to work, the glass method will cost nothing like the money which a Nicol would cost; and what to the young philosopher is of infinitely more value, *he can make it himself*. The writer's experience is, that far more pleasure and instruction are gained by working out details, grappling with difficulties, and overcoming them or finding the solution, than in purchasing an instrument, the construction of which is a mystery, and using it on lines laid down by some one else, the reason of which you do not see.

We will begin with the polariser. As it has already been stated, this may be made as a reflector. Make a cell similar to the one holding the mirror of the microscope, but at least 1 in. deep. Now, it is true that a single plate of glass will polarise light, but only a portion will be reflected; another portion will be transmitted. This being so, we must have several sheets, or plates; each one will reflect a portion transmitted to it, so that by employing, say, six or eight plates, we shall practically reflect the whole of the light under polarised conditions. Perhaps a larger number than this may be required. We must have the required number of plates cut out of the same sheet, which must be of the thinnest and whitest window glass possible, and free from specks and flaws. On the bottom of the cell lay a piece of black cloth, or velvet, and the plates of glass on it. Some experimenters recommend the plates to be separated from each other by bits of paper being gummed at the corners. I have tried the plan in experimenting, but I confess in my hands it made no perceptible difference. If a stout brass wire ring is sprung into the cell on the glass, the plates will be retained in their place; the cell can be japanned or lacquered, and be fitted to swing in the gimbal that usually holds the mirror. If there be a difficulty in procuring circular plates of glass, then let the cell be made square, and in any village a glazier can be found to cut glass square. When this polariser is used with the analyser, place a slide, mounted with selenite, on the stage, and turn the reflector at such an angle as shall produce the highest colour in the selenite; that will be the best angle to employ. A little practice will enable one to catch it very readily. It should be as near as possible 58°.

I will now describe the method for using transmitted light; and as the principle will be the same for both polariser and analyser, I shall simply describe the details of one.

In the eye-piece of the microscope which I described in WORK, it will be seen that I have drawn the cell containing the field lens to extend considerably beyond the lens. Now, if one is desirous of making the instrument as complete as possible, a thread should be chased on the inside of the projecting cell. Procure a piece of brass tube of the size that when a thread is chased on it, it will screw into the eye-piece. It can, of course, be made a tight fit, and so dispense with the screw. Next prepare a square block of wood, say 6 in. long, and of such a size that when rounded it will slip into the tube. On its two opposite sides draw a line at an angle of 26°. (See diagram Fig. 3.) Cut down to the line, and leave the wood as an acute wedge. The edges must now be planed off, and the wood rounded so as to slip into the tube. The end will now present an oval. Cut out of sheet brass or copper an oval of the exact size of the end of the wood. Cut out its centre, leaving it as a flat oval ring $\frac{1}{16}$th of an inch wide; or a ring may be made of brass or copper wire. Push the wooden mould into the tube, so that its end comes within $\frac{1}{10}$th of an inch of the end of the tube. Drop the metal ring in the tube, so as to lie perfectly dead on the wood, and solder it in its place. This can be done easily with a blowpipe, or even with an ordinary soldering tool. It need not be soldered all around, but only in such a manner that it shall be firmly held in its place. The tube need not be more than $\frac{1}{2}$ in. longer than the angle. Cut a pattern of the oval in paper, and send it to an optician—say, Mr. Lancaster, of Birmingham—and get a score of micro films cut to the requisite size. Ten or fifteen of these are put to lie on the ledge, which the ring in the tube makes, and can be retained in position by a paper tube cut to the same angle. When all are ready, the inside of the tube must be made a dead black, and each film must be carefully cleaned. This may be done without breaking the glass, by rubbing them between the folds of a silk handkerchief, held between the finger and thumb. This is now to be attached to the eye-piece, and placed in the tube, when it will admit of being rotated. For the polariser, Fig. 8, make or procure a tube, A, to fit into the tube attached to the diaphragm of the microscope described, and $\frac{1}{2}$ in. long. To one end solder a disc, B, $\frac{1}{2}$ in. larger in diameter than the tube, and with a central hole the same size as the tube. To this solder another tube, C, slightly less in size than the disc, and $\frac{3}{4}$ in. long. Turn the whole up true in the lathe, and mill the edge of the disc for finish.

A piece of tube, D, to fit tightly into this must now be used for the polariser, and made precisely on the same plan as the analyser already described. When made, films of glass must be procured to fit it. Of course it will be understood that both parts may be made of the same size. If so the same plates of glass will do for both; and perhaps it would be cheaper to have, say, forty films of one size cut than twenty of two different sizes. The number of films used will be determined by trial. What is wanted is the maximum of colour with the maximum of light. As the depth of colour is dependent on the number of plates, and as the decrease of light is in the same ratio, judgment must determine in each individual case, after experiment, when the loss of one makes up for the other.

Having got so far, we will put our instrument together. Place the selenite plate on the stage, and throw up the light by the mirror, and, just for a simple experiment, we will dissolve a bit of sugar in hot water to saturation. Put a drop or two on a clean slide, warm the glass until the sugar begins to crystallise, and place it on the stage, and focus the microscope. We shall now have an object worth admiring. Nothing, I think, in nature is more marvellous than to witness crystals being built up—here slowly, and seemingly by much effort; and then suddenly, in another part of the field, to see a crystal flash across the field of view too quick for the eye to follow, and all glowing at the same time with the richest colours, ever varying as we rotate the analyser or polariser. Such an exhibition as that will, if I do not miscalculate on the enthusiasm of the young philosopher and scientist, fully repay him for all his past labours in optics. Having finished our instrument, we must prepare our objects, both plain and polarising.

It will be understood that this is a wide subject. As I intend to prepare a brief paper treating on the various classes of objects and the methods of mounting them, I shall do little else in this place beyond indicating a few interesting objects and modes of mounting. It must be understood that each of the three great kingdoms will supply us with illustrations.

But in this utilitarian age of ours it may be asked of what practical use is the polariscope beyond being a mere instrument affording pleasure. The answer is that it imparts information relative to the structure of bodies; and although no great commercial advantage can at present be derived from it, yet it must be remembered that no true knowledge is valueless. The history of all human progress is the result and sum total of accumulated facts. The same substance when viewed by polarised light will always present the same appearance, as truly as the same elements give the same lines in the spectroscope. Hence in the hand of the chemist it is the means of detecting adulteration. For example, any substance added to butter will reveal itself. Or the starch of potatoes may be detected in corn flour.

As a variety, we may make up some slides of mineral salts. One of the most beautiful is crystals of nitrate of silver. A little should be dissolved, and then a drop placed on a slide and allowed to crystallise. Sulphate of copper, sulphate of iron, chlorate of potash are but a few to practise with.

We will now turn our attention to a few vegetable preparations. These, though equally beautiful, are much less difficult to prepare.

Cut a thin section of oak bark longitudinally, and plane with the tree. Soak it in turps to render it transparent, and mount with Canada balsam. Here we shall see the cells filled with star-like crystals. Sections cut from rhubarb, also from the onion, will show crystals. The hair-like substances under the shell of the chestnut are good specimens, mounted in dammar. Different kinds of starch, flour, potato, etc., are beautiful and instructive. Of animal substances, prepare a thin section of a corn from the foot section of whalebone, various fish scales, and white hair—human. These must be soaked in turps and mounted on balsam, and are really beautiful objects.

It must not be supposed that the subject of polarisation has been exhausted in this article. I have, in fact, but touched the skirts of the subject. And, indeed, it requires ability far greater than mine to bring the whole of this subject into such a form that it could be readily grasped by the scientific tyro.

LOCK REPAIRING AND KEY FITTING.

BY THOMAS WILSON.

Lever Locks: Their Construction, etc.

Before giving a detailed description of lever locks, it will be as well to commence with a general description of them. As I said at the commencement of these articles, backspring and tumbler, or warded, locks are really no protection at all against force or fraud, and as from the nature of their construction they are capable of very few variations, it follows that there are hundreds of a similar pattern in existence. Indeed, I have known instances where one street door key has opened half the doors in the street. It is, no doubt, very convenient to be able to borrow your neighbour's key if you have lost your own, but the advantage hardly outweighs the disadvantage.

Ordinary lever locks, however, though not absolutely unpickable, are sufficiently so for general purposes; and those made by Messrs. Chubbs, Messrs. Hobbs, and other eminent makers, with patented improvements, may be said to be absolutely unpickable. That Messrs. Hobbs and Co. consider theirs unpickable may be judged from the fact that at the exhibitions of 1862, 1867, and 1873, they offered a reward of 300 guineas to any one, skilled mechanic or otherwise, who could pick their locks; and it speaks volumes for their security when we find that no one attempted to do so, though they were examined and inspected by some of the best mechanics in the world.

The Barron lock, Fig. 4, although it can hardly be called a lever lock, may be justly considered the first foundation of the modern lever. It was invented in 1778 by Robert Barron, and, I believe, is still manufactured; at any rate, I frequently have them to fit keys to and repair.

This invention was a great improvement on the ordinary tumbler lock, as it has two tumblers, B, B, with two studs, C, C, which work in slots in the bolts, shown by dotted lines, D, D. The wards in this lock, too, are more intricate than in most warded locks; but they can, of course, be passed by a skeleton key, and as the bellies of the tumblers are nearly the same pattern as the key, they can easily be lifted to the right height by a skilled locksmith. To fit a key to this lock first cut the wards in the blank as described in page 322 (although, of course, a much finer chisel and file must be used); then cut the steps, F, F, in the key, so as to raise the tumblers to the right height.

Fig. 2 shows the ordinary lever lock. All the best modern locks are made on this principle, with additional protecting contrivances. No wards are used for these locks, except for arranging suites of locks with master-keys; and the single tumbler is replaced by a number of levers. Fig. 3 shows one of these levers with part of bolt. The lock shown in Fig. 2 has only two of these levers, but this is a very ordinary kind. Of course each additional lever adds to its security, and some of the best makes have as many as fifteen.

On looking at the illustration Fig. 3, it will be seen that the bolt, A, has a stump, B, affixed to it at right angles, and that the lever has a passage cut in it of sufficient size to allow the stump to pass through. In the illustration the lever is shown in the position it stands in when the bolt is locked. In unlocking the lock each lever has to be raised so that the passage comes exactly opposite the stump, and as each lever has the passage cut at a different height it follows that none but the original key will open it. That they are secure against opening with false keys may be judged from the fact that a seven-lever lock is capable of over four thousand (4,000) changes; or, in other words, it would be necessary to try that number of keys before there was any probability of succeeding in opening it.

In a paper read before the Society of Arts (Lord Grimthorpe in the chair) by Mr. Samuel Chatwood, the eminent safe-maker, he stated the manner in which his keys were cut by machinery. As this is very interesting, I will take the liberty of quoting it in full:—"A very important requirement in safe locks is that no two should be made alike, in order that there should be no possibility that the key of one safe should open another. The method in use in my works, and also, I believe, in some others, renders it absolutely impossible for two locks to pass, unless specially made to do so. The key consists of a number of steps corresponding to the number of levers—say, for example, eight. These are of different lengths. They are cut out of the key blank by eight circular saws of different diameters, placed in a pack on a mandrel. The key blank is held in a special vice fixed on a slide rest, and is brought forward against the saws by the screw of the slide rest. The saws thus cut out the steps. Each of the saws is numbered, and for the first key they are placed in the order 1, 2, 3, 4, 5, 6, 7, 8; for the second in the order 1, 2, 3, 4, 5, 6, 8, 7, and so on. The number of changes—*i.e.*, the number of different keys—which can be cut with a set of eight saws is 40,320, which may be extended almost indefinitely. To make a second set of 40,320, it is only necessary to alter the diameter of one of the saws, or to vary the depth to which they are allowed to cut into the key blank. Keys are made in this manner for store. When the locks are finished, with the exception of the cutting of the gatings, the locksmith receives keys from the store, and marks off and cuts out the gatings to correspond with them. The lock is made to the key, therefore, and not the key to the lock. A very beautiful machine was introduced by Mr. Fenby for cutting his key bitts by the use of one saw; but I prefer the plan of having a number of saws equal to the number of levers, each saw of different diameter from any other, and carrying its own number, and transposing the saws for each set of keys."

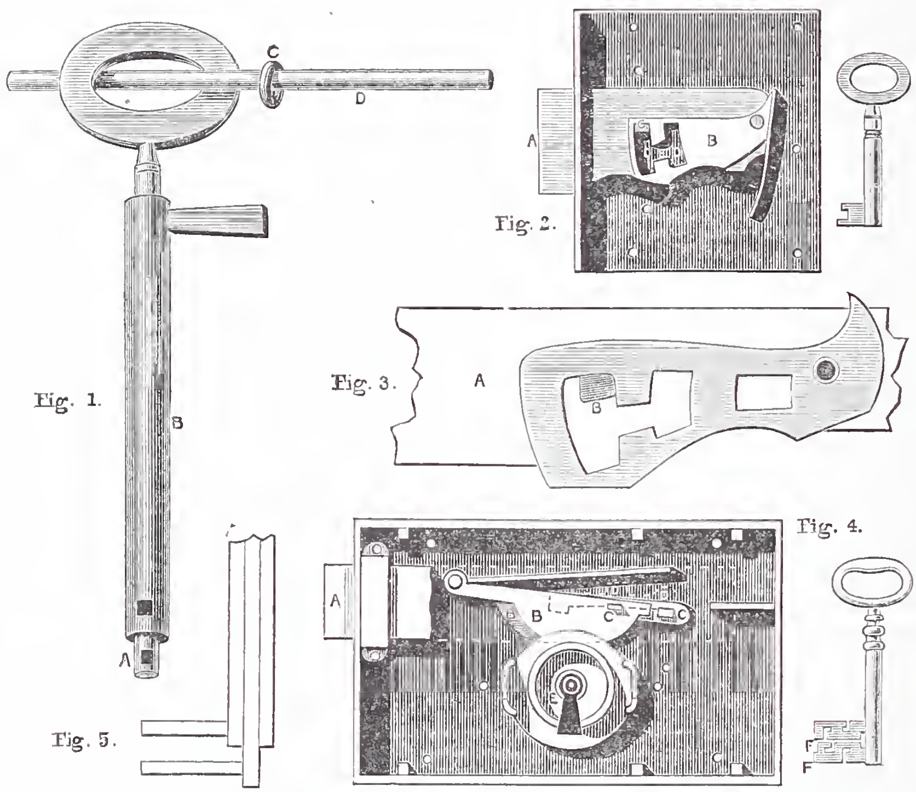

Fig. 1.—Instrument used for Picking Lever Lock. Fig. 2.—Ordinary Lever Lock. Fig. 3.—One of Levers in Best Lever Lock with Part of Bolt. Fig. 4.—The Barron Lock. Fig. 5.—Section of Fig. 1.

Though for a long time considered unpickable, it has been found possible to pick lever locks. Fig. 1 shows one description of instrument used for this purpose. A is a solid key with one step, used for engaging with the bolt, and B is a tubular key fitting over A, having a step for raising the levers. The weight at the end of A causes the bolt stump to be pressed against the face of the levers, and then by raising each lever in turn with the tubular key, B, the position of the passage or gating in the lever is ascertained by the difference in the friction when pressed by the stump, and when in position and no longer pressed by the stump. As each lever is raised the weight C is carried along the lever arm, so as to keep them in their position by the extra pressure, and when all the levers are raised the bolt slides back. Should the lock have a pin, as it probably will, the pin must be knocked out and a hole drilled in the plate to support the key, or two very thin tubular keys may be used, when it will be unnecessary to remove the pin.

But picking a lever lock is a very tedious operation, and can only be accomplished by a skilled locksmith, so that for general purposes ordinary lever locks afford ample security.

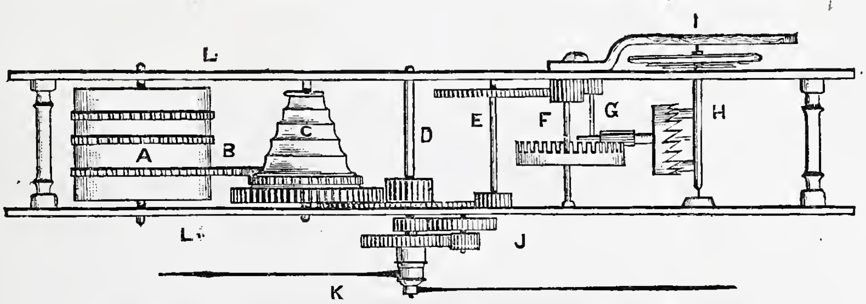
THE VERGE WATCH: HOW TO CLEAN IT.

BY A PRACTICAL HAND.

The old-fashioned or common verge, so dear to our ancestors, and even, in another way, to ourselves, is properly called the vertical, from the escape wheel being placed to turn in a vertical manner; this wheel is the one with saw-like teeth under the balance wheel; the wheel which turns the escape is the crown wheel, being in the shape of a coronet.

The amateur had best procure the following tools, etc.:—First, an eye-glass, costing 1s. 3d.; a pair of tweezers, 8d.; small tooth-brush, 6d.; small screwdriver, 3d. (a broken steel crochet hook, ground shape, makes a good substitute); a darning needle or large sewing needle driven into round piece of wood for handle, with the eye broken off and just touched up on stone for a push-pin; a piece of prepared chalk, 1d.; and 2d. worth of pure almond oil; this had best have two or three small slices of lead dropped in to allow the fatty matter to adhere to. In a day or two pour out the oil into a very small bottle for watches, and remainder will do for clocks. To the cork of the small bottle inside, fix a sewing needle with eye reaching into the oil; this is for oiling with.

Now place upon your table an oblong piece of clean white paper, say, 18 in. × 12 in., so that any small screw will easily be seen and not lost. Commence by taking the outer case from the verge, and open glass frame, notice, at 12 on dial, the hinge holding in the works; push this pin out with the push-pin (already mentioned) at the 10 o'clock side, thereby relieving the works from inner case. Now hold the watch movements in the left hand and study them well over—don't think it time lost—so as not to be at a loss how to put them together again. Now lift off the two hands at once, which is very easy in a verge. The blade of an old worn pen-knife is best to draw out the three dial pins, and be careful to hold it over your table in doing so. Lift off the two dial wheels, J, and then the steel one; it will be rather difficult; raise it gently all round with the knife point. The next is to let down the main spring. This is rather difficult for an amateur. First place a small bristle or piece of paper on the crown wheel teeth to lock it, and then unscrew the cock or cover of balance, holding the works very steady with left hand; lift off the cock with tweezers. You then expose the balance with hair spring attached; notice the square stud through which the end of spring passes and is so pinned in; make a small mark to where the end of spring comes, so that in replacing you can do so exactly in same position. This, of course, is only for amateurs; practical hands know how to place in beat at once, but amateurs cannot have it too clear. Now notice the way the pin is put in the square stud, and push it out with a screwdriver, and draw spring out with the tweezers, and be careful not to break the balance staff by lifting it out of its hole; place what you have taken out carefully on your paper out of the way of your work; now fix your winding key upon its square, and then lift out the bristle or paper. Immediately the wheels will swiftly commence to run down, but take hold of the key in your right hand and gently hold on until it is run down; be sure to do this, as some amateurs have lifted off the top plate before letting down—consequence, a broken pivot or two. Holding the movement still in the left hand by the finger and thumb, push out the four pins, one at each pillar, and then lift very carefully the top plate off. Now notice how the wheels are; you will find the escape wheel attached to the top plate, but at present we have to do with the others; and with tweezers lift out the crown wheel, then next small wheel, and now just turn the barrel or main-spring wheel (which every one knows) a little, and lift out the chain hook out of the fusee hole; now take out the barrel, and a small ratchet wheel will drop from it at the underside; be careful not to lose it, and then lift out the fusee wheel, next the centre wheel, and now all is clear. Unscrew the small screw holding the wheel in position upon the upper plate, and release that wheel carefully; put it separate with its stud and screw so as not to mix the screws; you may easily ruin a hole by trying to fix a wrong screw into it. Now all is to pieces, because very few ever take out the spring from the barrel; if they do it does not run long after until it breaks, which of course is good for the trade; why they break I need not explain. But notice a mark upon the barrel, another on the lid; these must be put together when you put it back; prise out the lid, brush out the old oil and dirt in every part, then just place the least drop of oil on the coils of spring, replace lid, the two marks together as stated before; now run the brush a few times over the prepared chalk, and holding the box betwixt a small square of clean soft paper, brush it quite bright, and place it under a wine glass (one whose shank has gone is best); now take the chain which was upon the barrel, and draw it a few times betwixt a small piece of wash-leather, and then draw it a few times betwixt a piece of oil paper; place under the glass. Take the fusee wheel, clean and brush the teeth crossways, be sure to leave no dirt or chalk in any part, add it to those under the glass, and so with the other wheels. Next the plates, but in brushing them be sure to use the brush in a circular fashion, or the brush marks will show. Now comes the most careful part—the balance. To clean and not to injure the spring, take a small piece of writing paper, size of half a crown, put a small hole in the centre, then from it cut to outer edge; slip this under the balance, but upon the hair spring; now clean the steel rim until quite bright, turn it over and dab the soft brush amongst coils of the hair spring, next clean the staff with its two pallets; place under the glass. Now brush the cock or cover of balance, and then clean dial and dial wheels; after this take a piece of hard wood (a restaurant tooth-pick does very well), make a fine point at the end, and with it clean all the jewel and other holes, also the cock hole and hole for end of balance at bottom. Now be sure all is clean; examine carefully with your glass, for one single particle of chalk or grit between a tooth will stop the watch, and cause you much trouble afterwards. Now see the holes are not worn oval, and the face of the pallets are clear of grooves worn in them by age; some people, actually watch repairers, profess to be astonished why steel pallets wear sooner than brass teeth of the escape wheel. The thing is quite simple: the two pallets receive all tappings of the escape teeth upon them, over a dozen taps for their one, every revolution of escape wheel.



The Works of the Verge Watch shown in Elevation on Enlarged Scale.

A, Barrel.
B, Chain.
C, Fusee.
D, Centre wheel, carrying minute hand.
E, Third wheel.
F, Crown wheel.
G, Escape wheel.
H, Balance wheel and pallets.
I, Cock or cover.
J, Dial wheels.
K, Hour and minute hands.
L L, Plates.

All being clean and in repair (repairs will be given in a future paper), now commence to put together. First take top plate and refix escape wheel into its place with the part that holds it there by the screw for that purpose; try if you have given it too much or too little end shake; it should spin easily around by the slightest touch, but not more perceptibly the other way; place one drop of oil on the watch glass; this will be sufficient to oil the whole movement. Amateurs always oil too much. Now from this large drop take the least particle and touch each pivot of the escape wheel; now take the lower plate in your left hand and lift the centre wheel into its place, the spring barrel; next the fusee wheel which works into the centre wheel, then next wheel, and now the crown wheel; put it into position, then carefully put on the top plate to fit the four pillars, and with your tweezers or the push-pin guide each pivot into its hole, and gently push down top plate. When all are near their respective holes this is not difficult, and do not damage or break a pivot by hurrying over the job; when all is right, and the wheels turn round, put in the pins to hold the top plate, using the two short pins for those pillars that will be covered by cock, etc. Now by pushing the fusee wheel all should run easily; if so it is all right so far. Now take the chain, and notice the two hooks; one is round and the other is flat; the last mentioned is for the main-spring barrel; be sure of this point. Now hook to barrel at the small hole and press it firmly in, then put on your key to the under square and turn gently until nearly all the chain is wound upon it; pass the other end hook under the pillar, and hook it into small hole with a centre bar in it; see you get it on to this bar, and the chain will lie in the first groove. Now tighten up the spring by putting on the ratchet and insert click; push the ratchet a little, passing the click in each notch with your thumb nail; give it a half-turn when tight, then wind up a little with key on fusee and see it runs all right.

We now turn to the balance. First touch each end with the least oil possible, also the two pallets; place it into the square hole to receive it, and see you get the bottom pivot to its hole; be sure of this (I want to be certain about this, as amateurs are always in a hurry). Now pass in the end of hair spring to the mark you made, and pin it secure and spring level, then drop last coil into the regulator pins, and now place on the cock and move it gently until top pivot goes into the hole; try it by seeing if the balance will vibrate; now screw down tight, put pressure on fusee, and the balance should work if all is right. Now wind up, but guide the chain first time into the grooves, and you will now hear it ticking away as of yore. With the remaining drop of oil touch each hole and pivot top and bottom. Now place it under the glass, face side down, and try it for a few hours, then if in full vigour, take up with paper and push on tight the steel wheel to centre pinion, under face, and push down tight; and now the brass one with small hole in centre to the pin near by, so that it works into the teeth of the steel wheel, and now place the remaining wheel on to the centre steel one so that it works into the brass one before mentioned. Now place on the dial and hold it firmly; turn over and pin it on safely; clean the cases with rouge and leather, and place in the movement; push in the large pin thin end first at the two o'clock side, and close the cases; put in the glass, of course, first, and the hands. Listen if it has an even beat; if not, see last paper for defects and their remedies.

We will now proceed with the well-known horizontal watch, which sometimes was called the anchor escapement, as the points of escape wheel are the shape of an anchor's points. The invention of this made a great change in the wearing of watches, as the price brought them within the reach of all, coupled with their accurate time keeping. The inventor of this escapement was George Graham, who also invented the dead beat in clocks. I have more faith in this make of watch than in many so-called cheap watches; they are reliable with fair usage, and are very durable, surpassing the verge in many ways, neat in appearance, weigh little, and cost 15s. to 80s., in fine silver cases. They are the watches to buy by those who have slender purses; some have more massive cases, and imitate the English lever in appearance.

To clean it, open the outer cases, inner dome, then the glass dome over dial; now turn it over, and with your eye-glass on look for a half-headed screw near the balance, cock, or cover, turn it half round, then push out the movement from the cases entirely, face side; take hold of them in your left hand, and lift off the seconds hand, and then minute and hour hands; now turn over and draw out the two pins which hold the dial (some dials have two small half-headed screws to hold them on); now take off the three dial wheels as described in last paper. Turn it over and place a small bristle in the escape wheel; now unscrew the cock or cover, and carefully take it partly off with the tweezers; you will see that the hair spring is pinned into a square stud at your right; lift out all together with tweezers. You will notice that balance wheel goes under centre wheel. Now, when all is free and clear of escape wheel, turn it over and lay that side up under glass; be careful of the balance part, as the cylinder is very expensive to replace, and liable to be broken unless every care is taken in handling it; 5s. to 7s. is sometimes charged for a new cylinder, which is little less than robbery in my opinion.

To proceed, put your key on the centre square, and now lift out the bristle and hold the key so as to let it gently down until spring is spent, then unscrew the small screws which hold the top and bottom plates together (but first draw out the centre square with small pliers), and you will find the barrel wheel will remain attached to top plate; now take out centre wheel and the next two, and place them so that you will remember which is which; of course, if they get mixed, you can easily see the two or three dots on the underside, which shows you plainly; next unscrew the small cover over the escape wheel. This wheel is a very delicate piece of mechanism; handle it with great care. It is considered the most wonderful piece in a watch, to be so finely made and so perfectly accurate. Now the movement is all to pieces, providing it is a skeleton movement, that is, each wheel is fixed by a separate cover and one or two screws (this make is easier for the amateur). Proceed by unscrewing the centre wheel at each side, then spring box, and next the two remaining wheels; now brush the plates in a circular way; clean the holes with peg wood, and with glass see that no jewels are broken or holes worn oval; if so, see last paper. Now brush with prepared chalk the various wheels, and be very careful with the fine steel escape wheel; notice how far the hair spring is through the stud, and make a mark as previously mentioned in the verge details; clean it same way; brush the cock well and polish the regulator. When all is clean, dial and dial wheels, take bottom plate in the left hand, place in the spring barrel, then the centre wheel; next two, and drop on the top plate and guide each pivot to its place; push down, and try if they turn easily; if so, screw down the plate and put in the centre square, and push down tight; next place in small particle of oil to each jewel hole of escape and balance wheel at bottom, and replace the escape wheel with its cover screw down, but be sure and try it to see if it is in the holes all right. Now oil all pivot holes. It should commence to tick by using a little pressure on large wheel; if it does, all is right; wind it up and place under your glass cover to try it for a few hours; should the beat not be equal you have not carefully replaced the hair spring; you can easily see if it is not so by gently holding back the centre wheel until the balance is at rest. Now notice one small dot on rim of balance wheel, and three small dots on bottom plate just under it; if the dot on rim rests opposite the centre dot on plate, it is in correct beat, if on either side it is out of beat, and you will have to take off cock and lift it and balance out at once, carefully. Of course, be sure to put in bristle to prevent movement running down. Now turn over the cock with balance attached, and partly push out pin holding hair spring, and move the hair spring the least bit the way that will place the dot on rim with centre one as before stated; pin it secure and try it; if not quite right move it a little more. You could do it without taking out, but for an amateur it is the safest way, as you might slip in pushing pin home, then the hair spring would be ruined. If you have the two dots right, screw down cock and take out bristle, and tick will be correct. You might touch the escape wheel two or three teeth with the least oil; some do and some do not; I think it is better. You can now replace the centre steel wheel under dial, pressing it firmly down, not too much, and place on the other two as mentioned in the verge instructions; place on dial, turn over and fix two pins to dial feet, or screws if they are used, clean the cases with rouge, and take the movement and replace in cases. Notice at one side three small studs on plate next to dial, and see that centre one goes to a notch in case rim, and then push down the other side, and twelve o'clock will be at its place under watch neck, unless it is in hunting cases, when three o'clock will be in that position. Now turn over and turn the half head of screw on to rim of cases to secure it; next put on the seconds hand and hour hand, press down to position so as to clear the seconds, and also give room for minute hand to pass over; now lay down the watch and press on the minute hand; sometimes it requires the least tap with small hammer to fix it tight, having the under square resting on your bench rivetting block; put the minute hand on 60 and the seconds hand on 60 also, when, if dial is correctly marked, they will always coincide. Do not turn the hand so much; many are continually forgetting to wind up regularly, so have to be turning hands frequently; this spoils the watch in time, requiring to be tightened up, etc.

Now, when in the cases, you can hear more distinctly if any rubbing sort of noise is going on; if so, see repairs in the last paper. If all right it will only require regulating. If it loses, touch the regulator point the least particle towards F and try it again; if losing still, move it a little more until it goes perfectly correct, or *vice versâ*; use your eye-glass so as to do it correctly; it is worth while timing it by a good clock or regulator. London is famous for some excellent timekeepers—Greenwich time. You may manage to time up to the minute a month, which some speak of their watches doing; if so, it will satisfy you.

A SIMPLE METHOD OF DRYING AND KEEPING WOOD.

BY R. W.

In an article that appeared in one of the early numbers of Work, entitled "Friendly Hints to Amateur Wood Workers," the writer speaks of drying seasoned wood. It struck me that an arrangement I have for keeping wood ready for working might commend itself to some of the readers of Work, who are put to the inconvenience that I was before I thought of this method, and who have the requisite features in their homes. These are a passage on the ground floor about 20 ft. long and easy accessibility from without.

I will first describe my own, and then, for the benefit of any who may adopt this method, suggest what experience has told me would be improvements. I had long felt the want of a place to keep boards, etc., dry, so as to have them ready for working. One day the following idea occurred to me: namely, to keep the wood on stages in a passage. I selected one in the basement, which was most suitable, as appearances did not matter, having only the kitchen, etc., leading into it.

This passage is about 14 ft. long, 3 ft. wide, and 9 ft. high, with a door at one end leading into the garden, by which I get the ood in and out. In it I placed a couple of ages, with about 6 ft. 1 in. head-room; hy I allowed so little will be explained ter on. No. 1 stage I placed about 4 . from the door, and No. 2 about 7 ft. om this. The uprights were made of in. × $1\frac{1}{2}$ in. batten, and the cross pieces r the wood to lie on were 2 in. × 4 in. laid at, which is quite strong enough for so hort a span. These frames stand on a oncrete floor that takes the weight, and re fixed by one or two nails into the walls, which are brick. If they had been lath nd plaster, I should then have used crews, and this would be quite steady nough. I now placed the cross pieces nd fixed them with small W. I. angle rackets, such as you can get at any ironmonger's; they are cheap, being only a penny or so each, and make a very strong job. I advise those who do not care to waste time on rough jobs, such as this, in making mortises, etc., to use brackets. I have a chicken house and run erected with them. Another advantage of using these is that they enable a job to be taken to pieces easily, quickly, and without damage to the different parts, being fixed with screws.

But to return to the staging: I have found by experience that a longer passage—say about 20 ft. or more if possible, so as to take floor boards, etc., without cutting—would be an advantage; also, if the stages had been closer together, say 5 ft. instead of 8 ft. between; and, in the case of a longer passage, more of them. The reason I allowed so little head-room was to keep the stage below the top of the doorway, allowing a space for the wood to be run in easily; but owing to its being so low, I found the top of the door when open fouled the ends of the boards. I therefore now have some pieces of wood, the required thickness, that I place under the boards when in position, to raise them up sufficiently to clear the door.

But this stage, I found, was not suited to keeping small pieces, such as ends 2 or 3 ft. long. So I decided to erect a second one; this I put in another passage against an end wall. I made the frames on the same principle as the others, but used stronger cross pieces, 3 in. × $4\frac{1}{2}$ in. batten, which I happened to have by me, as the span is 6 ft. instead of 3. This section is not too strong, if one wishes to keep a quantity of wood on it. One frame I placed 4 in. from the wall, and the other 3 ft. 6 in. from this, joining them with 2 in. × 1 in. laths laid flat, and 1 in. apart, so as to keep all sorts of odd pieces without any fear of them falling through.

This arrangement has the advantage of occupying nothing but waste room, is always easy to get at, and also keeps the wood in very good working condition, with no tendency to warp or twist, because the hot air from the kitchen and different gas brackets in the passages circulates all round, and therefore dries it evenly.

The following illustrates its efficiency: In the autumn of last year I brought in some matchboarding, $\frac{5}{8}$ in. × $6\frac{1}{2}$ in. × 10 ft. long—in all 8 pieces. They were thoroughly soaked, having lain in the open for some weeks; in fact, they were dripping when first brought in. These I placed on the rack on edge close together, and in about a fortnight they were fit for working; nor had they warped the least, being as straight as when cut. One would be inclined to think the wood would get too dry if on the rack long, but I do not find it so, for some pine after being there eleven months cut as clean and as sweet as possible.

WROUGHT IRON AND STEEL GIRDER WORK.

BY FRANCIS CAMPIN, C.E.

AUXILIARY BRACING, FLOOR COVERINGS, PERMANENT SET AND DEFLECTION.

IN order to maintain the stability and properly corresponding positions of the different girders forming a complete structure, and secure them against disturbance from vibrations due to load and wind pressure, various kinds of bracings are used, which being accessory and forming no part of the structural design of the girders themselves, may be distinguished as auxiliary bracing.

This bracing will appear in the form of ties and struts passing from girder to girder in either a horizontal or vertical plane, the ties usually being placed diagonally and the struts at right angles to the lines of the girders to which they are attached.

In Figs. 15 and 15A two kinds of bracings are shown. A A and A′ A′ show in plan parts of two main girders lying parallel to each other, and connected by horizontal bracing between them to prevent lateral disturbance, and, therefore, sometimes called lateral bracing. This system consists of tie bars, B B′, B′B″, C C′, and C′ C″, the pull upon which is resisted by the struts B C, B′ C′, B″ C″. These struts must be of some rigid section, angle, T, or H, to oppose the compression to which they are subjected. The ties, if not very long, may be flat or round bars, but if of great length a more rigid section is desirable to prevent their sagging with their own weight. Where cross girders occur they will themselves act as struts. In 15A, F F and G G show in vertical section two parallel main girders side by side, assumed to carry the flooring upon the top, and secured from overturning by vertical cross bracing, D D′ and E E′, lying horizontally, and D E′, D′E, lying diagonally; these latter, as well as the former, must be of rigid section, as either of them may be put in compression or tension according to the direction of the disturbing force, which tends to distort the structure.

It is very evident that the utility of these bracing bars, other things being the same, will depend upon the correctness with which they fit into their places, hence the holes in one end only should be drilled in the shop, the holes in the other ends being marked off from the girders when they are put in position, and drilled at the place of permanent erection.

It very frequently happens that part of the section of the bracing bar has to be cut away at the end for a short distance to allow of the joint being properly made; in such cases the section of the bar should be made up by welding a layer on the end as shown at B, Fig. 16, which represents the thickened extremity of a T iron. It will be observed that as the vertical limb is cut away the horizontal table is thickened, and this is to be done to such an extent as to make the area across the rivet holes, after these are deducted, equal to the full area of the bar in its centre parts, so that it shall have equal tensile strength throughout. This thickening also enables us to secure proper bearing surface for the rivets or bolts. Suppose we have a T iron bar 6 in. wide on the table, and 3 in. deep vertically by $\frac{1}{2}$ in. thick, then its sectional area, found by adding the vertical web to the table, will be $1\frac{1}{4} + 3 = 4\frac{1}{4}$ square inches; the table alone has 3 in. sectional area, so where the web is cut away its thickness must be increased to $\frac{3}{4}$ in. This is making it a little full ($4\frac{1}{2}$ square inches sectional area), but is practically near enough. The bearing of a $\frac{3}{4}$-in. rivet will be (thickness of bar multiplied by diameter of rivet) $\frac{9}{16}$ square inch, hence eight rivets will equal strength of bar.

When round bracing bars are used, they can be tightened up by coupling boxes such as that shown at H; the ends of the box are drilled, and screw threads cut in them in opposite directions—one right and the other left-handed — to fit which corresponding threads are cut on the inner ends of the tie bars, G and G′; thus by turning the coupling box while the tie bars are prevented from turning, their ends are placed nearer together or farther apart according to the direction in which the box is turned. In order to keep the full strength of the bars, the screwed end, D, must be made larger than the run of bar C, so that the diameter of the screwed part at the bottom of the thread shall not be less than that of the body of the bar. These ends are usually made from larger bars and welded on to the tie rods. Round ties are usually connected up with bolts passing through eyes in the ends, and these eyes must be made equal in strength to the bodies of the bars. The proper shape for an eye is shown at E, F; the distance from the edge of the bolt hole to the end of the eye should be one and a half times the diameter of the bolt, the bolt being properly dimensioned to suit the bar as follows:—The end of the tie bar being held between jaws or clips, the bolt will be in double shear, and, therefore, its sectional area multiplied by four tons per inch—the working shearing resistance—must equal half the sectional area of the tie bar multiplied by five tons; the working tensile resistance, that is, the sectional area of the bolt, must be $\frac{5}{8}$ths of that of the tie, but the sectional areas vary as the diameters squared, therefore the diameter of the bolt must equal that of the tie multiplied by four and divided by five.

A good water-tight bridge floor has always been a desideratum, but the difficulties of erection militate against its acquisition, and as might be expected many different forms have been patented and put upon the market. For many years Mallet's buckled plates have been very largely used for flooring, and possess many considerable advantages over the earlier forms, inasmuch as they have great strength and are self-contained. Plain cambered plates require ties, and corrugated plates have no lateral rigidity to speak of.

In Fig. 17, A A is a section, and B B, a plan of a Mallet's buckled plate. It will be seen that it is dished, having a flat fillet left round the edge which forms a tension ring to the flat dome into which the plate is shaped. At M is shown a top flange of a girder carrying a flooring of these buckled plates riveted on to it. This rivetting must necessarily be done by hand, and under the disadvantage that the man "holding up" the rivet is unable to see his mate, who is on the other side of the plate.

At C is shown in section a trough-shaped flooring; the troughs are placed side by side and connected at the top by the joint plate D. These troughs act as cross girders as well as forming a covering, but being of limited depth necessarily involve the use of a greater quantity of metal for a given strength than is required when built-up girders are employed; the sides, too, which form the webs are much thicker than is necessary for strength if they are acting merely as webs. Another form of trough floor designed to remedy this last fault to some extent is shown at E E and F F. In this construction the bottoms of the troughs are rolled much thicker than the sides, and the bulk of the metal thus placed in a more advantageous position than in the previous form, but the same rivetting difficulties are present in both as occur with the buckled plate floors.

The latest form of floor plate patented is shown in section at G G. It consists essentially of a buckled plate, with the fillets, H, vertical, thus affording facilities for rivetting with a portable hydraulic riveter, and also saving half at least of the number of rivets required with the common buckled plates. I I is a plate girder; to the web of which floor plates are riveted as shown. This construction admits of making very close work with a minimum of labour.

When continuous plate floors are used, lateral bracing is not required, its functions being filled by the floor itself.

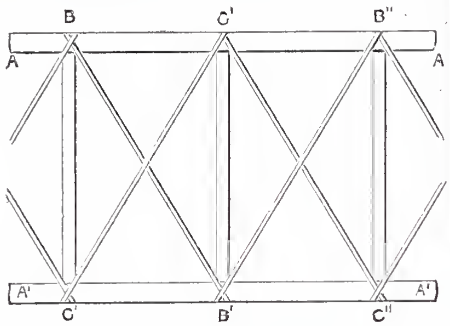


Fig. 15.—Horizontal Bracing.

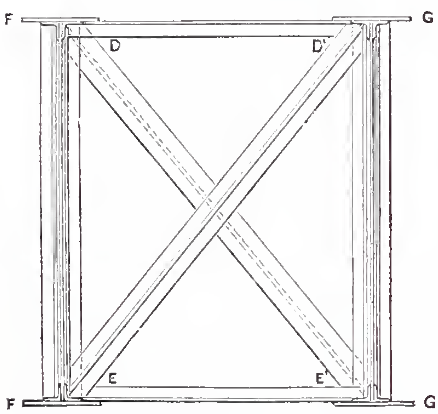

Fig. 15a.—Vertical Cross Bracing.

It is always advisable when girders are completed to test them, if not too large, previous to permanent erection, for although samples have been examined during the progress of construction, yet in the completed work some unexpected flaw may occur, or at some point the workmanship may be defective. It is from the deflection of the girder that its fitness for the purpose for which it has been designed will be judged. The deflection is divided into two classes, the permanent set under a test load, and the deflection which disappears on the removal of the load. In testing the solid metal itself before it is made up into girders, it may be found that on the first application of the load, a slight permanent elongation may take place without deteriorating the ultimate strength of the metal; this may arise from some want of uniformity of texture brought about by the exigencies of manipulation, and on repeating the test stress no further permanent elongation should occur, otherwise the material will ultimately break down under a stress much below its first breaking strength. At different times experiments have been tried to determine the effects of continuously repeating the imposition of stresses, and from them it may be generally concluded that so long as the applied load does not exceed one-fourth of the breaking load, it may be reapplied without danger for an indefinite number of times.

When a structure has been erected and all supporting scaffolding removed, a constant deflection due to its permanent load will occur and remain; on the application of running load, there will be some permanent set due to the joints settling to their bearings: beyond these there should only occur the temporary deflection due to passing loads. If the elasticity of the metal is known, the deflection can be calculated for any given girder. The value of the elasticity is the weight that will extend it a given proportion of its length, and the amount usually given is that load which, were it possible, would extend a bar one inch square to twice its length; this load is called the measure or modulus of elasticity. Although the supposed effect is not practically possible with iron or steel, this sum is convenient for calculation, as the extension and compression within the limits of elasticity vary directly as the stresses. The girder being assumed to have flanges of

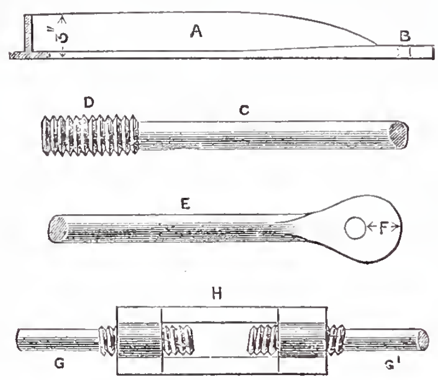

Fig. 16.—Ends of Bracing Bars.

equal length when unloaded, then on the application of a load the top flange will be shortened by compression, and the bottom flange lengthened by extension, and if the metal is so distributed that it is under the same stress throughout the length of the flange, for each square inch of cross sectional area, the central deflection will be found from the following rule:—The deflection of the girder at the centre will be equal to the span of the girder multiplied by the difference in length of flanges, and divided by eight times the depth of the girder.

The difference of length of flanges will be equal to the sum of the extension of the bottom flange and the compression of the top flange, and these lengths will be respectively equal to the strains per square inch of cross section on them, multiplied by the span and divided by the modulus of elasticity of the material. For example, let it be required to find the deflection at the centre of a girder 120 ft. span 11 ft. deep, having under a maximum load four tons per square inch compressive stress on the top flange, and five tons per square inch tension on bottom flange. The modulus of elasticity for good plate girder work is 8,000 tons; the extension of bottom flange will be 120 multiplied by 5 = 600, and this, divided by 8,000, gives $\frac{3}{40}$ ft. or $\frac{9}{10}$ in. The compression of the top flange will be 120 multiplied by 4 = 480, which divided by 8,000 gives $\frac{3}{50}$ ft., or $\frac{18}{25}$ in. These added together make the difference of the lengths of the flanges $1\frac{3}{5}$ in. (nearly). Applying the rule given above we have 120 ft. span multiplied $1\frac{3}{5}$ in. = 192, which divided by 8 times 11 ft. depth, gives $2\frac{2}{11}$ in. for the central deflection of the girder. It will usually be found that the actual deflection will be less than that calculated, because there is an unavoidable excess of metal in the flanges; should the contrary occur, therefore, it indicates the probability of a defect somewhere.

In measuring the deflection of a bridge its amount must be determined by deducting the depression at the bearings from that at the centre of the girders, for there will be some depression at the points of support during the passage of a heavy load.

The final stage of the work consists in painting or otherwise protecting it from external influences, and the choice of material

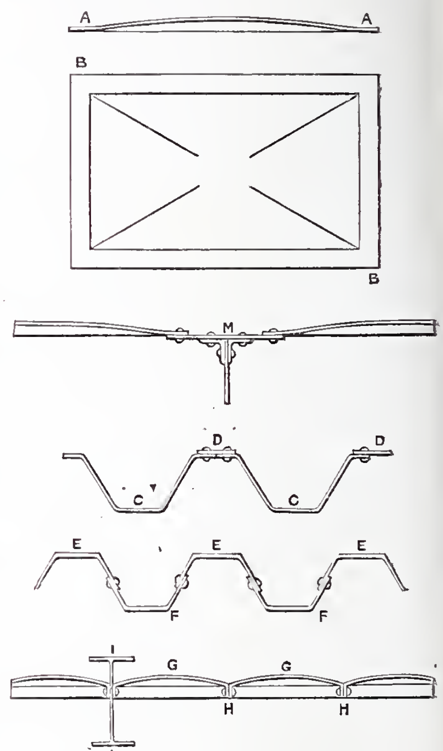

Fig. 17.—Forms of Floor Plates.

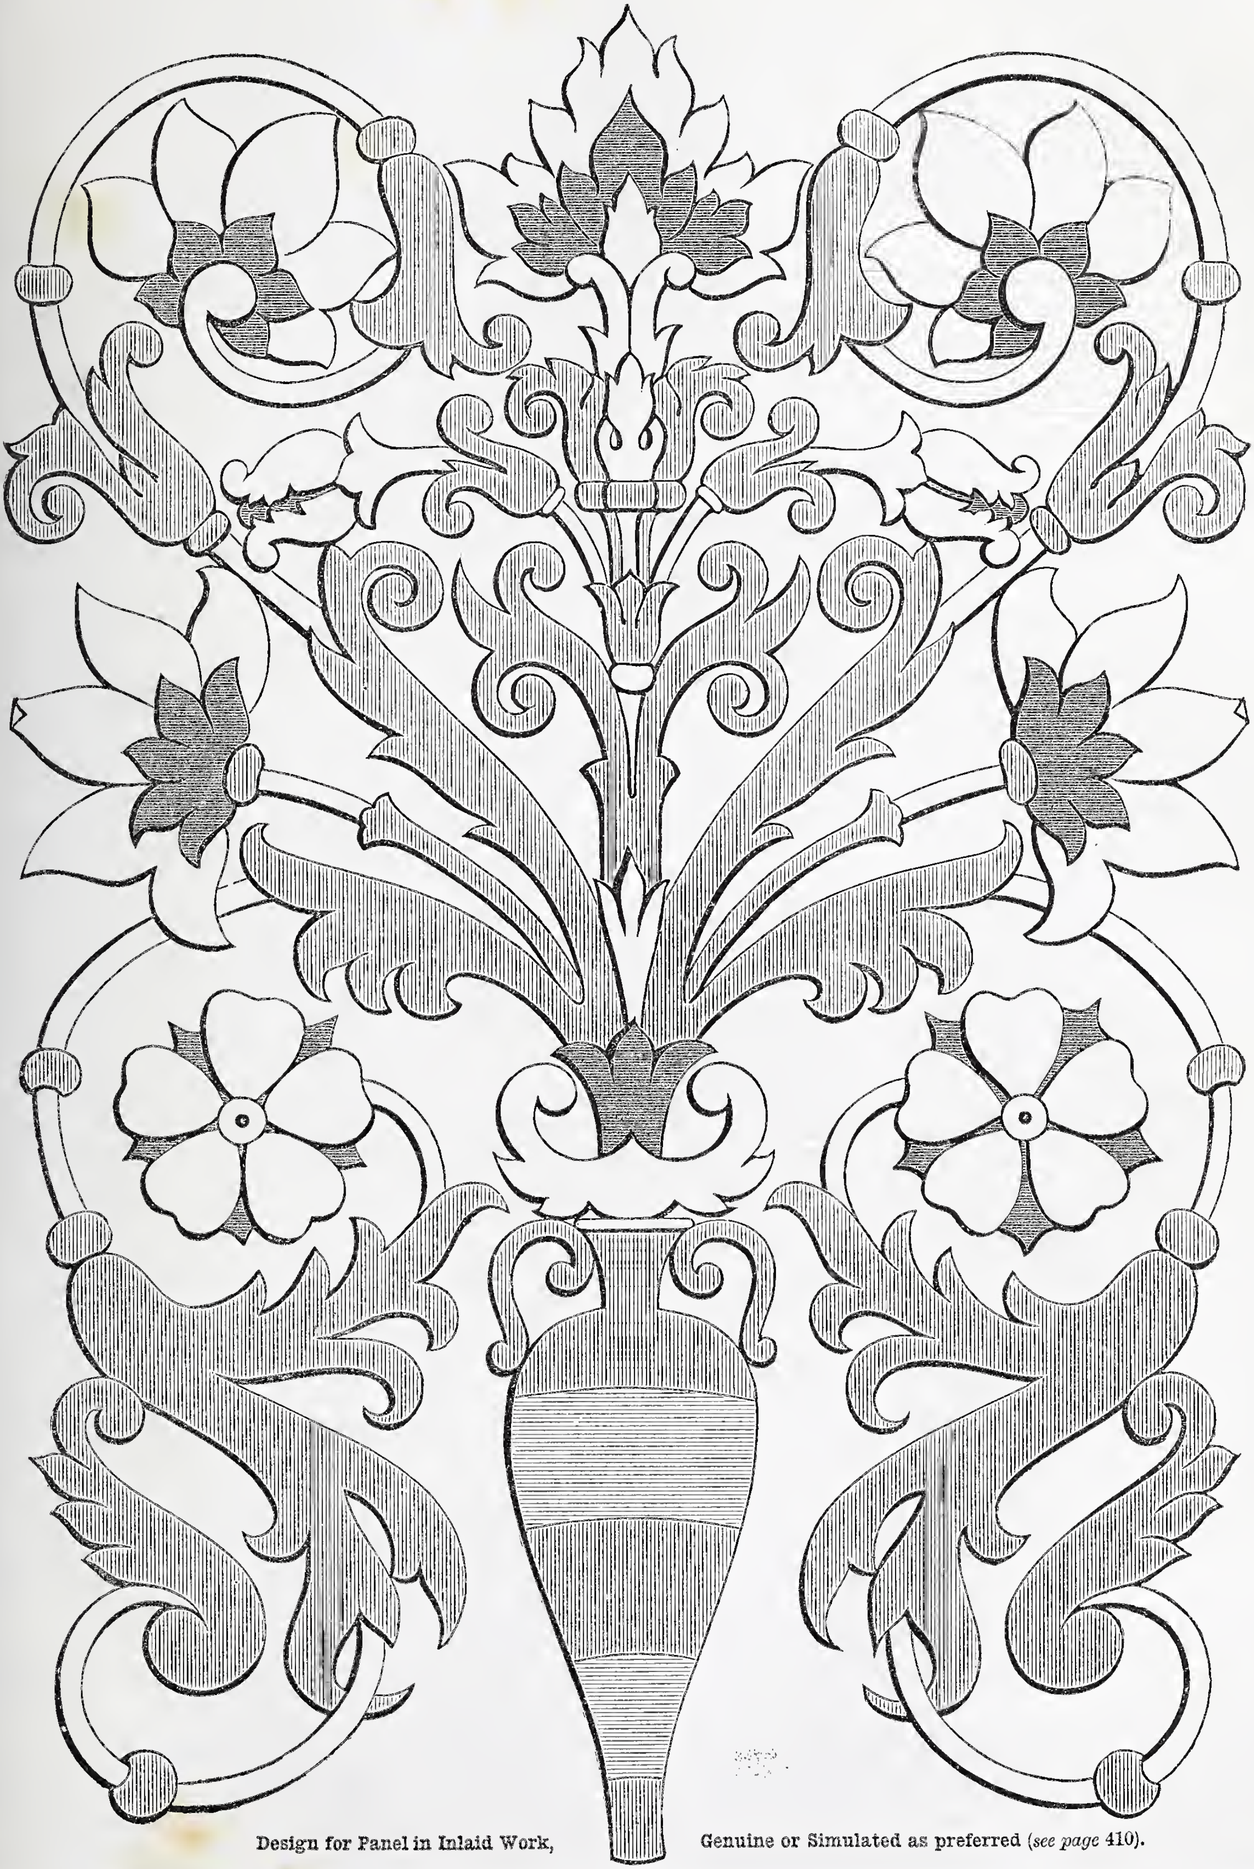
for this purpose is of considerable importance, for upon it the durability of the work is in some measure dependent. Paints made of iron minium have been much in favour, and the magnetic iron paints also have advocates; in all iron paints for iron work or steel work there is supposed to be the advantage over other metallic paints that dissimilarity of metals is avoided, and with it the risk of galvanic action being set up. A coating of iron rust, however, will not in itself protect the sub-lying metal from oxidation, but will even aid it to some extent, the corrosion eating into the body of the metal.

Looking at the matter from a purely practical standpoint, it would seem that the quality of the oil, or other vehicle carrying the colouring material, must be the criterion of its utility, as it is that which is in immediate contact with the work; it is, therefore, highly necessary to select a compound free from acid elements, and it must also be capable of resisting the acids and sulphurous compounds existing in the atmosphere.



Design for Panel in Inlaid Work, Genuine or Simulated as preferred (*see page* 410).

A PANEL FOR INLAYING.

BY E. BONNEY STEYNE.

REAL inlaid work—Marquetry, Buhl, Pietra-dura—all the varieties of the same idea, have been favourite modes of decoration in many countries and periods. And when employed with some reserve, used only to ornament the surfaces to which it is applied, and not to overload and conceal the natural wood thus treated. Inlay is a legitimate and effective wood decoration.

The genuine inlaid work presupposes a careful hollowing out of the solid wood for each separate detail of the design, and filling each space with its proper block of the chosen material carefully cut to fit the space. But this demands such absolute precision, and to some extent waste of labour, that the Buhl, or Boule, work, where veneers take the place of solid woods, and the fretsaw replaces the chisel, has been more largely used since it was introduced in France about 1680. But to fix a date for such work is misleading, as in Oriental work of fabulous antiquity the process is found to have been known in methods not unlike those now in use.

But modern substitutes have not stopped at imitating solid inlay by sawn veneers, and a variety of ingenious processes—one that by hydraulic pressure forces the material through the openings of a metal plate into the panel, some where printing simulates the real work, with many other modifications of these two—have replaced the real work with little loss of effect, however the lasting quality of the material so treated may have suffered.

To these there is a yet more simple substitute. It is to take a sheet of light wood, one with some natural grain, but not very distinctly marked pattern. Upon this, by means of the oily black carbonic paper, trace rather heavily, with an agate style, the design chosen. Then with a paint-brush fill up the pattern with various coloured wood stains and Judson's dyes, filling in the whole of the groundwork with dark brown or ebony stain. For a rough and ready decorative process that is almost mechanical, since not a single line of the design is drawn, but every detail traced from an existing pattern, this when well varnished or polished produces a fairly pleasant result.

The morality of all imitations is doubtful, but since they exist, it is better that they should be done as well as may be, and if the design to-day given has no peculiar charm, it is at least a possible one for practical work, and serves the purpose of a decorative centre for a larger panel fairly well. The parts left white are to be left untouched in the natural wood, the portions with plain shading to be in a darker tint, and those with crossed shading in a yet deeper colour. But the colours employed depend so entirely on their future surroundings that it would be folly to suggest them here.

HOW TO MAKE PHOTOGRAPHS ON BOXWOOD.

BY WALTER E. WOODBURY.

IT is many years ago since the first attempts were made to utilise photography as a means of producing pictures upon the box-wood blocks to be a guide to the wood cutter, but the results were found unsatisfactory. The reason of this was because, in the necessary manipulation the block was either spoilt by immersing in various solutions, or had to be coated over with a film of gelatine or albumen, which interfered with the work of the engraver.

The manner in which these blocks are produced at the present time is this. The drawing is first made by the artist direct on the wood in the same manner as if he were drawing upon an ordinary piece of paper, without regard to the effect of his block when printed from. This is the work of the engraver whose duty it is, as a rule, to break up the drawing into lines, dots, or stipple work, in order that the half tones or shadings will be truly represented, which they otherwise would not be.

So it will be seen that all that is necessary for the wood engraver is a picture of the desired subject as a guide for him to work upon, but it must in no way interfere with the surface of the wood or destroy its symmetry.

Those who are in possession of a camera and require to make printing blocks of landscapes, machinery, portraits, etc., for book or journal illustration, will find the following a far more simple and accurate method than employing an artist, besides being more economical.

We will presume you have the negative made of the subject you wish to transfer to the printing block.

First obtain a planished copper or zinc plate and scour it over with a piece of No. 2 emery cloth until it presents a rough appearance. Place it on a levelling stand on the hob of the kitchen fire, when there is a quiet fire burning. Get the plate quite level by the aid of the screws at the feet of the tripod stand and a spirit level. Then leave it to get warm, and prepare a solution of gelatine, 1 drachm dissolved in one ounce of water. Coignet's "gold label" gelatine will be found the best for this purpose. Dissolve, stir rapidly, and throw in gradually 5 grains of bichromate of ammonia. This quantity is sufficient for a half plate $6\frac{1}{2} \times 4\frac{3}{4}$; for larger sizes a proportionately larger quantity of course.

Now hold a thermometer two inches over the zinc plate, and when it registers 100° pour on the gelatine bichromate solution. If the zinc plate is properly levelled it will not run over, but can easily be spread evenly over the plate by means of a glass rod or strip of paper.

If the solution is found to contain any impurities it should be carefully strained through several thicknesses of muslin.

The zinc plate must not be too hot or all kinds of troubles will arise. When the coating is complete remove to a darkened room and allow to set and dry.

When dry it is ready for placing under the negative, but it must be remembered that it is sensitive to light.

If your negative is an ordinary glass one it will be necessary to make from it a reversed negative, otherwise your block when printed from will give reversed images, that is to say, objects to the right will be to the left, and *vice versâ*. In some cases this is of little moment, but generally it is necessary to make a reversed negative, unless the original is a film or paper negative, which can be printed from either side. These are invariably the best for this purpose.

The plate with the bichromatised gelatine film is then laid under a negative and exposed to light. The time required is a little less than would be necessary to produce an ordinary silver print. The exposure can be accurately gauged by the means of a photometer.

When the plate has been exposed to the light beneath the negative for the required length of time it is removed and placed in a bath containing clean cold water, and allowed to remain therein about ten minutes in order to wash out the bichromate which has not been affected by the action of the light.

Remove the plate from the water, and with a piece of soft muslin remove all the superfluous water by dabbing carefully over the surface of the gelatine. It will be noticed that portions of the gelatine film will be raised and others sunken to form the image. It has now to be inked.

Make an ink dabber by tying a few pieces of soft rags in a piece of soft muslin. A little letter-press or lithographic ink is taken on to a slab of glass, slate or metal, and with the rag dabber spread evenly over the slab. A very little ink is required, but it is necessary that it be kept evenly distributed.

The operation of inking is one that requires a little care and attention, though skill is not absolutely necessary. By taking up a small quantity of ink and dabbing on to the gelatine surface it will be seen that to some parts the ink will adhere; these are the exposed portions, while the unexposed parts will reject the fatty ink. The image will become visible, and it will be found that the inking can be well controlled by the pressure brought to bear upon the dabber; a heavy pressure deposits much ink, while a light one a smaller quantity.

When the plate is evenly and thoroughly inked the next operation is transferring the ink drawing from the gelatine to the wood block. For this we require a piece of bank post paper, or, better still, a sheet of Rives' or Saxe's paper. Place the sheet of paper between moistened blotting-paper in order to dampen. When sufficiently dampened it is laid on to the inky picture and contact established by means of a small wooden roller covered over with indiarubber tubing. Several sheets of blotting-paper are placed over the paper lying on the gelatine image, and with the rubber roller referred to carefully rolled until the paper adheres firmly to the gelatine film. With a moist sponge go over the back of the paper, and by taking hold of one corner and gently pulling the transfer paper will leave the gelatine, and will be found to have carried with it the fatty image. This transfer is now laid on the wood block, a few sheets of paper laid over it, and with the indiarubber roller well rolled into contact, and afterwards gone over with a piece of hard wood or the handle of a tooth-brush.

When the contact of the whole with the wood is thoroughly assured, strip off the paper by lifting from one corner, and the ink photograph will be found to have adhered to the wooden block.

This block is then ready for the wood engraver. In a future article I hope to give you a method of producing printing blocks by photography without the aid of either artist or engraver.

MEANS, MODES, AND METHODS.

A NOURISHING FOOD.

IT may not be generally known that the young leaves of the lime tree are excellent for food eaten as they are gathered, as salad, or boiled. Those leaves suitable are at the ends of branches or sprouting from the trunk of the tree, and have an amber tint.

hey are slightly sweet and mucilaginous, nd easily digested—more so than most raw reenery used in salad. I have, when out urveying, used lime leaves often as food ll I had a chance of getting a meal; and ly family have partaken of this refreshing iet as a food when obtainable in the spring f the year.

Remedy for Severe Cuts.

First stop the flow of blood as much as ossible by a ligature above the wound. If he cut be clean—that is, free from dirt or ag fibre—and the edges clean and level, se a needle and thread to draw the edges ogether, or stick pins—common ones will lo—lengthways with the wound into the dges of the flesh, and with any thread or tring draw the edges close by passing the tring from pin to pin fairly tight. Now ay over the wound a piece of cotton wool, nd pour on to the wool French polish till it is saturated; be sure to get the French polish well into the wool before the blood saturates it; now cover the wound with cloths, not too tightly put on. Keep the wounded limb or body resting as quietly as possible. If a ragged wound, as from a circular saw, apply a ligature above the wound, adjust the shreds of flesh as well as can be done, put on the cotton wool and pour on the French polish, then cover up from the air. If a finger be sawn off, do not throw the bit away, but see that the parts are clean, and put it back in its place, and bandage up in splints—any bits of stiff card or thin wood, about $\frac{1}{4}$ in. wide, will do, using enough to go all round the finger. It will grow, and be a stiff jointed one, but still useful, and more free from pain than a stump, and more quickly healed.

Treatment of Bruises.

If there is no fracture requiring surgical aid, pour on turpentine and rub in lightly; do not let the turpentine flow over the skin far and saturate the rag you cover the bruise with, as it may blister the skin beyond the bruise. Some bruises, as from the kick of a horse, are often best treated by the use of leeches round the edges of the bruise; wash the place with milk first; it makes the leeches bite; cover the place with a piece of washleather spread over with sweet butter or lard.

In such accidents the whole nervous system receives a shock. This should be allayed in the injured person by cheerful words of comfort, and the avoidance of exciting drinks or food. The following facts will attest the power of the nerves in influencing recovery from injuries. A lad was ascending a well eighty feet deep by the bucket, and was shouting in glee at the well-digging job being successfully completed, when just at the top the chain broke, and let the bucket and the youth fall to the bottom of the well. A new chain was obtained quickly, and a man lowered with a candle to bring up the dead body of the youth, as it was concluded he was killed; but to the surprise of the spectators he was alive, but with both legs broken off above the ankles, the bones protruding through the skin. The doctor saw it was a curable case if the nerves were strong, which seemed doubtful in so delicate a youth. So to cheer him he said, "Why, you have made a bad beginning at flying." The youth smiled wanly, and replied, "I did the flying right enough, but the settling was bad." The legs were set and soon healed, and he grew up a stalwart man and leader of men. In another case, in the backwoods of Canada, a lumberman was tree-felling, and his axe slid from the cleft of the tree he was felling and gashed through his stout leather legging down the shin of the leg. The man fainted at seeing a gaping, red wound. On recovering, he covered his leg up with a wrapper, and dragged himself to his sledge and hitched his horse to it, and galloped home. There he fainted again, and was put to bed. His wife, on his recovery, asked what was the matter. "My leg," he replied; "I have cut it through from knee to ankle." "It's all fancy," said his wife; "your legging was ripped open, but your new red stocking was not even cut." "I forgot I had put on those stockings to-day, and that is what I must have thought was blood," he answered. Even when sure he was not hurt his nerves were deranged for some time by the fancied injury.

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

84.—Kendall and Cockcroft's Patent Screw Holdfast and Cramp.

I take the earliest opportunity at my command of advising my readers that the "Patent Screw Holdfast and Cramp," noticed and described in "Our Guide to Good Things," in No. 19 (page 299) of Work, bearing date, July 27, 1889, as "Lister's Patent Screw Holdfast and Cramp," should have been attributed to Messrs. Kendall and Cockcroft, Cabinet Works, Lane Head, Horsforth, the inventors, patentees, and sole makers of the appliance in question, to whom all orders should be addressed.

85.—The "Rigid" Folding Curtain Frame.

This Curtain Frame is a patent of Messrs. Gibson and Glazier, 97, Tulketh Street, Southport, the patentees of the Locking Stay of the "Firm and Safe" Step Ladders, recently noticed in these pages. The size of the frame is 4 yds. by 2 yds., the longer sides folding on a hinge placed in the centre and rendered rigid when opened out by a clip which slides over the joint when the frame is in use. The shorter sides or crossbars also slide in clips, which also can be moved along the longer sides, and which are also instrumental in keeping the four sides at right angles to each other, so that the frame is always square at the corners. Holes at regular intervals are pierced in all the sides so that the frame may be reduced in length and breadth at pleasure, so as to take small curtains as well as large. When the sides of the frame have been adjusted to the size of the curtain that is to be cleaned, they are held firmly by a thumb screw at each corner, which is inserted in the holes made for its reception in the sides, passing through both of the contiguous sides at each corner, and is then screwed up tight. There are points at short intervals along the upper surface of each side, on which the curtains are stretched.

These points are brass nails inserted along the inner and narrower surface of each side, at intervals of about one inch, and appearing in a deep groove cut in the upper surface to admit of this. It will be understood that they are in a direction parallel to the upper and under surfaces of the sides.

This Curtain Frame is confidently recommended for home use as the strongest, neatest, and best of its kind yet introduced. As a reason for its general adoption by families who wash at home, it is urged that curtains cleaned at home last much longer than those sent out to be cleaned. The price of the frame is 10s. 6d.

The Editor.

SHOP:

A Corner for Those who Want to Talk It.

*** Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

A Correction.—S. K. R. (*New York*) writes:—"In No. 20 of your valuable Magazine, I see a notice of an 'Automatic Measurer,' of which I am the inventor and patentee. Your description and illustration are alike admirable; but may I ask a small portion of your space to correct a slight error in the title. It is printed 'Rolymeter.' It should be 'Polymeter,' a word of my own manufacture, and signifying 'many-measurer,' an 'universal measurer.' May I also point out that, besides the uses for it you have mentioned, it will measure *curved* surfaces with equal facility and accuracy, such as the inside or outside circumference of a glass shade, for example. Before closing, I must express to you my delight in Work. I have had it from the commencement, and am always in a hurry for Wednesday to come. My plan is to get a copy every week to read and carry around with me, and every month I buy the monthly parts bound up (6d.), which I put away till the first volume is complete, when I shall have them bound up. Any number having fretwork patterns in it (I am great on fretwork) I buy several copies of. I should like to personally thank Mr. Gleeson-White. His papers are invaluable to me, and could he see into my rooms, he would recognise more than one of his designs. May his shadow never grow less! I have a nine-light fretwork chandelier of my own design, which I should be pleased to describe at some future time should you consider it worthy of a place in your columns. I wish you a circulation of a million a week."

An Easily-Made Fret Machine.—Anxious (*Barnoldswick*) writes:—"No. 21, page 332, 'An Easily-Made Fret Machine.—W. R. S.' Please tell me how you would suspend the fly-wheel, and what with, and how long the bars of iron are to be, and if they both have to be fastened to a bench, or what. Please attend to it as soon as possible."

Plaster Modelling.—Clerk (*South Shields*).—Papers on modelling in clay will appear shortly; if, however, you refer to gesso work under the name of plaster modelling, an article on this subject appeared in No. 25 of this Magazine.

Hand-Saw Teeth.—A. R. (*Scorrier*) writes:—"In No. 20, page 317 of Work, J. H. writes:—'A. R. (*Scorrier*), before criticising an author, should ascertain his meaning.' Are we to suppose that an author cannot err as well as others? I think all are liable to errors, and shall be pleased at any time I make a mistake to be corrected. J. H. said, in No. 11 of Work, that Fig. 6 (see page 162) represents teeth used in cutting soft wood, but is unfit for general work; herein I think he admits his error. Again, in No. 20 (page 317) he says teeth to cut truly require a good deal of rake; but rake represented in Fig. 6 is unfit for general work. Does not this imply or indicate that it is fit for a certain class of work? and as J. H. wrote in reference to hand saws, I maintain that it is misleading, as such teeth in a hand saw are unfit for general or any other class of work. I hope J. H. will excuse me, as I mean no offence, but if possible would like everything to be made clear in Work."

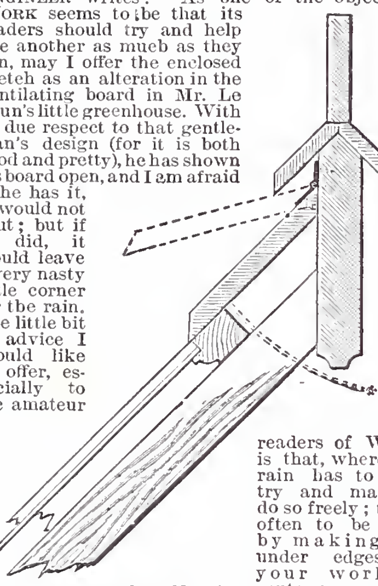
Powerful Rip Saw (*Highbury, N.*) writes in reply to Artist in Wood (see page 348):—"Being a reader of your paper I notice in No. 22, under head of 'Powerful Rip Saw,' a drawing of a small circular saw, and which I entirely fail to understand, I mean as to how it is to work. I say nothing about the saw itself or the wheels, etc., but what I fail to appreciate is, how is that treadle going to work that saw. The treadle is fixed to a cross bar at the bottom. I can understand that, but where is the necessary leverage coming in so as to make that fly wheel revolve? I mean the rod, D, how is that operated in order to make the necessary motion to this wheel? Taking the drawing as it is, you would think that when the treadle was pressed upon, that the rod, D, would be pulled down by the rod which connects D with the treadle, which rod has no name in your design. There was also another machine, a fret, intended to be of very simple mechanism, but which was as puzzling to myself and to several other parties to whom I showed it, as if it was one of the most complicated machines in existence; in fact it could not work, if the drawing produced in your paper was the correct one and not a mistake. These articles appeared in 'Shop' in your columns."—[You will oblige by sending a sketch of the machine as corrected by yourself.—Ed.]

Timber for Coach Building, etc.—Aye Work Awa' writes to make mention of Messrs. M. M'Neill and Sons, 24, M'Alpine Street, Glasgow, whose works are at Longford, Killarney, Enniskillen, and Sligo, and of whom North Countrymen may obtain hammer, pick, and shovel handles, round and oval, requisites for cart, coach, van, lorry, and barrow building, railway, pit and waggon wood, barrel staves and heading, home-grown timber, log or sawn scantlings, thread bobbins, or bobbin blocks, carpenter's wedges, oak crooks and bends, shafts, spokes, felloes, and naves for wheel-making, clog sole blocks, and rollers for washing and mangling machines.—[As it is possible that many readers may want one or other of the above-named articles, and not know where to obtain them, the above information may prove useful, and save many an inquiry.—ED.]

Easily-Made Fret Saw.—MANCUNIAM (*Manchester*) writes (referring to No. 21, page 332, a fret saw easily made):—"Will W. R. S. tell me, through 'Shop,' how C causes A to work vertical, as I cannot exactly see how it does with the wheel revolving?"

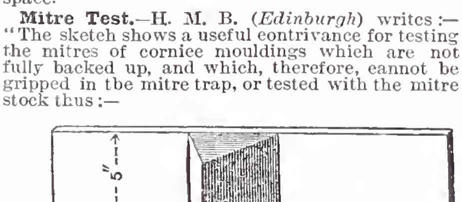
A Hopeful Subscriber.—R. Y. (*Canning Town*) writes:—"I have taken your paper, WORK, since the commencement, and hope to continue to do so for many years to come, in spite of the death knell which was rung by one of your subscribers, J. P. A., in your No. 12 issue; and being one of the spoilers, though not a clerk, I am sure there are many of those who will join with me in wishing you all success, and trust you will continue to publish your paper for our benefit when other readers fail. I am very sorry I can give no advice as to the way in which you should carry your WORK on; so knowing nothing about your business, I leave it to your own judgment, no doubt much to your loss and sorrow, hoping I have not taken up any space that might be made valuable, and that you will take these remarks in the spirit they are written in, and let WORK continue to live a long and vigorous life. If you should find anything in the above shaky, kindly put in a nail. This is my first attempt in writing for the press; please don't laugh."

Ventilating Board for Greenhouse.—CIVIL ENGINEER writes:—"As one of the objects of WORK seems to be that its readers should try and help one another as much as they can, may I offer the enclosed sketch as an alteration in the ventilating board in Mr. Le Brun's little greenhouse. With all due respect to that gentleman's design (for it is both good and pretty), he has shown his board open, and I am afraid as he has it, it would not shut; but if it did, it would leave a very nasty little corner for the rain. The little bit of advice I should like to offer, especially to the amateur readers of WORK, is that, where the rain has to drip, try and make it do so freely; this is often to be done by making the under edges of your work as acute as you can, as in the sketch I send. I trust these few remarks may be of use to some of your readers. I am another who has taken in WORK from the first, and let me wish it all the nice things I see others have wished it, which I will not repeat because of your space."



Arrangement for Ventilating Board.

Mitre Test.—H. M. B. (*Edinburgh*) writes:—"The sketch shows a useful contrivance for testing the mitres of cornice mouldings which are not fully backed up, and which, therefore, cannot be gripped in the mitre trap, or tested with the mitre stock thus:—



Mitre Test.

Two pieces of wood are fixed at right angles with each other, and a half of a square block cut through the diagonal line is fixed in the centre. After cutting the moulding in the mitre box, place the bottom edge of the moulding upon the sole, and keep the back of the moulding firm against the upright, and fit the mitred end close up against the centre block, after which it can be fixed on the job with the assurance of the returns intersecting accurately. The mitres of heavy gilt moulding can also be tested with it."

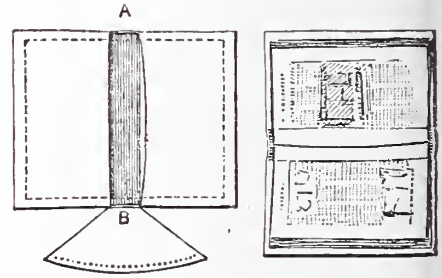
Weight of Fly-Wheel.—J. (*Twerton-on-Avon*) writes in reply to F. C. (see page 284):—"Mr. Campin's criticism of the formula for fly-wheels, given in page 189, is correct in theory. That formula is not strict in theory, neither is it given as fulfilling the requirements of theory, but as a working formula for rough-and-ready practice, and therefore suited for a book of workshop reference, like 'Molesworth.' Many rules in Molesworth, Hutton, and others would not fulfil the requirements of scientific engineering, but practical men find them useful because they give approximations sufficiently good for ordinary work. No one would think of designing the fly-wheel of, say, a mill engine, by such a rule, but it is correct enough for the common practice of makers of small engines used for general purposes—engines which are often run at very variable speeds. Only a few days ago a firm I know bought one of Hindley's engines, which was designed for a speed of 200 revolutions, but they ran at 60, altering the lead of the value to suit. But the fly-wheel is not altered, neither is it necessary to do so. Looking at Molesworth's formula, which is doubtless deduced from practice, and is still retained, in spite of criticism, in the latest, or 21st edition, as in previous ones, the factor N counts for little, because it is divided by 60, so that if the number of revolutions of the engine were 60, N might be struck out. The important factor in this formula is D, the weight varying inversely as D. Again I repeat this is not a perfect formula, but a good one. Because it is not perfect, I gave the correct theory at length in my reply on page 189. Molesworth—invaluable in the factory—contains a collection of rules largely empirical, but embodying good practice, hence the appreciation in which it is held. For nice calculations, requiring a strict adherence to fundamental principles, it is not intended, nor generally adapted."

Rustic Work.—A. R. (*Scorrier*) writes:—"In No. 16 of WORK, pages 248 and 249, there are designs of rustic work which, I am sure, should please all readers of WORK; not only so, but the very plain and able way the writer has given instructions how to proceed with the work is worthy of praise. In fact, I was so pleased with the writer's description of rustic work, that I read it over three or four times, and before I finished reading I had the porch and fence made without nails, hammer, or even a hand-saw, and felt only too sorry that I was not in possession of a good garden wherein to erect it. If everything in WORK is made so plain to the mind as the remarks on rustic work, the most simple may not err; and there will be no need of readers saying there is more talk than work in WORK. Again, I see some of our readers wish WORK to be enlarged, but there are two sides to everything; those that want a larger paper may have a lot of spare time, while many a working man, for whom I presume WORK is chiefly intended, will find there is quite enough in WORK at its present size to peruse in the little spare time he has in a week. Again, many an amateur and poor man will put a penny a week in a paper when they would not spend threepence. Therefore, I think it would be decidedly wrong to deprive the poor man of his little pleasure and instruction to oblige a few that have time and money to seek other pleasure after they have read the pages of WORK."—[There is not the slightest idea of raising the price of WORK. It is meant to be a poor man's pennyworth. Please send your name and address.—ED.]

Saws.—W. O. S. (*Manchester*) writes:—"I should be much obliged if one of your contributors could inform me as to the price of a saw suitable for comparatively heavy work such as sawing rough trunks of trees, either with or against the grain. The width of the key would not be a matter of much moment so that it cut rapidly. When I say tree trunks I don't, of course, mean large timber, but the trees which people frequently cut down for themselves in gardens where the size of the trunk is not, as a rule, over 8 in. or 9 in. Also the name of the maker, and probable price."—[The best saws for your purpose are—the one man cross-cut saw, 3 ft., 7s.; 3 ft. 6 in., 8s. 3d.; 4 ft., 9s. 9d.; 4 ft. 6 in., 11s. 3d. each; and the same perforated, to assist in re-gulleting, 3 ft., 8s. 9d.; 3 ft. 6 in., 9s. 9d.; 4 ft., 11s. 3d.; 4 ft. 6 in., 12s. 9d. Sold by Melhuish's, Fetter Lane, Holborn Circus, E.C.—ED.]

Subjects in WORK.—FRISBY writes:—"I have been a subscriber to your valuable Magazine, WORK, ever since it started, and as an amateur wood worker (or, as I have seen it put by one of your correspondents, wood spoiler) I have gained some valuable knowledge from it, and the simple practical way of explaining the work that is touched on in it has helped me much. While I have failed to find that those articles which are complained of by W. V. C. are written far above one's head, I have noticed that the writers of some of the papers have not followed out that simplicity in which Mr. Adamson set such a good example in his articles on the Screen Secretaire; for instance, the article on Soldering, in my opinion, might have been improved much by the addition of a word or two more in explaining Figs. 9 and 10—home-made gas stove and gas stove cover. This is only my opinion, mind. Of course you have to study economy in regard to space; and yet I see some are trying to intrude on our valuable space by inducing you to start a series of designs for a cottage first, and gradually go on to the mansion. Now, Sir, if I understand WORK rightly, it is to fill a gap, or, in other words, to treat that which other periodicals have never treated; and it cannot be said that designs for every class of dwellings, from the four-roomed cottage to the mansion, have lacked treatment or publication. Therefore, if WORK takes up this to oblige those few to whom it might be of some use, it would, in my opinion, be at once departing from its original purpose. Much might be said on both sides, no doubt, but it is needless, as the editor, to my mind, does not seem likely to yield too much to the opinions and advice of those who write to him, although he may seek to satisfy them, as far as he can do so, without abandoning his own opinion as to what may be expedient for the well-being and success of the Magazine."—[Your letter is precisely in accord with what I have been seeking to explain to my readers all along—namely, that if a paper be ever so good, there will be some to whom it may not appear entirely satisfactory. Everybody concerned in the production of WORK has done, does, and will do, their utmost to put forth in its pages that which will be generally useful and instructive. Of course every writer is pleased to know that his paper has given satisfaction, but most of them, I imagine, are like myself, tolerably pachydermatous, and very little disposed to be puffed-up with praise or depressed by strictures.—ED.]

Portfolio for WORK.—E. H. R. (*Edinburgh*) writes:—"In 'Shop' (No. 13) correspondence, I observe a portfolio for weekly numbers of WORK, which is very good, and I am glad to see some one as careful as myself in making something to preserve WORK, as it is well worthy of it. The way I have made my folio is simply this: Get two pieces of stout yellow straw board, 1 in. larger each way than your paper, that will give you ½ in. all round, which is plenty of protection, and a strip of American cloth, or as I have used, prepared artist's canvas 3 in. broad and 4 in. longer than your boards. Now use strong glue, and glue your piece of canvas all over on the unprepared side, laying it before you, glued side up; now attach your boards, taking ¾ in. of a catch, and you find 2 in. projecting at each end, which you will find of great advantage, as it is in these parts the strength of your work lies. Simply turn them in, and adhere them with glue. Now get another strip of calico the same breadth as your canvas or American cloth, and ½ in. less than the length of your boards for the inside of your folio; this strip of calico I would advise you to put on with strong paste, as it will make a cleaner job, and although it takes longer to dry it stands better, as it keeps the glue from cracking when you combine it with paste. This being done, having seen to everything being square, cut clean and well put together, lay flat out on a table, and put a slight weight on it overnight; next day take it out and have a look at it, when it will present a pleasing aspect. Now the next thing to be done is the way I have done my own, which is as simple as A B C, and of which



Portfolio for WORK.

I will draw you a sketch that you may understand it. As there will be fifty-two parts for the year we must make provision for them. The method I have taken is to get a needle and a ball of small but strong twine, and thread my needle with a very long double thread of it. Now I commence by dividing A and B into twenty-six equal parts with a pair of dividers, or what is often called compasses. As twenty-six is the half of fifty-two, and I have a double thread, so I set to sewing, passing my needle through the marks I have made with my dividers. I commence at A and go down to B, and from B back again to A, and so on, until I have completed my twenty-six double strings, and now my folio is nearly ready for its work. You will now see where your doubled parts of canvas are of use, as they contain all the stitches, and bear all the strain. Of course you might want your book to look better outside; but this I leave to your own good taste. I find this style of folio very useful, as it can be filled or emptied as you may want it. If Vol. 1 is completed send it to the binding, and your same folio is ready for Vol. 2. Another advantage is when you get your part before you can manage to read it it must be cut up, and by doing so every leaf is loose; to avoid them from being lost, many people stick a pin through the centre, which is not only ugly and marks the paper, but if not put with its nose inside, it is apt to prick your fingers, and suddenly reminds you that it's there. I require nothing of this kind: my folio supplies it, and keeps all together compact and neat, and I can have the full year's volume in my hand without inconvenience, if at any time I want to refer to anything in WORK or 'Shop.' The cuts given above will, I think, fully illustrate my meaning."

—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Banjo.—W. H. B. (*Leicester*).—Instructions in [ba]njo making shall be given at some future time, [bu]t they must be kept in abeyance for the present, [a]s you are just completing one you will hardly [re]quire them yourself, but you ask for them con[si]derately for the good of others.

A Clock that Never Requires Winding Up. —COTTAGER.—Thank you very much, but I really do [n]ot wish to see the diagram of the works of the clock [th]at will never run down. If your ideas were "both [fe]asible and practicable," you would have solved [th]e problem of perpetual motion, which has been [e]xercising the minds of many men from generation [to] generation for a long string of centuries. You [sa]y:—"If I receive no answer, I shall come to the [co]nclusion that this theory of perpetual motion is [a]lso a failure. Any advice you may be pleased to [g]ive will be thankfully received." I endeavour to [h]ave every query answered either by my staff or [m]yself, and to leave no applicant unanswered. The [o]nly advice I can give under the circumstances is [t]o turn from the impracticable to the practicable, [a]nd endeavour to use your inventive powers in [w]orking out something that will be really useful [a]nd helpful to those of your generation.

Barometer Tube.—W. M. (*Belfast*).—The air [b]ubbles got into your barometer tube whilst being [s]haken in process of removal. Although the tube was corked, this did not prevent ingress of air to the mercury, and the shaking caused some air to pass the agitated particles of quicksilver to the closed end of the tube. The tube will have to be removed, gently warmed, and shaken, as directed in my reply to BAROMETER, F.B., in "Shop," p. 158, No. 10.—G. E. B.

Magic Lantern.—J. H. J. J. (*Birmingham*).—The dimensions of a full size lantern are as follows:—Height, 13 inches; width, 6 or 7 inches; and depth front to back, 9 inches. These are about the measurements of Mr. Julian's lantern when turned on its end. To have it 11½ inches long is a disadvantage, as the light and reflector are too far away from the lenses, which should not be more than 6 in. focus, as longer focus will involve a loss of light, and shorter will endanger the lenses from the heat. Over the ventilating holes in the sides a false bottom must be soldered, which must be pierced with holes for ventilation. And it will be better if there is a sliding tray on the bottom (with a handle projecting through the back) to hold the lamp; by this means the lamp may be moved nearer to or farther from the lens without opening the door. Mr. Lancaster, of Colemore Row, Birmingham, will supply a set of lens, consisting of two for condensers, and two for the front. For anything like practical work not less than 3½ in. condensers should be used; these with front lenses can be had from Mr. Lancaster for 12s. 6d., or 3 in. for 8s. 6d. Measure the thickness of the two condensing lenses, and make a tin or brass tube large enough to take them easily, and ⅛ in. longer than they are thick. On the inside at one end solder a ring of wire (Fig. 1) to form a bed, against which

FIG. 1: A, cell for condenser; B, paper tube to keep lenses separate; C, C, wires to keep lenses in position.

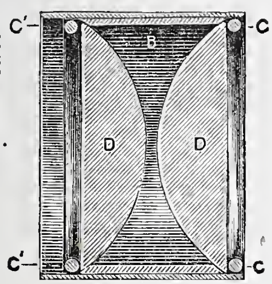


Fig. 1.

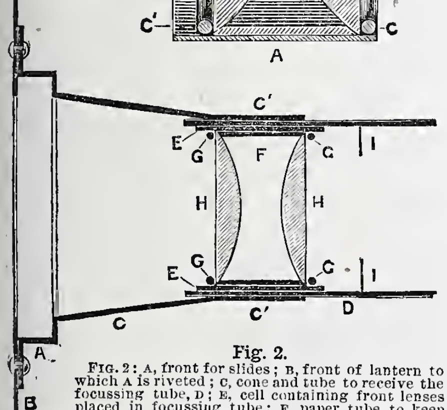

Fig. 2.

FIG. 2: A, front for slides; B, front of lantern to which A is riveted; C, cone and tube to receive the focussing tube, D; E, cell containing front lenses placed in focussing tube; F, paper tube to keep lenses separate; G, wire rings to keep lenses (H) in position; I, stop.

one of the lenses may rest. Now make a hoop, B, of stout cardboard to fit the cell, and to rest on the first lens, and of such a width that when the other condenser is placed in the cell they shall be separated about ¼ or ⅛ in. Care must be taken that the ends of the cell and paper tube are square and true, as the lenses must be perfectly parallel with each other. When they are properly adjusted a ring of stout brass wire, C, must be sprung into the cell, so as to keep the lenses in position (Fig. 1). Next a tube or collar large enough to take the cell, and hold it firmly, must be soldered on the inside of the front, or better still, if made with a flange and riveted. In fixing this collar great care must be observed, so that it be concentric with the opening for the focussing lenses. A cone must now be made to carry the focussing tube, which must be 4½ in. long, 3½ in. at the large end, and 2¼ in. at the small. It will be best to make a paper pattern first thus: On a sheet of paper strike an arc of 13 in. radius. Bring the pencil 4½ in. near the centre, and strike another arc. From the centre draw a line cutting the two arcs. From the point where the line cuts the larger arc, mark off 11 in., and from this draw another line to the centre. Cut out the piece between the two lines and curves, and we shall have a pattern of the cone. In cutting the tin plate leave ¼ in. on one side for overlapping the joint. If this is done properly we shall have a cone whose axis will be perpendicular to its base. Make a tube 2 in. long to C, fit the small end of the cone, and solder it perfectly perpendicular with it. The cone must now be soldered to the gallery for carrying the slides, and is known as the "front." A tube, D, 4 in. long, must now be made to fit the front, into which the front lenses must be fixed in a cell in a manner similar to that already described. These lenses must be ½ in. apart. Although for convenience of description we have mentioned this cell last, it must be made first and the tubes made to fit it. Sometimes amateurs find it convenient to procure parts already made. Mr. L. meets these cases, and supplies fronts with springs at 5s. I have overlooked the fact that a "stop" must be placed in front of the front lens with a central hole 1½ in. diameter (see Fig. 2). A lamp and reflector will, of course, be required. These are supplied for about 10s.; a treble refulgent patent lamp at 16s. 6d. When making the first attempt at exhibiting both the lamp and focussing tube will require adjusting. If the light is uneven move the lamp nearer to or farther from the lens to one side or the other, until the disc is uniformly illumined, and then adjust the focussing tube until the picture is crisp. It will be well to light the lamp for some little time before exhibiting, that the oil may be warmed, and so flow the better. The wick should not be turned up too high to commence with, else it becomes charred. With such a lantern certainly interesting exhibitions may be made; the inside of lantern and tubes must be blackened.

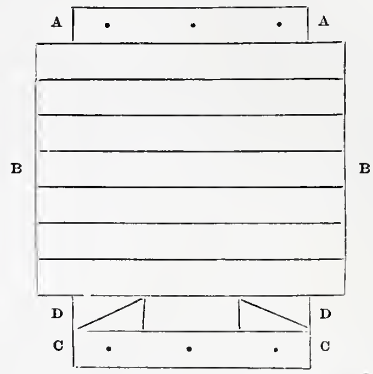
Enamel Paint.—W. H. D. (*Liverpool*).—I am afraid your difficulty in applying this must be owing to your having used an unsuitable brush. The paint being stiff you should use a hard brush. The less turpentine you use the better, though it ought not to change the colour. Of course, I am supposing that the turpentine you use is colourless. The wood should have been sized before painting, though four coats of paint should give a good ground. It is not necessary to rub down with pumice powder. The paint should dry glossy, and I can only suppose as it does not, and there is not sufficient body, that you have used too much turpentine. If you do not like the enamel paint you name, try the Falcon brand, which is made in your city.—D. A.

Gilding Fretwork.—W. H. D. (*Liverpool*).—You may do as you suggest, but it is not necessary. A better plan is to go over the parts to be gilded with one coat of gold size. As soon as this is "tacky," apply the leaf. Defects can then be remedied by going over any places to which the gold may not have adhered. A good deal, of course, depends on the kind of wood used. If the size is quite absorbed, you have no alternative but to repeat the sizing.—D. A.

Ebonising Wood.—W. H. D. (*Liverpool*).—Get your stain ready made, as you will do better than by preparing it yourself: Minton's, Manchester Street, is a good place. Wash the stain into the wood to be ebonised. When dry, if not black enough, repeat the operation; but remember that the stained wood when dry does not look so black as it will when polished. Proceed as in ordinary French polished work, adding a little gas black to the polish. Finish up as usual, and if "dull polish" is wanted, deaden the gloss by dusting on a small quantity of finest emery powder. Rub this on lightly with a brush or soft cloth, and take care that you rub evenly in the direction of the grain. Any wood can be ebonised. Bay wood, walnut (American), beech, and American white wood are generally used.—D. A.

Mounting Calendars.—AN OLD GLUER says:—"I am employed by a firm for mounting calendars, and each stick I have to glue one by one, and I have some thousands upon thousands in the course of the season. Could you kindly inform me if there is a machine for gluing the sticks, so as to save time and labour?"

[In reply to your appeal I can only say that I do not think there is any machine for the performance of work of this kind. If you could manage to place a number of the sticks—presuming they are flat sticks—together on a piece of board, so that the surfaces to be glued would form, as it were, one piece or plane, you might rub the brush over a good many at one and the same time. You would have to place the first stick against a fence or slip of wood screwed along one edge of the board, and then, when the last of the number was placed in position, tighten them up by a movable fence at the opposite edge actuated by a screw; or you might have both fences fixed, and tighten up by the action of reversed wedges. The annexed diagram will give



Contrivance for Gluing Calendar Sticks.

you an idea of my meaning:—A, A, is first fence fastened down to board; B, B, are the sticks; C, C, is the opposite fence, also fastened down to board; D, D, are two pairs of wedges driven in contrary direction, so as to clamp up the sticks, B, B.]

Choosing a Trade, etc.—EXCELSIOR.—To commence with, I think I had better give your letter in full:—"Will you kindly inform me if it is possible for a person to learn a trade without serving an apprenticeship—that is, by devoting three hours a day in working out the instruction given in books or journals like WORK? I am twenty-five years of age, and am very anxious to learn a trade, but I have not the means to apprentice myself, so I am taking the liberty to ask you, Sir, if you will kindly single out a trade which I can learn in the way that I have mentioned. What would you say about house painting or furniture polishing? Of course, I could practise these trades on my own house and furniture—but, there, I shall leave the matter in your hands, wishing you and your magnificent journal 'God-speed!'"—The difficulty, perhaps impossibility, of living while you are learning a trade apparently stops the way. To gain practice, you require to work at a trade from morning to night; but you can only devote three hours a day to practical work after the real business of the day is done. With regard to the choice of a trade, that must be left to yourself. If I could see you I could hear all you have to say, and advise you accordingly. I might suggest a trade for which you have a distaste—chimney sweeping, for example. I say this in order to show how difficult and even dangerous it is to attempt to choose for another without special knowledge of the person for whom the choice is to be made. You seem to gravitate towards painting and French polishing, which, roughly speaking, is decorative work. I see no reason why you should not follow this up if you have an inclination for it; but here a difficulty confronts you in the want of things to paint and polish. I myself should prefer carpentry and cabinet making; and my reasons are these:—(1) That if you have means of exposing for sale articles you have made, there are many things useful and ornamental which you could make at small cost during the three hours daily that you allot yourself for learning. (2) Carpentry is a clean trade, and can be put aside at a moment's notice; but this cannot be done in painting and polishing, or, at least, not done conveniently. But whatever trade you may choose, my advice to you generally would be, first to settle on a trade for yourself; then to make up your mind to devote your whole time and energies to the work, whatever it may be; and, thirdly, having done this, to seek some one in the same trade and endeavour to make an arrangement with him to pay you enough to keep body and soul together in exchange for your services while you are learning your trade. I can see no other way of bridging the gulf that lies between your present occupation and that which you wish to adopt. If possible, the tradesman to whom you hire yourself should be a friend, and one who would be in no way disposed to take advantage of you during the transition stage.

Coach Painting.—F. S. B. (*Bradford-on-Avon*).—A good practical work on coach painting, and things connected with it, is "Coach Painting," by Arlot, 6s., Spon & Co., 125, Strand, London, W.C. The subject, however, will be fully treated in the papers to appear in WORK on all branches of carriage building.

Plaster Casts.—J. S. (*Eastwood, Notts*) may obtain floral and ornamental casts, and, indeed, almost anything that is made in plaster of Paris, from Messrs. D. Brucciani & Co., 40, Russell Street, Covent Garden, London, W.C., at whose shop he will probably find the largest variety of such wares to be met with in England.—M. M.

Step Chair.—F. J. C. (*Brockley*).—A correspondent is at work on an article describing the step chair and its construction. You may rest assured that the index to contents issued with each yearly volume will be as complete as it is possible to make it.

III.—Questions Submitted to Correspondents.

Machine for Current of Air.—A. S. (*Liverpool*) writes :—"In respect to A. H.'s (*Wolverhampton*) reply to BELLOWS (*Gloucester*) in WORK for 27th of July, regarding a machine for current of air, I hope A. H. will be so kind as to give dimensions and diameter of pulleys to drive this machine that will answer for an amateur forge, and hints on constructing a cheap hearth for the above pattern of fan, and the mode of fitting water to run about the mouth of pipe that carries the air from machine to the hearth. Pardon me, Sir, in asking these particulars from you. Be as precise as you can, and plain, as I can see it is a good thing for amateurs. In answering questions of this description we can't be too plain."

Tondeur Photographic Developer.—E. L. H. (*Begbroke, near Oxford*) will be obliged to any reader who will give him the formula for the Tondeur Photographic Developer.

IV.—Questions Answered by Correspondents.

Paint on Leather.—T. C. C. writes in answer to J. B. S. (*Nottingham*) (see page 318):—"If the leather to be lettered is dressed with grease, the best way would be to scrape the surface with a pointed knife before applying the paint, or use turpentine, which will kill the grease; then the letters would not chip off."

Sheet Metal Book.—W. H. W. (*Seedley*) writes: —"I see in No. 20 of WORK that ST. MUNGO would desire to know the name of some book to assist him in sheet metal work. I, being a journeyman tinman, think that the book published by H. Warne, entitled 'Metal Plate Work,' would suit him, as it gives the patterns for baths and aquariums, the price being 10s. There is a very good one by J. Millas among the technical school series, price 6s. 9d., but Warne's would be the best for our friend. I suppose your correspondent will be able to manipulate the article after being shown the pattern, and having read Mr. Alexander's simple yet efficient paper on the metal plate subject."

Cleaning Oil Paintings.—H. G. (*Liverpool*) writes in reply to L. S. (*Lower Broughton*) (see page 190):—"Take the picture out of its frame, place it flat upon a table, face uppermost. Next provide two clean bottles, and a quantity of raw cotton wool. Place in one bottle sufficient spirits of wine of an ascertained strength of 58°, reduce by adding one-fourth part of spirits of turpentine; shake well, to thoroughly mix. Place in the other bottle a sufficient quantity of spirits of turpentine alone. Having the picture lying flat upon a table before you, and in a good light, proceed by taking in the right hand a small tuft of the raw cotton wool, slightly wetted with the mixture from the first bottle, which must be well shaken each time a fresh supply is required to moisten the cotton. Then take another tuft of cotton in the left hand, slightly wetted with the spirits of turpentine from the second bottle. Commence to clean by lightly rubbing the figure with a circular motion with the tuft of cotton in the right hand, examining the cotton every minute or so to see that none of the colour is being removed. When the figure is thoroughly cleaned, wipe it over lightly with the tuft of cotton held in the left hand and moistened with the spirits of turpentine alone. Repeat this process until the entire surface of the picture is quite clean. Care must be taken to change the cotton wool frequently, so that none but clean wool is brought in contact with the picture. When all the varnish has been removed the picture should be quite clean, and only requires to be revarnished. The greatest possible care must be used in passing over the shadows in the picture, which are produced by very thin painting and glazing, and if the tuft of wool in the right hand should show the slightest appearance of colour other than that of the varnish, which is usually of a faint yellow tint, the tuft of cotton in the left hand (moistened with the spirits of turpentine alone) should be applied at once, to prevent any further dislodgment of colour. If the picture in question is faded in any degree, it may be beautifully restored by being exposed to a strong sunlight for two or three months, when it may be revarnished with the greatest safety. To revarnish a picture, place a bowl or jampot in a bowl of boiling water. Pour into the jampot one-third of spirits of turpentine, and two-thirds of mastic varnish, mix thoroughly until a vapour arises from the mixture. Varnish the picture with this preparation as thinly as possible, applying the brush briskly until the entire surface is evenly covered with a very thin coat. This may be repeated two or three times, or until it gives complete satisfaction. Your correspondent should be recommended to consider well before he commences to clean his picture. None but those possessing a considerable knowledge of painting, and having considerable experience in cleaning, should attempt to restore or clean a work of any value. If considered of moment you may furnish your correspondent with my address, and I shall be very pleased to send him further information."

Dulcimer.—ALPHA writes :—"I see a CORRESPONDENT (see page 206) asks for a few hints on making a wooden dulcimer. I have one a wood frame, and strung with wires. I append a rough drawing (Fig. 1), showing general appearance and section. I hope it is what is needed. It is 1 ft. 3 in. long at top, and 3 ft. 2 in. long at bottom; the side is 1 ft. 8 in. long, and 3¾ in. wide by 4 in. deep; the top and bottom are made out of inch stuff 4 in. wide; of course, it is 4 in. deep all round, so the sides will be 4 in. by 4 in. The back is made out of 1 in. stuff; the middle piece put in to support the bridge is 1 in. thick, and the sounding-board rests on it; the sides have a slip of sycamore jointed to them 1 in. thick to hold the pins, and tightening pegs which are of iron; the

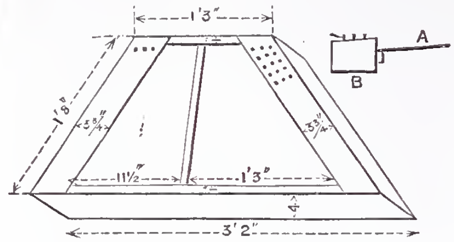


Fig. 1.—General Appearance of Dulcimer.

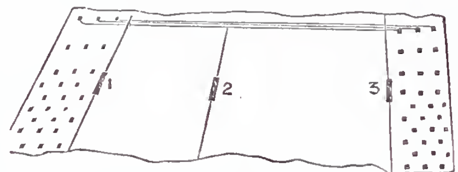

Fig. 2.—Pinning Wires and Placing Tuning Screws.

Fig. 3.—Construction of Bridge.

sounding-board is of mahogany ¼ in. thick. Fig. 2 represents how the wires are pinned and tuning screws are placed. There are fourteen notes of three wires each going over the bridge and seven going under the bridge. 1, 2, 3 are ⅛ in. wire, so that the sounding wires will not cut into the wood. Fig. 3 shows how the bridge is constructed. It is made of ebony an inch deep, about ¾ in. at bottom, and ⅜ in. at top: keep the sounding-board high enough so that the bridge will not touch the wires. It is all pine except what I have mentioned, which can be stained and veneered to suit.

Sloping Boxes and Hoppers.—B. A. B. writes in reply to X. Y. Z. and others :—"The directions given on page 173 give the angle of the edges, and of the mitre or butt joints drawn thereon, but the principal difficulty remains unexplained. It is, however, quite simple when studied for a little while. Let A B C in the figure be the angle as drawn on the elevation. We want to find the angle to cut our boards; we can obtain this in various ways. Let one be sufficient. From point B describe arc of circle having radius B C; then draw the line, D H, through the arc parallel to A B; from the line A B to the line D H is the width of the board required (after edges have been planed to the angle A B C); the angle can be had by drawing a line from C to E perpendicular; to line D H join E B. E B A is the correct angle for boards; this needs no proof, it is obvious. The

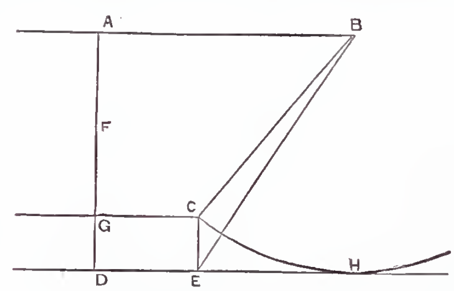

Diagram showing Mode of finding Angle at which to cut Boards.

side board being wider than the length of a perpendicular dropped from B to the base line, and it being as necessary for the bottom to be the correct dimensions, F must be equidistant, as C, from an imaginary perpendicular line—say F; therefore the angle A B C drawn on the elevation becomes the angle A B E drawn on the sloping sides. Let the querist draw on paper a parallelogram, or a square, representing the top of the box; at a distance equal to the width of sides, B C in the figure, and parallel to the representation of top, draw to same scale representation of bottom; draw centre line through both, cut out and fold, so that centre line lies in one plane, and he will at once understand the whole subject. In the diagram A B represents top edge of hopper, C G, the bottom edge, and B C, side, all in elevation; width of side B C is set off to H, as shown by arcs; draw line C E at right angles to G C; the angle to cut sides is then shown in E B A.

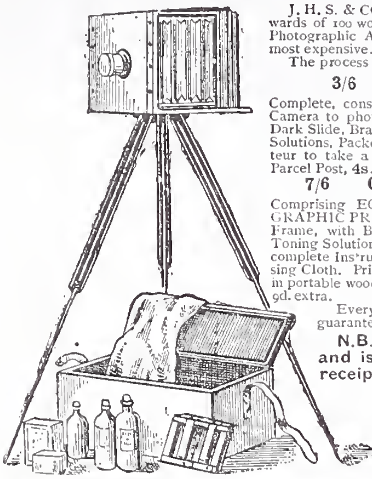
J. H. SKINNER & CO., EAST DEREHAM, NORFOLK,

Manufacturers and Importers of Photographic Apparatus and Fretwork Materials.



J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.

The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**, or securely packed by Parcel Post, **4s.**

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price **7s. 6d.** Securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. **J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.**

Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

Catalogue of Machines, Designs, Wood, Tools, &c., with several Hundred Illustrations, and full Instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. Good Fret Saws, 1s. 6d. per gross; best ditto, 2s. per gross.

Eclipse Design, No. 102.

Wall Bracket, Price 5d.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *boná-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

METAL BALL MAKING.

THE MODE OF STAMPING BALLS IN ONE SOLID PIECE OF METAL.

BY B. W. RAMSDEN.

Before giving a description of the way to make the balls, I will just say a few words to encourage young men not to give up in despair if they do not at first manage to make a success in anything they wish to do. The first thing a youth should learn is the value of small things. A very small thing to do is to carry a small book and pencil, and, as Dickens truly says, "when found make a note of it;" it is advice which I have always carried out, and I cannot tell the value it has been to me when in a difficulty, as I enter my notes in a large book indexed, which is a fine knowledge book. When a youth of sixteen, I saw some men making some cups, and from what I then entered in my book, I made these balls twelve years afterwards—that was in 1875. At first I made a failure of it, but after a few trials I managed to make some perfect, and this is how they are to be made.

They are made in sizes from $\frac{1}{4}$ in. to three inches in diameter, and are sold by Mr. Walter Walker, of Rockingham Street, Sheffield, tool piercer and stamper, from $4\frac{1}{2}$d. to 12s. per dozen, according to size. Three flies are necessary, according to size of ball required. A three hundredweight, a six and a twelve hundredweight, are the sizes mostly in use, as (Fig. 1) a very strong bench is required to put the fly upon so that it can be bolted fast, and a hole cut through to allow of the metal falling through when punched out by (Fig. 3) a tool called a boss or bed, with a slot and a hole in centre, so as to allow metal to fall out. When punches (Fig. 3) are used they are put in a slot (Fig. 2) and wedged tight with thin steel wedges, and are fastened down tight with the screw dogs (F, Figs. 1 and 2); then the top punch (Fig. 3) is fastened in the fly nose (G, Fig. 1) and screwed tight by H. The punches must fit very fine, or they will drag. Try them with a piece of good stiff writing paper, and if one side has a rough edge on screw up the boss a little on that side. When the tool is fixed get your metal; cut it in strips (as Fig. 6) 18 inches long by 12 inches wide, of No. 10, 14, or 17 Birmingham metal gauge. Put the metal under fly and pull handle (I, Fig. 1); for that work the balls (J) can be taken off, as they are not required, as very little pressure is needed. The metal when cut out will be like K, Fig. 3, and the sheet metal like Figs. 6 and 7, which show half cut out and half not. The little black dots show where smaller sizes are cut out so as to leave as little waste scrap as possible, as metal is 1s. 6d. a lb., and 10d. only is given for scrap. Having got all the blanks required, take out cutting tools (Fig. 3) and put in tools (Fig. 4): top punch in nose and bottom in boss. Do not take out the boss; just knock out the wedges. Take one of the round pieces of metal and put over the hole in bottom steel die, and pull on the handle. The first die being shallow, the balls will not yet be required. After taking all the pieces through put them on a stout sheet iron tray and anneal them by putting in a furnace or blowing upon them with a strong blowpipe; if with pipe and gas be sure not to make them too hot all at once. Commence very gently, and increase until the full heat is put upon them, so as to get them a good cherry-red but no more; then allow them to cool. Be very careful not to let any cold water fall upon them, or they will be full of cracks. When cold they are ready for the second punch (Fig. 8, A); then anneal as before. Put on bail to fly and use punch (Fig. 4), which will make them like Fig. 8, B. The process of annealing is again gone through.

A lathe, such as is advertised in WORK, must be brought into use. Chuck the metal cups (Fig. 8, B), which will be just like a thimble in shape. As lathes have been so clearly described in WORK, it is no use repeating it here. True the edges, and with a burnisher turn over the edges as Fig. 8, L; when in that shape the hollow cup punches (Fig. 5) are brought into use, which is just the same process as the other, only hollow top punches instead of round ones being used. When as round as can be got take them and put them in a revolving mill, as Fig 9, which has two pulley wheels, revolving the plates with balls top and bottom in opposite directions, which gives them a beautiful polish and even surface. A spring in the top part of the mill above small pulley presses down the top as they get into shape, thereby ensuring them being perfectly round. After first punch is used use plenty of oil; keep a pot of oil in reach, dip in your finger, and wipe top and bottom punches, which will ensure them leaving the dies easily.

If fancy balls are wanted the pattern must be cut in the dies, and the machine (Fig. 8) cannot then be used.

If any questions require answering, I will be pleased to receive them and give them my best attention in "Shop." If a hydraulic press is used the balls can then be done at once with only once lighting, as they will come out like Fig. 8, B, and by inverting in hollow cups after lighting would be like Fig. 8, E. I know of no firm in England which uses one in the silver plate trade; in America they are all made by that process.

PLAIN AND DECORATIVE HOUSE PAINTING.

A PRACTICAL TREATISE BY A LONDON DECORATOR.

INTRODUCTION.

AT no period of the Victorian era has there existed a spirit of more earnest inquiry for such knowledge as will enable the worker to know the true from the false in all matters concerning the application of art to industry than that which characterises the present time.

Since the year 1851, when the Great Exhibition in Hyde Park demonstrated to us so painfully, but, as it has proved, beneficially, our inferiority in the artistic aspect of our manufactures as compared with that of many other nations, a change has transpired which, although becoming but gradually apparent to the community at large, is none the less of a vital and extraordinary nature.

In no department of industrial art has this change and progress been more marked than in the design and production of decorative materials and wall hangings. As testimony to this, twenty years ago wall papers of purely home design and manufacture were but little used; to-day, however, we find British decorative hangings and fabrics able, not only to maintain their commercial position in our own country, but to compete successfully, both for artistic excellence and superiority of manufacture, with similar goods in foreign markets.

Although, by reason of the able editorial proclamation in which the general scope, aims, and ends of WORK were placed before the world of workers, any lengthy introduction of these chapters to its readers is rendered entirely superfluous, I will claim a short space in which to explain the mode selected for the treatment herein of this wide and comprehensive subject.

By a three-fold division of our theme, an arrangement is obtained whereby the compiler hopes to tender knowledge and practical assistance forthwith to all the various sections of workers, under one of which all house painters must come—to the apprentice, the improver, the amateur, and to the operative, wage-earning house painter. Believing in the importance of every craftsman and worker understanding the source and nature of that which he uses, ere he receives instructions how to use it, I purpose in the first part to treat on the elementary processes and materials of my subject, which will especially appeal to the young workers, both "amateur" and professional. In the second division will be taken such useful and decorative branches of house painting, known as graining, marbling, bronzing, gilding, hand polishing, etc., written for those operatives who are desirous of extending their capabilities beyond what is technically termed "brush work." In the third part the most advanced portion of modern decorative house painting will be both practically and theoretically considered. As being the most likely course to help the journeyman craftsman, this part will contain directions, accompanied by illustrations where necessary, for the decoration of a modern residence, with chapters especially devoted to the study of colour and its application to buildings. A consideration of the most useful and popular decorative materials and their treatment will here, appropriately, be placed before the reader; and, without dipping too deeply into the theoretical or philosophical aspects of decoration, the writer will endeavour to so ground the earnest worker in principles of decorative truth and beauty that he may himself be able with some degree of confidence to discriminate between the true and the false, and to be able to give a reason for the faith that is in him.

In these competitive days, when the much vexed question of amateur *versus* professional comes so often to the front, the operative painter may venture to inquire how far this giving of common technical instruction to both the two divisions of workers can fairly be justified. Our answer is this: That at such times as we live in, of advancing education and widely diffused literature bearing upon all trades and callings, the facilities of obtaining knowledge are, and should be, common to all sorts and conditions of men. That "a little knowledge is dangerous" in matters of decorative practice, every professional decorator, who has had dealings both with clients possessing that "little"—derived probably from the "art column" of a fashion paper, or a couple of terms at a school of art—and with those customers who lay claim only to the usual attributes of education, common sense, and observation, will fully bear me out. Again, that in consequence of the almost total decay of the apprenticeship system, in the great Metropolis particularly, there is a very urgent necessity for technical instruction in the higher grades, especially of house painting; and, although there exist at present various aids for the young worker, we have no hesitation in saying that these chapters in so cheap and popular a work will meet, to some extent, that very definite want of the painting trades. It is the writer's experience and belief that *decorative* supply will and does *create the demand*; and the more extensive the spread of knowledge on the subject, so will its practice and employment, therewith, proportionally increase. No apology can be needed if this knowledge and instruction is hereby extensively tendered to the so-called "amateur" class of painters.

John Ruskin, speaking on progress in life and art-workers generally, has expressed himself upon a very vital point somewhat in these words: "When," said he, "I hear of any young man as one giving promise of much success in his vocation, I invariably inquire whether he works hard and diligently at such profession or calling; for in the answer to this will be found the surest criterion of his future career."

Herein, therefore, will lie the success of the practically disposed reader of these chapters. Natural faculty and ability are of little avail unless supplemented by diligent and painstaking efforts. Technical instruction can but strive to point out the most direct way to the best ends, and, whether actuated by motives of direct profit or recreation, the results will very materially be governed by his own perseverance and application, in short, hard work!

Introductions, I am well aware, and preliminary disquisitions on the history that attaches to certain crafts are objected to very strongly by some readers, and I am of opinion myself that the pages of a magazine such as WORK are, perhaps, not the most desirable place for the ventilation of the latter. Nevertheless it is useful, and, indeed, necessary, for those who undertake to write on subjects that will from their nature occupy some considerable space in their treatment to foreshadow what that treatment will be that the reader may be enabled to comprehend in some measure what is to be placed before him. In my own case I have made my preliminary remarks as brief as possible, and in my next, I shall enter at once on the consideration of the sources, nature, and qualities of all materials used in house painting.

BURGLAR ALARUMS:

HOW TO MAKE, WORK, AND MAINTAIN.

BY GEORGE EDWINSON BONNEY.

THE BATTERY—THE LECLANCHÉ BATTERY—THE AGGLOMERATE BATTERY—THE GASSNER DRY BATTERY—ARRANGEMENT AND MAINTENANCE OF BATTERY—LAYING THE LINE WIRES.

The Battery.—Several types of battery have been used in ringing electric bells. These I hope to notice when dealing with the general subject. I now only describe the "fittest"—that is, the one in general use all over the world where electric bells are used, and its latest and most successful rival. It won't do, on a job like this, to employ an experimental battery. We must have one that we are sure of—one that has been tested by long experience. The battery must be reliable, ready to work at all times, and capable of maintaining its efficiency for long periods without attention. Some forms of battery choke themselves, so to speak, with crystals whilst they are at rest; others send up fumes or salts to corrode their connections, and cause failure just when the battery is wanted; others are soon exhausted, and do not recover their strength. It is clear that these will not do for electric alarums.

The Leclanché Battery.—This battery, invented by the late M. Georges Leclanché, has stood the test of many years' practice as the best battery for ringing electric bells. Each composite cell is made up of (1) a glass outer containing cell charged with a solution of sal-ammoniac, into which dips a rod of zinc to form the positive element; (2) a porous inner cell charged with a mixture of broken carbon and small lumps of manganese peroxide, surrounding a cube, or a plate of carbon, to form the negative element. The whole arrangement is shown at Fig. 37. The outer cell may be of any other ware, such as china, porcelain, stoneware, or glazed earthenware; and the pot may be of other shapes than that shown in the sketch. It is charged with a half-saturated solution of sal-ammoniac—that is to say, sal-ammoniac (ammonia muriate) is dissolved in warm rain water until the water is saturated; then it is diluted with an equal bulk of rain water. Ordinary well, spring, river, or pump water may be used; but rain water is best. The zinc rod is cast with a stout piece of copper wire projecting from its upper part to form a connection with the carbon of the next cell. This wire is coated with warm gutta-percha, or with tarred tape, from the zinc to within two inches of its other end, which is left bare and clean to make connection with the binding screw of the carbon. The whole, together with an inch of the zine rod at the top, is coated with Brunswick black. The inner cell is made of white porous earthenware. A prepared strip of carbon is set upright in the middle of the cell, and then closely packed with a mixture of equal parts by bulk of gas carbon, broken to the size of peas, and lump peroxide of manganese of the same size, all dust being sifted out of the mixture. The surface of this charge is covered with a thin coat of pitch to keep it in position, and two holes are made in this pitch seal after it has cooled, to allow the gases formed whilst working to freely escape. The strip of carbon is selected just wide enough to slip easily into the cell, and long enough to stand with its upper part about one inch above the top of the cell. This part is soaked in hot melted paraffin for some time; then allowed to cool. When cool, a few holes are drilled laterally through the paraffined top; a hole is drilled in the top near the middle to reeeive the end of a tang of a binding screw; the top part is inverted in a mould; and melted lead is poured in to form a head having a good contact with the carbon, and to hold the binding screw. The head, and a strip of carbon just below it, are painted with Brunswick black, and this, together with the paraffin, prevents the lead head being corroded away with the ammonia fumes formed in working the battery. The cells are made in various sizes, but most vendors sell three stock sizes, numbered respectively 1, 2, and 3. All do not agree in the sizes apportioned to the several numbers, but the following may be taken as generally correct:—

No.	Size of Porous Cell.	Size of Carbon.
1.	5in. by 2in.	6in. by 1¼in. by ⅜in.
2.	6in. by 2¼in.	7in. by 1½in. by ⅜in.
3.	6½in. by 3in.	7½in. by 2in. by ⅜in.

No. 1 will take about 6 ounces of the carbon mixture; No. 2 will take about 8 ounces of the carbon mixture; and No. 3 will take about 10 ounces of the carbon and manganese mixture to charge each cell. Manganese peroxide costs about 6d. per lb., and broken gas carbon about the same, if bought retail in London, but is much cheaper in some districts. The various parts of the battery may be bought and put together. Their cost may be nearly estimated as follows:—

No.	Porous Cell.	Carbon Capped.	Zinc.	Glass Cells.	Porous Cells charged.	Battery complete.
1.	4d.	1s. 0d.	5d.	0s. 9d.	1s. 8d.	3s. 0d.
2.	5d.	1s. 3d.	6d.	1s. 0d.	2s. 2d.	4s. 0d.
3.	6d.	1s. 8d.	8d.	1s. 3d.	3s. 0d.	5s. 0d.

Sal-ammoniae costs 1s. per lb.

With respect to the size and number of cells required to ring an electric alarum, we must be guided by the work to be done. If the bell is a large one, and wound with thick wire, or if several bells are connected to one battery, we should use No. 3, or largest size cells, to furnish a sufficient volume of current. No. 2 cells will ring a 4-inch bell fairly well, and three of these coupled in series will be all sufficient for an alarum system in an ordinary-sized house furnished with one bell only. If the bell has to be rung through a long line of wire, or through a line of fine wire, we must add more cells in series to overcome the extra resistance. All users of electric bells are agreed that it is false economy to stint battery power.

The Agglomerate Battery.—This is only a new form of the Leclanché. The porous cell is dispensed with, and the manganese and carbon mixture is made into agglomerate blocks by machinery, under enormous pressure. The usual capped carbon plate is enclosed between two of such blocks, which are kept pressed together by crossed rubber bands, the loops of the bands serving as a holder for the zinc rod, as shown at Fig. 38. When these were first introduced, they were thought to be superior to the old form of Leclanché, but it is now found that their sole recommendation lies in offering less resistance to the current. In practice they are said to be more troublesome than the old form.

The Gassner Dry Battery.—This battery bids fair to rival the Leclanché, and oust it from its long-sustained high position of being the premier electric bell battery. Each cell is complete in itself, instead of being a composite cell made up of inner and outer cell. There is no porous cell, nor any outer cell of glass, porcelain, or other breakable material. Each cell of the battery is made of thick sheet zinc, and this forms the containing case as well as the positive element of the cell. This case is nearly filled with a paste composed of zinc oxide and gypsum, moistened with a solution of zinc chloride. A capped cube of carbon, bearing a binding screw on its head, forms the negative element in the centre of the case, where it is surrounded with the conducting and exciting paste. The whole is sealed over with some dark composition resembling marine glue. It will thus be seen that there is no liquid to spill, nor any required, as the porous mass is moist enough to excite the zinc, and retains its moist condition for any length of time. The cells may, therefore, be laid on their sides in racks, as wine is stored; or turned upside down without impairing their working qualities. They may be placed in any convenient position, regardless of the temperature of the room in which they are located. As to power and constancy, they take their place cell for cell side by side with the Leclanché, doing equal work, and recovering their normal strength, in equal time. Here, however, they possess an important superiority. When a Leclanché cell is quite exhausted, we have to take it to pieces, clean, and perhaps renew the zinc, and renew the porous cell, with its contents. When a Gassner cell is exhausted, we have only to send a strong current of electricity (such as that from a battery of Bunsen cells) through the cell from carbon to zinc for about an hour to regenerate its contents and make the cell even more powerful than it was when first constructed. I hope to go into this part of the subject more fully when I treat of electric bell batteries. The battery has stood the test of nearly three years' practical work, and is fast growing in favour. The wholesale agents in London are Messrs. Mayfield, Cobb, and Co., 41, Queen Victoria Street; and the batteries are also sold by Messrs. Gent and Co., Faraday Works, Leicester. Fig. 39 shows the round form of cell used in this battery, and this is sold at 5s. per cell.

Arrangement and Maintenance of Battery.—Fig. 40 shows how an electric bell battery is connected up and arranged. It will be noted that one wire, A A, leads *to bell*, and this is connected to the carbon element of the battery. The wire leading from the zinc of this cell is connected to the carbon element of the next cell, and the wire from the zinc of this to the carbon of the last cell of the series. A wire leads from the zinc of this cell to the line wire, B B, *from bell.* This method of connecting cells to form a battery is called connecting in series, and is always the method adopted for electric bells. It is immaterial which wire is connected to the terminal carbon or zinc, for the bell will ring equally well whether we connect the wire coming direct from the bell to the zinc or connect it to the carbon. The path of the current is, however, from zinc to carbon.

I have shown the battery of three cells in a box; but it is not necessary to thus enclose them. It is, however, usual to place Leclanché cells in a box, for several good reasons. A box protects the cells from accidental blows, and from dust. It also serves as a check to meddlesome children and servants, for the box may be securely fastened, and the wires brought out through the back or side. I have not shown the cover and one side of the box. Both of these are hinged to each other and to the bottom, and the cover opens from the back. When constructed in this way, the cover and side fall down when opened, and allow free access to the cells for adjusting screws or seeing the condition of the battery. If made for a Gassner battery, it will be advisable to partition off each cell with a thin partition of wood to prevent accidental contact. Half-inch deal, or pine, or any other wood may be used in its construction, and the outside may be stained, painted, grained, or polished, as taste may dictate.

In arranging a suitable place for the Leclanché cells, it should be borne in mind that they work best and last longest when put in a moderately cool and damp room, such as a cellar, or in a washhouse. In dry situations the solution rapidly evaporates, and the salts creep up the sides of the cells and over the connections. The salts formed in a Leclanché cell by the union of sal-ammoniac with zinc have a tendency to thus creep up the sides of the cells. This may be guarded against by greasing the inside of the glass cell down to water line. Messrs. Gent and Co. have their glass cells made with a narrow channel around the top, and this is filled with a composition guaranteed to prevent the salts from creeping over. If the glass cells are allowed to get dirty on the outsides from this cause, or are left wet, or stood on a wet shelf, a part of the current will be lost by leakage. Cells must be looked to from time to time, and all such causes of leakage stopped; at the same time, the loss of solution from evaporation must be made good. It is not necessary to add sal-ammoniac when water is added to make good this loss. Use clear rain water if procurable.

Some makers do not amalgamate the zinc rods used in a Leclanché battery, but I have found that they work best when amalgamated. To do this, well clean them in hot water with some washing soda; then dip them in dilute sulphuric acid, and rub some mercury well into the rods, with an old rag as a rubber. If the zincs turn black soon after the battery has been set up, and there is a strong odour of ammonia from the battery, together with white specks on the porous cells, we may suspect a leakage either between the cells and elements of the battery, or in the outer circuit; this must be promptly detected and repaired, and the zincs cleaned up again.

it, so that he may be awakened at the first alarm, and be able to switch off the current as soon as he can after the alarm has been given, for the burglars may promptly decamp and be left uncaptured if the bell continues to ring for some time, and so alarm them with its din. The main line from the bell to the main-line battery should be of No. 20 copper wire, coated with indiarubber, and double cotton-covered. This may be had covered with any colour of cotton to match the painted woodwork or the ground tint of the wall-paper, at a cost of about 12s. 6d. per 110 yards. Run bells, the wires can be run along the tubes provided for this purpose, the old system wires being drawn out as the electric bell wires are drawn in. If different tints of cotton are used in covering the wires, one colour of covered wire should be used to go from the bell to the main-line battery, and from this outwards to the end of the line. The return wire should have a different tint, and thus the going and return wire can be easily recognised, a matter of importance in connecting them to the various contacts. Be careful, in driving the staples, not to cut through the covering, nor to abrade this when drawing the wires tight through holes or around corners. Let all be done neatly, out of sight as much as possible, and out of the probable course of the housemaid's broom.

From the main line, several branches will be thrown out towards the various points of contact. If each room is connected to a separate indicator, one of the wires will be connected to the outgoing main from the battery, whilst the other will go direct by a path of its own to the indicator and bell. Each point of contact must have its own two wires; one from the main battery

Fig. 41.—Diagram showing how to connect Branch Wires from Burglar Alarum Contacts to Main-Line Wires of Electric Bell—A A, Main-Line Wire to Bell; B B, Main-Line Wire from Battery; C, Door Trigger; D, Door Post Contact; E, Special Line to Indicator; F, Door-Mat Contact. Fig. 42.—Sketch showing how to Strip Covering from Electric Bell Wires preparatory to connecting Wires together. Fig. 43.—Sketch showing how to Twist End of Branch Wire round a Main-Line Wire to form a Junction with it.

Laying the Line Wires.—Before laying the line wires, we must not only decide upon a place for the battery, but also a position for the bell. This may be on a wall, or in a cupboard in the master's room, or in that of a trusted man servant. The local battery, to work the bell through a relay, should be in the same room with the bell, and not far off from it. If a Gassner battery is used, the cells may be enclosed in an ornamental box of small dimensions, and the bell may be mounted on the same box. If the Leclanché is chosen, a cupboard near the bell may be utilised; or the wires may be brought through a wall or partition from a closet or other anteroom. The bell should be near at hand to the person in charge of the line wires along by the wainscoat, the skirting, or by any woodwork, in preference to pinning it against walls. If there is a chair rail around the room, one wire may be carried above, and the other beneath the rail. In no case should the wires be laid side by side together under one staple. In passing from room to room, pass the wires through the hind doorpost, where they will be least observed, boring the holes with a fine long gimlet. Secure the wire at intervals of about 18 inches or 2 feet with small staples. Messrs. H. Dale and Co. sell a hard, sharp-pointed staple for this purpose, which enters the wood easily, and does not readily bend. Where provision has been made, in building the house, for a system of line, the other returning to the bell or else back to the indicator. Several contacts in one room may be connected to one branch main, but in this case the indicator will only tell the room from which the bell was rung, not the particular door or window. Perhaps a clearer idea of how this is to be done will be gathered from the accompanying diagram, Fig. 41.

To connect a branch wire to the main line proceed as here directed. First lay bare about $1\frac{1}{2}$ inch of the covering of the main line at the point of junction by scraping it with an old knife. Clean the bare copper bright with a piece of emery cloth. Strip about 2 inches of the end of the branch line wire, and clean in a similar manner. Lay the two wires together, as shown at Fig. 42, and twist the end of the branch wire around the clean part of the main wire, as shown at Fig. 43. Drop a little melted composite candle, or a little powdered resin, on the joint; run a hot tinned soldering bit along the twisted wire to tin it; then follow with a drop of solder; wipe the joint with a rag to get off any trace of soldering flux remaining; cut the loose ends off close to the wire; and then cover the whole with a few strands of soft cotton dipped in melted paraffin.

In my next I will endeavour to show several forms of door and window contacts, and how to connect these with the bell and battery.

A CHEAP BELL CHUCK.

BY F. J. GOODACRE.

WHILST fully admitting that a row of chucks in burnished gun metal or brass has a very effective appearance, yet there are no doubt many of "ours" who are unable to pay the high price demanded for them. For instance, a 2-inch bell chuck made in gun metal is to be had at 14s., and is probably not dear if the actual cost of labour and material be taken into consideration. Iron chucks of this class may be made from castings, but there is then a considerable amount of labour involved in finishing them —labour which many persons have neither the time nor inclination to undertake.

Probably there are few persons who have not noticed, at one time or another, the "reducing sockets" used so extensively by gas and water fitters for connecting large pipes to those of smaller diameter. These may be obtained up to 6 inches in diameter at the large end, and with the other considerably reduced. These are just the shape for bell chucks, and being of wrought iron, and averaging about $\frac{1}{4}$ inch in thickness, are of very great strength.

Assuming that it is desired to fit up a 2-inch bell chuck, and that the mandrel nose is $\frac{3}{4}$-inch thread, a reducing socket of the size known in the trade as $1\frac{1}{2}$ inch by $\frac{3}{8}$ inch will be required. Mount this by the larger end on a face plate, or in a self-centreing chuck; or, if neither of these happen to be available, turn a piece of wood to fit the inside of the socket. Assuming that the piece now runs true in the lathe, the first operation consists in turning out the existing gas thread in the smaller end, thus enlarging the orifice until it is of sufficient size to permit of the $\frac{3}{4}$-inch tap being introduced. In tapping, it is as well to bring the back centrepoint up to the end of the tap, so as to ensure the thread being accurately cut. This having been accomplished, a small recess should be turned in the end, as shown in the illustration. (Fig. 1.) If the foregoing operations have been carefully carried out, on screwing the rough chuck on the mandrel, it should run truly and bed nicely against the shoulder. Set the lathe in motion, and with a graver or point tool mark two rings on the circumference of the chuck. Each ring is to be divided into six divisions. Drill and tap with $\frac{1}{4}$-inch thread each *alternate* division in the two rings, taking care that the three holes in one ring are midway between those in its fellow. If the divisions are marked with a punch, the back centre can be used, placing its point in one mark, when the one opposite can be drilled with a tool in the lathe, and so on until the three holes in each ring are completed. By this means the proper position of the holes is ensured, it being important that, when the screws are put in, each set of three should meet accurately in the centre. The chuck now only requires to be furnished with screws to complete it. It is hardly worth while for any workman to make these, seeing that they may be purchased at Nettlefold's at the very low price of fourpence per dozen. The heads require cutting off, and a square should be filed at the top of each one, the opposite ends being slightly coned, as shown in the figure. The screws should be made a medium fit in the chuck; neither tight nor loose; but so that they may be readily turned by the fingers. For light work a spanner is hardly necessary, but will be

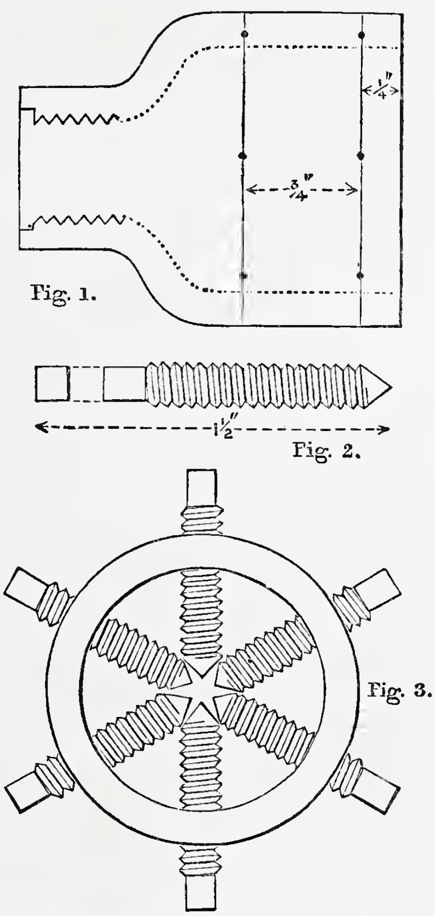

Fig. 1.—Socket Tapped for Mandrel and Marked for Screws. Fig. 2.—Screw. Fig. 3.—Front View of Chuck complete with Screws.

useful for heavy work, and can easily be made by drilling and filing a square of the required size in a small piece of iron or steel.

A shaving may be taken from the mouth of the chuck, and the body turned up bright and smooth, if it is thought desirable; but a very good plan is to give the outside one or two coats of black enamel.

If a 4-inch chuck, say, should be required, it will not be possible to obtain a socket small enough at its "reduced" end to fit the mandrel. It is easy to get over this difficulty, however, by plugging up the end entirely, and then drilling out afresh to the size required for tapping.

The total cost of this chuck (2-inch) should not exceed one shilling, exclusive of time and labour, and when finished it will be found of great value for holding many articles whilst being turned. For large drills it will be found even better than a self-centreing chuck, as with a little practise it can be adjusted to run dead true.

SOME FACTS ABOUT MAHOGANY.

BY DAVID DENNING.

MAHOGANY is a wood so well known, so generally used, not only by the cabinet maker, but by others, that we are almost naturally inclined to regard it without any particular interest. We take it as one of the common materials of daily household use, and looking round our rooms we can hardly conceive the time when it was unknown. Nevertheless it is to all intents and purposes a modern introduction, comparatively. Not till well on towards the middle of last century was it in anything like general use, although it was not unknown at the end of the sixteenth, when it is stated to have been brought to this country, not as part of the cargo, but as portion of a vessel which had "got into lumber," and had been repaired with it. To Sir Walter Raleigh is credited this first importation, and little could the great Admiral have imagined that the timber he found useful would one day be found to possess qualities which should lead to its general adoption as a furniture wood.

Evidently, at first it did not appeal to popular taste, or possibly while mens' minds were excited with the idea of discovering an Eldorado, whence gold in unlimited quantities could be had almost for the trouble of taking it, the notion of importing bulky timber may have seemed too ridiculous. If it was an age of strength it was also an age of rudeness, almost of barbarity, when domestic comforts as we understand them were little thought of. Going back in fancy to those "good old times" we can well imagine that any one who proposed to import mahogany because of its beauty would have been looked on as a man whose schemes were not worthy of serious consideration. Even were the wood appreciated, how could it be brought over in sufficient quantity to make its sale remunerative in the little vessels in which the navigators of those days sailed on their half-marauding, half-trading expeditions? Any cargo must necessarily have been such that it could be stowed in a small bulk. Whether a few logs may have been brought over from time to time or not, after Raleigh used the strange new red wood to repair his leaky vessel, it certainly was not much heard of in this country, though it is reported that the Spaniards employed it for ship-building purposes in the sixteenth century. It seems probable that Raleigh availed himself of this wood simply because it was handy and known to be suitable, just as, had the repairs been effected in Britain, oak would have been the most convenient wood. Truly these old seamen found an Eldorado, but not such as their greed-inflamed imagination suggested. By discovering the products of other lands—nay, by their discovering in the first place the other lands beyond the seas—they have done the world more good than had they only and solely come across the mythical golden city. They searched for gold, and in so doing paved the way for modern commerce in all its extended ramifications. Whatever the quantity of mahogany that may have been brought to this country during the seventeenth century, we seem to have few reliable details by which to trace its adoption till well on into the eighteenth, when we again meet with some tangible evidence of it during the reign of George I. A certain Dr. Gibbons, of whom I believe history is otherwise silent, had a brother engaged in the merchant service, by whom he was given in the year 1824 some pieces of mahogany, the gift being probably induced by the fact that the doctor was then having a house built for himself in King Street, Covent Garden. Whether they were handed to him with the intention of being used for decorative purposes, or simply because they were looked on as waste, is not known, but there is no doubt that they stood a very good chance of eventually becoming the latter, for the joiners refused to work it on the plea that it was too hard. Apparently the doctor had recognised its beauty, or it may have been that he only wished to have some trifle as a memento of his brother made from it. Whatever the motive, fortunately he didn't accept the builder's decision of its unworkableness as being final, for we find that he arranged with a cabinet maker named Wollaston that a candle-box—strange reminder of the primitive modes of illumination!—should be made from some of it. Wollaston also seems to have found fault with the wood on account of its hardness, from which we may reasonably infer that it was a piece of finely-figured Spanish—otherwise, had it been of the inferior bay wood, men accustomed to work in oak, the till then ordinary furniture wood, could hardly have complained of its being unworkable. Be this as it may, the candle-box when finished gave satisfaction to so great a degree that, as one writer says, "it outshone all the other furniture belonging to the doctor, who gave Wollaston the remainder" of the wood, though another writer distinctly attributes to Wollaston the credit of having "recognised the fine qualities of the material." However, without discussing whether to the doctor or to the tradesman is due the chief credit of sufficient discernment to appreciate the merits of mahogany, there is no doubt that, speaking from a commercial point of view, it is owing to their joint enterprise that the wood took at once a leading place as a furniture material. The story goes that out of the remainder of the captain's present Wollaston made two bureaus, one for Dr. Gibbons and the other for the Duchess of Buckingham. After this the demand seems to have increased, and Wollaston is supposed to have amassed a considerable fortune by the manufacture of mahogany furniture.

Within the next few years the importation of mahogany must have greatly increased, for even before Chippendale's time we find it extensively used, while the fact that Chippendale made most of his furniture from it is too well known to require comment. It is hardly too much to say that to the introduction of mahogany much of the change which took place in the fashionable styles is owing, an impetus having been given to the study of designs suitable to it; and whatever the opinions of the designs themselves, there is no question that Chippendale and his contemporaries made the most of their material. It was delicately worked up in a manner which conclusively proves that it was not regarded as a common material, but rather as one to be treated with respect. Other causes, no doubt, contributed to the improvements which took place, not only in furniture but in general household decorations during the last century, but there remains the fact that in mahogany the great designers and artisans to whom English furniture owes so much of its present position as a fine art industry found a congenial material. It may be interesting to note that mahogany, even in its commoner qualities, must have been a comparatively valuable wood, for it is not uncommon to find old articles of furniture veneered with it on a foundation of oak.

Later on, as inferior, *i.e.*, plainer figured mahogany, became a commoner commodity, the custom of veneering on it became more general, and it is rarely nowadays that one finds any other wood used for the purpose, except when for the sake of cheapness pine is used. No one, however, would think of laying mahogany veneer on oak.

Mahogany has remained, par excellence, *the* cabinet-maker's wood, although within the last few years it has fallen into comparative disuse for the best, or say the most fashionable, furniture. Various causes have contributed to this, among them the rage for the plain severe styles which for a time had sole sway, and the outcry raised in certain quarters against veneer. Unreasonable though it might be, this had great influence on public opinion, and ash, walnut, or oak, solid, or supposed to be solid, largely supplanted mahogany in popular favour. Nothing can be urged against these woods being unsuitable for furniture construction, except that in point of beauty they are not equal to mahogany. They are good enough in their way, but when it comes to be a matter of richness of colour and variety of figure, they are, to use a colloquialism, "not in it." We are, after having kept our eyes partially closed to the merits of mahogany, and sought more or less vainly to find the same qualities in other woods, just beginning to open them again, and to see that there is after all nothing like a handsome piece of mahogany furniture. Not that I would advocate its exclusive use, but do not let us remain under the impression that ash or walnut for bedrooms, walnut or oak for dining-rooms, is only to be employed if we want to have "art-furniture." This can be made in any and not necessarily the plainest wood, although there seems a certain amount of misconception about this sometimes. In mentioning the claims of mahogany it must be recollected that the style in which it was worked up, say thirty, or even twenty years ago, is not a necessary concomitant. It is not, however, all mahogany that is equally beautiful; indeed, there is hardly a wood with which we are acquainted that presents more variety than this, varying from the plain coarse Honduras to the richly variegated Spanish. It was in this latter that the Georgian cabinet makers principally worked, and when a fine piece of "city" wood can be obtained it is a thing to be valued.

The mahogany tree is found more or less abundantly in the West Indies, whence comes that known as Spanish. The best of this was formerly imported from San Domingo. Indeed, at one time, it appears as if this were the only port of shipment for, at any rate, the choicer varieties, whence the designation of "city" wood. Other islands were found to produce mahogany, some of it, notably that from Cuba, little, if at all, inferior to the old "city" wood, and from these we now import most of the Spanish. Mexican mahogany is also of good quality.

As regards figure and colour, Honduras mahogany, commonly spoken of as bay wood, is inferior, though otherwise it presents all the good qualities of the choicer kinds, *i.e.*, it is as reliable in work, and forms an excellent ground for veneering on. Most of the finest wood is cut into veneers which, according to the figuring, are known by various names, such as curls, feathers, and various fancy titles, not now so much regarded as formerly.

From what has been said about the extensive variety of qualities it will easily be understood that there is an immense range in price between the highest and the lowest. Fabulous sums have been given for choice logs, and though there are certain indications by which experts can form a fair opinion before cutting, the probable amount of figure cannot be accurately foretold. One may buy half a dozen logs supposed to be fit for choice veneers, and find them after all very ordinary stuff, while on the other hand a log from which nothing much might have been expected will supply veneers with the choicest markings. To give some idea of the high prices which logs have sometimes realised it may be said that they have sometimes reached four figures, or £1,000 per log. This seems almost incredible were it not that fine veneers are known to be beyond ordinary market figures, and to command "fancy" prices. However this may be, it has been stated on good authority that logs have been sold for the sum named. A well-known firm is reported to have given this figure for three logs, which, as was pointed out some years ago, would probably give a cost of from £5 at least per cubic foot.

It must not be imagined that all Spanish wood is finely figured, nor that all bay wood is plain, for though these are the general characteristics of the two kinds, instances are not unknown where the latter has been finely figured, indeed it is said that the three logs above referred to were Honduras. Spanish mahogany is sometimes spoken of as though the name alone would be enough to support its claim for figure, the fact being often overlooked that the stuff may have very slight markings, as most that shows any fine variety is used up in veneers. As Spanish is supposed in every instance to indicate a fine wood, so Honduras is taken as being very plain, and undeservedly so, for the quality of the timber depends very much on the situation in which the tree has grown. That from the low marshy districts in the south of Honduras is mostly plain, while that from further north approximates more closely to the genuine Spanish. In addition to American mahogany—including that from the West Indies—there are at least two other kinds, viz., the African and the East Indian varieties. These, however, even if they can be classed as true mahoganies, do not enjoy the same repute as the others, as the timber is inferior in many respects. It is also probable that other varieties from different parts of the world, closely resembling the real mahogany, find their way into the market, and are sold under its name, for we find that the natural order of plants which produce similar timber is very widely diffused in tropical and sub-tropical climates. Among them may be mentioned the West Indian or Barbadoes cedar, which is often used for making Havana cigar boxes.

Perhaps a glance at the subject from a botanical point of view may not be uninteresting, though it must be confessed that for workshop purposes it may not help us much; however, if it does nothing else, it will at any rate help us perhaps to understand how and why there are, for example, an East Indian and an African kind, and how it is they differ, although generally spoken of as mahogany.

The real stuff from the West Indies and America is from the tree *Swistenia mahogani*, one of the natural order of *Cedrelaceæ*. Its growth is slow, and from the immense size of some of the trees, which often reach 80 to 100 feet in height, with a trunk 6 feet thick, it has been calculated that many of them must have been growing for approximately 200 years. As has been incidentally mentioned, those grown on low swampy ground produce inferior timber. Perhaps owing to the great difficulty of transportation from the place of growth to the port of shipment, there is an increasing tendency to deterioration in quality. The best accessible trees have been felled, and as distance from the coast increases there is less possibility of picking and choosing; the trees instead are taken as they come.

East India mahogany is produced by the *Soymida febrifuga* or Rohuna tree; as its name almost implies, it, or rather its bark, is occasionally used medicinally as a febrifuge. The bark of the mahogany tree has also been used for the same purpose.

African mahogany is the produce of the *Khaya Senegalensis*; West Indian cedar, or, as it is often familiarly called, though erroneously, mahogany, is supplied by the *Cedrela odorata*.

All of them belong to the natural order *Cedrelaceæ*, which includes many other kinds of woods, that best known perhaps being satin-wood, which, apart from its distinctive colour, bears a very marked resemblance to mahogany in figure and general marking.

Every one who is accustomed to handle it knows that mahogany is a reliable wood—pleasant to work, and susceptible of a high degree of finish. It is obtainable in large planks clean and sound, *i.e.*, free from knots and shakes. One sometimes hears that really fine mahogany is difficult to procure nowadays, or even that it cannot be got. This, however, is hardly correct, for there is no doubt whatever that by care and the payment of sufficiently high prices, mahogany of the very finest figure is still to be purchased. Naturally, it will not have the fine dark colour of old mahogany, but that will come in time, unless, indeed, the stains which, at the request of ignorant purchasers, are so freely used to give an artificial appearance of age have a prejudicial effect. Stains may produce a pleasing appearance on new wood, but it may very reasonably be supposed that the benefit is only a temporary one, and that instead of improving as time goes on the colour will be anything but agreeable. If any mode of artificial darkening be resorted to that by ammonia vapour is the least harmful, and gives a nearer approach to the colour of old mahogany than any other process. Of few woods can it be said that they improve with age, but mahogany is certainly one of them; but to let old Father Time have fair play the wood should be simply oiled, or at most French polished without any staining. Of course, I do not refer to that very inferior wood, which hardly deserves the name of mahogany, so largely made up into furniture in the East End of London, and either coloured a fiery hue, or, if it is made up into "second-hand stuff," a dirty brown. The natural colour of such wood ean hardly be spoilt, but on the other hand the practices that prevail to give it a good colour, or what is supposed to be such, cannot be spoken of in terms of commendation.

Very much more might be said about mahogany, and there can be little doubt that the intelligent worker would occasionally derive more pleasure from his work—or from his materials—did he know a little more than is commonly the case about them. By way of a few suggestions on mahogany in this direction the foregoing remarks are offered to those who take some interest in knowing all—or at any rate something—about everything they come in daily eontact with

It is not, however, only as a furniture wood that mahogany is useful, though naturally the choicer varieties are reserved for this purpose. Its use in ship-building has already been referred to, though, notwithstanding the fact that its durability is so great, it does not receive the highest class at Lloyd's, a fact which may be accounted for by the best sorts not being employed for the purpose.

BICYCLE PLATING, BISMUTH, AND BLOODSTONE.

BY GEORGE EDWINSON BONNEY.

Bi.—The prefix "bi" means two, and is synonymous with the prefix "di." Thus dioxide and binoxide have the same meaning, viz., two atoms of oxygen.

Bicarbonate of Potash. See *Potash.*

Bicarbonate of Soda. See *Sodium.*

Binoxide of Mercury. See *Mercury.*

Bisulphide of Carbon. See *Carbon Bisulphide, etc. etc.*

Bicycles.—New bicycles are usually sent to the plater in pieces, fresh and clean from the maker's hands. The various pieces are cleaned and treated as pieces of steel to be plated.

If the spokes of the wheel are sent separate, they should be slung together with stout copper wires so as to form a ladder of spokes, and these hang in the dipping and bath solutions. The rim of the wheel is plated in sections when the bath is not large enough to take the whole wheel. These sections must be so arranged in the bath as to cause the deposit on one section to overlap the ends of the other section. Old bicycles must be taken to pieces. Every part that can be unscrewed must be separated and cleaned separately. Clean first with emery, then with a leather buff charged with Trent sand, and polish off with Sheffield lime. As high polish as can be obtained should be given to each part, and then they should be transferred to a strong potash bath to remove all the grease. It is sometimes advisable to brush the pieces in the potash liquor, then rinse them and scour by hand. They are then again rinsed, placed in the acid dip, well rinsed in clean water, and transferred at once to the plating vat. As it is not always practicable to take the wheels to pieces, these may be plated entire. When the parts are plated they are rinsed in clean hot water, dried, and finished with lime, that is, well polished with Sheffield lime applied on a dolly revolving in a lathe. The wheels are polished by hand with chamois leather.

Detailed information on this subject, illustrated with diagrams, is given in Mr. A. Watts's book on "Electro-deposition," to which the reader is referred.

Bismuth.—Chemical symbol Bi., combining weight 210, specific gravity 9·8. A reddish-white metal of a highly crystalline and very brittle character, found with the ores of nickel, cobalt, copper, and silver. It melts at a very low temperature, 507° Fah., and expands so much on cooling as to occupy $\frac{1}{32}$ more space when cold than it does whilst in its melted state. When strongly heated, it burns with a blue flame and forms an oxide of bismuth. It dissolves freely in nitric acid. Bismuth is an important ingredient in the composition of fusible alloys and soft solders, its presence contributing largely to their fusibility. See *Fusible Alloy*, *Stereotype metal*, *Type metal*, *etc.*

Bismuth is electro-positive to eopper, silver, mercury, platinum, iridium, osmium, gold, antimony, and carbon. It is electro-negative to tin, lead, cobalt, nickel, iron, zinc, manganese, aluminium, and magnesium. Plates of bismuth, I must not omit to say, form the positive element and plates of antimony the negative element in some thermo-electric batteries.

Bisulphite of Carbon. See note on *Carbon Bisulphite* and *Brightening Solution.*

Bloodstone.—The name given to the stone used in the manufacture of best quality burnishers. It is generally supposed to be a variety of a native oxide of iron. Mr. Bloxam in his book on metals, says: "*Red Hæmatite* has been so called from the Greek word signifying *blood*, on account of its dark red colour, and is sometimes erroneously called *bloodstone*—the true bloodstone being a dark green variety of silica (*heliotrope*) with red spots. In appearance it is the most striking of the ores of iron sometimes appearing in rounded masses, having externally a liver colour with considerable lustre, and internally made up of layers having the appearance of the thick shell of some huge fruit, or of bundles of fibres which look like petrified wood. The specific gravity of this variety is about 5·0. Such specimens are, in general, remarkably hard, and are useful for burnishing metals."

The lumps of this substance that are used for burnishers are held in the ends of metal tubes by solder. See remarks on *Burnishers.*

THE KALEIDOSCOPE: ITS CONSTRUCTION AND APPLICATION.

BY THOMAS RICHARDSON.

THE COMPOUND KALEIDOSCOPE.

THE engravings which accompany the present article illustrate a new type of kaleidoscope, combining in one instrument many important properties, which may be briefly stated as follows:—

In the simple form a defect was referred to which mars the symmetry of the picture, caused by the interposition of a blank space at the junction of each direct and inverted image, equal to the thickness of the glass of which the mirror is composed. In the present case this is obviated by silvering the first surface of the reflectors in place of the posterior surface, so that each image merges directly into the adjoining one, forming, when the reflectors are placed at any angle which is an *even* aliquot part of a circle, a series of sectors arranged with beautiful regularity round a common centre; the number of sectors being always equal to the number of times that the angle formed by the junction of the mirrors is contained in a complete circle, or 360 degrees. The reflectors are so mounted that the angle can be varied at will, and clamped in any position, within a limit of 72 degrees, by means of a pair of milled heads (A and B, Fig. 5) at the back of the instrument, which actuate a pair of pinions sliding in vertical slots, and working in racks attached at each end to the inside of the case. The mirrors recede from each other at their upper edges on turning the head (A) in the same direction as the hands of a clock move or clockwise, and approach each other when the head is turned contra clockwise. One of the reflectors is shown at the extreme limiting angle in Fig. 2. In order to produce annular or arched and rectilinear pictures, the reflectors are moved apart at their lower edges by a motion the reverse of the preceding, and of which it is quite independent, viz., by turning a milled head (C, Fig. 5), which is secured to a pinion rotating in bearings at each end, and moving in opposite directions a pair of racks attached at their ends to the arms (K), which support the reflectors. A second milled head (D) acts as a clamp. The reflectors can thus be separated to a distance of 2 inches, and parallel to each other, as shown in Fig. 1, any intermediate position, either oblique or parallel, being obtainable on turning the heads A or C as required. The whole instrument is capable of being rotated through an arc of about 170 degrees, the rings shown at X (Figs. 1, 2, and 5), secured to each end of the instrument, being supported by the uprights (V), the upper ends of which are hollowed to fit the rings, thus

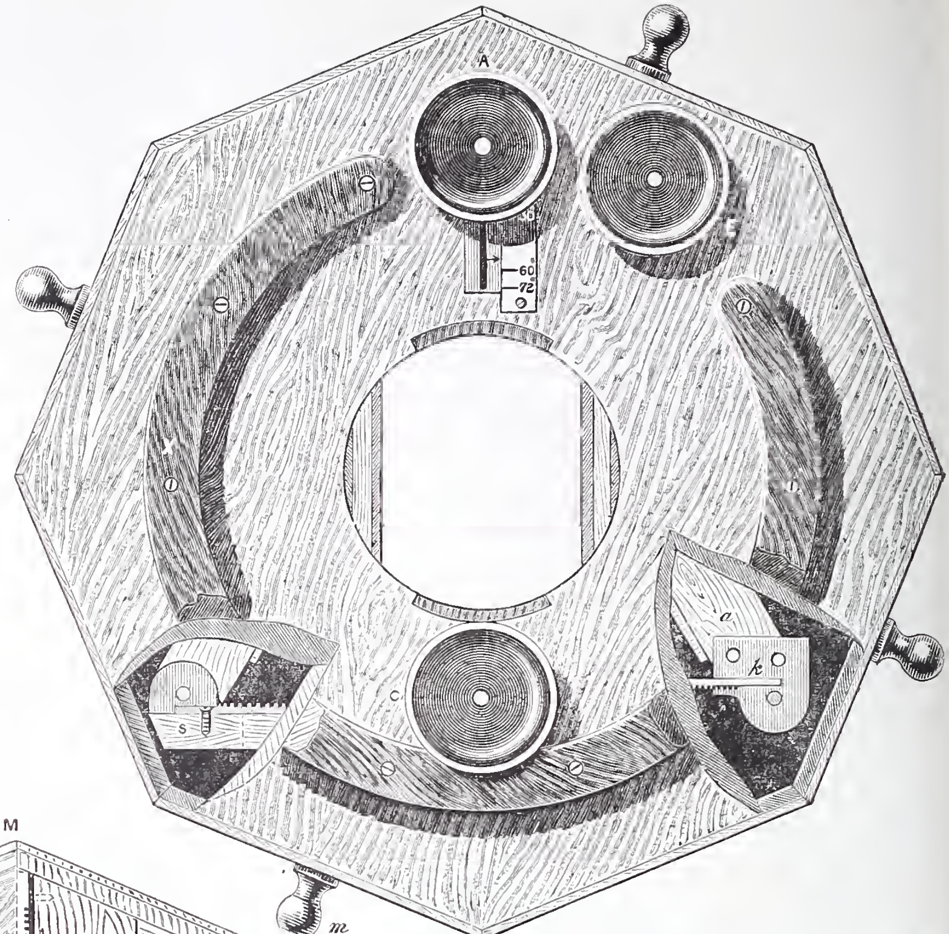

Fig. 1.—Elevation of Eye End of Compound Kaleidoscope, showing Mirrors parallel to each other, with Portions of the End Plate removed to show Method of attaching Rackwork and Slide to the Arms which carry Reflectors. (Scale, half size.)

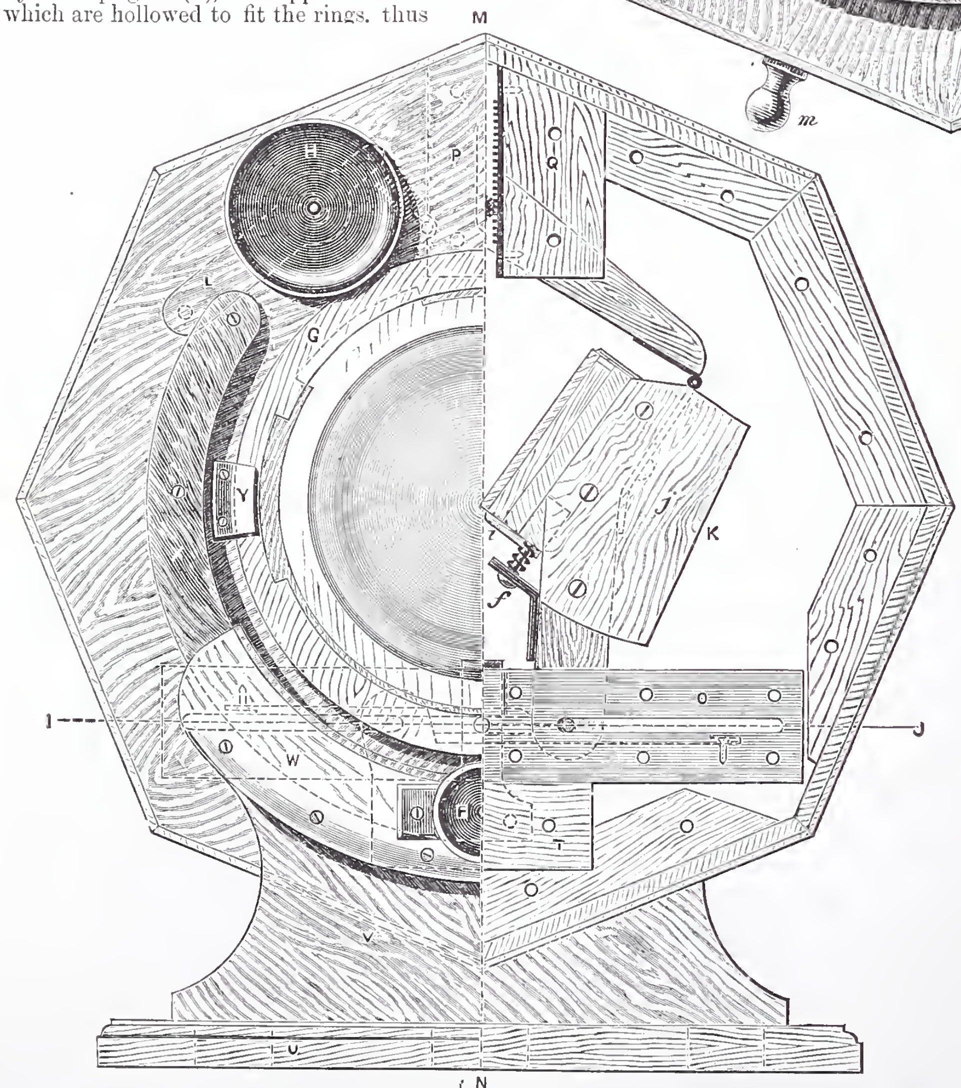

Fig. 2.—Elevation of Object End. One half of the End Plate and the Slotted Vertical Plate P is removed to show Interior. (Scale, half size.)

forming a bearing, and the necessary leverage is provided by the handle seen at *m* (Fig. 1). By means of a milled head at F (Fig. 5), this motion can also be arrested to admit of the picture being copied. The object box is enclosed in a carrier (G), which allows of continuous, clockwise rotation, through the medium of a small rubber-covered disc of wood (H, Figs. 2 and 5), actuated by a milled head, seen at E (Fig. 1), the tension of a coil spring applied to the end of a lever (L, Fig. 2) being sufficient, on turning the disc, to transmit motion to the carrier. In addition to the advantages already enumerated, other accessories, rendering the instrument still more complete, will be described and figured in due course. Meanwhile, sufficient explanation has been given to make the reader conversant with the motions of the several parts before us, and we may now turn our attention to the various details involved in its construction.

It may be argued that were the instrument constructed entirely of metal, the mechanism necessary to produce the several motions recorded above might have been enclosed in a circular tube of very much smaller dimensions than the one here presented; but to have carried out the idea in a confined space would have required an amount of precision in the use of tools seldom attained by any but professional hands. Sacrificing space in order to avert the exclusion of the amateur mechanic, I have endeavoured o so combine wood and metal in its construction as to avoid having recourse o any particularly delicate mechanical operations, the pieces composing it being on that account relatively larger than would be the case if of smaller compass, as it is much easier to file up a level surface an inch wide than one of half or quarter that width; and the same remark applies with equal force to woodwork; therefore, wherever possible, pieces of wood having a small sectional area should be prepared in lengths of 12 or 15 inches.

To those who contemplate engaging in the project, I would suggest at the outset the production, on cardboard, of a full-size drawing, with the aid of the description, where necessary, so that the dimensions of the several parts can be obtained without the trouble of further calculation. Further, as being principally of wood, every care should be exercised in its selection, nothing being allowed to pass muster, especially where lathe work is concerned, except well-seasoned, close-grained mahogany. In the pieces composing the support and sides of the case a more open grain is admissible, although if it is intended to be French polished, it would be well to have the outside of uniform grain throughout for appearance' sake.

Before attacking the woodwork generally, there are a few trifling patterns of the brasswork which it will be well to prepare, so that the castings (which should be thoroughly sound) may be ready to hand when wanted. They comprise patterns for the milled heads shown in Figs. 1 and 5. First turn a pattern for C (Fig. 5); as this will be moulded shank downwards, the latter must be tapered slightly from the point upwards, omitting the hollow shown in the diagram, as also the groove on the edge, which must be tapered in the same direction as the shank. The same pattern will serve for the heads A and E; $\frac{1}{16}$ in. all over the surface must be allowed for turning. One pattern each is also required for the heads B, D, and F, and a plate into which the latter is screwed ($1\frac{3}{4}$ in. long, $\frac{5}{8}$ in. wide, and $\frac{1}{8}$ in. thick), with a circular boss cast on one side as shown. Other materials in metal required are some pieces of brass tube: one piece for sliding pinion, $7\frac{1}{2}$ in. long, and $\frac{1}{4}$ in. outside diameter; with a piece to slide over this $5\frac{1}{4}$ in. long; a piece for the stationary pinion, $7\frac{1}{2}$ in. long, and $\frac{1}{4}$ in. outside diameter. To support the arms which carry the reflectors we require two pieces $7\frac{1}{2}$ in. long, and $\frac{1}{4}$ in. outside diameter; two pieces $5\frac{1}{4}$ in. long, to fit the exterior; and two pieces of steel rod ($8\frac{1}{4}$ in. long) to fit the interior. The best material for the latter would be silver steel wire, such as is used for drills and taps, and sold in 12-in. lengths by dealers in watch and clock materials.

The rackwork figured has thirty-seven teeth in 2 inches, and the pinion wire has twelve leaves. One length of pinion wire and three pieces of rackwork 7 in. long are required. They may be procured from Messrs. James Lancaster and Son, opticians, of Birmingham. A letter enclosing P.O. for 3s. 6d. would, I am persuaded, meet with prompt attention, if addressed to the above most obliging firm.

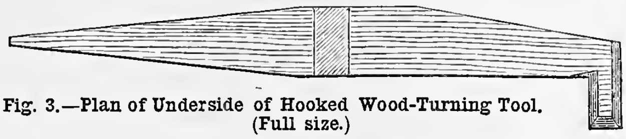

Fig. 3.—Plan of Underside of Hooked Wood-Turning Tool. (Full size.)

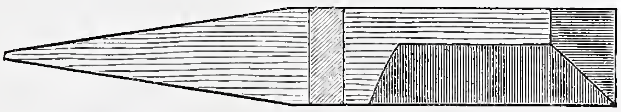

Fig. 4.—Plan of Underside of Side-Cutting Wood-Turning Tool. (Full size.)

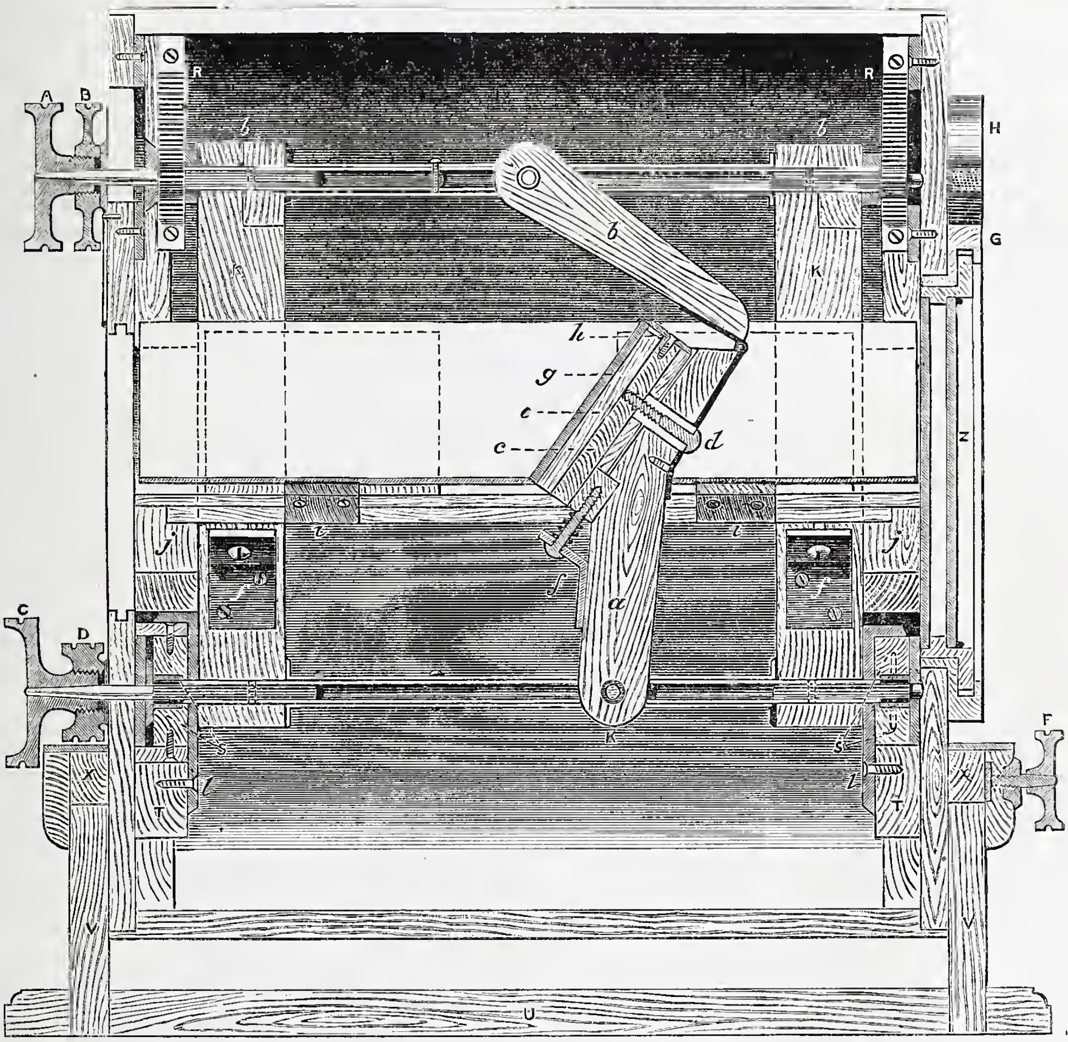

Fig. 5.—Sectional Elevation on Line M N in Fig. 2, showing also Portions of Interior (Mirrors Inclined) and Section through Centre of Arm. (Scale, half size.)

We will commence operations by turning the carrier for the object box G (Fig. 5). For this we require a piece of specially sound, close-grained mahogany, $5\frac{1}{2}$ in. square and $\frac{3}{4}$ in. thick. At $\frac{5}{8}$ in. from the edge, set off four holes, one at each corner; bore these to pass a $\frac{1}{4}$-in. screw, and countersink them, so that the heads shall not be less than $\frac{3}{8}$ in. below the surface; if necessary, level the other side, and fix to the true face of a hard wood chuck. Having trued up the face, find the centre as it spins, and scribe a circle with the compasses, $4\frac{1}{4}$ in. diameter, which is the size of the opening in the object end of the case; outside this circle turn down to a shoulder, barely $\frac{5}{16}$ in. deep, so that when in position it may not project beyond the edge of the opening into the interior. Scribe a line $\frac{1}{2}$ in. beyond the shoulder, and remove it from the chuck, replacing it with a piece of $\frac{3}{4}$-in. deal, 7 in. square; true up the face, and bore to fit the part already turned on the carrier. Cut off the superfluous corners of the latter, and if not sufficiently tight to drive by friction, fix with a couple of screws an inch or so from the centre. Thus secured, true up the face and the edge square with the same to $5\frac{1}{8}$ in. diameter. Now scribe a centre line across the face, and sink a recess $\frac{1}{4}$ in. deep and $4\frac{3}{8}$ in. diameter, with a groove flush with the bottom, bored with a special hooked tool shown as viewed from the underside in Fig. 3. Another tool, which may be made by grinding a firmer chisel at the side, as in Fig. 4, will be found most suitable for finishing the interior portion, which may next be bored to $3\frac{7}{8}$ in. diameter. Using the centre line as a guide, set off an opening at each side, as shown in Fig. 2, and carefully remove a portion of the outer edge of the groove with a dovetail saw and gouge, so as to admit a similar pair of projections on the object boxes, forming what is known as a bayonet joint. Each end of the case is formed of a piece of mahogany, which, for convenience' sake, we will distinguish by the term "plate." These plates measure $9\frac{1}{2}$ in. across the corners, and $8\frac{13}{16}$ in. across the flats. The back plate at the eye end is $9\frac{3}{4}$ in. square, and $\frac{7}{16}$ in. thick to commence with; one face is dressed with a trying plane until it will lie without flexure close to the true face of a wood chuck, on which it is to be mounted by a screw at each corner. To ensure the plate being left of the same thickness throughout, a straightedge must be diligently used to test the surface until it is quite level; then reverse it on the chuck, and reduce it with equal care on this side also to a thickness of $\frac{5}{16}$ in.

Here I must pause to mention the necessity to provide a steel scriber, having one end sharpened to a needle point, and the opposite end like a turning chisel. Mark the centre lightly and exactly at this point with the cutting edge; mark the centre line, M N, right across the grain, and $2\frac{3}{16}$ in. below the centre; scribe the line, I J, perpendicular to M N. We also require three circles on this face of $9\frac{1}{2}$ in., $4\frac{1}{4}$ in., and $2\frac{3}{4}$ in. diameter, respectively, the last-named being the size of the opening for the eye-piece. It may now be bored out, and a groove produced on its edge of the same character, and to serve a similar purpose as in the carrier, the whole being made as smooth as possible with the finest glasspaper.

Following the same directions with the front plate, set off the centre lines and a circle $4\frac{1}{4}$ in. diameter; after removing the central portion, work carefully up to the line, so as to fit the carrier neatly; the surface which comes in contact with the latter to be finished by rubbing with a piece of Nixey's blacklead, in order that the carrier may slide smoothly within it.

WHY FURNITURE IS VENEERED.

WITH REMARKS ON SOLID WORK, ETC.

BY DAVID ADAMSON.

I MUST altogether dissent from the remark about it never being "worth while to buy furniture veneered with mahogany, for a little extra cost may procure the same articles in solid wood," as it is quite inaccurate, if it may be assumed, as I presume it may be, that the furniture, whether solid or veneered, is to be good, that is properly made and finished. If it is to be only common Curtain Road stuff, then certainly the case is rather different, for rubbish can be had at almost any price.

The fact is that the cost is not altogether regulated by the wood being veneered or not, *i.e.*, so far as labour is concerned. It depends far more on the value of the veneer. Now, if we are to understand that any article veneered with finely figured mahogany is to be had made solid of equally finely figured wood, I am afraid the difference in cost would rather startle any one. On the other hand, presuming that the fine veneer is laid on a mahogany base, as it generally is in good work, and that this or a comparatively plain mahogany is worked up solid without veneer, then the solid form would be very much less than the other. Hence there is no cause to wonder at a solid oak table having been obtainable at a smaller price than a veneered one. Given equally good wood to serve as a foundation for veneering on, or to be finished without veneer, it stands to reason that a veneered piece of furniture will cost more than a similar article unveneered. It cannot, however, be expected that a really choice wood—I refer, of course, only to the more valuable kinds—is to be used solid. To do so, apart from other considerations, would be simply a waste of material, or if this is too sweeping an assertion, let it be said that few would be willing to pay the enormous difference in cost for any ordinary article to be made of solid wood fit for high-class veneers.

If, as sometimes happens, pine is the wood on which the veneer is laid, and the veneer not of the most costly, then it would not be incorrect to suppose that a plain solid mahogany article would cost a little more. In the one case we have a fine, handsomely marked surface with a pine backing, in the other a plainish piece of wood, but solid. Of course, the notion of pine may not be agreeable to some, but there is no doubt that for many positions it is quite suitable; and that apart from its softness, it is, when selected with care and proper knowledge, by no means to be despised. I do not advocate its use as a foundation for really fine veneers, but I must confess that for comparatively cheap work, it seems to me that there can be no more objection to veneering pine than to staining pine, say, walnut or mahogany colour, and polishing it. The greatest purist hardly objects to the latter; indeed, some of them rather suggest that it is a very appropriate way of finishing pine furniture, but why veneered pine should not be equally so, I am at a loss to understand. The only reason can be that those who object to it have had the misfortune to meet with some uncommonly bad specimens of furniture of this kind, and that on them they have too hastily formed opinions. The critic of woodwork frequently does so, or those acquainted with the trade of the cabinet maker would not be so much amazed as they are sometimes with the extraordinary statements made with all the confidence of an intimate knowledge of the subject. That good and bad furniture is made cannot be disputed, but the former is always to be had by going to respectable cabinet makers and paying a fair price for it. The individuals who, without any practical knowledge of the subject, but with an overweening confidence in their own ability to distinguish between the false and the true in quality of wood or workmanship, and it may be added, actuated by an unhealthy desire to pick up bargains, rely on their own judgment, are principally to be credited with the immense quantity of slop furniture which is made and sold. It is not made for sensible people, but for the other sort; and as according to the sage of Chelsea, the majority belong to this other sort, it would be very remarkable if a certain proportion of furniture as well as other things were not prepared for their special delectation.

It is sometimes erroneously supposed that articles of furniture are veneered solely that the profit of the maker may be unduly increased, and it is not uncommon to hear a would-be purchaser inquiring if such and such is solid, apparently under the notion that it will be worth more, or be better value if it is. I don't think any honest tradesman would hesitate to say which parts are solid and which are veneered; but sometimes the discovery that a particular thing is veneered comes too late to the user, and disturbs his peace of mind. To do what I can to restore it to any who may happen to read these pages, let me say that, if the things were sold by a good, reliable cabinet maker, or, rather, made by one, that whatever the construction is, they may be depended on. With regard to solid work, there is a point which is liable to a slight misconception, viz., when wood of the same kind as the veneer is used for the foundation; let us say, for example, a mahogany sideboard top. This, for the sake of the extra beauty of surface, might be veneered, but to distinguish it from pine, similarly veneered, it would be called a solid mahogany top, if referred to, by many tradesmen. The fact of the surface being veneered by no means prevents its being a solid mahogany top, as it really is; the error, if any, in description being merely that it is not stated to be composed of two thicknesses. I merely mention this, as I have heard of people supposing themselves to have been deceived by statements about solid wood, but almost invariably it will be found that their questions leading to them have not been sufficiently explicit to elicit a correct answer. I trust, however, I have said enough to show that veneering should not be indiscriminately condemned, and that when properly done, it is not only a judicious, but sometimes a necessary, method of working up a material. I think all the more common forms of objections to it have been discussed in such a way as to dispel from the reader's mind any prejudice he may have insensibly formed against veneering. Though much more might be said to the same purpose, we may take leave of this part of the subject, and concern ourselves with the practical work of veneering. In connection with this, I may say that many different methods are adopted, and that in competent hands they are all capable of producing good results, some better than others, but none of them utterly bad. Do not, therefore, let it be thought that if no allusion is made to some favourite mode of preparing or laying veneers, or I may go a little farther and say, that if some other is stated to be better, that it is done with any intention of inducing practised artisans to abandon their old systems of working. I am quite prepared to admit that any method which has been found in practice convenient and durable, is just as good as any which may be mentioned by me. I am not bigoted, and would let every one practise his own method, *i.e.*, any one who is competent to form an opinion, or is an experienced craftsman; so, good readers among these, don't think I wish to disturb you in your present modes of veneering, but at the same time, please remember that the operations to be described, however they differ from yours, are also quite reliable. I say this with full knowledge that the practice of veneering is subject to many variations in detail, and that men equally competent to form sound opinions differ materially in their views as to what is best; also, I cannot forget that discussions about practical methods are not always carried on with that freedom from acrimony which is desirable. May I therefore suggest, that any one who can add to the lamentably small amount of published matter on veneering, will do better by sending on an account of his methods, than by simply contenting himself with saying that the present writer "is altogether wrong." The following instructions are based on a fairly wide experience of the methods generally practised, but there is no assumption that all the methods in particular shops or istricts are known to me, and I for one hall be grateful to those who are able to uggest improvements. This, however, can nly be done by experts, for veneering is a elicate operation. The present seems to be n opportune time for some addition to the terature of veneering. Many of our younger rtisans are practically ignorant of the pro- ess, which in the immediate future bids air to be more practised in connection with ood work than it, till very recently, has een for some years. Unless it is performed y competent hands, it will soon prove un- eliable, and without saying that the art of eneering is ever likely to be lost completely, ull advantage may not be taken of its apabilities.

To the young workman—I mean the pro- essional—I would therefore especially ad- dress myself, while I hope making my re- marks so plain that they may be easily followed by the amateur who may be in- clined to turn his attention to veneering. As the needs of the latter class of workers must be considered, the following instruc- tions and remarks must necessarily contain much that may seem superfluous to those who have even a modicum of experience acquired in practical workshops, but no doubt, though I may appear prolix, they will forgive me now that I have stated the reason. If such a thing be possible, I want to help those who have hardly seen a veneer till after it is laid, who have not the slightest idea of either caul or hammer-laid veneer, or, indeed, anything about the work to set about it intelligently, with results that will neither be disappointing to themselves, nor yet afford opportunity to their most critical friends to find fault with it.

Of course, it will be readily understood that for any written instructions to be of much use, the learner's co-operation is needed, for unless this can be given the novice need not hope to profit by the plainest directions. In the practice of veneering, the beginner is sure to encounter difficulties; he must make up his mind for that, for success de- pends very largely on judgment as well as care and knowledge of what to do. He should not commence operations with large or costly veneers, nor attempt to lay these until he has had some practice with the commoner kinds.

This, it may be said, applies specially to the amateur working alone and not able to command the assistance usually available where several artisans are working together, in case of anything going wrong unexpec- tedly. The young professional's foreman may safely be trusted to see that he does not make his maiden effort at veneering with any valuable material, and, indeed, he should be guided exclusively by his foreman, notwithstanding that his details may pos- sibly differ from anything written here. Directions in WORK are written to aid be- ginners, not to supersede their employer or foreman's preference for any course of manipulation, and, perhaps, they will pardon my hinting that some of them are just a trifle inclined to air their very superior knowledge of a method which they have seen described "in print." This may in itself be better, but for yourself your em- ployer's is the best in the meantime. Forgive my plain speaking, but if you will take the advice, it may save you now and again a little unpleasantness with your "boss," in which you are sure to get the worst of it. But this is in danger of leaving me to talk of behaviour in the workshop instead of dilating on veneering, and the way in which this kind of work is done.

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

86.—JONES'S STENCIL PATTERNS AND CUTTINGS.

MR. G. JONES, East Cowes, Isle of Wight, Decorator to her Majesty, and Designer and Stencil Cutter to the trade, has sent me for inspection and notice a few of his cut stencils and patterns. I have never had the pleasure of seeing patterns that can be surpassed for beauty and excellence of design, nor have I ever had the satisfaction of handling patterns as well cut and as well tied, for my readers will readily understand what an important factor tying is in stencil cutting, inasmuch as the stability and endurance of the perforated sheet, if I may apply such expressions to this work, depend entirely on the skill of the designer in this respect and the care of the cutter in confining himself precisely to the outlines of his designer, and keeping his knife exactly in the tracks thus laid down for him, jealously guarding the passage of the tool a hair's breadth beyond the termination of any two lines, whether straight or curved, that meet at a greater or less angle in any point of the pattern. Mr. Jones's patterns were accompanied by a long roll of stencillings, from plates many of which are much longer than the patterns sent, and which exhibited a boldness of design combined with delicacy of execution and manifest comprehension of the effect to be obtained when the pattern is reproduced on the walls or ceiling of a room, in colours contrasting with the ground or repeating the ground in deeper tints, that it would be difficult to excel or even to equal. It is really a matter of difficulty to single out any patterns for special commendation where all are good, but there are two to which I may call special attention, from the fact that they form part of the decorations in stencil of her Majesty's residence at Osborne, and which, on this account, may be regarded as patterns of more than usual interest. One of these is a floral ornament of great beauty and simplicity which appears on the panels of the ceiling of the Queen's private chapel, and the other an ornament of the same character, exhibiting a pleasing arrangement and adaptation of the national emblems of England, Scotland, and Ireland—the rose, thistle, and shamrock—which forms part of the decoration of her Majesty's council chamber. Mr. Jones's stencil patterns are all distinguished by numbers, and, in accordance with this plan, I may say that the former is distinguished as No. 7, and the latter as No. 10. I venture to suggest to Mr. Jones that he should have a book of his patterns in miniature prepared, in the same manner adopted by Mr. Henry Zilles, Messrs. Harger Bros., and Messrs. J. H. Skinner & Co., and others, so that intending purchasers may be enabled thus to judge of the suitability of the patterns for their purpose before giving their orders. I presume that if Mr. Jones had such a book, he would have sent me a copy of it with his stencils. With each pattern its size, that is to say, its length and greatest breadth, should he stated, and the purpose it is chiefly intended to serve. The price, also, should be named.

Some of Mr. Jones's stencil patterns are intended to render assistance in graining. These are known collectively by the name of the "Arcundian Oak Grainer," and are sold in sets, more or less, I presume, in number. The set supplied at 5s. comprises seven different patterns which are cut to follow on to any length. The directions given for using the "Arcundian Oak Grainer" are as follows:—"Rub in the work very smoothly and clean with graining colour. Comb first with coarse and then fine comb. When the work is properly dry, leather it over with a little whiting and water. Place the grainers where required, and stencil on the veins with Vandyke brown and water, care being taken not to have the brush too wet (an ordinary sash tool answers very well). You will find by rubbing the brush to and fro, instead of dabbing, the veining will come out much cleaner." For oil-graining colour, raw umber should be used, mixed with boiled linseed oil and turps. The following are Mr. Jones's directions for water-graining. Rub the work in very quickly with Vandyke brown and water, and stipple it clean. Comb and proceed as in oil-graining, except the whiting and water. If the graining is required light, place the grainers and sponge out the veins.

Reverting once more to the stencil patterns, there is one of special excellence to which I feel bound to call attention. This is pattern No. 155, in which flowers of the daisy type, conventionally treated with foliage, all symmetrically arranged, rise from a vase of simple design, but producing a remarkable effect by the clever manner in which ornamental bands in the ground colour are contrasted with the dark hue of the oak.

87.—THE NEW WATERPROOF LIQUID GLUE.

I am loath to be in any way behindhand in bringing under the notice of my readers anything that may prove to be a valuable invention, and as pressure of work on my time is so great just at present as to prevent me from making any particular tests of the "New Waterproof Liquid Glue," of which a sample has been sent me by the New Glue Company, Grange Yard, Valley Road, Shipley, near Bradford, Yorkshire, I have elicited from the Company statements which lead me to draw the following inferences with reference to the speciality they are now prepared to supply.

The New Waterproof Liquid Glue, just placed on the market, is a step in the right direction, and marks an area in advancement towards perfection so far as the production of that indispensable article glue is concerned. The trade mark "Water Glue" fairly describes its leading qualities. Being always liquid, it is always ready for use, requiring no boiling. It sets quickly, and when thoroughly dry will bear lengthened exposure to water without visibly decreasing in strength. In every household, how often have articles come asunder, the glued joints having succumbed to the invisible but deadly enemy, damp? To those who use the Water Glue, such a thing cannot happen. The amateur carpenter and joiner will find a true and trusty friend in this glue, always ready, reliable, and strong. Canoe and boat builders will at last obtain a watertight joint without the aid of the troublesome pitch pot. To builders of model yachts, the Water Glue will be highly welcome, as built models, by its aid, can now be planked up with the certainty of being watertight afterwards. For cyclists, this glue, used as a liquid-tyre cement, will supply a long-felt want. Workers in metal will find it invaluable as a means of causing leather to adhere to smooth metallic surfaces, and it can be used as a lacquer for polished metal, giving it a good colour, and being perfectly impervious to water. It is made up in tins containing 2, 4, and 8 fluid ounces, sold respectively at 3d., 6d., and 1s. per tin by all chemists, ironmongers, and oilmen.

I asked the Company to give me some idea of the merits claimed for it over Le Page's Carriage Glue, a preparation which has hitherto been found most useful of its kind. They claim that taking equal quantities of each, and comparing prices, the Water Glue is cheaper, and that Le Page's Glue is not waterproof or even damp-proof. The American Glue, if allowed to stand in a cold place, will solidify so much, that the pot must be heated by standing it in boiling water. Water Glue is always ready, and can be used for all purposes that Le Page's or any other glue can be used for. I intend myself to give this new glue a trial at the first opportunity, and I trust that those of my readers who may procure and make trial of this new article for public favour will give me an account of the results obtained.

THE EDITOR.

SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** NOTICE TO CORRESPONDENTS.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—LETTERS FROM CORRESPONDENTS.

About Work. — GENIUS writes: — "I was pleased when I read T. O. P.'s letter on July 13th in reply to J. P. A. I fully endorse his remarks, and I am really surprised that such wise individuals as J. P. A. should ever think of subscribing to WORK. If he is such a practical man as he professes to be, why on earth, Mr. Editor, do you not put him on your staff? He would be the right man in the right place, just as WORK is right, and in its right place. WORK is a stepping-stone to mechanical ingenuity. By the aid of WORK many will be led to think and undertake work they never dreamt of. Well, Mr. Editor, I am an amateur worker. I have been practising and inventing about fifteen years. I have made several articles all my own ideas, and was thinking of sending some of them for the benefit of the readers of WORK. But, ah! I stand aside; how dare I, when such men as J. P. A. are on the scene? they will be counted as twaddle."—[Send any papers you like on approval. I do not suppose they will in any way be twaddling.—ED.]

About Work.—W. B. (*Ince, Wigan*) writes:—"I beg to add my opinion to others who have written you week after week on the usefulness of WORK, and how they prize it, notwithstanding the few dissentients who think you could do better by treating only on the subjects that are useful to them. It seems very narrow-minded indeed, considering the wide range and different desires of your various readers that you are expected to supply with information on so many different kinds of work, that you should be expected to deal only with the subject adapted to their own particular calling or liking. For myself, I think a ramble through 'Shop' is well worth the price of the whole. A fellow-clerk of mine first called my attention to No. 1 of WORK through the presentation plate that was given with it—both of us do a little fretwork—and I found such useful information in it, and just the sort I had wanted a long time, that I have continued to take it ever since. I wish you every success in your work, and trust you will keep on the same lines as hitherto."

Tube Saws.—S. M. (*Skelwith Bridge*) writes:—"Seeing an article on tube saws in 'Shop,' I may say they have been in use in our trade for nearly forty years (bobbin-making). They are used to cut small circular blocks out of large timber instead of squaring with circular saw. They are made by W. A., Fell Bridge Iron Works, Windermere, and Gilkes & Co., Canal Iron Works, Kendal. They are made in all sizes down to $\frac{5}{32}$ in. to order. The process of making is by forging a piece of steel, boring out inside to diameter required, placing on a mandrel, and turning to size. Of course they revolve when in use, being fixed in a chuck at the end of a vertical spindle. The block of wood being stationary, they would be easily used, as your correspondent F. A. M. says, as the saws are about 10 in. long. I am glad to say that I have received many useful hints from WORK. I wish you success."

Correspondence.—GAUGE POINT (*Paris*) writes:—"I notice many questions remain unanswered. Give and take is the rule of space in correspondence in WORK, I suppose. I should like to see an increase of 'give;' it only costs a little well-spent time in writing and a half-penny wrapper round it marked 'printer's copy.' It does more good to the writer in his first attempts at stating facts than the writer is aware of. It starts his latent powers of thinking with a flow of ink after his thoughts. One illustration will suffice to explain how it did good. A foreman of a large shoptul of machinists and engineers noticed the superior manner adopted by one man in forging, hardening, and tempering steel springs, and said to him, 'You should write about your work.' 'But I cannot write—that is, fit to be read,' he replied. 'You are mistaken,' was the answer. 'Editors seek facts, and pay no attention to fitness of penmanship. You write mighty facts daily with your bellows, hammer, and tongs. You draw well, and chalk up your notes and marks all right that your mate can understand. Let me have those chalkings in pencil; I will see to the rest of the job; leave plenty of room between every line for my writing.' With much persuasion I got a capital succinct account of his mode of procedure that surprised me by its brevity and lucidity, also some good drawings of tools, and suggestions for improving them, and how to do it; for spring-makers make nearly all the tools they use. I wrote an introduction, added preliminary drawings, and let him tell his work tale in his own way. The subject had not been written upon technically before, but when published in a trade journal, his employer brought the work to me, with the workman's name to it, and asked if it were possible for W. T. to write so capitally. I pointed to his superior work around, and asked, 'Why not? He does more than write: he creates. This is an effort to make others as clever as himself.' He was pleased to see himself in print, and soon afterwards to get a cheque for his writings, which was what he least expected."

Incandescent Electric Lamps.—WHEATSTONE BRIDGE (*Enfield*).—Your letter has been forwarded to our contributor, who thanks you for your kind correction of his reply. You are quite right. The process described is one performed some six years ago, when the writer saw some bulbs being exhausted through tubes left in the necks of the bulbs. WHEATSTONE BRIDGE writes to correct a reply given by G. E. B. on page 157, in answer to G. K. on electric lamps for Bunsen battery. W. B. says: —"The lamp is (as regards the bulb, carbon, and connecting wires) complete before it goes to the pumps for exhaustion. The rough sketch will help to explain, as it shows the lamp as it leaves the glass-blower's hands. You will observe that the wires attached to the carbon filament are already fused into the glass. At the opposite end of the bulb there is a short length of glass tube left on, which is contracted at A. The end B is sealed to the pumps, and the lamp exhausted. The workman then plays with a fine blowpipe jet upon the tube at A, and the outside pressure of the atmosphere (as soon as the glass softens) presses it together, thus sealing the lamp. The workman then draws off the lamp, and the glass assumes the form C. On applying the jet to D it melts the glass, and he removes the lamp. He then melts the sharp point so left to a round end, and the lamp is ready for testing." You will observe that we have taken the liberty of making a few slight alterations in your communication, to render it more readable.

Glass for Electric Lamp.

Wanted, Advice.—J. J. (*Bradford*) writes:—"I have been a subscriber to your valuable paper from the first. I read it every week, and am especially delighted with the 'Shop' column; and I am now taking an opportunity of sending to ask if any reader can inform me how to make something profitable with the tools I have—jack plane, smooth plane, fret bow-saw, chisel, and saws? If so, I shall be highly delighted, for I have been at a standstill, waiting for something cheap to turn up."

Folding Screen in Egyptian Trellis Work.—C. H. O. (*Alderney*) writes:—"In my paper, which appears in No. 18, I observe some slight errors, which may be worth correction. 1. The hinges joining the right hand and centre folds are shown on the face of the framework, instead of being on the edges of the two folds, in which position, of course, all excepting the knuckles would be invisible in the sketch. 2. The title of Fig. 1 should read, 'Details of work in centre panel of recess (half-size).' The trellis work in the lower half of body of screen is only slightly larger than that in Fig. 3, and is like Fig. 1 in pattern, excepting that the intervals between the beads are plain."

"Muntin."—R. J. W. (*Derby*) writes:—"On page 277, No. 18 of WORK, Mr. David Adamson mentions the orthography of the shop word 'muntin.' I beg to say this word puzzled me for years, and I, too, looked in many a dictionary without success. One time, however, I dropped across the word 'mullion, an upright division in a window frame, and have since consoled myself with the idea that 'muntin' is a corruption of 'mullion.' I am a railway coachmaker, and should be glad of instruction in private body-making, especially the mysteries of the 'cant board.'"—[Articles on coach building, etc., are in preparation.—ED.]

Trimming Work.—D. T. D. writes:—"Enclosed please find a query to be answered through WORK. I am still pleased with its appearance, and I think it a great credit—as all their works are—to the publishers. One reader desired you to get the leaves of WORK trimmed or cut, as he termed it. My advice is the same as Punch gave—Don't! Trim your correspondent's if you like, but not mine. I have more respect for WORK when bound up than he has. Great success to WORK and your efforts.—Please don't forget promised article on Zinco."

About Work. — FLAX SPINNER (*Longton*) writes:—"I am writing partly on purpose to congratulate you on the success of WORK, and also to ask for a little information. In the first place, I must congratulate you on the fact that you have had the common sense to see the necessity for such a paper, combined with the pluck to venture the launching of it, and I don't think you will have any cause to regret having done so. I have been a first subscriber to more than one or two trade and technical papers, and I have always found them to split on the same rock. They have not been satisfied to treat work from a working or workman's standpoint, but, after their first temporary success, have launched out in a direction in which the average workman was totally unable to follow. Such groupings of letters as

$$T=\frac{c}{Q-g} \text{ or } V=R-\sqrt{R^2-(\frac{1}{2}C)^2}$$

mean nothing or so much Greek to 90 per cent. o those who take in such a paper as WORK; and hope that all articles, however otherwise mer torious, will be tabooed by you, especially as ther are so many subjects of general interest that can b treated without ascending, or rather descending, t the use of intricate algebraic formulæ. I woul also wish to exclude subjects requiring scientifi knowledge to understand and jaw-cracking scie tific terms to express. I must also express my i dividual objection to a lot of space being cribbe for the purpose of advertisements that do not i any way interest the average reader or trad written for—I mean those quack and medical an other notices which are nowadays crowded int almost every paper we can buy. Surely you ca find enough advertisements of trade requiremen for WORK without offending the eye with the othe I have mentioned. I expect a page or two of Jacol Safe Cure or Warner's Oil some week. Please don't d it."—[I thank you for your commendation of WOR and the manner in which the subjects treated in i are handled. With reference to the advertisement that appear in WORK, I have already pointed ou that differences of opinion exist with regard t these as well as on everything else that is said c done under the sun. Some correspondents say with regard to everything that is done with respec to WORK, "Pray continue to do it;" while the er of others is "Pray don't." If attention were paid t all such conflicting opinions, WORK might come ou one day as a blank sheet with nothing more tha the heading. With regard to every publicatio that sees the light, it is as well to put up with tha which you may not like in it for the sake of tha which appears in it in accordance with your ow particular views and proclivities.—ED.]

Engineering.—YOUNG ENGINEER writes:—" have been a subscriber to WORK since it first cam out, and as I see several of your readers hav offered their opinions on each side, I beg to offe one on the grumbling side. Now, when the pro spectus came out, it said for 'all workmen, pro fessional and amateur.' I have before me the las number, and, so far as I can see, two-thirds of th paper is devoted to joiners and cabinet makers Now, I am an engineer, and the only article tha has appeared is 'Wrought Iron and Steel Girde Work,' by Mr. Campin, that has any direct refer ence to the engineering trade. I should be glad t see a few papers on 'Principles of Machinery, 'Strength of Materials,' 'Designing Machinery, 'Mechanical Drawing,' and other articles on engi neering; and I have not the slightest hesitation i saying they would be appreciated by all those o your readers engaged in the engineering trade I wish every success to WORK, and I hope soo to see it enlarged, supposing you have to increas the price."—[Your subjects will not be neglected You have had evidence of that in the paper by Mr Campin. You must bear in mind that carpentr finds most favour among those who adopt practica work as a hobby.—ED.]

About Work.—SPECTATOR writes:—"I have taken your admirable paper from its commencement, and beg to express my unqualified approva of the manner in which it is conducted. I hav noticed the fault-finding and carping spirit of som of your correspondents, and for my own part, I think if these gentlemen were to consider that th title of your paper is WORK, and *not* 'Talk,' ther would be less of this everlasting grumble, grumble grumble, which, to say the least, is only irritating to the overstrung (?) nerves of poor Mr. Editor, and equally annoying to that portion of your subscribers who are not martyrs to dyspepsia, from which disease your critical correspondents are evidently suffering, if one is to judge the state of their health by their letters. I have introduced the paper to a good many of my friends, and every one of them is thoroughly satisfied and pleased with it."

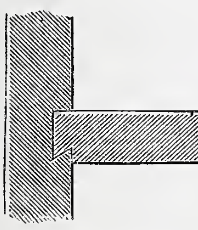
About Work.—G. B. (*Glasgow*) writes:—"DA CAPO thinks there is more talk than work in WORK. It must cause a feeling of sadness to think there is even one reader who can fail to recognise the literary merit of the articles contributed to your journal. They are not only masterpieces in the way of instruction, but bear the stamp of high literary ability, and have afforded me great pleasure in their perusal, quite apart from the instruction they convey. Take, for example, 'Frames' and 'Fretwork,' by J. W. Gleeson-White; 'Binding,' by E. Bonney Steyne; David Adamson's 'Old Bureau;' the 'Folding Chair,' by J. H. Moody; 'Smith Work,' by J. H.; and Fred Miller's 'Wood Carving.' To my thinking, those writers have attained the highest possible perfection, bringing into their subject all that engages the intelligent cultured mind. But I fear we may say to DA CAPO what J. W. Gleeson-White says of Ruskin—the writing in this journal is 'transcendentally' above him; and I trust his remarks will in no way influence past, present, or future writers in WORK."

Building Construction.—T. G. (*Hetton-le-Hole*) writes:—"I have taken in WORK from the first. I like it very well, and I always recommend it to others; but I do think you will make a great mistake if you introduce building construction. There are already many works on building, so I hope you will not take up this subject."—[You are aware, perhaps, that when doctors disagree, those who are not doctors have difficulty at arriving at a decision. Your remarks are inserted to show how hopeless it is for any individual, even an editor, to please every one, and how necessary it is for him to rely on his own opinion.—ED.]

—QUESTIONS ANSWERED BY EDITOR AND STAFF.

Straightening Bird-Cage Wire.—G. C. (*Leith*). As G. C. remarks, this, though a simple question, is a somewhat difficult one in practice. It uld have simplified matters very much, and perps save valuable space, if G. C. had intimated at plans he has tried. Greater difficulty will be perienced in straightening brass wire than iron, being so much harder. Some time since I needed her stout wire in straight lengths, and accomshed the work by fingers and thumbs, making it rve in the opposite direction to the curl. This is effective, but slow, and only practicable for a all quantity. It can also be done by striking it th light blows on hard wood with a wood hamer. This, too, is rather slow. The most successl plan, however, that I can suggest for large antities of wire is to cut it in suitable lengths, d run it through a tinman's set of rollers, which arranged with two soles under and one on the p. Perhaps G. C. is aware that there are two alities of brass wire in the market—a soft wire, d what is known as "hard rolled," used by wellers, etc. I should advise him to get the rmer. Perhaps G. C. will pardon me if I remark at brass wire is not the best for the purpose he quires; it soon gets discoloured, but worse than at, the clear musical ring which it gives when ruck by a bird is said to destroy the purity of a rd's song—it picks up the sound as a false note. I ve known a canary whose song was spoiled by e piping of a chicken which it had heard, and inoduced into its music. Personally, I should not ge a valuable songster with brass wire.—O. B.

Fixing Tops.—E. W. (*East Sheen*).—Yes, the st way of fixing these in similar positions to that ferred to is undoubtedly by dovetailing them into e ends; and you are also correct in supposing at this form of construction is independent of achinery: in fact, it is a very ordinary joint. No ecial tools are required. All you have to do is to ark and cut the dovetails on the ends of the tops. his can easily be done by running the gauge along, f course after you have squared them up, and then rming the dovetail with chisel. Mark off the ovetail on the back edges of the end pieces. With e square scribe lines from back to front of the ner sides of the ends. These lines serve as guides work to, between which the wood to the required epth must be removed. This can be done with a hisel, using if necessary an "old woman's tooth," a ol with which you are doubtless acquainted, to vel the bottom. Should you not know what the old woman's tooth" is, may explain that it a router, and that a hort description of one r home manufacture ill appear ere long. he sloping side of the roove for the dovetail also formed by cutng away with the hisel. Such, in brief, an outline of the proess, which will be more ully treated in some rojected articles on ovetailing. Instead of oing the whole of the utting with a chisel a ne saw may be run along the lines to the depth equired, leaving the waste wood to be removed vith the chisel. Do not cut right through to the ront, unless the front edges are to be faced, and f course, whatever distance you stop from the ront will have to be removed from the front edge f the dovetail on the top or shelf. In cabinet work is only necessary to form a dovetail on one side f the tops, usually on the under side, the other eing left square. The diagram here given will ake this clear. You will see that it is a comparaively easy matter to get the top on the upper side o shoulder well to the end, or, in other words, to ake a good fit, as all you have to do is to cut the roove straight. The appearance of the lower side not of so much consequence, as it is not seen. he parts are to be fastened together with glue, vhich, however, should not come within a few nches of the front.—D. A.

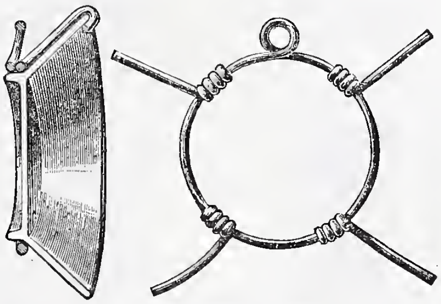


Dovetail for Tops.

Minor Carpentry.—W. H. R. (*London, W.*) vrites:—"Might I ask your kind help in the folowing:—I am desirous of doing various little jobs t home, such as making picture frames, flower oxes, foot-stools, salt boxes, benches, and suchike odd articles; and if you would tell me the tools, vith their length and weight, I should require, I hould be much obliged. I notice that some saws vith a rimmed back, such as butchers use, are also nade use of by wood workers. Would I require uch an article? What is your opinion of the patent crewdriver advertised by Harger Bros.? The tool loes away with the necessity of holding the screw. t is called Kolb's 'Common-Sense Screwdriver.'"—You shall be shown how to make the articles you nention, and a paper shall be written on a handy cit of tools for beginners. The saw with the immed back that you speak of is a tenon saw, and s used chiefly for cutting across the grain and for ard wood. I have one of Kolb's "Common-Sense Screwdrivers" in use. It is a handy tool, but I have een so long accustomed to the ordinary screwdriver that I prefer it to any of the patent screwdrivers.—ED.].

Insurance of Tools.—T. T. (*Kennington*) vrites:—"A question I wish to ask is, Can you tell me if I can insure my tools from fire anywhere, and also, if possible, the cost of a policy? I shall feel greatly obliged if you can answer these questions in their turn."—[I do not think there is any office in which men can insure their tools. I shall be happy to consult with any who are interested in this direction as to the practicability of setting on foot a Company with this object. There are difficulties in the way; but doubtless these may be overcome. If any established industrial office, with a large staff of agents, would take the matter up and create a new branch for the development of this object, it would be the more easily carried.—ED.].

Hanging China.—G. D. M. (*Inverness, N.B.*).—It is true that one often finds the old Delft plates with holes bored through them, and a huge knot of string defacing the plaque itself; but, in addition to the risk of drilling the hole, would it not be wiser to hang it with an ordinary plate wire, sold nowadays at most china-ware shops, or, if needs be, made at home easily enough? As the diagram shows, it is but a circle of wire, large enough to slip over the rim—the foot, so to speak—of the plate, with four other pieces twisted on. These are bent



Wire for Hanging China.

over the edge to the front of the plate, and then nipped close off, say, ½ in. from margin, and may be safely trusted to support the most valuable old china. A round frame, turned to enclose the plate as though it were a mirror, is also used at times; but to me it is too heavy for the decoration of a plate, unless, indeed, it be one of the old majolica ones with a pictorial treatment, where, save for the accident of being on earthenware, instead of on a panel or canvas, the plate is to all intents and purposes a round picture.—T. G. W.

Draught Screen.—W. M. D. (*Govan*).—I am sorry I cannot possibly tell you how to make a screen of the kind you describe for the sum you do not wish to exceed, any more than I can tell you how to make a half-sovereign worth 20s. I take it from your description that you want to use Japanese leather paper, but of course common embossed wall paper will be much cheaper. Your question is, however, couched in such very vague terms that I am by no means sure of what you really do want to make. For example, though you give dimensions, you do not say whether you want a folding screen. I can only suppose you do, and you will easily see that the cost depends greatly on the number of folds wanted. With every disposition to assist all who apply for information in "Shop," it is utterly impossible to do so satisfactorily unless inquirers will state clearly what they want. If you write more fully, I shall be able to answer you more helpfully.—D. D.

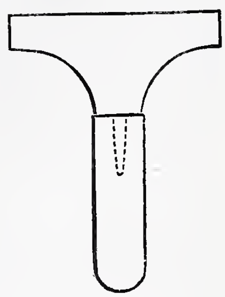
Fire Blower.—R. B. (*Colne*).—Your sketch gives a very fair idea of the thing you want, so that with the following hints no doubt you will be able to make one to suit your purpose, though, if for an ordinary fire, you will find the common bellows do just as well. I do not think the kind you want would be sufficiently useful to justify a lengthy description—at present, at any rate; but if it should seem likely to meet the wishes of any considerable number of readers, an article may be devoted to the subject. Meanwhile, you or any other reader inquiring on any point you may be in difficulty about, will be answered in these columns. Size, of course, depends on use to be made of blower, which consists essentially of a thin narrow box with a revolving wheel inside. This wheel is something like a steamboat screw or propeller, the number of blades depending on circumstances. The blades for a small one may be made of thin brass or block tin fitted into a hub or axle. One end of this projects through one side of the box and has a pulley wheel fixed to it. Near to it is another revolving wheel with a handle. A cord communicates motion from this handle wheel to the other connected with the fan. If preferred, geared wheels may be used instead. A suitable nozzle and spaces for the admission of air complete the arrangement.—D. A.

Inlaying.—H. L. M. (*Birmingham*).—Gum is not suitable for fastening the pieces of inlay together or to the ground. Good ordinary glue is the best thing you can use. Unless the pieces are very thin they will not be injured in colour, though of course if the inlay is very light you will choose a colourless glue. With Lepage's carriage glue you can lay any inlay without fear of discoloration. Fix the inlay up first on a sheet of paper. When dry clean up with a toothed plane, the veneer and inlay being in one sheet supported by the paper. Lay the whole paper side upwards, with a cant on the panel; after the glue has set clean off in the usual manner. You must remember that though it is of comparatively small consequence what kind of glue you use to fasten the pieces of inlay to the paper, if there is much light wood, colourless glue is necessary to attach the veneer to the ground, as the heat of the cant may cause a dark coloured glue to leave a stain. The pattern for fine work should be pounced, as sufficient accuracy cannot be got by tracing. Use powdered asphalte in a piece of muslin or a roll of flannel well dusted with asphalte. After pouncing the design down, hold the pounced pattern to the fire. This melts the asphalte, and the outline is then indelible. You may use coloured chalks instead of asphalte, but the outlines require careful handling, as they are easily erased. By a little adaptation you may use almost any of the ordinary fretwork designs for inlaying purposes; but if you mean designs for marquetry inlays, such as are seen on so much modern furniture, you will find a considerable difficulty in obtaining them, as none are published in this country. Tiersot, of Paris, publishes designs for inlays, but they are not in the style now fashionable here; so they may not suit you. The only thing you can do, or, at least, that I can suggest, is that you apply to any furniture designer whom you may know. He may be willing to supply you; but, as the designs will have to be specially drawn, you must be prepared to pay fairly for them. Possibly Mr. David Adamson, whose name will be familiar to you in these pages, may be willing to supply you. The whole subject of marquetry inlaying will be treated of in these pages in due course.—D. D.

Linseed Oil.—CUMRO (*Rhyl*).—Raw linseed oil may be made thicker by boiling, but by doing this it is rendered unsuitable for French polishing purposes. It will not injure the polish, but if thickened it clogs the work; and it is just because raw oil is thin that it is preferred. I do not know whether I am right in supposing that you wish to render the oil serviceable both for oiling and filling at one operation; but if so, let me attempt to dissuade you from doing this. Your question is put rather obscurely, so I may be wrong in supposing that such is your intention.—D. A.

Reproduction of Fretwork Designs.—I. C. G. (*Reading*).—Yes, fretwork designs can be multiplied by the blue printing process, the reproduction, of course, showing the dark lines of the original white on a blue ground. The original must be interposed between a sheet of glass and the blue paper either in a frame or otherwise. Both papers must be kept in close contact during the printing, or the print will be indistinct. Patterns printed in blue ink, such as those of some of the Italian designs, cannot be copied by this means. The printing may be much expedited by oiling the original, so as to make it semi-transparent. A colourless oil should be used for the purpose.—L. I. P.

Lettering in Gilt.—F. W. H. (*Sheffield*).—In lettering in gilt on leather proceed thus:—Wash the leather with paste-water, *i.e.*, water with a little flour paste mixed in it. When it has become thoroughly dry, coat it over evenly with glaire (prepared from fresh hen eggs); use the whites only, and beat up until a dry-looking, white froth has been formed of the whole mass. After heating allow it to settle. The froth will disappear and leave a clear amber-coloured liquid as thin as water. When the first coat is dry, give it a second, and allow it to dry also. Rub it over with a little hog's lard or olive oil, and lay on the gold leaf. The letters used are made of brass with wooden handles; they are heated over a gas stove, and, when the proper degree of heat is obtained, they are pressed one by one on the top of the gold leaf; the heat causes the gold to adhere to the leather. When the lettering is completed, the surplus gold is rubbed off with an oily rag kept for the purpose. The procedure for cloth is much the same. Omit the paste washing, and give only one coat of glaire. (See reply to ANXIOUS ONE in No. 14, page 221.) In doing the lettering for your sister, you should get a hand palette made with the name and address engraved in relief upon it. Any engraver could make it for you, but it would be best to apply to Messrs. Royle and Son, Lovell's Court, Paternoster Row, as they will know exactly what you want. However, the sketch given above will show the shape of the palette; the lettering is cut on the face.—G. C.



Hand Palette.

Fretwork Designs.—W. V. T. sends a modification of design for cabinet in fretwork, by Mr. Gleeson-White, in No. 1 of WORK, and writes:—"I should be also much obliged if you could tell me of a firm who would be likely to buy designs, and of the usual means of transacting that sort of business."—Your modification of Mr. White's design is very nicely rendered; but I must ask readers of "ours" to take my word for this, as it is not possible to find space to publish it. J. H. Skinner and Co., East Dercham; Harger Bros., Settle, Yorkshire; Booth Brothers, Dublin, all buy designs; but purchase will depend entirely on suitability of designs for their purpose. The usual mode of transacting business of this kind is to submit designs, and name terms at which you would part with them.

Griffin's Fret Saws.—J. A. J. (*Stratford, E.*)—In reply to your intimation that you "would esteem it a favour if I could give you the address of the makers of Griffin's patent fret saws," I regret to say that I am unable to do so. Possibly Messrs. Churchill & Co., 21, Cross Street, Finsbury, E.C., may give you the information you require, or what would do very nearly as well. If you want to sell them retail they would supply you on the most favourable terms.

Enlarging Camera.—CUPID (*Castlejohn*).—If you have made the enlarging camera as described, you will find the process of making enlargements very simple indeed. The *modus operandi* is as follows:—Put your negative in the carrier with the film side inwards; focus sharply upon the ground glass to the size you desire, in which you are guided by the lines on the glass. Then, in the dark room, put the paper in the slide, fastening it in position with fine drawing tacks, and keeping it to the lines corresponding with those on the glass to which you focussed your picture; put the slide in the camera, draw the shutter, and expose. Return to the dark room and develop the picture. The developer is made up as follows:—No. 1. Neutral oxalate of potash, 8 oz.; boiling water, 16 oz. No. 2. Sulphate of iron, 12 oz.; boiling water, 16 oz. No. 3. Bromide of potassium, 60 grs.; water, 1 oz. For use, mix the developer in the following order:—No. 1, 5 oz.; No. 2, 1 oz.; No. 3, 12 drops. Put the paper in the dish and flow the solution over it; gently rock till the image appears and develops to the required tone. Pour off the developer, and, without washing, flood the print with a clearing solution of sulphuric acid, 1 oz., water, 80 oz. Allow it to remain one minute, pour off and repeat. Then wash well and immerse in fixing bath (hyposulphite of soda, 4 oz., water, 20 oz.) for ten minutes. Wash in running water for two hours; then hang up to dry. Do not dry between blotting paper as in the silver print process. There are various brands of paper in the market, all of which are fairly good and give pleasing results. I should, however, recommend you to use Eastman's C paper; it has a rough surface, and is easy to work, giving pure blacks and whites similar to good pencil drawings. The most difficult thing is to gauge the right exposure—everything depending upon the quality of the light, which in this country is a varying quantity. The best way to find the proper time of exposure is to put a strip of the bromide paper in the slide, giving it different exposures by drawing out the shutter one-fourth of its length, then half, then three-fourths, and then full out, with a pause of, say, half a minute between each pull. Develop the strip and see which part is rightly exposed; then expose your picture accordingly. Keep the camera close to a window, with a northern exposure, if possible, but in no case facing the sun, and raise the carrier end of it as much skywards as you can. Avoid walking about or shaking the floor during the time you are making the exposure, or you will get a blurred image. The foregoing is as concise a description of enlarging as can be given in "Shop:" but if you already know something about photography you will easily grasp the details, and after a few trials succeed in making good pictures; but I must remind you that under-exposed negatives will not do for enlarging from. Use negatives that are rather over-exposed, thin, but full of detail, and the results will be pleasing.—G. LE B.

Brass Finishing.—C. H. C. (*Margate*).—This subject will be touched on in due time; but, as I have said before, it is impossible to handle at once everything that it is desirable to handle.

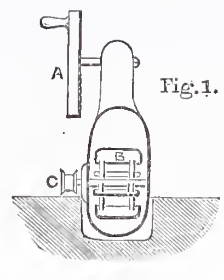
Wooden Beehives.—G. G. (*Hammersmith*).—In reply to your inquiry for papers on the construction of wooden beehives, I will endeavour to give you something to do in this direction in the winter months.

Designs for Wood Carving.—J. P. (*Dundee*).—Mr. George Alfred Rogers, wood carver, 29, Maddox Street, London, W., not only supplies designs for wood carving, but he also lends specimens for learners to copy, carved by himself. It is some time since I have seen or heard from him, but I furnish you with his address, trusting that he is still in the land of the living.

The Tenant's Greenhouse.—G. J. (*Peckham, S.E.*) and J. W. C. J. (*East Dulwich*).—In reply to your letters let me say that Mr. Le Brun's mode of construction referred only to a mode of barring the *landlord's right* to claim a greenhouse erected by the tenant for his own convenience. As to the points mooted in your letters, it would be better for you to place the matter before your respective lawyers, who will advise you according to their conception of the bearing that the Metropolitan Building Act (1855) has upon the subject.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Machine for Current of Air.—CENTREBIT (*Tullow*) writes in reply to BELLOWS (see page 190), who asks in No. 12 of WORK for a machine to give a constant current of air:—"I enclose a few rough drawings of a fan much used in various parts of this country, especially in those districts where the anthracite, or native hard coal, is abundant. It is made entirely of iron, of which Fig. 1 gives the general shape; in height it is about $2\frac{1}{2}$ ft. by 6 in. broad. The large wheel is turned by the hand, and imparts the motion by means of a belt to the small wheel, C (Fig. 2); this is on the fan axle, and the fan, B, inside moves in conjunction with it, drawing in the air at A (Fig. 1), and expelling it through the pipe, B (same figure). It is shown in position in Fig. 3, of which A is the machine, B the hearth, C the fire,



Side View: Section.

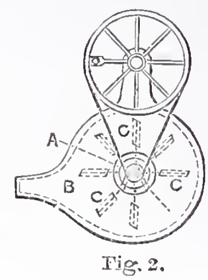

Fig. 2.

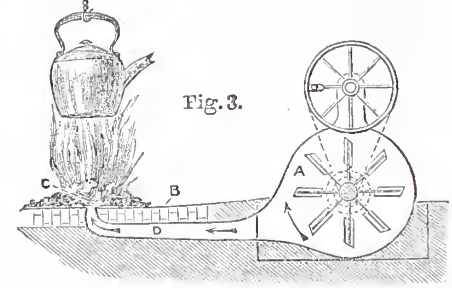
Front View.

A, Hole to Supply the Fan with Air. C, C, C, Shows Position of Fan.



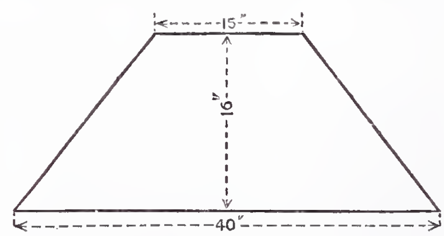
Section in Position.

A, Machine. B, Hearth. C, Fire.

and D the supply pipe. As you see by Fig. 3, it is used with the flat hearth and large open chimney; but I have no doubt that it could be fitted to a fire-place. It is made by Peirce & Co., Wexford, and costs 9s. 6d. I do not black on different parts of it. On the top I drew the flying stork; on the left top corner and right side, the stork standing, and several others on different parts. It made a great difference in the frame, and made it look very pretty."

Drilling Square Holes.—T. M. B. (*Colchester*) writes in reply to A READER (see page 270):—"This appliance was introduced into England many years ago, and Britannia Company advertised it. But not one was sold. It is so much quicker to bore a round hole and drift it out with a square drift with cutting edges. This applies to either metals or wood. The drifts can be driven through with a hammer, or drawn through by a screw and proper appliance."

Dulcimer.—MUSIC (*Govan*) writes:—"In reference to question by T. C. B. in 'Shop,' July 13th, page 268, about sound board of dulcimer, will you allow me to send enclosed sketch with singer marked, as I know it to be the angle to please any one who tries? I am only an amateur, but like T. C. B. have made three dulcimers, and have one at present to dimensions given, which is capable of



Sounding Board of Dulcimer.

playing on platform, or with other instruments if desired, or for that matter anywhere—the corner of the street if you like. Hope you will excuse the amateur sketch, but I like a tip myself, and therefore like to give one when that is possible. Should it be convenient I shall be pleased to let T. C. B., or any others who have a taste that way, examine mine, the shape I mean, not the workmanship, which is only amateur. I trust this may be of some use to those who want to know."

Child's Wooden Toys.—B. A. B. (*Hampstead*) writes in reply to W. A. (*Hanley*) (see page 270):—"He can obtain toys wholesale at several houses in and close to Houndsditch. There is a good little book on making toys, published by Gill, 170, Strand, W.C. It is by J. Lukin, B.A., price 1s."

Trade Note.

"SCRIPP'S League of Newspapers," composed of six newspapers published in the leading cities of the Central States, and circulating largely among working-men, have sent, at their own expense, a deputation of representatives of trades and industries to the Paris Exhibition. These representatives are forty in number, four of whom are women, and include the engineers, foundrymen, sewing-machine makers, blacksmiths, car builders, safe and lock makers, shipbuilders, stove makers, and others, each individual of the forty representing a distinct occupation. Most of the men occupy positions of trust and responsibility in their respective vocations, and the names of several are familiar to us upon this side of the water, as Mr. Robert E. Masters, Joseph Thorpe, Edmund G. Vail, and William J. Keep. It is a pity that our shrewd, practical workmen have not more opportunities for indulging in travel; it would counteract that narrowness of mind which, through no fault of their own, is too generally a feature in their characters. Their observations would certainly be as fruitful as those of their employers.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

MELHUISH'S New Pattern

Combined CARVING and WORK BENCH — CABINET, £8 14 0. —

Made from American Bass Wood, Stained and Polished, and can be made to Harmonise with any Furniture.

Fitted with the following List of Warranted Tools, precisely the same as we supply to Practical Workmen:

	s.	d.
1 Duplex Iron Plane	1	3
1 Straightedge, 3 ft. 6 in. ...	1	6
1 Bright Hammer	1	6
1 2 ft. 2-fold Rule	1	0
3 Twist Gimlets	0	10
3 Patent Bradawls	0	8
1 Screwdriver each, 10d., 1/6	2	4
1 Cabinet Scraper	0	5
6 Assorted Firmer Chisels ...	4	2
3 Assorted Firmer Gouges ...	2	1
1 6 in. Combination Square	2	4
1 Bright Bench Holdfast ...	5	6
1 Boxed Oilstone	3	0
1 Can Liquid Glue	1	6
1 Beech Mallet	1	6
1 Beech Mitre Block	1	3
1 Frame Bow Saw	3	6
1 9 in. Tenon Saw	3	0
1 $2\frac{1}{4}$ in. Jack Plane	5	0
1 2 in. Smooth Plane	3	4

		s.	d.
1 Joiner's Hammer		1	2
1 Melhuish's Handsaw ...		3	6
1 Box Drawing Knife		1	9
1 Brace, and Set of 24 well-assorted Bright Boring Bits		6	9
1 Pair Pincers		1	3
1 Spokeshave		0	9
1 Beechwood Gauge		1	3
2 Rasps, handled		1	10
1 Pencil		0	1
And our Patent Combined Tool, Joinery, and Wood-Carving Work Bench Cabinet, with Vertical Bench Stop and Patent Vice, &c., complete	£5	10	0
Total	£8	14	0

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the ***Inventor and Manufacturer,***

Highest Award—Gold Medal for Tools and Patterns.

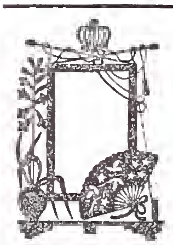
Machines, Designs, Tools, Wood, Mirrors, Hinges and Fittings, Varnish, Etc.

Fret-saw Outfit on Card, with Instructions free, 2s. 6d.; No. 2, with wood, 3s 6d.; Superior ditto, 6s. 0d.; Set of 12 best Carving Tools, with boxwood handles, ready for use, price, free, 9s. 0d.

If you want good designs, and are competing for exhibition, try ours, for which we receive testimonials daily.

☞ See our complete Catalogue, 64 pages, quarto, containing the best variety of designs published, sent free for 6 stamps.

HARGER BROS., SETTLE.



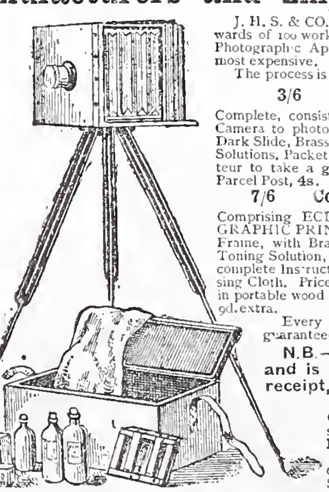
FRETWORK PATTERNS.

FRETWORKERS who appreciate First-class Designs should write for our Catalogue of nearly **400 Patterns**, admitted to be the best in the Trade. Catalogue sent post free on receipt of **4d.**, stamps. List of Tools and Materials is also enclosed.

BOOTH BROTHERS,
63. *UPPER STEPHEN STREET,*
DUBLIN.

J. H. SKINNER & CO., EAST DEREHAM, NORFOLK,

Manufacturers and Importers of Photographic Apparatus and Fretwork Materials.



J. H. S. & CO. have now a large Factory with accommodation for upwards of 100 workmen, which is used exclusively for the manufacture of Photographic Apparatus of every description, from the cheapest to the most expensive.

The process is simplicity itself. Full Instructions supplied with each set.

3/6 The Eclipse Camera Set. 3/6

Complete, consisting of a Polished Mahogany Sliding Bellows, ¼-plate Camera to photograph full-size carte-de-visites, with Focussing Screen, Dark Slide, Brass-mounted Lens, Brass Fittings, Developing and Fixing Solutions, Packet of Dry Plates, and full Instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**, or securely packed by Parcel Post, **4s.**

7/6 Complete Photographic Outfit. 7/6

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of Hardwood Printing Frame, with Brass Spring Back, Sensitised Albuminised Paper, Gold Toning Solution, Fixing Solution, Glass Rods, Cards for Mounting, with complete Instructions. Also Hardwood Folding Tripod Stand and Focussing Cloth. Price **7s. 6d.** Securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in illustration, 9d. extra.

Every Set is carefully examined before being sent out, and guaranteed to be in working order.

N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase money.

Better Sets, 10s. 6d., 21s., 42s., 100s., and upwards. Complete Catalogue of Photographic Apparatus, one stamp. **J. H. SKINNER & CO., EAST DEREHAM, NORFOLK.**

Wholesale Agent for London—J. MOTHERSILL, 60, Holloway Road, N., and 6, Southampton Row, where Samples may be seen.

Timber Yards, Sawing and Planing Mills covering about Two Acres near Railway Station.

J. H. S. & CO. keep regularly in stock about **120,000 FEET OF FRETWOOD,** solid and 3-ply, veneers, &c., besides a very large quantity of Logs, Planks, and Boards, Carving and Turning Wood, &c., and **200,000 FULL-SIZE DESIGNS for Fretwork, Wood Carving, &c.,** besides an immense Stock of Joiners' Tool Chests, Fretwork Outfits, Drills, Saw Frames, Hand and Treadle Machines, Saw Blades, &c. &c.

Specialities for 1888 & 1889.—Books of New Designs. FRETWORK No. 1, containing 12 Large Sheets, price 1s. No. 2, containing 20 Sheets of larger and more elaborate Patterns, 2s. 6d. Book of Wood Carving Designs, containing 14 Patterns, price 1s.; these are all New Patterns, not sold in any other form, and would, if sold separately, cost three or four times the amount charged. Fretworker's Handbook and Workshop Guide, price 1s. New Designs. All Patterns greatly reduced in price.

Complete Fretwork Outfit, comprising 12-inch Steel Frame, 48 Saws, Awl, File, 4 Designs (with sufficient planed Wood, gratis), and 1s. Handbook on Fretwork, price 3s. 6d., carriage paid. 12 feet Assorted Planed Fretwood, 3s. 6d.

☞ Special Fretwork Design, in commemoration of Her Majesty's Jubilee, size, 36 in. by 26 in., price 2s. 6d.

Catalogue of Machines, Designs, Wood, Tools, &c., with several Hundred Illustrations, and full Instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. Good Fret Saws, 1s. 6d. per gross; best ditto, 2s. per gross.

Eclipse Design, No. 102.

Wall Bracket. Price 5d.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 28.] SATURDAY, SEPTEMBER 28, 1889. [Price One Penny.

. HANDY FOLDING BENCH FOR WOOD WORKERS.

BY DAVID DENNING.

'ERHAPS the following account of a small arpenter's bench may be of some assistance o wood workers who are cramped for room, ıs I was when I contrived the one I purpose lescribing. It certainly was not as good as ı properly-made bench, but then this takes ıp a considerable amount of space, and, noreover, requires almost a special work-oom. In the house ıt which I was then iving, no such room vas available, and the lomestic workshop ıad to be dispensed with—only for a time, ıowever; for before very long the contrivance to be described was rigged ıp, and, in default of ı better, answered its purpose well enough. One often hears amateurs complain of having no place which they can use as a workroom; but, after all, there are, I take it, comparatively few houses in which they might not gratify their tastes. In the one referred to, there seemed no likely spot, and the position I ultimately chose—it certainly was "Hobson's choice:" either avail myself of it or go without a bench—may not commend itself to the fastidious worker. I mention the situation and surroundings to encourage others who may be similarly placed. To begin with the "shop" was underground, and, beyond a mere glimmer, no daylight was ever visible in it. It was, in fact, nothing but an underground passage from which coal cellar and larder opened out. A permanent standing bench of the usual size was out of the question, and I resolved to see what could be done with a folding one. It should be said that no heavy work was contemplated, nor yet any of large size. The limited area, apart from other considerations, would prevent that, something that would do for odd jobs and small work being quite sufficient for my purpose. Therefore those in whose minds the above title may have raised visions of a perfectly appointed work bench and all its accompanying outfit will, I fear, be disappointed; still others, no doubt, will welcome a few suggestions which, however primitive they may be, at least have the merit of being based on personal experience. It may further be added that no unnecessary expense was incurred, and that this, as will be seen, was of the most trifling character. Were I to suggest possible improvements, whatever value there might otherwise be in the following description I fear would be reduced. I shall, therefore, content myself with saying that the bench, though of the crudest form, answered very well in the circumstances, and I think it will be more helpful to tell exactly what it was than to tell how it might be improved on.

In order to get to one of the compartments opening out of the passage—the coal cellar, I think—it was necessary that the bench when folded should not project more than a few inches from the wall to which it was attached, and only one part of the wall was available for this purpose. Fortunately, there was a gas bracket just above the place the bench was to occupy, so that no great inconvenience was caused by the light. If that from the fixed bracket did not suit for any particular piece of work, the difficulty was easily got over by having a piece of indiarubber tubing and a very

rough but serviceable portable gas stand or bracket. A description of this must, however, stand over, as it can hardly be considered part of the bench.

The top of this was formed of a couple of 1-in. pine boards, screwed together to form one piece. Only the top surface and front edge were planed over, the remainder being left quite rough. Perhaps I should say that when I began it the intention was that the bench should be only of a temporary character, or a little more care might have been taken both in material and finish. Pine, for instance, is not so suitable for the purpose as some harder wood, though this, after all, is only preferable on account of its being more durable and not so likely to be injured. The screws, of course, were driven in through the bottom board, care being taken that their points did not project beyond the upper surface. By using plenty of them—and, if I remember, some glue between the two boards—a plank practically as useful and solid as if it had been formed of one piece was got. The only reason for building the top up in this way was that I happened to have the inch stuff by me, but had none thicker. If I had had any sufficiently thick I should have used it, and avoided the then unnecessary labour of screwing two pieces together. The size of the top was about 4 ft. long + 11 in. wide. To attach this to the wall another piece of wood, say 4 in. wide, was taken, the same length as the top and of 1-in. stuff. Writing from memory, I am unable to give exact sizes, but these are of little consequence, as if the principle of the contrivance be understood there will be no difficulty in any one making a similar bench of such dimensions as may be most convenient to himself. Where sizes are mentioned, it will therefore be understood that they are given more by way of suggestion, though in the main they approximate very closely to those used. I should explain here that the wall to which the bench was fixed was of brick, not of lath and plaster, so that there was no great difficulty in securely fastening it. Lath and plaster are, no doubt, good enough in their way, but I don't advise any one to fit his bench against such a wall; but even then, by tapping on them, he will soon find out where the solid wood into which nails may be driven lies. However, in a brick wall holdfasts were easily driven—too easily, indeed—into the mortar, or stuff so called, and sufficiently resembling it to have passed the authority duly appointed to certify that everything was fit and proper. We who have inhabited houses erected by the speculative builder know how very careful he is only to use the very best of everything; otherwise, in this particular instance, in my ignorance I should have called his mortar sand. Whatever it was, nails would not hold in it, and it is not altogether easy to drive them into bricks. The alternative, therefore, is to plug the walls wherever a nail is to be inserted. This I managed, and I think it is a way commonly adopted, by clearing out some of the mortar here and there between the bricks, making, in fact, a good hole between them, and hammering in pieces of wood to tightly fill them. A small ordinary hammer is no good for this, but the coal hammer will do very well, as it is of the utmost importance that the plugs or wedges be very tightly fitted in. Nails may then be driven in and held securely.

The wall having been prepared at a suitable height for the bench, the piece of wood by which it has been stated it is attached to the wall was nailed up. The extra hold which nails have when driven in slantingly in opposite directions has already been referred to in an early number of WORK by Mr. Adamson, in his articles on "Artistic Furniture," and the novice cannot do better than refer to them.

With regard to the height of such a bench there is no reason why the maker should not suit his own convenience. The practised worker becomes accustomed to work at the ordinary bench height, but it seems absurd, apart from custom, to suppose that one height can be naturally the most convenient for both tall and short people. I venture on this digression to prevent any amateur thinking that the regulation height of benches must necessarily be the best for him whether he be short or tall. Let him choose the height at which he can have the most command over the tools he is using, and that this in practical workshops is to a great extent a matter of custom may be seen by noticing the equal facility with which both the tall and short men work at benches of the same height. The amateur who may be supposed not to be able to work more freely at one height than another should have his bench at such a height that he can do his work conveniently without the necessity of stooping too much. At the same time, he must not have it so high as not to be able to stand well over his work. It will thus be seen that considerable latitude is allowable, although no doubt something near ordinary bench height is about the best. This may be stated as about 2 ft. 6 in. Personally, I find this the best; but an inch or two for general work does not make much difference. In an ordinary bench the height can be easily altered by either cutting the legs shorter or putting something under them; but as this folding bench is hinged to the wall, it will be as well to decide beforehand on whatever height may seem most convenient, to avoid troublesome alterations afterwards.

Three good strong iron butt hinges formed the connection between the top and the piece nailed to the wall. The hinges were fastened to the back edge of the top with knuckles upwards, as the top, when the bench was not in use, was designed to fold in this direction, and not to hang downwards. Those who have read the recent instructions on "Hinges" will not require to be told that back flaps might be used instead of butts, and that they would have to be fastened to the upper surface of the top, or, rather, sunk into it. For further directions about this part of the work the beginner who has no very definite ideas how to go about it may be referred to the above-mentioned articles, in order to save recapitulation of the instructions they contain.

So far as we have gone, it will be seen that the bench, though supported behind, has nothing to sustain it in front. Without some arrangement to do so, the hinges could not bear the strain, nor even if they could would the top be rigid enough to be worked on. I used two legs, which were hinged to the top near the ends and front, so that on this being lifted they hung down and were out of the way. They were, if I may use so grandiloquent a word to such a very simple arrangement, self-adjusting, for on lowering the top they naturally fell into their proper position, and required the smallest possible amount of humouring to get them in their places exactly. The legs themselves require very little description, as they were simply a couple of $2\frac{1}{2}$-in. squares; one of them, I think, was an old kitchen table leg, and the other was an odd bit that came in handy. Beyond cutting them to the right length and squaring off both ends, they required no preparation.

Back-flap hinges were used to attach them to the top, one to each leg, where, of course, it was fastened to the back. Before hingeing them to the top both legs were connected by a piece of board. This was nailed on to the front sides, and being subsequently bored with holes, in which pegs were placed, served to support boards while their edges were being planed up. The width of the board was not great, say, 8 to 10 in., as no large work was done on the bench. It was of 1-in. stuff, and the holes were simply made as wanted till there were enough of them with a centre bit.

I have mentioned this board, as on its thickness depends to some extent the exact distance at which the legs are placed from the front edge of the top.

Perhaps I can make their position clear by saying that the front of this board should be flush with the front edge of the top when the bench is in use. The object of this will be apparent on trial if it is not already so.

At first, instead of a bench screw, I used a small stop, screwed to the front edge of the top, as shown in Fig. 1, the triangular space being prepared to jamb the end of anything being planed up into it. Of course this, though fairly good, is not so satisfactory as proper bench screws, of which I afterwards got one. These, as I daresay is well known, are both single and double, *i.e.*, with either one or two screws; and it is almost needless to say that only a single one was used on this bench. A few words describing the way it was fixed may not be amiss.

With the appliance are included two blocks, one of which is threaded for the screw; the other simply fits quite loosely. The former one must be fastened in some way to the bench top, so that on turning the screw the other is brought up to this as far as may be necessary to hold anything it may be desired to fix. I managed as follows. The screwed block I made fast to the under-side of the top, removing a piece of the board last referred to away for the purpose of affording it space. To keep the movable block with its upper edge level with the top of the bench, I affixed a wooden guide rod to it. This was of some strong, tough wood—probably ash—glued into the movable block, and sliding with a hole bored through the other. This hole should be large enough to let the guide pass quite easily and freely through it.

As a bench stop, a piece of wood was used which fitted quite tightly within a rectangular hole bored through the top. The stop itself should be at least an inch or two longer than the thickness of the top. When not required for use, a tap with the hammer from above levels it with the bench, and to raise it the hammer is applied underneath. Such a bench stop is by no means to be despised, and it may be questioned whether some of the patent arrangements are superior to it in every way. Anyhow, its simplicity is the reason why it is recommended here, and any man who can't use it may depend that it is not so much owing to the inefficiency of the stop as to his own want of skill.

So far as the bench goes this completes its description; but there are—or, rather, were—one or two little matters which, though not actually part of itself, in connection with it may very appropriately be noticed. For one thing, it soon became evident that when folded up against the wall something more than a piece of board resting on the ground was necessary to keep it there. Somehow or other, the end of that unfortunate plank, which seemed quite out of the way, was always coming in contact with somebody's beetle-crushers, or they with it. It was not altogether satisfactory, and nobody ever thought, apparently, that it might be avoided by the simple expedient of walking in the centre of the passage. My own private conviction is that before that bench was put up those who used the passage kept close to the wall on the side opposite to it; ever afterwards, however, rubbing along the bench side, till I put up a catch, which held the bench to the wall. This catch, like everything else about the bench, was of the most simple construction. It is shown in Fig. 2, which explains it so clearly, that remarks about it can hardly be necessary. It was made of wood, and was hung on a screw nail, the neck of which passed loosely through it. The thickness at one end, of course, was merely to keep the catch end away from the wall; but if the screw were put through the middle of a sufficiently long piece of wood it would do just as well. In this case, it would not do to screw the wood close up to the wall, as a sufficient space would have to be left for the thickness of the top.

Another little arrangement, if not an absolute necessity, was at any rate soon found to be a convenience. When working at the bench its front supports were apt to get pushed back, as, of course, there was nothing to stop them at the bottom.

This having resulted once or twice in an upset of everything that was lying on the bench at the time, led to the stop, as shown in Fig. 3, being fixed to the floor. One or two nails being driven in between the flagging prevented it being forced backwards, which was all that was necessary, there being no upward strain. These blocks were rather in the way of people passing to and fro, so these were altered for another arrangement, which got over any difficulty of that kind. To the back of each leg I hinged a piece of wood, to fold upwards when required and at other times to extend backwards as far as the wall, where it rested in a cleat of very similar shape to that which had been previously used on the floor. This arrangement prevented any further mishaps, and served till the bench on removal to another house was finally dismantled.

In connection with this, I may mention a convenient way of keeping one's tools—at least, a good many of them; for, as will be seen, it is not suitable for planes, large saws, and a few other things. For chisels, screwdrivers, and all the smaller articles, it is well adapted, especially if, as in this case, the bench is against a wall. The tools are visible, and each can be reached down as required and put up again when done with without any of them lying about on the bench—an important consideration with a small one. Every one knows the waste of time caused by hunting up a tool, whether it be from among others lying on the bench or from the chest, and all this can be avoided by slinging them in a kind of rack against the wall. I call it a rack, as I do not know very well how to describe it otherwise; but the name does not matter much so long as the contrivance is understood. A piece of wood, say 2 or 3 in. wide and $\frac{1}{2}$ in. or so thick, of any convenient length, forms what may be called the foundation. On this some upholsterer's chair webbing is fastened with tacks, the web being left loose lengthwise between the tacks, so that it forms a series of loops. In these loops the tools are placed, blade downwards. The handles prevent them slipping through. So convenient have I found this arrangement that I regularly keep many of my tools permanently this way in preference to any other. For instance, my lathe—a Britannia, No. 10—stands in a recess of my workroom, for, fortunately, I am not driven to a cellar passage now. Behind it are arranged my turning tools. On another piece of wood, similarly looped with web, are my carving tools. In a workroom tools hung this way are not only ornamental, but, what is more to the purpose, it is very easy to select any one that may be required.

It seems, somehow or other, that this description of my folding bench has run on to a considerable length; but all I can say in extenuation is that when I was a younger and a wiser man (in my own esteem) I should have been glad of similar suggestions to assist me. That these are perfect I do not pretend; but, in the belief that they will be welcome to some among the hundreds of thousands of all sorts and conditions of men who read WORK, they are set down in black and white.

Everything that seems necessary has been described; but if the written explanation is not sufficiently lucid few will experience the slightest difficulty in knowing what is meant if they will refer to the accompanying illustrations (Figs. 4 and 5), the first of which shows the bench open for use, the latter closed or folded against the wall. Should I not have made myself sufficiently intelligible, I will endeavour to rectify any defect in the "Shop" columns, only—may I, without offence, say it?—I would suggest that it will be better for the young worker not to write off immediately he meets with a difficulty, but to try and solve it for himself. It will prove much more useful to him to do so, and he must remember that the object of this article is not so much to tell him how to make a bench exactly like, or, in other words, a copy of, mine, as to suggest plans by which he may profit. Still, should any one meet with a difficulty he feels himself unable to surmount in fitting up a similar bench, I will gladly help him as far as I can in "Shop."

LOCK REPAIRING AND KEY FITTING.

BY THOMAS WILSON.

PATENT LOCKS FOR SAFES.

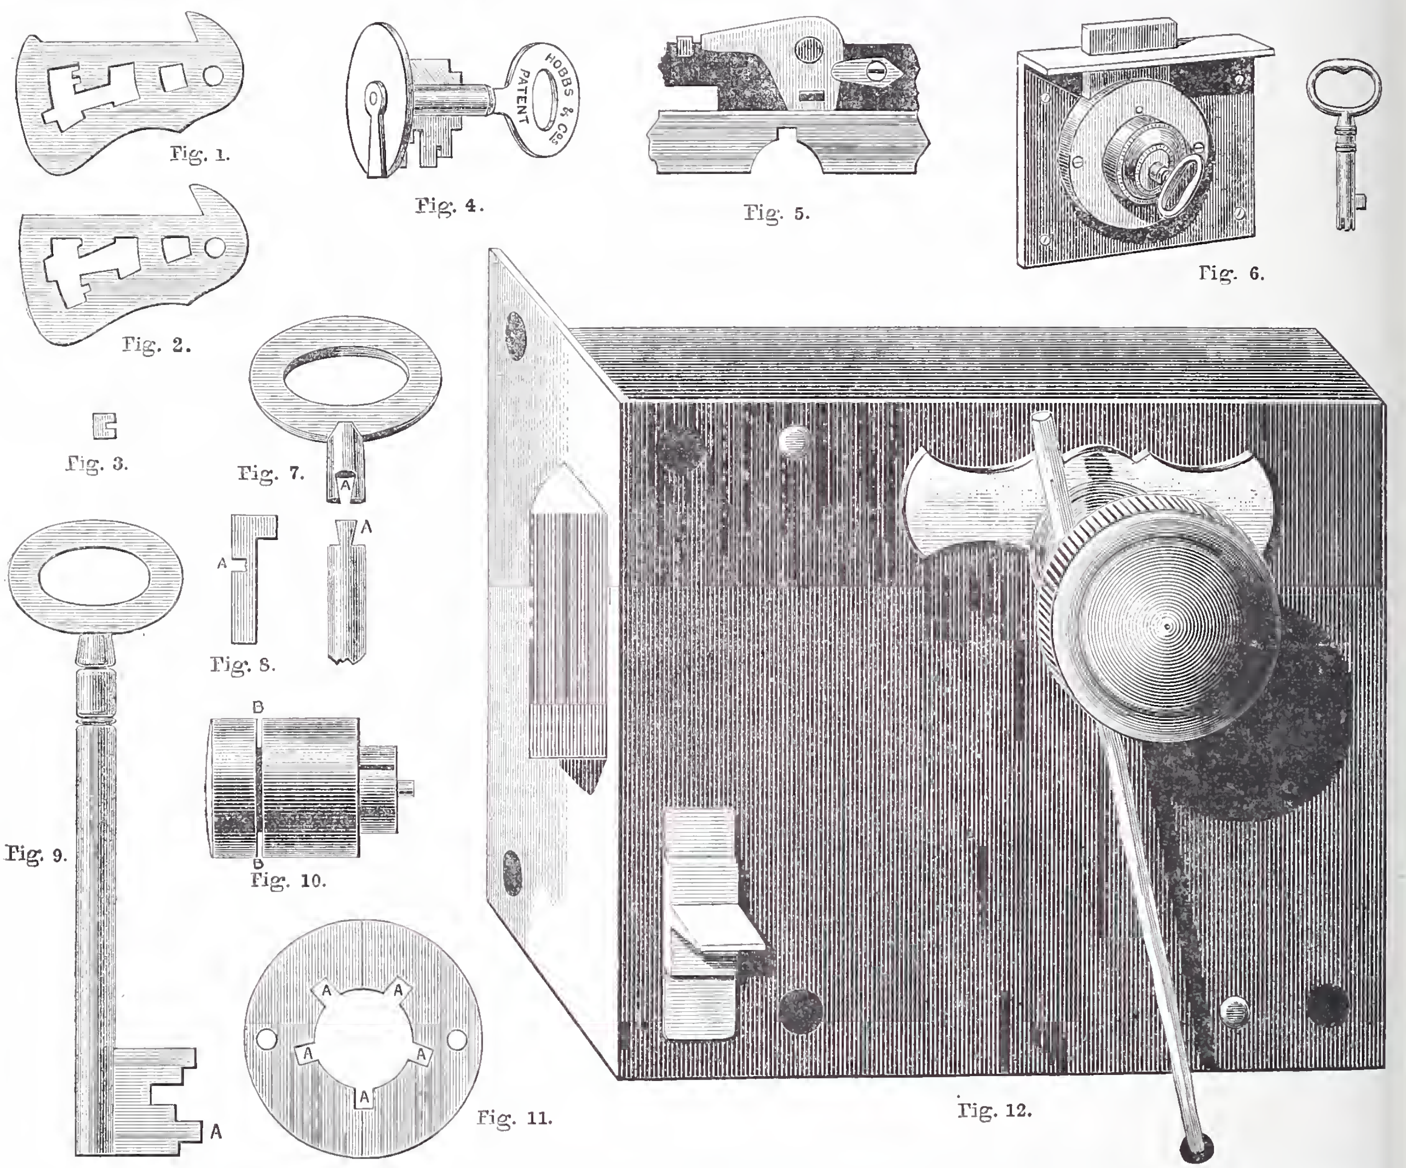
As I remarked at the conclusion of my last article, ordinary lever locks afford ample security for general purposes, but for safes, or where perfect security is required, it is necessary to render them unpickable. There are various means in use for attaining this end, most of them protected by patent. It would be outside the scope of this article to describe all of them, but I will briefly describe those of Hobbs, Chubb, and Bramah, inasmuch as they have been before the public longest.

Messrs. Chubb use levers with notches (or false gatings as they are technically termed) cut in them, as shown in Figs. 1 and 2, so that the bolt stump (Fig. 3) can enter a short distance, and where these are numerous it is almost impossible to tell if the bolt has entered the true or false gating. The makers, however, do not rely entirely on these, for they use a detector, which, briefly described, consists of a trigger so arranged that if any lever is raised too high the bolt is blocked, and it cannot be withdrawn even by its own key. It can, however, be released by turning the key slightly in the other direction. This detector, besides assisting in rendering the lock unpickable, serves to show if the lock has been tampered with. Messrs. Hobbs rely on their patent movable stump, shown in Fig. 5, by means of which any pressure, if applied to the bolt before raising the levers, is transferred to a fixed part of the lock, so that the levers are perfectly free. Both these methods render the locks practically unpickable.

There is one other defect in lever locks which I have not mentioned, and that is the risk of the bolt step, A, shown in the key, Fig. 9, being worn (or, perhaps, wilfully filed or ground down) so that it is not long enough to throw the bolt home, which remaining in the passage of the levers can easily be thrown back by an ordinary pick. To obviate this danger, Messrs. Hobbs introduced their patent protector, in which the bolt step or talon is fixed to a revolving nozzle instead of on the key (see Fig. 4). With these improvements their locks may be said to be perfect. Space will not permit of mention being made of the inventions of Chatwood, Tucker, Parnell, Tann, Price, Fenby, Hart, Cottrell, and Hodgson, all of which have demonstrated the possibility of producing locks capable of defying picking instruments in the hands of experts.

To cut a key to a lever lock it is necessary to remove all the levers, laying them carefully on one side in the order in which they are taken out. Now cut the first step in the blank so that it will throw the bolt, then replace the first lever and cut the second stop so that it only raises the lever to the necessary height to allow the stump on the bolt to pass the gating; next replace the second lever and proceed in the same manner, continuing until all the levers are replaced and the corresponding steps cut in the key. Fig. 9 shows a lever key for a night latch. The first step in this is a sham, as the bolt is thicker than the lever, and takes up the first two steps, so that it follows that the key belongs to a four lever lock. It will not do, however, in buying a lock, to be guided by the key unless it is by some well-known maker, as I have known a lock with only two levers have a key like the illustration (Fig. 9), the levers being kept in their places by a pin riveted in the covering plate, so that it is as well, in buying a lock, to have the covering plate removed and see that the levers are actually there. Fig. 6 shows a Bramah lock. This well-known lock is in principle the same as a lever lock, but instead of levers small guards of sheet metal (Fig. 8) are used. These work in a cylinder (Fig. 10), carrying a stud which turns the bolt; a flat steel ring (Fig. 11) projects into a groove in this cylinder, and the ring is notched to correspond with the notches in the guards, as shown at A, Fig. 8. In unlocking, the key presses the guards down until the notches are opposite the corresponding notches in the ring. The cylinder can then be turned round and the bolt thrown back, a small spiral spring at the back of the guards replacing them in position when the key is withdrawn. Those made by Messrs. Needs and Co., the successors to Joseph Bramah, the patentee, are very secure, but common Bramah locks are seldom perfect, and can be opened in many different ways.

To cut a key to one of these locks it is necessary to fit the blank to pass the outside cylinder, then to take off the cylinder, when it will appear as shown in Fig. 10, with the ring, Fig. 11 (which is in two pieces), in position in the groove, B B; now file down the end of the blank until the stud on the key nearly enters the cylinder, then blacken the end and press it in the cylinder. It will then show the impression of the guards on the end, and these should be cut down equally in the blank for a short distance, say, an eighth of an inch. The cylinder should now be held in the hand with the key pressing it, so as to see the distance back the handle with a piece of wire. Fig. 12 will illustrate my meaning. For this reason I prefer Chubb's Combination Night Latch, in which the levers themselves form the bolt, and which is opened from the inside by turning a handle, and not by drawing it back. A night latch on this principle can now be bought for as low as 3s. 6d. or 4s., and is about the best that can be used. No direction need be given for cutting keys to this kind of lock, as all lever keys are cut in the same manner as twisted round the joint. Get a pennyworth of borax, powder and moisten a piece of it (do not buy it powdered as it is not pure), and put a little over the brass wire. Now hold it with a pair of tongs in the fiercest fire at your command. An ordinary kitchener will do if all the dampers are opened and a clear fire made; in fact, I have brazed them in this way myself, when a long distance from the shop. An ordinary grate would probably do if the top was covered down to the bars with sheet iron to increase



Figs. 1 and 2.—Chubb's Levers with Notches or False Gatings. Fig. 3.—Bolt Stump. Fig. 4.—Hobbs' Patent Protector. Fig. 5.—Hobbs' Patent Movable Stop. Fig. 6.—Bramah Lock (Till Lock). Fig. 7.—Dovetailing New Bow to Key. Fig. 8.—Notches in Guards. Fig. 9.—Key for Lever Lock, showing Defect at A. Fig. 10.—Cylinder of Bramah Lock (Night Latch). Fig. 11.—Ring. Fig. 12.—Mode of opening Night Latch.

necessary to cut the notches in the key, which may be ascertained by holding the cylinder to the light and looking at the groove, B B. The notches in the key should be cut down one at a time, until the gatings in the guards are opposite the grooves in the cylinder, when if the lock is put together the key will be found to fit.

These locks are now seldom used for safes, but they are frequently used for purposes where a small key is preferred, such as night latches, jewel cases, etc. For night latches, however, they cannot be recommended, as like all drawback locks, however good the works may be, they can easily be opened by boring a hole under the latch, and turning previously described. Before closing this paper, it may be as well to describe the method of repairing a broken key (broken, that is to say, at the bow, for if the bit is broken it cannot be repaired). If the bow is twisted off and not damaged, a slot should be filed in the top of the key and the bow driven on but should the bow be broken, an old key must be found with a sound bow.

In ironmongers shops all old keys are preserved for the sake of the bows, so that one could be bought for a trifle, if there did not happen to be one in the house. Having procured the bow, it and the key should be dovetailed together, as shown at A A, Fig. 7, and a few strands of brass binding wire the draught. When the brass has melted, turn the key round once or twice until it has cooled, so that the brass may be equally distributed, and then put it on one side to cool. Take off the surplus brass, and clean up the key with emery cloth, and it is finished, and will be found equally as strong as a new one.

I think I have enumerated now all the ordinary repairs incidental to locks in general use, and have enabled those of a mechanical turn of mind to keep their own locks in repair at a very small cost. As I stated before, I shall be pleased to give any information that may be required through the medium of "Shop."

METAL SPINNING.

BY F. J. DURRANCE.

To those of my readers possessing a lathe, there can be no more interesting or pleasant way of using it than in the process of metal spinning. Very little is known amongst amateurs of this method of sheet metal working, too little, in fact, considering that hundreds of useful articles in daily use can be easily and simply made by this process—pin trays, egg-cups, candlesticks, etc. And most of the articles produced are specially fitted for embellishment by the two methods known to readers of WORK as repoussé work and chasing. The tools required are very few, and can be easily made by any one having a little mechanical knowledge. And the necessary skill is soon acquired, and the results obtained very satisfactory. Now to work. Presuming you have a little knowledge of wood turning, I will commence by describing the making of the simplest thing I can think of—a cigar-ash tray. Take a piece of hard wood of a close grain (beech or birch for instance), about 4 in. square and an inch thick; by any of the well-known methods, fasten it to a chuck. A good way is by the taper screw, or attach it to the face plate by screws from the back, Fig. 5. Now turn it up to the shape of sketch, Fig. 1 (the drawings are not to size, merely theoretical); make it nice and smooth, but do not polish it. Next get a piece of sheet metal to commence practice—lead, pewter, or better still, sheet zinc used for covering the counters of hotel bars is preferable, as it keeps its colour and takes a good polish. Most plumbers will pick you enough out of the scrap for a few coppers. Now cut a piece of metal a little larger than the pattern mould, and attach it to the face of pattern; this is the most difficult thing in this work, to hold the metal close up and prevent its turning. In this case we turn up a piece of hard wood the shape of Fig. 2, then put a little powdered resin on the flat surface of pattern, also a little on the largest face of the retaining block, insert the metal sheet *between* the two, and bring up the back centre against the small end of block. Run the lathe slowly round, and centre the metal sheet. Now screw up the back centre *firmly* and lock it, put a little oil on centre, and we are now ready to begin

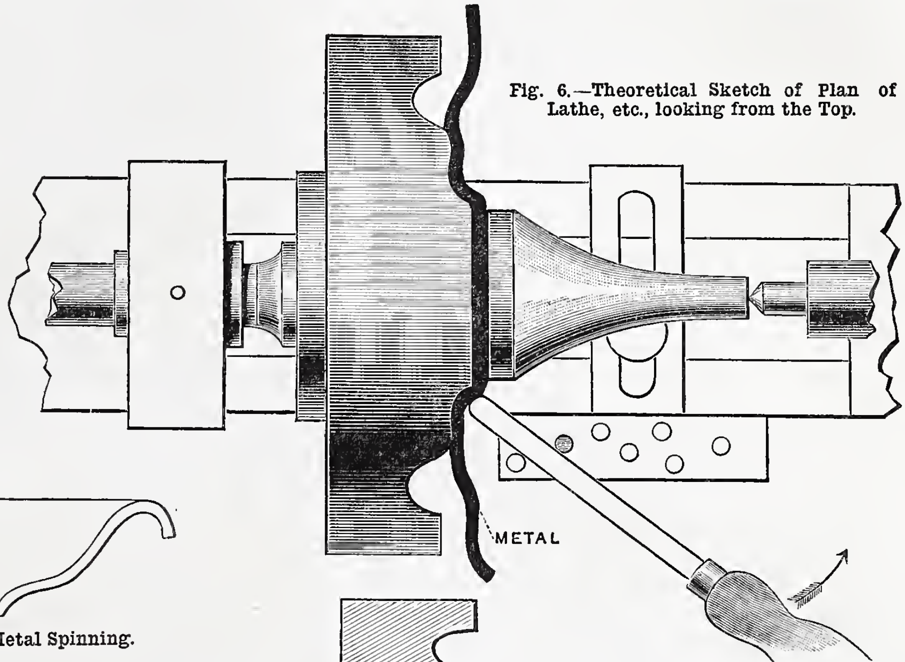


Fig. 6.—Theoretical Sketch of Plan of Lathe, etc., looking from the Top.

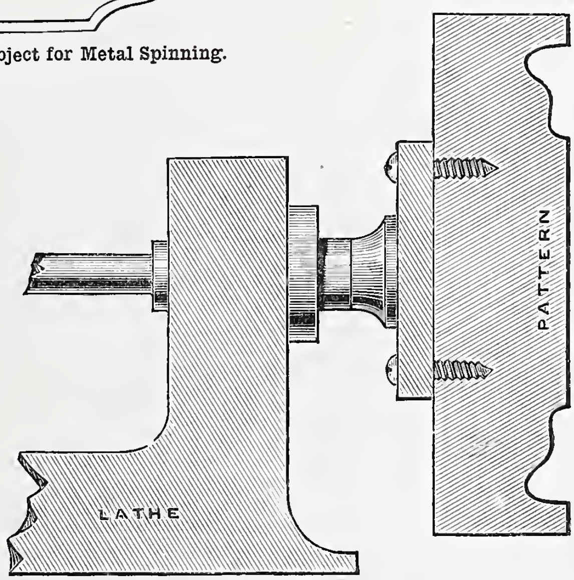

Fig. 5.—Mode of Turning Pattern on Lathe.

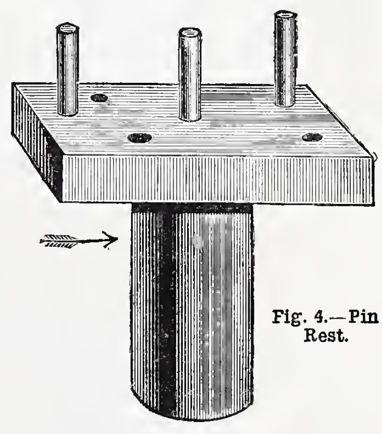

Fig. 4.—Pin Rest.

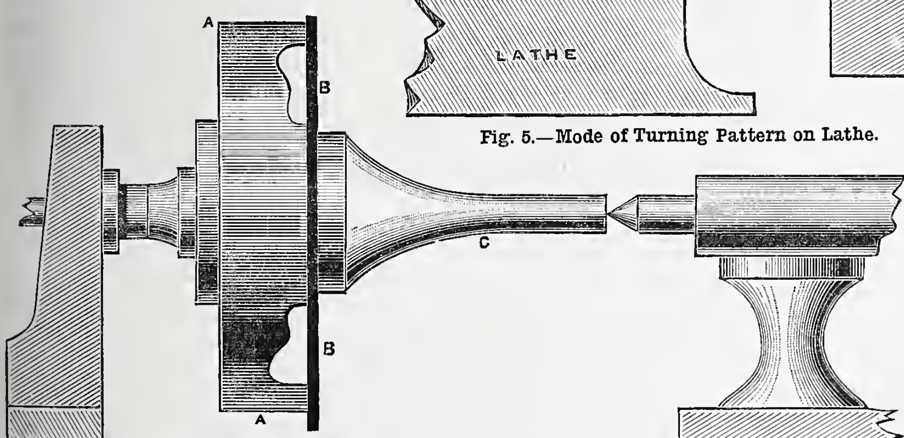

Fig. 3.—Sketch showing Pattern (A), Sheet Metal (B), and Holder (C) in Position on Lathe.

(see Fig. 3 showing all *in situ*). But as we cannot go on without tools these must be our next consideration. These consist of pieces of steel of various forms, and really consist of what are known as burnishers; for the work we have in hand a simple piece of steel rod or wire, about $\frac{3}{16}$ in. thick, rounded off at the end, smoothed and polished, and driven into a good long handle, will do, although it is always preferable to have the steel of *flat* section, square or oblong, as they lay flat on the rest and do not require so much holding. We now come to the *rest* used for this work, which is rather different to that used for wood, but very similar to the one used for metal turning. It is flat on the top, and has a few holes drilled into the upper surface for the purpose of inserting steel pins (see Fig. 4); the lower part fits into the T rest, and is fastened by a screw in the ordinary manner; put on a good quick speed for this work, the quicker the better. Now look carefully at the theoretical sketch, Fig. 6, fix the rest in the position shown, and just a *little under the centre*; next get a piece of suet from the butcher's, and as the lathe revolves hold it against surface of metal sheet so as to well grease it. Suet is preferable to oil, as the oil would fly off and dirty everything about the place; now put a pin into one of the holes in rest, and placing the tool on the rest, and against the *left* side of pin, press firmly against the metal as it revolves. The tool in this case becomes a lever, and the pin the fulcrum, allowing you to exert a great pressure against the metal, which is required in brass or other hard metal. The grease forms a lubricant, reducing the friction to a minimum. Working always from the *centre*, you will see the metal gradually give way and conform itself to the shape of the pattern. When you have got the metal well home to the pattern, cut off the superfluous metal with an ordinary V-tool used for metal, and make the edge round and smooth with emery paper. Clean and polish the surface with fine flour, emery, and oil, finishing off with whiting and water; now remove the retaining block and polish the flat part. The metal tray will not come off yet, as the heat engendered will have made the resin stick inside, and you may have to make metal hot to get it off pattern, which you can do by unscrewing chuck of lathe, and hold the metal tray over a gas flame. You can take off the resin with boiling water. The tray is now finished and can be chased, or a design worked on it by repoussé work, just as the fancy of the workman may lead him to prefer. Of course there is no limit to the number of articles which can be made from the same mould or pattern. In real practice the patterns are made in brass or iron, as the extreme pressure used tends to destroy the shape of a wood mould. In our next we shall try something a little more difficult—an inkstand and a circular box with lid.

SOME NOTES ON SCREW CUTTING.

BY A WHITWORTH SCHOLAR.

Probably one of the greatest difficulties with which the young mechanical engineer has to contend, is that afforded by the subject of screw cutting. Indeed, not only is the pupil or apprentice often perplexed, but the practical mechanic is also frequently at a loss as to what arrangement of wheels is required in order to cut a screw of a given pitch.

This fact is rendered more noticeable inasmuch as the subject is in reality by no means a difficult one to acquire when once the leading principles involved have been thoroughly grasped. Feeling sure that a large number of the mechanical engineering readers of Work will have experienced the want of information on this subject, I will at once proceed to place the matter before them in as simple and concise a manner as due regard for accuracy will allow.

The screw-cutting lathe presents a highly interesting example of the important *copying principle* so often employed in engineering tools. The "guide screw," or, as it is sometimes called, the "leading screw," is an accurately finished screw of about the same length as the lathe bed, and placed exactly parallel to the centre line of the lathe. Upon the exactness of this leading screw depends the accuracy of all screws cut in the lathe; hence the necessity for carefully protecting from injury this most important part of the machine. The pitch of the leading screw—that is the length occupied by a thread and a space—is usually $\frac{1}{2}$ inch or $\frac{1}{4}$ inch; or the screw is said to have two or four threads per inch, as the case may be; the former being generally adopted in large lathes and the latter in the smaller sizes.

A progressive set of change wheels is also supplied, the smallest of which has usually 20 teeth, and the largest 120 teeth, the intermediate sizes varying by 5 teeth. There are generally two wheels of the same size in the set, as two of 90 teeth, and sometimes also two of 25 teeth. Additional wheels of 130, 140, and 150 teeth are occasionally included in the set; but usually the 120 wheel is the largest.

It is scarcely necessary to state that one end of both the guide screw and the lathe spindle or "mandrel" project beyond the end of the lathe bed, and that the extremities are arranged to receive any of the 22 change wheels. To enable us to communicate motion between the mandrel and the guide screw, an adjustable quadrant is provided which contains a stud or pin, upon which another wheel can be placed so as to "gear" with both the wheel on the mandrel and with that on the guide screw.

Now suppose we place one of our two 90 wheels upon the mandrel and the other on the screw, communicating the motion between the two by means of an intermediate wheel of convenient size placed upon the stud in the quadrant. Then for every revolution of the mandrel, it is clear that the guide screw will also make one revolution, and a moment's consideration will show that the pitch of the screw cut by such an arrangement will be exactly similar to that of the guide screw. The whole problem of screw cutting can, in fact, be resolved into the question of the relative velocities of the lathe mandrel and leading screw, and we will now proceed to consider the means whereby desired variations in this relative velocity may be effected.

In the first place it is necessary to remark that the wheel placed upon the mandrel is a *driving* wheel, that upon the guide screw is a *driven* wheel, and the intermediate wheel which connects these two is called a *stud* wheel; the whole system as described being known as a single train of wheels, to distinguish it from the arrangement known as a double or compound train, to which we shall presently have occasion to refer.

The axiomatic principle which underlies all problems in screw cutting may thus be stated:—The number of teeth in the driving wheel must bear to the number of teeth in the driven wheel, the same proportion that the number of threads per inch in the guide screw bears to the number of threads per inch in the screw to be cut. This consideration is the foundation of—

Rule I.—To find the wheels to cut a thread of a finer pitch than the guide screw:—Place the number of threads per inch in the guide screw for a numerator, and the number of threads per inch in the screw to be cut for a denominator. Add a cipher to each, and we have the required wheels. Thus supposing the guide screw has two threads per inch, and that we wish to cut a screw of three threads per inch, then—

$$\frac{\text{Number of threads in guide screw}=2}{\text{Number of threads in screw to be cut}=3} \text{ adding ciphers } \frac{20}{30}$$

that is, the wheels required are of 20 and 30 teeth.

As a beginner might have some confusion in his mind as to which wheel is to be placed on the screw, and which on the mandrel, I may mention that such a doubt may easily be dispelled by remembering that if the screw to be cut is of finer pitch than the guide screw, the smaller wheel is the driver, and must therefore be placed on the mandrel. But if the screw to be cut is of coarser pitch than the guide screw, the positions are reversed, and the small wheel is then placed upon the guide screw.

It is necessary to observe that it is the *relative* and not the *actual* number of teeth which is the important requirement. As a consequence of this, both the numbers of teeth as found by Rule I. may be multiplied by any suitable common multiplier, or divided by any suitable common divisor, without affecting the resulting pitch of the screw. This fact is often of very great service, since wheels which are of inconvenient size may thus be replaced by those of more suitable dimensions.

For our next example we will take a case in which the number of threads to be cut is uneven, as:—Required the wheels to cut $3\frac{3}{4}$ threads per inch; guide screw 2 threads per inch.

Proceeding as directed by Rule I. we have

$$\frac{\text{Number of threads in guide screw}=2}{\text{Number of threads in screw to be cut}=3\frac{3}{4}}$$

and in this form we cannot add the ciphers as directed. In order to proceed we must first reduce the expression to a simple fraction, and for this purpose we multiply both numerator and denominator of the fraction by the denominator of the fraction belonging to the mixed number, in this case, 4. Thus $\frac{2 \times 4}{3\frac{3}{4} \times 4} = \frac{8}{15}$. Adding ciphers we have $\frac{80}{150}$ as the wheels. As, however, the largest wheel in the set has only 120 teeth, we may conveniently divide this result by 2, and we shall then have 40 and 75 as the wheels required.

The size of the intermediate wheel is immaterial in all cases of single train gear, convenience of communicating the motion between the driving and driven wheels being the only consideration.

Let us next endeavour to find the wheels to cut a screw of 14 threads per inch, with a guide screw of 2 threads per inch, and the smallest and largest wheels having 20 and 120 teeth respectively. Proceeding in the usual way we have $\frac{2}{14}$, which, by adding ciphers, becomes $\frac{20}{140}$. Here we see at once that any attempt to divide both numerator and denominator with a view to reduce the size of the large wheel will also have the effect of reducing the small wheel, which is already of the smallest size provided.

This gives rise to the following statement:—The ratio between the largest and smallest change wheels multiplied by the number of threads per inch in the leading screw will give the greatest number of threads per inch that it is possible to cut with a single train. In the case before us the ratio is $\frac{120}{20}=6$ and $6 \times 2=12$ threads as the finest pitch which can be cut with single train.

For finer pitches than this we shall require a "double" or "compound" train consisting of four wheels, of which two are driving and two are driven wheels. One of the driving wheels is placed upon the lathe mandrel, as in the single train, but it now gears directly with one of the driven wheels, which together with the second driver is fixed to a socket, turning on the adjustable pin in the quadrant; the second driver gearing directly with the second driven wheel which is placed upon the guide screw.

Perhaps the most satisfactory method of finding these four wheels is the following:

Rule II.—To find the four wheels necessary to form a double train. Proceed as in

Rule I., and assume, in conjunction with the pair of wheels thus found, two equal wheels of convenient size. Then divide the driver or driven of the one pair and the driven or driver of the other pair by any suitable number.

To make this clear, let us take the foregoing case in which the single train failed. We have here $\frac{20}{140}$, and assuming two equal wheels of 100 teeth in connection with these, we then have $\frac{20}{140}\ \frac{100}{100}$, and dividing both the first driven and the second driver by 2, we obtain $\frac{20}{70}\ \frac{50}{100}$ as the wheels required. Either of the driving wheels—the 20 or the 50 — may be placed upon the lathe mandrel, and either of the driven wheels upon the screw, without affecting the result.

It not unfrequently happens, especially in the case of screws coarser than the guide screw, that the pitch of the screw is given instead of the number of threads per inch. Suppose, for instance, we require to cut a screw of $\frac{7}{8}$ inch pitch—that is, a screw in which a thread and a space together occupy $\frac{7}{8}$ inch in length. This can be done most conveniently by—

Rule III.—To find the wheels to cut screws of a coarser pitch than the guide screw. Multiply the required pitch in inches by the number of threads per inch in the guide screw, and then add ciphers as in Rule I.

Thus $\frac{7}{8} \times 2 = \frac{14}{8}$, or by adding ciphers $\frac{140}{80}$ and dividing by 2 we have $\frac{70}{40}$ as the wheels required.

Again, supposing the pitch of the screw required is $6\frac{3}{4}$ inches, $\frac{27}{4} \times 2 = \frac{54}{4}$, adding ciphers $\frac{540}{40}$, and assuming two additional wheels of 120 teeth, we have $\frac{540}{40}\ \frac{120}{120}$; then dividing the first driver and second driven by 6, we obtain $\frac{90}{40}\ \frac{120}{20}$ as the required wheels.

In all the examples hitherto given we have dealt with right-handed screws, of which the guide serew affords an example. If a left-handed screw has to be cut, it will be necessary to interpose a wheel of convenient size between a driving and driven wheel after determining the required wheels as before. An extra adjustable pin is provided in the quadrant to carry this additional wheel.

Rule IV.—To prove the wheels to be correct:—Multiply the driving wheels together and multiply the driven wheels together. Divide the greater quotient by the less. Then this result is to be multiplied or divided by the number of threads per inch in guide screw, according as the screw to be cut is of finer or coarser pitch than the guide screw. The final answer should give in the first instance the number of threads, and in the second instance the pitch of the screw to be cut.

To render this clear, we will prove the wheels in the examples given to illustrate Rules II. and III. In the first case we have $\frac{20}{70}\ \frac{50}{100}$ as the wheels. Multiplying the drivers together, $20 \times 50 = 1{,}000$; multiplying the driven together, $70 \times 100 = 7{,}000$; dividing the greater by the less $\frac{7000}{1000} = 7$; and multiplying by number of threads in guide screw, since the screw is of finer pitch than the guide screw, we have $7 \times 2 = 14 =$ the number of threads required.

In the second case (Rule III.) we have $\frac{70}{40}$ as the wheels, and we can at once divide the greater by the less, thus:—$\frac{70}{40} = 1{\cdot}75$. But as in this case the screw to be cut is coarser than the guide screw, we must divide by the number of threads in the guide screw, and we then have $\frac{1{\cdot}75}{2} = {\cdot}875 =$ $\frac{7}{8}$ inch as the pitch which would be cut by such arrangement.

In the last case we have $\frac{90}{40}\ \frac{120}{20}$ as the wheels. $\frac{90 \times 120}{40 \times 20} = \frac{10800}{800} = 13{\cdot}5$. Dividing by the number of threads in the guide screw we obtain $\frac{13{\cdot}5}{2} = 6{\cdot}75 = 6\frac{3}{4}$ as the resulting pitch in inches.

I have thus endeavoured to indicate the principles involved in screw cutting rather than confine myself to mere statements of hard and fast rules. For by this means the student or the workman will be enabled to understand whatever theory is involved in the practice of the workshop, and the application of which he will then be in a position to modify or extend.

THE SPEAKING TELEPHONE AND MICROPHONE.

THEIR CONSTRUCTION, AND HOW TO USE THEM.

BY WILLIAM DUFF.

The speaking telephone is without doubt the most wonderful invention of the nineteenth century. Its usefulness for business purposes is beyond question. It has in a great many instances made its big brother, the "electric telegraph," stand aside. And yet it is so simple in construction that any schoolboy, with a few simple tools, and the merest trifle of mechanical knowledge, can easily put it together.

It consists essentially of a wooden or ebonite case, being hollow throughout its entire length, a round steel bar magnet fitting into the case, having a small bobbin of very fine silk-covered copper wire surrounding its north pole, which is placed at the speaking or hearing end of the case. Directly over the bobbin is placed a circular disc or plate of thin sheet iron, fixed round its edge, but free to vibrate at its middle.

The ends of the coil of wire on the bobbin are connected by two wires running the length of the case, ending in terminals or binding screws, for the purpose of connecting the instrument with the line wire.

Formerly, two such instruments were simply joined up to the line and the earth, as shown in Fig. 2, and no battery was employed, for on speaking into the mouthpiece of one, the vibrations of the voice bent the iron plate to and fro in front of the magnetic pole, and thus by magneto-electric induction set up undulatory currents of electricity in the little coil around the pole. These currents were of a strength and form dependent on the vibrations of the voice, and after travelling along the line they passed through the coil of the receiving instrument, where, by a reverse action, they set the iron plate into a vibration sympathetic with the vibration of the plate of the transmitting instrument. The result was that an ear placed at the mouthpiece of that instrument could hear a feeble imitation of the distant speaker's voice. I can well remember the first time I heard a telephone speak. It was then only in the experimental stage. The instruments were the property of Sir Wm. Thomson. When I placed the instrument to my ear, at first, I was so much excited I could hear nothing, but gradually the tones of a well-known voice became recognisable, and when I laid down the instrument, I resolved to set at once to work and make for myself a set of this wonderful apparatus. It was not until long after, however, that I did actually make a beginning, and I have now a pair of as good telephones as any one could desire.

I had a little knowledge of the science of electricity, and knew something of the why and wherefore of certain laws which govern things electrical, so I made my telephones to please myself. I had no figures or diagrams to go by, save an advertisement cut of the Religious Tract Society.

I will set out the details of one of these instruments, hoping to make them plain enough to the ordinary reader, and if any electrical engineer happens to come across this description I hope he will wink at any miscalculations he may find; and should he be inclined to find fault, I will ask him to remember that I am not writing for him. But at the same time, let me assure the amateur that if he follows my directions he will not need to be ashamed of the telephones, for mine *can* speak, and speak well, and the best instrument that ever left the electrician's workshop can do no more.

The outer case then, to begin, is made of mahogany, and is in three pieces, which I will call the body, the mouthpiece, and the cap. The body will be easier to make in two pieces, for if made solid or in one piece it will be very difficult to drill the hole for the magnet. Get two pieces of mahogany, 4 in. by 2 in. by $6\frac{1}{2}$ in., and fasten them together in the usual way for turning—*i.e.*, plane two sides and glue them with a piece of soft paper, such as newspaper, between. They will have the appearance of one piece, measuring 4 in. by 4 in. by $6\frac{1}{2}$ in. Turn them any shape you fancy; but that shown at Fig. 3 will suit the purpose. Make the cavity at the end the sizes indicated in the figure, viz., $2\frac{3}{4}$ in. by $\frac{1}{2}$ in. When you have the body turned and finished, split it (the paper between the halves makes this easy), and make the hole for the magnet with a gouge, taking care to have it in the middle of the entire piece. The hole should be made so that the magnet will fit well and not rattle about; but it must not fit too tight, so as to prevent easy adjustment. Turn the mouthpiece out of a piece of the same stuff as the body, measuring 4 in. by $\frac{3}{4}$ in. Fig. 10 gives the exact sizes to which it must be turned. The cap is shown at Fig. 5; but it can be dispensed with, without in any way lessening the effectual working of the instrument. The bobbin to take the wire for the coil is also of wood, preferably boxwood, and it will require some care in turning, for it is so small and so thin in every part that it will be easily broken. It can be made of paper, with pasteboard ends. I made mine thus: a narrow strip of cream laid paper, glued and rolled round the magnet several times till about $\frac{1}{8}$ in. thick, and two round discs of thin pasteboard, with holes, the width of the magnet, glued at each end of the paper. Fig. 7 shows it in section, and the proper sizes are given, which must be the same whether made of paper or wood.

The wire for the coil is No. 36, silk-covered; about $\frac{1}{4}$ oz. will be sufficient. It should be wound on the bobbin as evenly as possible, and free from kinks; both ends must be left free for connecting up; one end taken through the side of the bobbin, and the other one left where the winding stops. After winding steep the coil in melted paraffin wax. In winding the coils for the pair of instruments one will have to be wound in the contrary direction to the other, and in joining up, the beginning of the one and the end of the other must be connected together.

The ends of the coil are soldered to two stout copper wires, and carried inside through holes to the top of the case, and fastened to binding screws. The diaphragm is a thin ferrotype plate, to be procured at a photographic apparatus shop: cut it 3 in. in diameter, and don't have any wrinkles in it, especially round the edge. After all the pieces have been made and fitted, the best means to put them together will be to begin by gluing the two halves of the body. Previous to this have the two small holes to take the wires from the coil running parallel to the large hole for the magnet, one on each side. When dry and hard put the magnet in place, with its south pole at the top, and insert the adjusting screw, which should have a neck to work in a little collar screwed to the end of the body (see Figs. 4 and 8). Screw and collar should be of brass. Push the wires from the ends of the coil through the small holes in the body, and bring them out at the top; place the hole of the bobbin on the protruding end, the north pole of the magnet; the bobbin should fit tightly; it will be held in position by the wires, which may now be fastened to the binding screws at the top; turn the end of the wire two or three times round the stem of the screws; screw them tightly into the wood. The diaphragm may now be laid in its place; but just before doing this place a piece of paper over the magnet, and with the adjusting screw bring the magnet to touch the paper; place the mouthpiece over all, and fasten with four brass screws; before fastening up tight withdraw the paper; this will leave a space of about a 32nd of an inch, or the thickness of the paper, between the magnet and the diaphragm: the mouthpiece clamps it round the edge, and leaves it free to vibrate at the centre. The magnet, it should be said, will require no further adjustment. It should be strongly magnetised to begin with, and capable of sustaining its own weight.

The instrument just described is what is known as the Bell receiver, and two of these instruments will speak or hear if they are alternatively held to the mouth or ear. The method of connecting them to the line is already described.

There are a great many different telephones in use, and a great many more have been invented that will never be in use. They are all dependent, more or less, on the same principle.

After the invention of the telephone, Professor Hughes, of telegraphic fame, invented an instrument known as the microphone. He had been investigating acoustical phenomena by the aid of the telephone, and discovered that a delicate contact between two conductors could be made to transmit speech. In the course of his experiments he had been using a strained wire, when suddenly the wire broke, causing a great rush of sound to be heard in the telephone which he held at his ear. He sought to imitate the condition of the wire at the moment of rupture by replacing the broken ends and pressing them together. This he did with three common nails; two joined to the ends of the wire lying on the table side by side, and the other lying across them. The effect was improved by building the nails up log-hut fashion. This crude apparatus reproduced sound with remarkable fidelity. Acting on the facts brought out by these experiments, he devised an instrument for magnifying weak sounds, which he called a microphone.

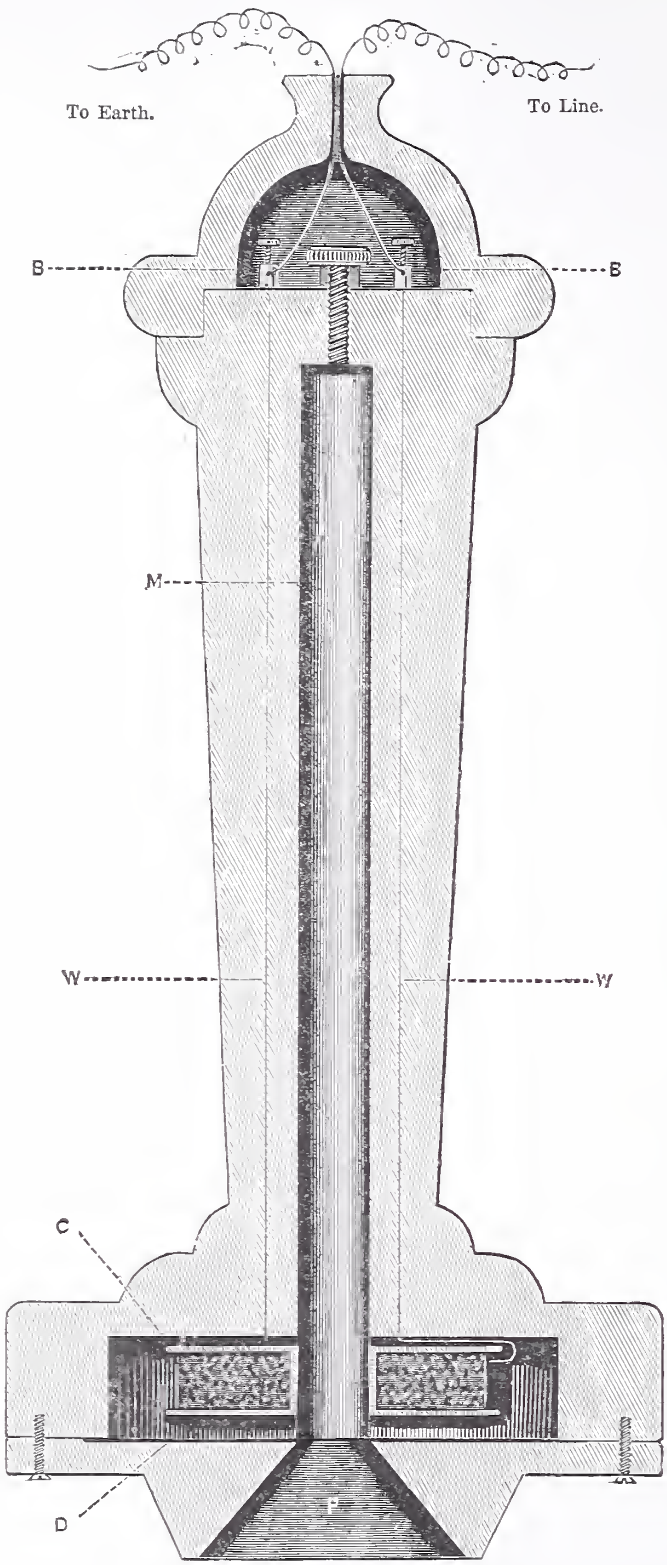

Fig. 1.—Section of Bell Telephone Receiver, of which the Outer Case is of Mahogany or Ebonite.

M, Magnet fitted with Adjusting Screw. C, Coil of Silk-covered Wire. W, Wire from Coil to Binding Screws. D, Diaphragm of Ferrotype Iron. P, Earpiece.

As he made it, it consisted of a lozenge-shaped piece of carbon one inch long, a quarter of an inch wide at its centre, and one-eighth thick. The lower end rested as a pivot upon a small block of similar carbon, the upper end being made round, so as to play free in a hole in a small block of carbon similar to that at the lower end. The lozenge stood vertically upon its lower support.

The form of the carbon is not of importance provided the weight of the upright contact is only just sufficient to make a feeble contact by its own weight. Carbon is used in preference to any other material, as its surface does not oxidise or rust. The general appearance of the microphone will be seen from the drawing, Fig. 6, and the method of connecting it to the line and battery will be understood by reference to the section given at Fig. 11.

This instrument is capable of detecting very weak sounds made in its presence. If a pin, for instance, be laid upon or taken off the table, a distinct sound is emitted; or if a fly be confined in a matchbox, or other suitable prison, it can be heard walking with a peculiar tramp of its own. Thus, the beating of a pulse, the ticking of a watch, the tramp of a fly, can be heard at least a hundred miles distant from the source of sound. The success of the telephone is largely due to the microphone, for the transmitters which are now in use, in conjunction with the telephones, on our exchange systems are, to a great extent, modifications of Professor Hughes' simple contrivance.

When a microphone is used a battery will be required to generate a current. For the fly-walking and watch-ticking experiments a sufficient battery can be constructed for little cost. The following will suit all requirements; it is a modification of the Daniell cell. Three jam pots, three plates of copper, with a gutta-percha-covered wire soldered to each; three plates of zinc, with a copper wire also soldered to each, which may be bare; a few grains of bluestone (sulphate of copper), a little sawdust, and some salt and water. These are all the materials necessary. Put a plate of copper at the bottom of each jam pot. Allow the wire to come up the side; put a little of the sulphate of copper on the top of each plate; pack in the sawdust until a few inches from the top of the pot; place a sheet of zinc on the top of sawdust; allow the wire to come to the opposite side of the pot from that where the wire from the copper plate comes; moisten the sawdust with the water in which the salt has been dissolved; a cork may be fitted to each pot to keep them clean and tidy. Connect the cells together as in Fig. 9.

With this arrangement speech can be carried on, and a great number of wonderful experiments conducted. To have a direct communication between two stations a duplex set of apparatus will be required, including call-bells, etc., mounted upon a switch-board, with all the paraphernalia of practical telephony; but as these do not come within the scope of the present paper, I will leave them to some future time. Perhaps an abler pen than mine may write upon this subject. At all events, I have endeavoured to do my best to put the matters of principle and construction plainly and clearly before the reader, and I hope I shall have succeeded not only in doing this, but in interesting many in a subject which is possessed of considerable importance.

CONSTRUCTION OF BOTTLE BICHROMATE BATTERIES.

BY F. W. MASON, F.S.S.

As many amateurs, and likewise professional men, use these in their experiments, it would perhaps not be out of place for some to know how to construct them. These bottle batteries, though generally known by the name of "Bottle Bichromate Batteries," may really be used with any single fluid cell solution; and at the conclusion of this article I will give a few different kinds of solutions which have been practically tested and used for some time past both by myself and many leading electricians.

In the first place take any ordinary wide-mouthed bottle. If it be preferred to use the regular form, bottles can be obtained at any electrician's for about 9d. or 1s. each. They should have the capacity of about one pint. Of course smaller ones can be used if desired, but this size is the one I always recommend. Take a piece of ebonite, or any hard wood, about $\frac{1}{4}$ in. or $\frac{1}{2}$ in. thick, and, by means of cutting and turning it in a lathe, obtain it so that it will just fit loosely inside the neck of the bottle; then take another piece of similar material, about $\frac{3}{16}$ in. thick, and turn this slightly larger than the neck of the bottle, so that it will, when placed on the top of the bottle, rest there without in the least entering the neck. Put these two pieces together by means of glue, so that their centres exactly coincide with each other. Thus we shall have our lid made. When these are dry and firm, drill a hole through the centre about $\frac{1}{4}$ in. diameter; then fit through this, by means of marine glue, a piece of brass tube $\frac{3}{16}$ in. diameter. This should project about 1 in. above the lid, and about $\frac{1}{8}$ in. underneath; it should also have in it, at the upper extremity, a hole drilled and tapped, and a screw fitted to it. This is for the purpose of holding the brass rod (which is attached to the zinc element) in any position.

Having done this, the next step is to take a piece of zinc $\frac{3}{16}$ in. thick and of a suitable size so that it will go through the neck of the bottle into the interior; then drill in this (at the end which is designated to be that which is to be connected to the brass rod) two holes about $\frac{1}{8}$ in. or $\frac{1}{4}$ in. from each end. Then take a strip of ebonite $\frac{1}{2}$ in. thick by (if the zinc is, say, 3 in. broad) 3 in. long and $\frac{3}{4}$ in. width; cut a channel in this about $\frac{1}{4}$ in. or $\frac{3}{8}$ in. deep to receive the zinc (the width to be regulated according to the thickness of the zinc employed); two holes are then to be drilled at each end so as to be level with those holes drilled in the zinc, and by means of two small screws the zinc and the ebonite strip can be attached together. The ebonite strip should also have in its centre another hole drilled and tapped about $\frac{1}{8}$ in. diameter.

Having done all this, next take a piece of brass rod $\frac{1}{8}$ in. diameter, tapped at one end so as to screw into the ebonite strip; pass one end of the rod through the brass tube in the lid, and we have the zinc element complete (except the amalgamation). Then attach to the lid, by means of very small screws, a U-form piece of copper so as to encircle the brass rod without touching it. It should leave a space of $\frac{7}{16}$ in. between the edge of the copper and the brass rod. This copper strip should be about $\frac{1}{16}$ in. thick, and should also be attached to a terminal on the lid. It is to this copper strip that the carbon element is joined (one on each side of the zinc).

When we have got this into its place and properly fixed, we can then choose our carbon plates. These should be made of good hard porous carbon, exhibiting no cracks or coloured marks whatever on its surface. They should, of course, be of such a size as to suit the cell itself; they should reach from the lid to within $\frac{1}{4}$ in. from the bottom, and should be, at least, the same size in width as the zinc plate. Before we can attach our carbon plates to the copper strip we shall have to copper one of the ends of each; and to do this we shall have to make use of the electro-plating process. Take any wide jar holding about a pint, and nearly fill it with the following solution:—Copper sulphate, 1 lb.; dissolve in hot water, and add, when this is cold, 9 oz. of strong sulphuric acid. Be careful in the adding of this, as it will cause the liquid to become hot and spirt; it should be added very slowly. If the reader should not like to make up a quantity of this, he can use the following smaller proportions:—Copper sulphate, 2 oz.; sulphuric acid, 1 oz.; water, one pint.

When we have obtained our solution, and have filled our jar with it, we must obtain a cell of some kind of battery. The Bunsen is very good here; or, if the reader has a Daniell, he can use it in place of the Bunsen. If we have the Bunsen, attach a wire to the zinc, and also one to the carbon plate, and bring them to our jar of copper solution. To the wire coming from the carbon of the battery attach a piece of copper plate, and immerse in the jar of solution; string the carbons to be coppered to the other wire coming from the zinc of the battery. They should be attached to this wire by means of thin copper wire. Immerse the ends of the carbons in the jar of coppering solution to about the depth of 1 inch. Be sure that the carbons and the copper plate do not touch. Leave them in for about one or two hours (according to circumstances), and in about that time we shall find we have a fine firm coating of copper deposited upon them. Then swill these well in cold water, and wipe.

Having done this, the next procedure is to prepare a bath of wax: take an old tin tray about 2 in. deep, and put some good paraffin wax in it, and apply a source of heat (as gas) underneath. Fill this tin up with melted wax, and regulate the heat so that it will just barely keep the wax boiling; then immerse the coppered ends of the carbons in this for about 2 inches. Allow these to remain in for twenty or thirty minutes. Then take out and well wipe with dry cloths. Be careful and well wipe the coppered ends, or else it will be found that we shall never obtain the solder to stick to them; and it must be also understood that the waxing of the carbons must *always* take place *after* the coppering and never *before*, because if the carbons were waxed first we should never obtain a good coating of copper on them, and it is for this simple reason they are waxed afterwards. The waxing is to prevent the salts of the battery solution creeping up and destroying the connection. When we have well wiped and again washed our zincs in water, we can attach them to the copper strip by means of soldering the copper strip to the coppered ends of the carbon. Use ordinary solder and spirits of salts, and well wipe and wash the joint afterwards. Many electricians prefer to use resin for these joints; but I should not advise any of my readers to use it, unless they have the patience of Job, a good temper, and also have had a little experience of using resin with solder. I never use resin in any of my apparatus, and I have never had any fault to find with any of it yet. When we have finished our carbons, we have the battery complete, except the amalgamation of the zinc and the zinc terminal. To make the latter, you can either tap a hole in a brass rod and screw a small terminal in to it; or else, if the battery is for use and not for show, we can drill a small hole down the rod, say for about $\frac{1}{2}$ in., and then drill another hole through the rod, and across this other hole—say about $\frac{1}{4}$ in. from the top of the rod—tap the hole that is drilled down the rod, and insert a small screw. If then we pass a bit of wire through the other hole, and then screw the screw down, we shall have a handy and cheap terminal. It is the method that I always use in similar cases where my object is not show.

Now for the amalgamation of the zinc. This is, in my idea, a very important part. Many seem to think that if there is just a little mercury on the zinc, that is sufficient; but this is *not* sufficient. The zinc plate must have a thorough bright and regular coating of mercury on it. There are two methods of doing this: one is by means of the old troublesome rubbing method with mercury and sulphuric acid, and the other is by the method designed and improved by myself. I will give them both. The one that is the least troublesome to use, and the one I always use, is the latter; nevertheless, as only a very few use this, I will give both. First, the old method:—Take a little mercury in one saucer, and a little sulphuric acid in another; pour a very little sulphuric acid on the mercury. Then, with a piece of rag tied on the end of a stick, dip first in the sulphuric acid, and then well rub the plate; then obtain a few globules of mercury on the plate, and well rub them with the rag till a bright uniform amalgam of zinc and mercury is obtained. Be careful that you do not get the acid on your hands or clothes. If you get the acid on your clothes, a little strong ammonia will remove the red stain, but will not, as may be supposed, turn tailor and mend the burnt hole. If you get any of the acid on your hand, rinse it well in running water; but my advice for these two points is, Do not get acid on your clothes or person unless you possibly can help it.

Second and best method of amalgamation, but slightly dearer; it costs four times more than the old method, and it is this ground that debars many from using it:—Take nitrate of mercury, 1 oz.; chloride of mercury, 1 oz.; dissolve in water to which a little hydrochloric acid and ammonic nitrate have been added; make up with distilled water to one pint. The zincs, before being immersed in this, should be well cleaned with sulphuric acid and water, and should then be swilled with distilled water; or, failing this, with water that has been vigorously boiled and then filtered. I fear I cannot recommend the use of ordinary water as it is. If the zincs have been well cleaned, when they are taken out of the bath they will be found to have a splendid bright coating of mercury. This arrangement, as will be seen, constitutes one of cleanliness and portability. The solution will last for a long time if it is kept well corked in a bottle when not in use.

Now for a few solutions. First of all, the bichromate of potash solution:—Take bichromate of potash, 1 lb.; dissolve in four pints of hot water; allow to cool, and when cold add sulphuric acid, $10\frac{1}{2}$ oz.—This solution is one of the best known, and has been regularly used by me for some years past.

Chromic acid solution: — Chromic acid, 1 lb.; sulphuric acid, 8 oz.; water, four pints.—Very good, and gives an intense current.

Permanganate of potash solutions:—Mason's solution consists of permanganate of potash, 6 oz.; sulphuric acid, 2 oz.; water, 1½ pints.—Gives a most powerful current for same length of time as bichromate.

Bromine cell. — Same solution as permanganate of potash, with a layer of bromine under the solution. It is the most powerful solution known, giving over 2·0 volts E.M.F., and also having an extremely low resistance. The solutions above given have all been tested for a great number of years, and so can be thoroughly recommended to all those that are in want of a good strong solution. They all give at the least an E.M.F. of 2·0 volts.

Any matters pertaining to batteries I shall always be very pleased to answer. I should have before stated that there could, and should, be run round the lid of the bichromate bottle battery a strip of brass, fitting nicely the outside of the bottle. This sets the bottle off, and makes the job look workmanlike, as all work should that is made from instructions given in WORK.

OUR GUIDE TO GOOD THINGS.

**** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

88.—HOME ART WORK.

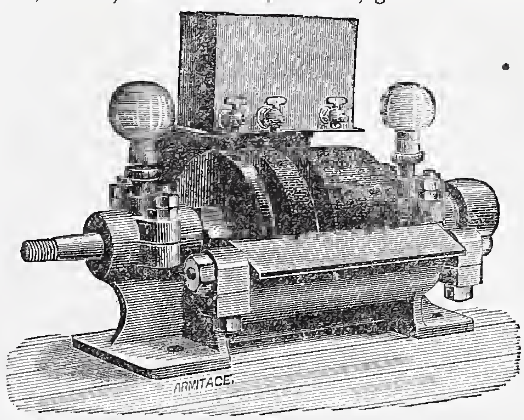
MANY readers of WORK are, without doubt, interested in the employment which is well expressed in the title of the magazine now under consideration, namely "Home Art Work." It is, as the wrapper tells us, the new monthly series of "The Art Designer," and is "A Monthly Portfolio of Full-Sized Designs for Painting and Artistic Work," edited by Mrs. Conyers Morrell, and published at and by Mr. John Heywood, of 1, Paternoster Buildings, London, and Manchester. There is, as a matter of course, much to interest and amuse in the letterpress, but the chief attraction lies in the sheets of designs that are issued with each monthly issue. In the parts before me are two small sheets—one, that is to say, in each part, with some well drawn classical figures from the antique, the most noticeable fault being a somewhat exaggerated gap between the great toe of each foot and the toe next to it, which gives one the impression that the classical figures had originally rejoiced in the abnormal number of six toes in each foot and had lost one of the number by amputation. The larger sheets are very good. One of these has on one side a spirited full-size design by Walter Crane, for the corner of the border of a table-cloth, exhibiting two winged dragons in mortal conflict; and, on the other, designs for glove and handkerchief boxes, adapted for needlework, repoussé work, poker painting, or wood carving, by Mr. G. C. Haite, F.L.S.; a design for a plaque of water lilies, tadpoles, and frogs, by Mrs. Ernest Peel; a border for altar linen by the Rev. Aymer Vallance; a tea cup and saucer, with violas, by E. Hall; and two pincushion needle-boxes, one in the form of a violin and the other resembling a guitar. The other large sheet contains on one side Andromache, reclining on a couch, and on the other the same subject on a small scale, surrounded by a border of flames; various small designs including some Old English patterns for muslin embroidery; two circular designs for needlework or repoussé work for embroidery, the subject being wild boars in some well-conceived scroll work by the Rev. Aymer Vallance, and some seventeenth century designs for gloves useful for painting on needlework. The list of illustrations just enumerated will give intending purchasers a sufficient idea of the nature and contents of this magazine. The large sheets, it may be said, are about four times the size of the small sheets.

89.—HARGER BROTHERS' IVORINE AND VULCANITE.

Messrs. Harger Brothers have sent me specimens of two materials which they have recently added to their large and varied stock of tools, appliances, and materials. They are called ivorine and vulcanite, and, as may be supposed, the former material is of glossy whiteness, and the latter black; the ivorine for fretwork, inlaying, and overlaying in fine work, and is supplied at 2s. 6d. per square foot. The vulcanite is dearer, being 3s. 6d. per square foot, but it is much thicker than the ivorine. Any one who stands in need of them at any time, will find these materials both useful and serviceable for the purposes for which they are supplied.

90.—EXAMPLES OF LATHES, APPARATUS, AND WORK.

This is a very useful pamphlet, by the author of "Lathes and Turning," published by Messrs. E. and F. N. Spon, 125, Strand, W.C. In his preface, the author says: "The following pages are written with a view of describing the construction and capabilities of some of the most recently designed lathes, apparatus, and tools. Those who want further information on the general subject of turning are recommended to read "Lathes and Turning," second edition, published by Longmans, price 18s. The pamphlet is, in fact, an agreeable form of catalogue and price list of the specialities of the London Lathe and Tool Company, many of which were noticed and illustrated in the earlier numbers of this Magazine. Some interesting examples of ornamental turning are engraved, and notably a peculiar specimen of turned work consisting of a cube, having within it a smaller cube, with a horn projecting from each of its sides. This is all turned out of the solid. Ivory or hard wood is the best material of which to make it. Some excellent specimens of geometric turning are also given, which, up to the present time, have been produced only by means of expensive apparatus. The author, however, tells us that he has devised a simple and inexpensive instrument by which this class of work can be executed in a plain lathe, without overhead motion and without division plate. This will manifestly be a great boon to amateurs and others who wish to execute a little ornamental turning of the kind mentioned, but are not possessed of means wherewith to furnish themselves with the costly apparatus that, up till now, has been absolutely necessary. The author of the pamphlet does not tell us what the instrument is, but he refers us to a volume of his "Geometric Turning Simplified," in which all those who want to know how these and other figures can be produced, will find the means of slaking their thirst for knowledge. While writing on this subject, I may call attention to the London Lathe and Tool Company's Grinding Machine, a compact and handy appliance, which has not yet received notice in WORK. "The small cutting tools," says Mr. Northcott, "now used in the best organised workshops, for even tolerably heavy work, are ground far quicker and better by these small tool-grinding machines than by the old-fashioned grindstone, which latter, with its dust, dirt, and disorder, may be relegated to the yard and used only for rough grinding. Unless otherwise ordered, the spindle carries three wheels; the first, a wide and moderately coarse emery wheel for doing most of the work; the second, a fine emery wheel for smooth grinding; and the third, a metal wheel, used with the finest emery or other fine grinding material, for giving the polished edge required by some cutting tools. The spindle end is made to carry a face grinder, buffing wheel, etc. The guide bar or rest in front may be fixed at any angle, and the cutting tool is generally carried by a small adjustable sliding rest, pushed along the guide bar by hand. By these means, all cutting tools may be ground to correct cutting angles, and much better work produced by them than by badly shaped hand ground tools. The grinding machine may be mounted on a bench or upon special stands as preferred." Prices range as follows: — With six-inch wheels, £10; with nine-inch wheels, £15; with twelve-inch, £20. Countershafts complete for each size of wheels are supplied, complete, for £2 10s., £3 5s., and £4 respectively. A representation of this desirable and useful machine is given in the accompanying illustration.



London Lathe and Tool Company's Small Grinding Machine.

This pamphlet, small as it is, for it comprises only forty-eight pages, will, I am inclined to think, give all those who wish to take up ornamental training, and attain proficiency in it, as good an insight into the tools and appliances that are needful and the work that can be executed by them as well as by making reference to, and searching the pages of, many a more pretentious and costly work. At the end of the book are given engravings of many of the simpler varieties of ornamental work produced by many of the lathes and apparatus described in its pages. Although the author speaks of them as "simpler varieties," they present many complex arrangements of curved lines that are almost bewildering in their crossing and recrossing. I believe that all these diagrams are engraved on the wood in the lathe, for they could hardly be produced in all their regularity and intricacy by the artist's pencil and the engraver's graving tool. The pamphlet is appropriately brought to a termination by some specimens of turning in the solid, produced in one of the Company's five-inch geometric lathes by an apprentice who had never before done any ornamental turning. In this page illustration are twenty-five napkin rings of different patterns, most of which were shaped by the Universal Cutting Instrument, aided by the division plate, while some were shaped by one of the Company's Drilling Instruments. I regret that it is not possible to produce here the illustration to which reference is made. I can only hope that a desire to see it, and to judge in some measure of the excellence of the work that is figured, will cause many a reader to send to the Company for a copy of the book itself.

It will be found that some of the appliances described in this pamphlet have been noticed in the earlier numbers of this Magazine, but this need not deter any one who may wish to possess it from sending for it, as the tools and machines which have not been mentioned in these pages considerably outnumber those which have. Added to this there is much information with reference to the uses of the machines that are mentioned which the author of "Lathes and Turning" supplies in an attractive and desirable form.

THE EDITOR.

SHOP:

A Corner for Those who Want to Talk It.

*** Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Broom and Brush Making.—Brushmaker writes:—"I see on page 253 of Work an answer to a query regarding broom and brush making which is very misleading. I understand the material your correspondent has sent you a sample of is called bass. It is of a dark brown colour and very stiff; it is used to make stable brooms with. I will try and explain to the best of my abilities the proper way to tie a knot. Say that the holes in the brush-head are ⅝ in. in diameter. Take up as much stuff as you think will fill a hole; have your pitch melted; dip the one end in it to the depth of full ½ in., so as the pitch will penetrate through it; then take a piece of thin cord about 12 in. long, and roll it tight at the top; then dip it in the pitch a second time and put it in the hole with the right hand with a half circular turn, just as if you were screwing it in. This spreads the knot and puts it to the bottom of the hole."

A Complaint.—W. W. W. (*London, S.E.*) writes:—"After taking in Work regularly since commencement, and waiting for my turn (wheelwright and coach painting), I was astounded to see the article on Battlesden Cart. I supposed your writers were practical men, not clerks. I supposed Work was for the benefit of beginners and improvers of all trades. In your article on cart the writer doesn't mention birch for panels, elm being seldom used, owing to its being liable to cast in drying; walnut is far too costly. He also mentions elm for shafts, but I have never seen an elm shaft in my life, especially one of that description. To an outsider, no doubt your other articles appear reasonable enough, but having asked the opinion of others in the trades, they say the same, being far too amateurish to be of use to improvers like myself. Most of your subscribers being lads like myself, they will admit that 'Shop' is the best portion of the paper (iron trades and sign-writing excepted). However, I shall stick to it, hoping it will improve and become useful."

Metal for Repoussé Work.—F. U. (*Hereford*) writes:—"I have taken in Work from the commencement, and I consider it really the best of its class published. I have obtained much that is useful from it, and should therefore like (with your kind permission) to call the attention of your readers and workers in repoussé (that is, of those who do not already know it) to a very beautiful metal for this work, far superior to either brass or copper in working and in looks when finished. It is known as aluminium bronze or sun metal. The patentee is Mr. John Clark, 80, Great Brook Street, Birmingham, but no doubt it can be got through any ironmonger. I have just finished a piece of work which put it to a very severe test, and it came out victorious in every instance. I see the metal is patented in Belgium, France, Germany, United States, Great Britain, and India, the price of it being very reasonable."

An Opinion of Work.—Stoker writes:—"Allow me to say a few words about Work. Your correspondent W. V. C. (page 268) says that most of the articles in Work are far above his head. Perhaps so, but why don't he try something that won't require so much skill to make as 'A Cabinet in Fretwork for Skilled Workmen?' It only needs a bit of courage and determination to succeed, and then I am sure he will have no cause to grumble when he looks upon his handiwork. Now, here is an instance that should encourage him. Till I had the first number of Work I had never used a carpenter's tool, and I have never been inside a carpenter's shop, or scarcely ever seen a carpenter at work, so surely I was about on a level with W. V. C. in the matter of carpentry. I had very little money to spare, yet I purchased a small plane for 2s. 6d., begged an old file from the scrap heap, and forged myself some chisels out of it, with the kitchen fire for my hearth and a shoemaker's iron last for my anvil, and then I went to work and made a table as described in No. 1 of Work, with turned legs and plain top. I met with many difficulties, but believing that perseverance conquers everything, I worked away with a will, and succeeded in making a good job of it. I then French-polished it, and here again Work came in, for I had never done any French polishing before, but thanks to Work, I succeeded in this also. And now I have sold the table for what I consider a good fair price, and am going to buy a few tools with the money. I might say I made a lathe to turn the table legs, and the ideas for this I got from Work also, and although it is very rough, it does a lot of good work, and the materials in it only cost me about 4s. 6d. I would send a description of it, but I think it unnecessary after what has been said by Self-helper in page 261 of Work, and, as you see, I am not good at writing, and I hope my fellow-readers will excuse my badly-turned sentences. In conclusion I beg to state that in my opinion Work is supplying a long-felt want. I am sure it is just what I've been longing for many years, and I heartily thank you for the good it has done for me."

Simple Measurement of Timber.—Timber Trolly writes, in reply to A. G. H. (see page 269):—"A. G. H. does not understand the reason of timber measurement as given by Hoppus in his calculations, or he would not have intruded his views of which is right: by trade usage and fairness in buying and selling; or by cylinder measure. In measuring timber in the round it is usual to allow from 2 in. to 3 in. less circumference for the bark, if on the tree. A. G. H.'s omission of this fact plainly indicates his ignorance of the usage of the trade. Round timber cannot in fairness be measured as a parallelopipedon, as if it were the outside or inside of a mathematical figure—as for engineering calculations—but for what it will fairly produce to the buyer when the sap is hewed off and the timber squared. Having bought and sold many million cubic feet of timber, 'growing,' 'round,' and 'squared,' and knowing the usage in Europe and America, I may state that the system common to all timber-selling countries for measuring round timber is the quarter-girth squared, or multiplied into itself, and the product multiplied by the length of the piece of timber; this product is then divided by 144; if the calculation is in feet and inches the dividend is the answer, as shown in Hoppus. Now for matter of fact. Has A. G. H. never heard of tare and tret, the long-hundred, heap-measure, the barn gallon, the baker's dozen? Timber measure comes under the same category of reckoning, or it would be called cylinder measurement if that plan were used. From my experience, the difference between timber measure and cylinder measure is as 102 to 120, or 18 ft. of that latter measure or less is charged to timber buyers proportionately, as well as several feet less allowed off for bark, according to local custom or sort of timber; and if the tree has a top, even several feet long, that will not square up 6 in. in quarter-girth, that is given to the buyer, if the timber be ordinary English wood. Limbs, in like manner, that will not measure the 6 in., are also given in, if they happen to be left on the 'but.' Is all this giving-in fair? it may be asked. As a seller more often than a buyer, I can affirm it is only fair. How so? Because timber is not sound and serviceable to its outer circumference. The sap of some trees is useless unless specially converted to other purposes than the 'heart-timber' may be used for—as, oak for spokes for wheels, for instance. The 'but' is useless because of the turn of the grain; the top, because too small; even slight curves out of the straight line have to be cross-cut out and thrown aside for other jobs, and every bit of sap must be got off. This sap may be 2 or 3 in. thick in a large tree, so that the sound part of an ordinary oak tree would not yield much more timber than was charged for, by reason of the sap alone, without reckoning 'but' or crooks in the piece. A variety of chances rise against a tree turning out well when opened. Perhaps it has been stricken by lightning, which even a critically experienced forester cannot always detect, as the five radiating shakes from the heart to outer rings do not show when the bark is on, and sometimes even when the bark is off. The tree may be hollow, or gnarled, or have stones and iron nails in it; even a cannon shot has been found in the sound wood of a tree, and the saw is damaged in finding it. ('The Technics of Forestry,' illustrated in the *Journal of Forestry*, by Rider, St. Bartholomew Close.) It must not be forgotten timber in the round does not represent cost commercially so much as sawing does, which the buyer has that to incur. It might surprise A. G. H. if he had his round log cut down the middle, or 'opened,' as it is called, and the measure showed 80 square feet, to have to pay double for that cut, or for 160 square feet; yet it is the rule of pit sawyers of round and even square logs; and as an arbitrator and referee on sawing matters, I feel sure it is only fair, as it is a payment for the labour of 'hewing,' 'pitting,' 'dogging-down,' 'lining,' and 'hauling' the cut stuff to stack, done by sawyers who make this charge; for on 'opening,' the tree may be 'hollow,' 'doated,' or worthless, and no more cuts put into it, all after cuts being actual square measure reckoning. Did A. G. H. ever buy a plank cut from round timber with a section thus?

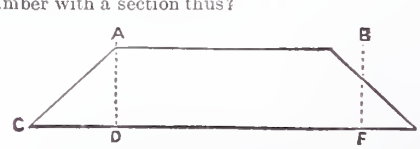


Diagram showing "Wane" of Timber.

The triangle called the 'wane' of the timber, A, C, D, is not measured, but the other 'wane' is, to half its measure, as shown by the dotted lines B, F; thus the buyer of plank has some of the round timber and sawing given to him. If the plank is less than, say, 30½ feet long by ½ in., the bare half foot, or 5½ in., is given to the buyer; this, with the sawing, has been paid for, with all its risks, by the round timber purchaser. If this lesson in timber dealing does not convince A. G. H., let him buy a carpenter's slide rule marked for round timber measure, no matter of what nation, or one of the more elaborate sets of logarithmic scales with gauge points for round timber measure, and test my experience by them, and he will find Hoppus's calculations right. But a visit to a wheelwright in the country, who deals in round timber, with a few questions, will, if intelligently made, teach him the difference between common sense and knowledge: one is the applied science of everyday life, the other may be only the recollection of a dunce or the oracle of a fool—if mere blind book learning which may mislead the inexperienced."

Proportions of Lathe Fly Wheels.—J. W. C. (*London*):—I have received a very silly letter, through the Editor, from an anonymous correspondent, signing himself "J. W. C.," giving his address very precisely as "London;" *re* my reply to J. P. A. on p. 220 of Work. As I much question if the Editor will sully the pages of his journal with my correspondent's sneers, I will mention in brief that J. W. C. speaks of my sketch as "that wonderful design of a tight-laced figure 8," as a "pretty piece of figure skating, but somewhat far fetched, and just a little too much *work* in it," and as an "antiquated idea." After a maundering "tale of the Ark," J. W. C. triumphantly flourishes before my benighted and antiquated mind a "problem" reclaimed from Noah's stomach by a "wily" engineer "in his greed for knowledge." This elegant correspondent informs us how Noah had worked out the problem on the skin of the hard-boiled egg which he was eating: hence the "wily" engineer employed a stomach pump for the reclamation of this famous "problem." The problem is that $1 + 2 = 3$, and $2 + 1 = 3$, whence the obvious inference that, instead of giving the method on p. 220, "with just a little too much *work* in it," I ought simply to have said that the sums of the diameters of each pair of pulleys should be alike. Passing by the sneers in which J. W. C. indulges, I ask him if he thinks that I, who have been among belts and pulleys daily for nearly thirty years, would, in this particular case, commit so stupid an error as that embodied in his arithmetic. J. W. C. imagines that the problem is the same when the centres of pulleys are very near as when they are an infinite or a long distance apart. In stepped pulleys whose centres are not far apart, as in the lathe matter in question, this arithmetic $1 + 2 = 3$ and $2 + 1 = 3$ does *not* hold good, because the angle at which the belt runs on to and leaves the pulleys has to be taken into calculation, and this governs the proportion of circumference of the pulleys embraced by the belt. If it were simply a case of 1 + 2, etc., why the elaborate formulæ for belt lengths given in the books (see Unwin and others) where trigonometrical functions of the angle θ are employed? These formulæ are Greek to most workmen, and I, therefore, gave a graphic method that everybody could understand, and certainly do not think I put "too much *work* in it." Yet it seems that it is not sufficiently clear to the dense intelligence of J. W. C. But will J. W. C. be good enough to set out stepped lathe pulleys as on p. 220 according to the $1 + 2 = 3$ theory, and then set them out according to my directions? Having done so, will he take a pair of dividers, and step round the path of the belt on each pair, and acquaint the readers of Work with the result, omitting the stupid rigmarole about Noah, which would probably be "declined with thanks by our friend Sloper, and is certainly unfit for Work?" For myself, I may say that, though I have been at the pains to correct J. W. C. in this matter, yet in future, when assailed by an ignorant and anonymous and ungentlemanly correspondent, I shall, whether in the right or wrong, treat the communication with the silent contempt which it deserves.—J. H.

II.—Questions Answered by Editor and Staff.

Coach Building—the "Cant Board."—T. T. (*Kennington*) writes:—"If you are not tired of hearing them, allow me to offer you a few words of praise and my testimony as to the usefulness of Work. In my humble estimation it is the one thing that was needful. May I be allowed to ask at the same time if it is a part of your programme to give any practical papers on coach building? It seems in most books to be entirely neglected—why, I know not. I hope Work will be an exception. I happen to be a body maker (improver), and some papers on that subject, especially on the 'cant board,' would be read with great pleasure, and profit, no doubt, by myself."—[I think we must be content to regard Work as one of the things that are needed, and not as the "one thing needful," which is a matter of far higher and greater importance, as you will see if you turn to St. Luke x. 38-42. Your request with regard to coach building generally, and the "cant board" especially, has been forwarded to a skilled coach builder, who will take the matter in hand.—Ed.].

Leclanché Battery for Disposal.—J. C. F. (*Otford*).—Advertise your battery for sale in the "Sale" column of Work. The cost will be one shilling for twenty words. Or advertise it for exchange for something useful to the value in this paper, *The Bazaar, Exchange and Mart*, or *The English Mechanic*.—G. E. B.

Electro-Plating. — J. T. D. (*Sunderland*).—I hope to give full instructions on the art of electro-plating in some future number of Work, in a style easily understood by amateurs and young workmen. Meanwhile you may learn much from my occasional "Notes for Electro-platers." The best book on the subject is "Electro-deposition," by

.. Watt, latest edition, price 12s. 6d. I am glad to now that such a young amateur electrician is aking an interest in electro-plating. I shall be ery pleased to give you instructions in "Shop" if ou meet with any difficulties in your studies.— ;. E. B.

Dry Plates. — Tortoise-shell Tom (*London*). -The preparation of your own dry plates would be , tedious and troublesome job, and unless you are iossessed of a large stock of patience and a cheerful emperament, I would not advise you to attempt heir manufacture; better buy the larger size, a: 'ou are doing, and cut them down. But why not ilter your dark slide, or insert a carrier to take ;-plate size? Then you would be working to a recog-iised standard, and plates, paper, mounts, and leveloping dishes could be used more economically, ind you would have no waste, as at present. To :oat plates requires a rather heavy outlay for apparatus, and the actual process occupies a deal of time, while the result, even when the greatest pains are taken, is often failure, besides which even a brief summary of the process would, to be intelligible, take up about a couple of pages of Work. For further information on the subject, you should procure Burton's "Modern Photography," price 1s., where you will find at page 143 full details of the coating of dry plates and formulæ for emulsion-making. Cassell's also publish an excellent shilling book on "Photography for Amateurs," by T. C. Hepworth.—G. le B.

Electric Bell.—Amateur G. A. S. (*Stepney*).— As your bell stopped ringing when the armature was pressed to the cores, and did not recover itself when the finger was removed, this showed that the cores retained some magnetism after the circuit was broken. This defect was confirmed by the experiment you tried with the iron filings, since they also stuck to the cores after the circuit was broken. The iron of the cores is therefore, hard. Now for the remedy. The surest is, to take out the cores and anneal them as directed on page 180. Sometimes (unless the iron is very hard) the sticking propensities of the armature may be remedied by pasting a bit of paper (gummed paper from postage stamps) on each of the cores. The magnets for a 4-in. bell will take 47 yards of No. 22 B. W. G. silk-covered copper wire. This will weigh nearly six ounces, and cost about 2s.—G. E. B.

Magnet. — Flax Spinner (*Longton*). — The information you give respecting your battery and horse-shoe magnet is insufficient to work upon. I must know exactly the diameter of the magnet cores as well as their length, as I shall have to calculate the cubic contents of the iron in the magnet to arrive at its capability for receiving magnetism. Therefore kindly oblige by giving me the *length* and the *diameter* of the magnet legs, and I will then tell you the size of bobbins to be placed upon them, together with the gauge and length of wire to be wound on the magnet. As the magnetic force developed in the iron of an electro-magnet is proportionate to the strength of the electric current passing around its coils, I must also know the number of cells to be placed at my disposal, as well as the size and nature of the plates. It is not enough to say you "have a lot of Smee cells;" I must know *how many cells*. By-the-bye, your cells are not Smee's, but Walker's, as shown by the carbon plates. The electro-motive *force* of both is low, and not at all suitable to develop the full power of an electro-magnet. I will try to instruct you how to alter your battery, too, if you will write again and give all particulars.—G. E. B.

Corner Bookcase.—E. S. (*Clapham*).—I have a design and description of a corner bookcase, which will appear shortly, and which you may be able to adapt to your own special requirements. It is seldom possible to do more than give a good type of the article required, but this done, advice and suggestions with regard to modifications desired by correspondents can always be given.

Overmantel.—Brushmaker wishes to make an overmantel with mirrors and fretwork panels, and desires a design for one in Work from the pencil of Mr. J. W. Gleeson-White, and adds, "I have made up one of his designs already, which I exhibited at the Glasgow Exhibition last year." I am sure Mr. Gleeson-White will be as pleased as I am to hear of your success. I have many beautiful designs from his pencil awaiting publication, and in course of time you shall have a design for an overmantel in fretwork.

Hot-Air Engine.—C. J. W. (*Beccles*).—Space forbids any further attempt to notice articles of any kind on show at exhibitions. A mere cursory mention of them is of little, if any, practical use, and it is not possible to devote to it the room that the subject demands. For this reason I cannot give a review of the machinery at the Royal Agricultural Society's Show at Windsor. But as soon as it can be managed, descriptions will be given of engines and motions, including a hot-air engine.

House Repairs.—Aitch.—Articles on general house repairs would have to be hypothetical to a certain extent; that is to say, we must first suppose certain damages and the causes thereof, and then describe process of repairing according to the supposition. The term "general house repairs" covers a wide area. If there are any particular repairs that you wish to carry out, put a question to us on the subject, and you shall receive instructions through the medium of "Shop." I am glad you found the first paper on Burglar Alarums "very good, and quite interesting, also instructive."

India-rubber Stamp Making.—Hallamshire. —When I can meet with any one who can and will write on this subject a paper or two descriptive of the appliances and materials used and the process to be followed, it shall be given. I must, however, first catch my writer. Probably this reply to your appeal may bring a volunteer to the front.

Photographic Camera. — H. M. (*Oldham*). — The construction of the camera is already commenced. With regard to the cost of lens, it is not possible for me, being in ignorance of the sort of lens you want, to name a price. The best course you can adopt is to send for the price list of any dealer in photographic appliances, and select for yourself the kind of lens that will meet your requirements in price as well as other points. In the "Photographic Annual for 1889," issued by Mr. Jonathan Fallowfield, 35 and 36, Lower Marsh, Lambeth, S.E., which, in fact, constitutes his price list, twenty-six pages are devoted to description and prices of lenses. You can get lenses at all prices from 4s. 6d. to £50, and even more, but good lenses for ordinary purposes may be bought from £1 to £5. It might be useful for you to watch the photographic journals for advertisements of lenses to be sold cheap by those who wish to part with them.—E. D.

Working Drawings to Scale.—E. J. E. (*Abingdon*).—For the benefit of yourself and others who find a difficulty in reading and understanding working drawings to scale, an explanatory paper shall be written on the subject. You will find "Drawing for Carpenters," published by Messrs. Cassell and Co., Limited, a most useful book. It will not be possible to comply with your suggestion to enlarge Work and raise the price to 3d.

Index to Numbers.—Barrhead writes:—"If the contents of each number were printed in small type over the top of the word Work on the front of each number, I think it would be of great assistance to any one looking for a certain article that he remembered having seen in some back number. It would save his looking all through each number." In reply to your suggestion, which is a good one, the position proposed would not be a convenient one for index to numbers; it would come in better under the date, but as so much room is wanted in the front page of some numbers for cuts, it would be difficult to provide for an index in this page. Still there is so much reason in your suggestion that it shall have careful consideration.

A Wooden Affair.—Progress writes:—"I have taken Work in monthly parts from the beginning, and was induced by your prospectus to do so, there being many subjects mentioned about which I should like information, particularly watch-jobbing, horology, and other kindred arts, but up to the present your Work has only been a wooden affair, and I am glad to see you had complaints from other subscribers. Evidently you put your trust in wood, and I hope it won't fail you, for you will have none but wooden customers unless you give a better all-round pennyworth. Of course, you can't give everything at once, and so I shall continue to take it in till it has had a fair start, and as questions are permitted I will ask one or two."—[The prospectus did not say that every subject was to be commenced and dealt with at once. You will not be long without information on watch-jobbing at all events. "Like cures like," the homœopathists say, and "like seeks like," in accordance with the old saying, "Birds of a feather flock together," so that you may trace if you like the woodiness of Work to the material of which its Editor's head is constructed. Yes, I certainly like wood working myself, although it can hardly be said of me that I put my trust in it altogether. Wood is a material that is far more tractable and easily worked than metal, and hence it is that wood working finds favour among the majority of those who take up manual labour as a hobby. Moreover, the outcome of this is that it is far easier to get writers on carpentry, joinery, and cabinet making than on other subjects, which, although quite as important, are, perhaps, not quite so popular. But you will find plenty to interest you, as successive numbers appear, even in your own particular subjects.—Ed.].

Watch Maker's Mandrel. — Progress. — For my own part, I prefer a largest size "Boley" turns, with universal head and extras, as then you have a good combination tool, but if cost is no object, then a good American lathe, with a mandrel head. To fit a new jewel, if the setting is bad, I should think you could turn out a new sink with a fine lozenge graver, but must confess I have never done so, as when too bad to hold a jewel have usually sent to a jeweller's.—A. B. C.

Spinning Tin Plate —J. C. G. (*Nenagh, Ireland*).—I quite agree with you that spinning in the lathe is a fascinating art, but it requires much practice. Tin plate can, to a limited extent, be spun in the lathe, but to nothing like the depth you name. In trade a great deal of work that used to be spun is now pressed. I cannot give you the amount of pressure to apply; it will depend upon the thickness and quality of plate upon which you are engaged; this and the velocity are best found by trial. You should begin with a light pressure and gradually increase it, but you must be careful not to increase it too suddenly. You cannot anneal the plate without burning the tin off; but why not get the charcoal plate and spin it, and then tin it afterwards? You could then anneal it as often as you liked. Tin plate is not a favourable material, because the iron will not "flow." You would find Britannia metal work better. I believe the best account of spinning metal is to be found in Holtzappfel's "Mechanical Manipulation."—F. C.

Brittle Electrotypes. — A Beginner (*Foley Street, W.*).—In your case, the brittleness of the electro is evidently caused by too much current. In making such small electros as you describe, and in copying coins, you must adapt the surface of the zinc in the battery to the size of surface to be covered, or use fine connecting wires so as to reduce the volume of current. The current may also be reduced by exposing a small surface of anode to the solution (the size of anode should always be adapted to size of mould), and by placing the anode and mould farther apart in the solution. A few practical experiments embracing those varied alterations will soon put you in the way of getting good, tough copper. The solution may have something to do with your failure. The best is made up of:—Saturated solution of copper sulphate, 6 pints; water, 2 pints; sulphuric acid, 16 fluid ounces. You do right in using the large Daniell cell.—G. E. B.

Photo-lithography.—J. P. (*Glasgow*).—When a suitable opportunity offers, this subject shall be touched on.

Model Yacht and Boat-building.—There are so many subjects on hand just at present that some of them must of necessity be cleared out of the way before this and others can be taken in hand.

Catapult.—G. S. W.—You say:—"Could you tell me how to make a catapult in a proper and scientific manner—not a mere child's toy, but one that is capable of throwing a long, straight, dead shot—giving details as to size of shot used, material, whether wood or wire, and how to make it properly?" To this I can only reply, I could, but I would much rather not, as the girl said when her father told her to come off the grass. Catapults are dangerous things; and, as I am obliged to draw a line somewhere, I must draw it at catapults and all things that might be attended with damage to life, limb, and property, if brought into play. However, that you may not be entirely disappointed, I will refer you to Dr. William Smith's Dictionary of Greek and Roman Antiquities for information on the balista and catapult—ancient engines of war that were capable of doing all you want or wish for in the way of throwing "a long, straight, dead shot," and did it well, too.

Work behind Time.—C. H. C. (*Margate*) writes:—"Can you inform me how the delay is caused through my bookseller not receiving Work? I have been a subscriber from the commencement of the valuable work, and I don't think it is quite right that the delay should be so long that I never receive it regularly. I should be pleased if you could assist me at all."—[Your bookseller ought to have Work for each week on sale on Thursday morning at the latest, Wednesday being the date of publication. I cannot *tell how* the delay is caused; but I have a suspicion that it is either through the remissness of the bookseller's London agent, or the inability or disinclination of the bookseller to look properly after his business. If I did not get things up to date myself I should try another bookseller.—Ed.].

Upholstery Work. — G. F. (*Bristol*). — Carpet planning cannot be treated of in these pages yet awhile, as there are many subjects of more general interest awaiting their turn. Bed hangings have been under consideration, and a design may now and then be given, but, like the former subject, this must wait, unless I should find I am mistaken in supposing that there is no large demand for instructions on this kind of work. As you are, no doubt, aware, if I may judge from the heading of your note, with the exception of planning, etc., draperies, the actual making up is done mostly by women, and Work is a magazine for men. The same objection does not apply to stuffing and general chair upholstery, which will take its turn with other subjects. An article on making, stuffing, and covering a chair will shortly appear. I cannot advise you to attempt to make your own buttons as per sample sent. As a matter of business, it would not pay you to do so, and surely you have no wish to make them *en amateur*. You can buy the buttons for far less than it would cost you to make them, and I take for granted you know how to cover them whenever it may be necessary.—D. A.

Electric Light for Photo Dark Room.— Correspondent.—Procure a six-volt 2½ c.p. lamp. Rig up a four-cell battery, double carbons, with single zincs between, each plate being 2 in. by 6 in. by ¼ in. Let the cells in which these dip hold not less than a pint of liquid. Attach the elements to a board as long as the four cells together, and as wide as one. Connect the elements in series. Attach a hook at each end of board, and, by means of a pair of catguts and a weight, counterpoise the whole, so that the entire arrangement can be lowered into, or withdrawn from, cells by a mere touch of the finger. Charge the cells with:— Chromic acid, four ozs.; water, one pint; sulphuric acid (1·840), three ozs. by weight. Mix and allow to get quite cold. Couple up to lamp by means of well-insulated wires. When using, lower the plates only so far as is necessary to give the required light, since at the start, when the solution is fresh, so much current is produced as to endanger the lamp if the whole length of the plates is immersed at once. If your lamp is of higher volt size than six volts, you must use correspondingly more cells, allowing one cell for every two volts over the first four.—S. B.

Dressers. — GIMLET (*Coventry*). — An article describing the construction of one of these useful pieces of kitchen furniture will appear ere long. Meantime the following hints may be of service to you. As I gather from the nature of your inquiry that you are not a practical joiner, fasten the parts together with nails wherever practicable. You will find some valuable suggestions in the description of the overmantel illustrated in our articles on artistic furniture, as well as in other articles treating of cabinet making. Do not attempt sliding doors, but be contented with the ordinary hinged construction. Good, sound pine will do very well for the material, but use the red instead of the white kind, and remember that you will find No. 1 or a good quality cheaper in the end than thirds, though it may not be so low in first cost of timber. Your sketch does not show any plinth, which there certainly ought to be below what you represent as the bottom of the dresser.—D. A.

Bookcase Competition.—CHIPS.—I have given all the information that it is necessary to give in the notice respecting the competition, and all competitors must use their own judgment in preparing designs. You can determine exactly what is asked for from the wording of the notice, and I cannot say any more on the subject. The great object is to elicit the ideas of competitors according to the base of operation set forth in the notice.

Electric Bell Magnet.—J. B. (*Glasgow*).—The magnet of an electric bell should be constructed as described and illustrated on page 180. When two cores are employed, they must be united by a yoke of iron, so as to form a horse-shoe magnet. I have not tried the effect of mounting the two cores on a piece of wood or other insulating substance, so as to form two independent magnets. Small bells are sometimes rung with one core only. Thanks for your expressions of kindly appreciation.—G. E. B.

Mixing Oil of Gold Size. — GILDING (*Walworth*).—Take equal parts oil gold size, linseed oil, and copal varnish, mix well together, and strain through a fine strainer. Young's patent size is equal to parchment size, especially in warm weather, to dry quick. To dry extra quick leave out linseed oil and add terebene.—G. R.

Patent.—MINERVA.—The advice of AJAX was, no doubt, well intentioned, but evidently not very practical. Very few manufacturers or purchasers care to take up an article which is only provisionally protected; they generally ask to know that the complete patent has been applied for. Those who thoroughly understand patents are well aware that this provisional protection is, in reality, a very questionable monopoly, and that no action for infringement would lie against any one for pirating an invention only provisionally protected. All those who have good inventions so protected should lose no time in obtaining their complete patent; and we think that the advice of your agents has been well given.—R. and C.

Silver and Gold Solution.—GALVANUM (*Manchester*).—When you have your nitrate of silver solution ready, add to it a strong solution of cyanide, and when the addition of more cyanide does not cause any further precipitate of silver cyanide, stop adding the cyanide solution, throw silver cyanide on a filter, wash with distilled water, and collect silver cyanide in some vessel. Then add to it one pint of distilled water, with $\frac{1}{2}$ oz. cyanide dissolved in it. Make up to one quart, and then add another $\frac{1}{2}$ oz. of cyanide to it. Do the same with the gold, but, instead of adding $\frac{1}{2}$ oz. free cyanide, add $\frac{3}{4}$ oz. or one oz. If solution should work slow, add a little more, say, at the rate of one drachm at a time. I have a chain which was in the bath for two hours that has been in use for the last fifteen months, and it is not altered much; but it is very hard to state on such matters as these, as it depends upon mode of working, strength of solution, and experience of the depositor. Your deposit ought to have lasted longer than it did. If you make up a solution as in my article, and use these proportions of cyanide, you will, if you are careful in the depositing, be able to obtain a serviceable deposit. I am at present preparing an article on the use of cyanide of potassium, which, no doubt, will be of great interest to you. If you cannot succeed, write again, and send me full particulars of your process and preparations.—F. W. M.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

Circular Latch Needle Machines.—CONSTANT READER (*Glasgow*) writes:—"Could any of your correspondents to your valuable paper inform me how the cylinders of knitting machines are made and cut, with the easiest way to make them, the tools required, and where such are to be bought?"

Tool Wanted.—GAUGE POINT (*Paris*) writes:—"Wanted, a rule for prompt and accurate measurements to the $\frac{1}{16}$ of an inch of openings and spaces, as doorways, windows, arches, lengths inside tubes, etc, from 2 to 10 ft. It is done variously by workmen, but all are more or less dissatisfied with the makeshift plans they adopt. Something reliable is wanted suitable for all workers, and yet to be a cheap handy tool, bevel for stair-rail joints, a grip vice for veneer or a door, etc. Those who use such tools might give the best they know in a few words in return for what they take."

Carriage Paint. — W. W. W. (*London, S.E.*) writes:—"Will you kindly submit the following query to your correspondents? To make a dark claret colour for carts as on bus panels. Rose pink is the right colour, but it fades even after varnishing, lake being too costly."

Fretwork and Carving.—W. W. M. (*Glasgow*) writes:—"I would like to know if Mr. Henry Zilles & Company, Wilson Street, London, E.C., could supply me with a few designs, fretwork and carving, for a knife-box, same as engraving in WORK August 10th. If he can supply me with a few, to mention the cost?"

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Hand Circular Saw Bench.—A.R. (*Scorrier Saw Mills*) writes in reply to G. H. L. (*Hull*) (see page 222):—"I understand by your question that you wish to make a bench of wood, which will do for such work as you state, if properly put together. The kind of wood I should select would be red or pitch-pine, the frame to be nicely mortised and bolted together with $\frac{3}{4}$ in. bolts; the top of bench to be 3 ft. 6 in. long, and 2 ft. wide, and about 1 in. thick of hard wood screwed down on the top of frame, so that it may be taken off should the bearings require looking to. The spindle should be of 1 in. or 1$\frac{1}{4}$ in. iron, with three places turned for the bearings, one near the collar washer, one on the other end of spindle, and another a certain distance from the end to set in a bearing fixed on the frame of bench; the end bearing on the outside of bench should be fixed on a horse, and between these two bearings a small pulley should be keyed about 4 in. diameter. This pulley is to take the driving belt, which should be of leather about 2 in. wide, and driven from a wheel, say 4 or 5 ft. in diameter, keyed on a short countershaft about 12 ft. between centres. The rim of this wheel should be heavy, and a handle fixed well up one of the arms to turn it. The belt should be crossed so as to have more grip, and to drive with less tension. The bearing next to the collar washer should be fixed on a piece mortised in the ends of bench, about 8 in. from the side nearest the saw pulley. Saw to be from 9 to 12 in. diameter, and teeth as in a hand rip saw; the timber should be fed very slow, your power being limited. Even this mode of driving a small circular saw will be far from a pleasant job for the man who has to turn the wheel. In fact, all circular cutters should be driven by motive power, as they should attain a high speed, and are continually cutting. Fuller information could be given by giving sketches of bench, etc.; but as I have not time to give sketches now, and at which I am not a good hand, I hope the above will be of some service to G. H. L."

Paste. — THOMASO writes in reply to J. R. (*Skerries*) (see page 238), who wants a paste that he can keep on his office table to use instead of gum—a paste that will not turn bad:—"Personally, I prefer gum for small office jobs (dextrine, or as it is sometimes called, 'powdered gum,' can be got very cheaply at the oilshop, and makes good mucilage), holding the gluepot in reserve for parcels, etc. But the paste. Put a heaped-up teaspoonful of powdered alum into a breakfast cup of cold water, and stir till dissolved. Use this alum water to mix the paste with, and a flat stick of wood to crush all lumps. If properly mixed, the paste will look like cream—or paint. Boil very slowly with constant stirring, until the stick will stand alone. A quarter pint of paste should take about ten minutes to get in this condition. It is, of course, easy to boil it up in a minute or two; but it must be remembered that paste wants *cooking*. I usually tell when it is done sufficiently by smelling it. If not done enough it smells *raw*. This paste can be kept until it dries up into a solid lump. I have never found it go watery, get mildewed, or smell offensive; and it has this advantage over the bought 'office pastes;' it has no strong smelling or perhaps poisonous preservative in it. Better not cover up too tightly, and do not keep it in a tin, or put a tin mounted brush in it, because of rust. An everlasting brush is made by inserting some bristles, cut from an old broom, into the end of a piece of very small lead gas pipe ($\frac{1}{4}$ in. outside measurement), and then smashing the lead so as to grip the bristles, trimming them up with scissors, and inserting a piece of wood into the other end to make it longer, if necessary."

Drilling Square Holes. — F. H. (*Plumstead*) writes in reply to A READER (see page 270):—"In No. 17 of WORK I see a correspondent asks for a description of the scientific method of drilling square holes patented in Austro-Hungary. I cannot give that, but will gladly try to explain a method I have seen practised in my own shop. This would be more correctly described as boring square holes. A piece of steel was fastened in the bell-chuck of a lathe, and a hole was bored up just a little less in diameter than the width of the square across the flats. The outside was turned down so as to let a nozzle on, which had a square hole drifted through in the centre, so as to act as a guide for the squaring tool. This tool was made in the same manner as an ordinary half-round bit for a lathe, except the cutting end, which was made an equilateral triangle, whose side was the width of the square required, and whose length was rather longer than the length of square hole required and the thickness of the guide plate together. The triangular end was inserted into the guide, and the poppet head centre was run up to the back end of the bit, and fed up by it. The bit was held back against the centre by the mechanic, who had fastened a carrier on the shaft of the bit, and at the same time he let one end of the carrier rest on the slide rest to prevent the bit from turning. The lathe was driven in the ordinary manner. Some of the holes made were very good, but, unfortunately, there were about as many bad ones, so that it had to be given up as a bad job."

Trade Notes and Memoranda.

THE number of applications for patents in 1888 exceeded those of the previous year by nearly six per cent., and were 19,103 in number. Of designs, 25,923 were applied for, 568 of which were refused registration, on account of their similarity to designs already registered. The total number of applications for trade marks was 13,315, as compared with 10,584 in 1887.

THE distressing strain put upon tram-car horses on starting the car from a state of rest can be obviated by the use of an automatic starter, invented by Messrs. Vercker & Yeates. It consists simply of a coiled spring in connection with a clutch arrangement, and a speed on the driver's platform. A simple movement of the driver's foot will throw the apparatus into and out of gear, and one revolution of the car wheels is sufficient to charge the spring for the purpose of restarting. On starting the car, the first forward movement of the horses causes tension on the traces, and at once releases the spring, which, acting upon the wheels, causes the car to move gently forward several feet; the car, in fact, following the horses up. This has been in use for the past six months on a car belonging to the Southwark and Deptford Tramway Company. The invention is being introduced by Mr. John Record, of 5, Frederick's Place, Old Jewry.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

TERMS OF SUBSCRIPTION.

3 months, free by post	1s. 8d.
6 months, „	3s. 3d.
12 months, „	6s. 6d.

Postal Orders or Post Office Orders payable at the General Post Office, London, to CASSELL and COMPANY, Limited.

TERMS FOR THE INSERTION OF ADVERTISEMENTS IN EACH WEEKLY ISSUE.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances**, which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

Prospectus, Pamphlet and Sample, post free on application to the Inventor and Manufacturer,

G. MELLIN, Marlborough Works, Stafford St., Peckham, London, S.E.

WORK

An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

Vol. I.—No. 29.] SATURDAY, OCTOBER 5, 1889. [Price One Penny.

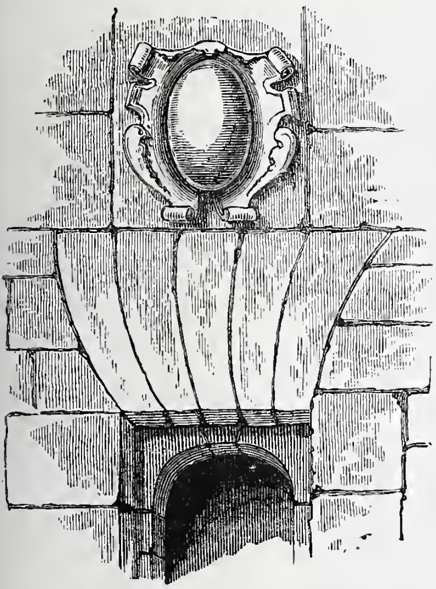

Fig. 1.—Arch in the Calle de la Madre de Dios, Murcia.

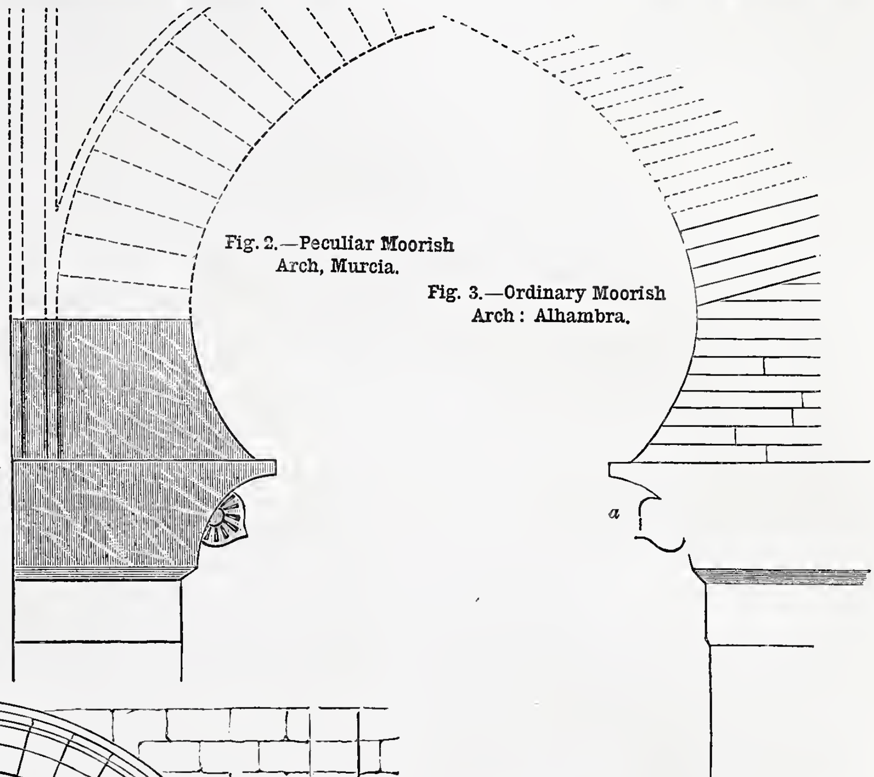

Fig. 2.—Peculiar Moorish Arch, Murcia.

Fig. 3.—Ordinary Moorish Arch: Alhambra.

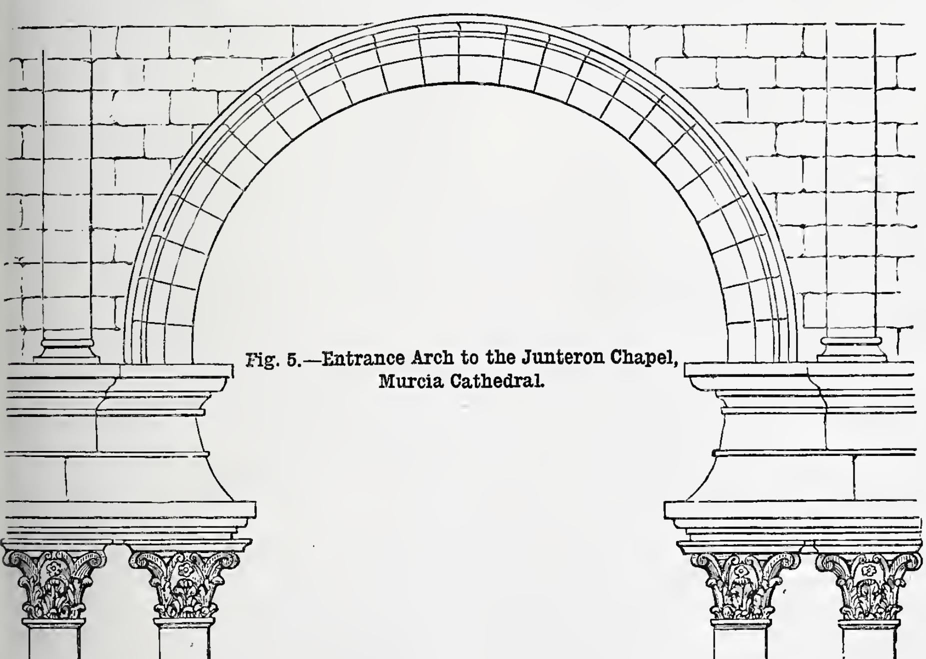

Fig. 5.—Entrance Arch to the Junteron Chapel, Murcia Cathedral.

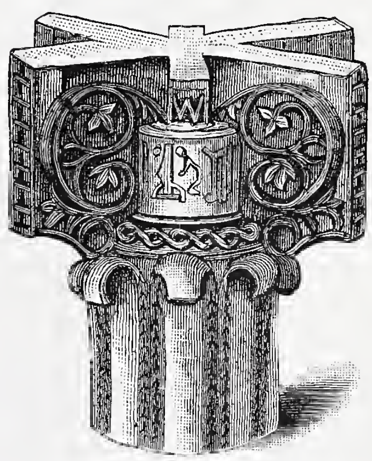

Fig. 4.—Moorish Capital: Murcian Type.

SOME CURIOUS PIECES OF BUILDING CONSTRUCTION.

BY C. C. C.

The very remarkable arch shown in the accompanying illustration, Fig. 1, may be seen over the doorway of an old house in the street of the Madre de Dios, in the Spanish city of Murcia—a city which, from the fact of its having been the capital of a Moorish kingdom through seven successive reigns, proudly styles itself, "The Seven-times Crowned Murcia."

In this city there may still be found some few remains of Moorish architecture, and the arch before us is commonly spoken of by the Murcianos as one of them. This is an error, for it is undoubtedly a work of the seventeenth century, constructed to suit the whim of some eccentric hidalgo. Standing alone as a single arch, it is certainly more curious than beautiful; yet it might, perhaps, if placed in apposition with another similar arch, the stones of which curved in a contrary direction, produce by the combination something more pleasing to the eye, though still impressive from its strangeness. Advantage might also be taken of the curved form of the stones to connect the two arches by a circular dripstone moulding, or an ornamental extension of the keystone might probably be made with good effect. It is laid before those interested in building matters as a text upon which to exercise their ingenuity.

Though this queer arch is certainly not Moorish, the house in front of which it figures, and which towards the public street shows early seventeenth century work only, is undoubtedly Moorish in its origin. On entering and passing on into the *patis*, or small open court, the visitor will come upon some remains of genuine Moorish arches, and these, too, are so far removed from the commonplace as to be worth the attention of those who have an interest in building. Their construction is, as construction, superior to those ordinarily met with; the springstones, which are of dark marble, being of a size sufficient to reach not merely to the nominal but to the actual spring of the arch. Fig. 2, in which a portion of one of these arches is shown, will explain our meaning. The ordinary construction of the Moorish horse-shoe arch is illustrated in Fig. 3 (from a sketch taken by the writer in the Alhambra). In this the springstone, *a*, is of white marble, but above it, to the actual springing of the arch, it will be seen that the work is carried on in horizontal brickwork, the thin bricks rather resembling quarries in their general proportions than what we should call bricks. It must be obvious that such construction will be far inferior in strength to that of the horse-shoe arch in the Murcian house of which we are speaking. The strange mixture, seen in Fig. 3, of costly with common materials, of marble and mere brickwork, is by no means unusual in Moorish building.

Although Murcia is set down in "Murray's Handbook" as a city worthy of only a single day's visit, it has been found by the writer to be singularly rich, as regards its architecture, in examples of workmanship so far removed from ordinary types as to be full of interest and suggestiveness. Fig. 4 illustrates a Mooro-Murcian style of capital different in form (so far as the writer is aware) from anything to be met with elsewhere. Its upper part consists of six arms, four long and two shorter ones, and all richly decorated with carving. Unfortunately it is not in the writer's power to say what form the abacus assumed, as he was unable to meet with any complete capital. The material of the example sketched was white marble, but there is much about the form which suggests its adaptability to wood. Possibly the English wood carver or cabinet maker may be able to derive some useful hints from it.

That he may pick up a wrinkle from Murcian work of a different school, the reader is referred to Fig. 5, which shows the entrance archway to the Junteron Chapel, Murcia Cathedral. This arch is interesting as showing how its architect, building in the pseudo-classical Italian style of his period, contrived so to handle it as to produce an effect approaching that of the Moorish horse-shoe arch of the country.

The story of this chapel is as interesting as its architecture. Its founder, Juan Rodriguez Junteron, was, according to the popular legend of the place, the son of a poor Murcian cobbler, but gifted with a natural aptitude for learning. The contempt with which, in his younger days, he was treated by his fellow-townsmen sank deep into his heart. He made his way to Rome, where his abilities met with more appreciation. He found favour at the Papal Court; became a Cardinal; and eventually returned to Murcia as its Archbishop. In this dignity he had abundant opportunities for paying back with interest the scorn with which the Murcians had treated him in former years, and he neglected none of them. The buildings which he raised, this chapel and his house, the latter a structure consisting of four towers clustered round a central and taller one, are noteworthy as being architectural embodiments of revenge. Cardinal Junteron left them as monuments of his hatred to the Murcian people. It was in words equivalent to "Thou art Junteron!" that he had been taunted when a poor youth, and these words he adopted in his prosperity as his motto. They appear on the front of his house, and wherever they can be introduced among the decorations of his chapel. This chapel he built as his last resting-place, and it is said that all the wrought stones used in it he caused to be carved in Italy, that the Murcian artificers might derive as little benefit from the work as possible. The dome of the chapel is, as regards its carved decorations, as unique as the entrance arch. These decorations consist of dismembered parts of the human body, combined with ornamental details, no complete figure appearing anywhere.

These curiosities of workmanship from a somewhat out-of-the-way corner of Europe are not brought forward as mere curiosities, but as matters which may afford valuable "wrinkles" to those interested in building and decorating, and as showing how, in certain architectural features which we are accustomed to consider as unalterably fixed by custom, the bolder designers of other lands have succeeded in introducing originality and novelty.

PLAIN AND DECORATIVE HOUSE PAINTING.

BY A LONDON DECORATOR.

WHITE, YELLOW, AND RED PIGMENTS.

LET us now consider the sources, nature, and qualities of the most useful pigments, material colours, oils, varnishes, and other mediums used for house painting.

White Lead.—Of all preparations used in oil painting, white lead—white oxide of lead—is at once the most useful and important. It enters into, and forms the "body" of, most light oil paints, and, by the addition of other material colours, tints and hues of every description may be obtained. For covering power, or opacity, it stands pre-eminent amongst all whites. If it is genuine in quality, and has been properly prepared for use, it is a very reliable agent in obtaining a successfully painted surface, viz., a compact and pleasing incrustation, which, under fair conditions, maintains its colour, and is impervious to moisture for a great number of years.

The ordinary process of obtaining white lead is by the slow corrosion of small castings of metallic lead, caused by its exposure over acid in small earthenware vessels. This is known as the Dutch method. Of recent years, however, a successful American invention has been introduced into this country, by the processes of which the dressed ore is volatilised by heat, the resulting fumes are carried forward by air currents, and ultimately solidified, instead of escaping into the atmosphere. The end of which is that, after necessary refining processes are completed, there remains a fine, sublimed white lead, which has been obtained without the escape of any poisonous fumes, and presented fit for practical use without any particular danger to the health of those engaged in its manufacture.

Flake White, Nottingham White, Silver White, etc., are all preparations of metallic lead, differing in process of manufacture and minor resultant qualities, but are not necessary here to be further considered.

The ordinary white lead for painting is obtained, ground to the form of a thick paste, in linseed oil, the heaviest and whitest being the best. It is, as a commercial article, extensively adulterated with sulphate of baryta, whiting, etc., and it follows, therefore, that the surest way of obtaining it genuine is by purchase from a vendor or firm of reliable reputation, and to be willing to pay a fair price according to the fluctuations of the market.

Zinc White.—Oxide of zinc is a very useful pigment, being permanent in both oil and water. To no extent, however, does it rival, for general use, the oxides of lead, since it is vastly inferior in body—covering power—to genuine white lead. Contrary to the latter, however, it does not discolour and blacken by the action of sulphuretted hydrogen—poisonous air; but its principal merit is found in the fact of its being entirely free from the dangerous attributes, both during preparation and use, which attend the handling of white lead. Although there can be only one opinion of the value of the last-mentioned quality of zinc white, the entire advantage of the former particular is open to being questioned. Probably, few persons outside the trade are aware that by use of white lead paint they have in their houses a sensitive detector of poisonous sewer gas—a sanitary quality of which most of the "sanitary enamels," that are now the rage, are, by reason of the entire absence of lead in their composition, almost or entirely destitute.

In practical house painting, zinc white is often used in obtaining the finest white surfaces for enamelling and hand polishing of woodwork, of which more hereafter. Since this class of work is of a very laborious and expensive nature, it naturally follows that a pigment should be used which maintains its colour for a great number of years.

Charlton White.—Of recent years, Mr. J. B. Orr, originally a Scotch chemist on the banks of the Clyde, after much laborious toil of study and experiment, has succeeded in obtaining a preparation of zinc, possessing all the advantages of the ordinary zinc whites, but also, it is contended, equal in body and brilliancy of white to the best leads. Since about the year 1880, when Mr. Orr became connected with a silicate paint company, this pigment has steadily been growing into favour for interior purposes, and is now well known to the trade as "Charlton white," from the vicinity of the works to Charlton, Kent.

Although this article is scarcely likely to supersede white lead for general purposes, it is rapidly getting a wide reputation. Its elementary sources are, I believe, barytes, strontium, and zinc; its market value is about the same as the best white lead. It may here be in place to mention that, mainly by the instrumentality of a notable and successful French house decorator and economist—the late Ed. Jean Leclaire, of "Maison

Leclaire" fame—a preparation of zinc is the principal white pigment used by the painting trade of Paris.

Having thus made familiar to the reader the pigments of white, we will turn our attention to what are generally termed "colours," but more correctly, coloured pigments, or material colours, treating herein only of the most common and useful, and leaving what are termed "fine colours" for consideration in the more advanced portions of our subject.

Yellow, as a colour, having the most affinity to the neutral white, and its pigments being much used for admixture therewith, we will enumerate, firstly, the most serviceable of its pigments:

Yellow Ochres.—For all purposes of house painting, the yellow ochres are the most useful. These pigments are found in a native state in most countries, and plentifully in our own. In colour they vary from a bright golden, but not "lemon," colour of "yellow ochre" to the dull or "sad" brownish-yellow of "spruce ochre." From the earliest days of history, they have been known and used, being of good body, and very reliable, if suitably prepared, for both oil and water painting. The variety of tone and shade in which they are to be found is endless, and to the action of iron is due the colour of them all. As all varieties of ochre, Oxford—a more reddish hue—stone and spruce can be produced artificially and cheaply from iron, and since all native pigments require grinding and washing before being fit for painting, it need scarcely be added that the bulk of such yellow pigments used are of the manufactured kind. For making with white the very serviceable "straw," stone, and buff tints for large, plain surfaces, and the "grounds" for graining, as will be shown in another part of my subject, the ochres are quite indispensable.

Terra di Sienna, or Raw Sienna, is another native yellow, also of an iron nature, and a very useful pigment. Although not so clean and bright in yellow as good ochre, it has more staining power when used with white, with which it forms very soft and agreeable cream tints, and the so-called "ivory whites," so much in demand of late years. It is obtainable ready ground both in oil and water, is equally serviceable in either case, and is reasonable in price. For the imitation of maple, satinwood, pitch pine, etc., it is very popular and useful, prepared in water, whilst its semi-transparent nature renders it valuable where transparent effects are desired in oil painting processes.

Burnt Sienna.—Although coming more under the heading of red pigments, by reason of its bright, if impure, orange red, this is, as its name implies, a burnt preparation of the mother pigment. By the latter process, it gains also in transparency and staining power, and it is equally indispensable when graining some kinds of wood.

Chrome.—This pigment is generally known in three varieties of colour, appropriately enough as "lemon," the palest; "orange," the strongest and reddest; and "middle chrome," the latter a rich golden colour. Notwithstanding so many house painters like to handle chrome, its brightness and purity appearing to have some sort of fascination for them, it is anything but a desirable pigment for house painting. Being chiefly derived from lead, they have a good solid body and appearance, and make with white very bright tints. They do not, however, maintain their purity of colour for very long, and where they have been used a perceptible darkening is soon noticeable, whether in oil or water; neither are they good pigments to use in admixtures or "compositions" of colours. Of this more anon.

Red pigments of a permanent nature are both necessary and forthcoming for our use, and range from the most vivid tones down to the subdued shades of reddish brown.

Vermilion is pre-eminent for its brilliancy and purity of red, and is one of the pigments known and used by the ancients. Although it may be found in a native state, principally in China, requiring grinding, however, before being fit for use, the vermilion of commerce is principally an article manufactured from mercurial sources. It is seldom in much requisition for house painting in its full strength, being too vivid for the light, climate, and social sentiments of this country; and being also very heavy, and ranging from 3s.6d. to 5s. 6d. per pound retail, it is too costly for large surfaces. Vermilion is, however, very useful for obtaining, with white, pure and clean pink, and similar delicate tints, which are permanent; if required in its full brilliancy, vermilion stands best mixed with, and applied in, good oil varnish alone.

The most invaluable, and also the cheapest, red pigments are the class known generally as red ochres, the best for house-painting purposes being Venetian and Indian reds and purple brown.

Venetian Red, or scarlet ochre, is a fairly bright pigment of a "brick-red" colour. It is thoroughly permanent, of good body, makes clean tints with white in both oil and water, and is sufficiently cheap for any purpose.

Indian Red, originally coming from Bengal, is a rich, deep red, of slightly purple tone, with all the good qualities of body and permanence of its preceding pigment. Of late years the supply of that brilliant and rosy-toned pigment which we originally knew as Indian red appears to have been exhausted, its place now being taken, or rather its name usurped, by the comparatively dull and muddy reds of artificial source.

Purple Brown, as its name implies, is the lowest in the scale of brightness, being, in fact, a dense brown. It is most in demand for external painting, when it forms the basis of most so-called "chocolate colours." Although not being useful for admixture with white—muddiness resulting—it presents in mass a comfortable-looking appearance used alone, in oil or water processes.

All these reds having sufficient covering power to hide in one coat, if properly mixed and used, almost any other coloured surface, are, therefore, very useful and economical for preservative and plain painting in such a climate as our own. Although existing in a native condition, these commercial reds are usually manufactured pigments, viz., burnt ochres, and the colour is due to the presence of iron. They are all sold in powder form, but Venetian red and purple brown are generally to be had ready ground in linseed oil. Vermilion and Indian red, from the reason of their more heavy nature, would soon become solidly caked, and, therefore, are only ground in oil or turpentine when so ordered. Of course, I do not here allude to colours in collapsible tubes.

Red Lead is a preparation of burnt massicot, of a bright scarlet colour, and although, if used by itself in oil or varnish, it will retain its brightness for some, it is useless for mixing tints. Being a good dryer—a subject we will shortly touch upon—it is used for hardening white lead, when mixed as a putty or as paint for preservative purposes.

HOW TO MAKE A PIANO.

BY "NIL DESPERANDUM."

Introduction—Tension of Piano—Strength of Back—Material Required—How the Back is Made.

There are no doubt many readers of this Magazine who not only desire the possession of a piano, but who would wish to construct one for themselves. It is with this twofold object that I write this series of papers. I shall not aim so much at literary precision as a desire to be explicit, and so simplify everything, with words and sketches, that the amateur will readily understand. To those who do not wish to make a piano, but who possess one already, I hope they will be interested in the perusal of these papers, as they will know how their own piano was made. The reader will see that I have adopted for my *nom de plume* "Never Despair," and I hope the amateur, if he starts making a piano, will adopt it for his motto. I remember about twenty years ago seeing the play of *Richelieu.* When the Cardinal asks his page to deliver an important despatch, the page asks, "What if I fail?" Richelieu exclaims, "Fail, boy, fail! In the bright lexicon of youth which fate has destined to a glorious manhood, there is no such word as fail;" so I hope the reader will omit the word fail from his dictionary.

I can imagine the reader saying, "To make pianos you must have a factory and appliances." To make pianos as a commercial commodity, certainly, but I do not want our reader to rent a factory, or to have special appliances, but that he shall use a spare room, or ordinary workshop, having a bench, a pair of trestles, and ordinary carpenter's tools, such as a saw or two, planes and chisels, brace and bits, and some of the minor tools, such as rule, squares, etc. Of course, in a factory, the facilities are greater, for they are needed, to turn out the quantity of work required, manufacturers making from one to forty pianos a week, according to the size of their premises; but it may interest the reader to know that several of our manufacturers have started in a humble way, not occupying more than one apartment for a workshop. In this series of papers I shall take the reader by short and easy stages, so that he can follow me, and, if he does so, I hope that he will be rewarded by possessing a piano of his own make.

Having said so much by way of introduction, I would impress on my readers that if a thing is worth doing, it is worth doing well; and in making joints, or gluing any part of the work together, see that everything fits, so that when you have put it together you shall be satisfied with it.

The strain, or tension, on a piano is very great, according to the size, or how it is strung. The tension from top to bottom of a cottage piano is about seven to eight tons, while a grand piano has a tension of about sixteen tons. So that the reader will see that the back of the piano, or foundation, must of necessity be strong to bear this great strain. If the back is not strong enough, then the piano would never stand in tune, for the two extremities would be gradually drawing together, so the strings would slacken accordingly.

The parts of the back are named bracings, linings, wrest plank, and bent side. The back of the piano I propose to make will be composed of nine bracings or uprights, the size of the back 4ft. 2in. wide by 3ft. 6in. high. The bracings are made of spruce, as free from knots and as dry as you can get it, 4in. by 3in. It will take about 50 ft. of this. The wrest plank is the upper portion of the back, where the wrest, or tuning-pins, to which the strings are attached, are placed. This is made from beech, 1½in. in thickness, and 8in. wide, and 4ft. 3in. long. Then there is the bent side; this is also made from beech. Pins are also driven into this to attach the other end of the strings. This beech is cut specially for the trade, as it is cut on the quarter, that is, the tree is cut in four parts, and this cut off the faces, so that it is not so liable to split. Wrest planks and bent sides can be purchased from Mr. Burch, timber merchant, Prince of Wales Road, N.W.

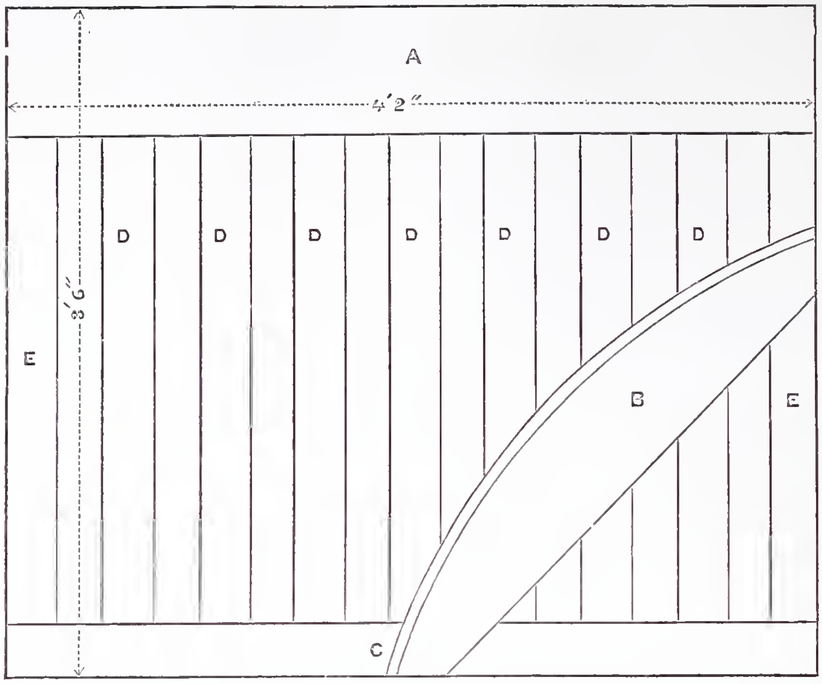

Fig. 1.—Front View of Back—A, Wrest Plank. B, Bent Side. C, Bottom. D, Bracings. E, E, Linings. (Scale, 1 inch to 1 foot.)

I must now speak of the glue, a very important item in piano making. See that you get the best. The best I know of is Cox's Scotch glue. It has the trade mark of "Chanticleer" on each cake. To prepare it, break it in pieces, and cover it with cold water, leaving it to soak all night; then put a portion in your glue-pot with the water, and boil thoroughly, stirring from the bottom occasionally.

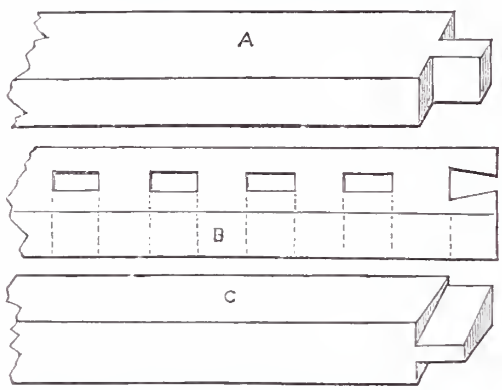

Fig. 4.—A, Bracing with Tenon. B, Plan of Bottom; same for Top. C, Lining with Dovetail.

To use a nautical phrase, having cleared the decks for action, we will commence making the back. Cut nine lengths of bracing 3ft. 6in. long, also two lengths 4ft. 3in. Now start planing one side of each, straight and out of winding; take a straightedge, put it on the work from corner to corner, and if it is hollow, plane off those two corners until you get it straight, that is what is meant by taking it out of winding, or twist; when you have got the 4in. side straight, you square the edge or 3in. side of each, and make a mark, so that you will know them; now take the rough off the other sides, and stand them by to dry, as they dry quicker when planed over. Now prepare the wrest plank and bent side by planing over, so that they will lay level and square across. You now require a couple of sheets of sycamore veneer. You cut it the width of your wrest plank until you have sufficient to cover its entire length, then joint it edge to edge on a board by tacking it temporarily, then glue strips of paper over to keep it together. When this is dry, tooth or scratch it with the edge of a saw. Now you want a board made hot, and glue your wrest plank, also the side of your veneer that is not papered, and place your hot board on, after being rubbed with soap, to prevent sticking, and press with hand-screws. After leaving this an hour or two, take your hand-screws and board off, and plane over with a smoothing plane set fine, and scratch the surface of the veneer. Now take the sheet of veneer the length and width of wrest plank, and glue as before.

Now the reader can make the frame of his back. It is to be 4ft. 2in. by 3ft. 6in. finished. The two lengths of bracing you cut 4ft. 3in.; they are for the top and bottom of your frame, so that their exact length will be 4ft. 2in. I gave you ½in. at each end to work with, for cutting square, etc. Now your outside bracings are called linings; these are dovetailed into the top and bottom, and the bracings tenoned into the top and bottom. You must divide the spaces apart for the bracings about equal; if anything, a little closer together in the centre, as the strain is greatest at this part. If you take the thickness of the bottom and top off the height of the piano, this will give you the measurement between the tenons; for instance, say your bottom and top were 2½in. thick, that would make 5in.; take that from 3ft. 6in., that would give you 3ft. 1in. between the tenons. The mortises you can bore out with a 1in. centrebit, leaving your tenons 1in. to fit. In putting the back together, before gluing see that it all fits together nicely and square; this try by placing a rod from corner to corner; they ought to be the same distance as each other; if not quite, a good push at one corner will make it right. Attend to this also when gluing together. When ready to glue together, get some friend to assist you. Just place the ends of the tenons in their respective places, just so that it holds together, then warm both ends well, and glue with a brush as quickly as possible the parts of the tenons that are visible.

Now knock together with a heavy hammer, and see that it is square,

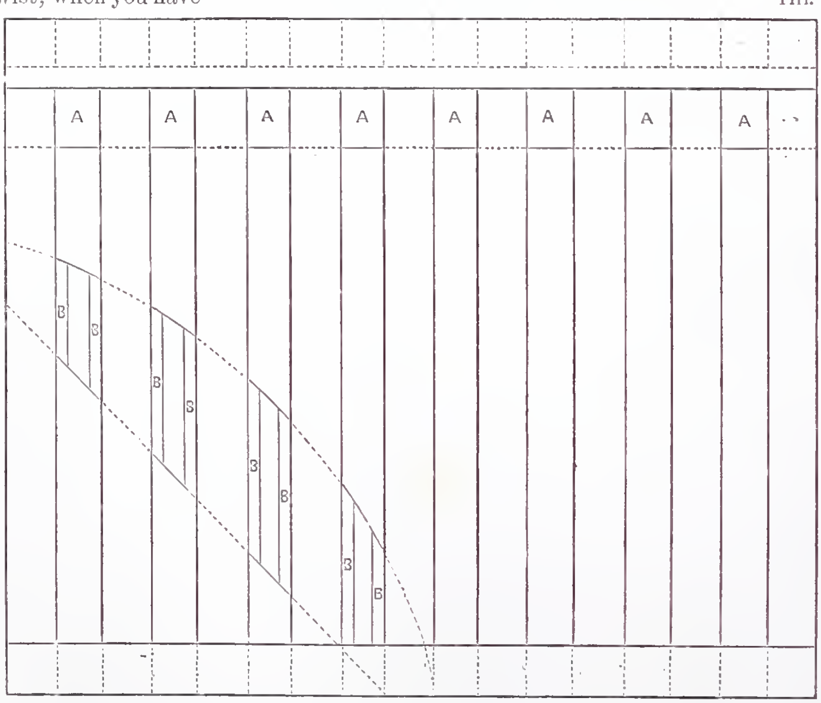

Fig. 2.—Back View of Back—A, Blocks behind Wrest Plank. B, Blocks behind Bent Sides. (Scale, 1 inch to 1 foot.)

Fig. 3.—End Section, Treble, showing how Back is put together.

and lays flat on the floor, and leave it to dry. When the glue is dry, plane over both sides clean. Make a pencil-line 8 inches from the top, and fill up the interstices to this line with blocks 6in. long; this is to make a good bed for your wrest plank to be glued on. When these are dry and levelled, tooth it well, make it warm, also warm the wrest plank. After it has been fitted knock two nails at each end of your line, and glue and put on hand-screws. The reason one veneer crosses the plank, and the front one is put on straight, is to prevent the plank splitting. Now you gauge a line ¾ of an inch from the bottom of your bent side, on the round edge, and ¾in. on the top; then put in your bench screw, and saw with your hand saw down the line on your edge; then chop out with your chisel from the line on the top; this will form a rabbet for the sound-board to lay in. When the back is facing you, with the plank at the top, the treble will be to your right hand. On your treble lining under the wrest plank mark 5½ inches. From your bottom corner at the bass end mark 2ft. Knock two nails in temporarily, and lay your bent side on and mark round with pencil, then fill up the interstices with short pieces of bracing, as you did for the plank. When dry, level and tooth, and glue your bent side up to the nails. After this is dry, get out two pieces of spruce 3in. wide, ¾in. thick, and 4ft. 3in. long. After planing, glue one top and bottom at the back of your back. Your back is now complete. In my next paper I shall deal with the construction of the sound-board.

PRACTICAL VENEERING.

HAMMER-LAID AND CAUL-LAID VENEERS.

BY DAVID ADAMSON.

The first thing that will probably cause the young veneerer to pause will be a doubt on learning that there are two kinds of veneers, or rather, that they are prepared in two different ways, which of them is the best, or as price will probably show him this, whether for practical purposes one is better than the other. He will soon find out that broadly, without referring to kinds of wood specially; veneers are to be obtained either "knife-cut" or sawn. This indicates the way in which they are prepared, the one being sliced or cut with a knife, the other with a saw, as their names imply. So far as I am aware, knife-cut is seldom, if ever, used for good work, partly no doubt owing to its extreme thinness, but, perhaps, principally because the best wood is always sawn. It is rarely that one sees much figure in knife-cut veneer, and I certainly cannot recommend its general adoption. The extra cost of saw-cut veneer is so slight that it is hardly worth while using the inferior kind. Perhaps here I may as well say something about the cost of veneers generally. These are in the ordinary kinds, that is those from logs, usually sold by the foot super. like ordinary timber, but burrs, which by the way are knife-cut, and such like are reckoned at so much each, the price depending not only on size, but marking, probable amount of waste, and various other considerations which need hardly be gone into here. Occasionally, however, whatever their kind, veneers may be quoted for by the foot, which, of course, always means superficial. Prices vary enormously, not only for different kinds of wood, but for different qualities of the same wood, and it may be taken as a fixed rule that the really choicest veneers of any description are more valuable than even ordinary good sorts in the solid, say, of 1 in. thick. Naturally, some sorts do not vary so much as others, and fashion as well as supply has a good deal to do with prices. These matters, however, are for the purchaser to settle with the veneer merchant, and beyond the mere mention of them they hardly come within the scope of this paper.

Fig. 1.—Hammer generally used by Cabinet Makers in Veneering. A Home-made Tool.

The terms "hammer-laid" and "caul-laid" veneers have already been alluded to, and it will be necessary to explain them in order that the learner may have a proper comprehension of the work implied by them.

In the former class of operation, the veneer is laid by pressure with a hammer specially made for the purpose. Perhaps the name hammer may be rather misleading to novices, as according to the ordinarily accepted purpose of this tool it might be inferred that the veneer is laid by knocking. This, however, is not the case, as the veneering hammer is used as a squeegee with constant equable pressure instead of a series of impacts or blows. From this it will readily be understood that a hammer in the ordinary sense of the word is rather a misnomer, and but for the "veneering hammer" being so well known in workshops, it might be more appropriately referred to as an iron squeegee. The face or striking part of an ordinary hammer head is, therefore, of little or no consequence in a veneering hammer, the opposite end of the head or pane being the all important part. This, accordingly, is widened out very considerably in order to cover as wide a surface as is compatible with convenience. It is hardly worth while to buy such a hammer, as it can very easily be made by the worker himself. A strip of iron of, say, from 3 in. to 6 in. long and of any convenient width is firmly fixed between two pieces of wood, or in a groove cut in one piece to form the head. In this a handle is inserted. The precise shape and size of any part are quite immaterial, the principal points to be observed being strength and convenience. The iron edge of course must project beyond the wood, and it must be straight with a smooth

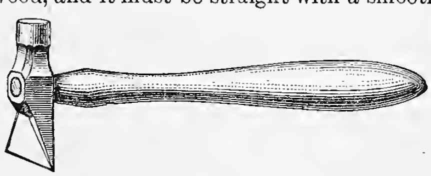

Fig. 2.—A Form of Hammer sometimes used in Veneering.

rounded edge in order to allow it to be passed freely over the veneer. To prevent this being injured, it is also well to slightly round off the lower corners. Fig. 1 is an illustration of a veneering hammer of this kind, and I think it will be sufficient guide to those who wish to make their own. Perhaps I ought to say that the metal should be thick enough not to bend when the hammer is used, and that the smoother the edge is the more easily the tool can be used. Fig. 2 is a form of hammer that may be used, but I have never seen such a tool in the hands of a cabinet maker when veneering.

In the other kind of veneering, viz., that with a caul, the hammer is not used, its place being taken by a uniform equal pressure over the whole surface of the veneer, which is kept in close contact with the foundation on which it is laid till the glue has set. The caul itself is either wood or metal, either of which must be shaped exactly to fit the surface to be veneered. Thus for a flat panel it must be flat, while for a concave surface it must be convex, and so on. The object of the caul is to squeeze out any superfluous glue, for I presume it will be almost unnecessary to remind any one who contemplates doing veneering that too much glue is as bad as too little. Therefore, unless the caul accurately fits to any shaped or moulded surface it is defective. Where large quantities of the same size and shape are required, the necessity of having a caul to fit is not much trouble, but those who have only to veneer a moulded surface now and again will find it scarcely worth while to prepare a specially shaped caul for each, and for such work a substitute will be mentioned later. To do so at present might only confuse the beginner, who should be well acquainted with the way to use a plain flat caul before attempting anything of a more complicated character. As has been said, the caul may be either of wood or metal, but for general purposes a combination of the two may be advocated. Wood

Fig. 3.—Section of Board showing Heart Side uppermost.

alone, unless carefully used, is apt to get burnt while being heated, as will be explained in due course. Iron again is for many reasons unsuitable, and, without going into all the reasons, it will suffice to say that zinc is the metal generally employed for hand-cauls. Other kinds, whether steam or gas, being more of the nature of machines, and only likely to be used where much veneering is done, may very well be left out of consideration in the present directions, which will, however, enable any one who wishes, and has access to a gas or steam caul, to use it intelligently. The actual process of veneering is the same, the difference being in the preparation and management of the caul. For cauls for occasional use wood alone will do very well. I mean by this that the result will be as good as if zinc were used, and the amateur, at any rate, will seldom wish to do so much veneering as to make it worth his while to incur the expense of metal. On the whole, perhaps there is less risk of spoiling work by using wooden cauls alone, provided they are not burnt, than there is with metal, but with a little caution injury should not happen whichever is used. With metal the danger lies in overheating it so that the glue between the veneer and the foundation is not merely softened but gets burnt, and the same thing may happen to the veneer itself. With a wooden caul, of course, such a mishap is much less likely to occur, as the caul itself will probably burn before it is too hot to damage either the glue or the veneer. Of course, I am not wishing to say that a wooden caul cannot be overheated, for it is quite possible to do so, and whether with wood or metal care, to say the least, is highly desirable. To sum up, zinc is desirable because it lasts longer than a plain wooden caul, though otherwise wood is, on the whole, as serviceable for occasional use, though its liability to get out of shape or twist is sometimes objectionable. In thickness the zinc employed may be almost anything over that, say, of a penny. If it is too thin it does not retain sufficient heat, while excessive thickness simply means waste of money. Perhaps as a general thing the zinc is usually preferred of from $\frac{1}{8}$ in. to $\frac{1}{4}$ in. in thickness, the former being quite sufficient for ordinary purposes. Less might do, but I cannot state that it would from personal knowledge. One well-known authority recommends $\frac{1}{4}$ in. as the best thickness. I do not pretend to say which is best, as I think more depends on the way the work is gone about than on the thickness of the zinc, but I may state that in one shop with which I am acquainted, where some of the soundest furniture procurable is made, there is no caul (zinc) over $\frac{3}{16}$ in. thick. Even with a zinc caul a backing of wood is necessary to keep it flat down to the work, and to prevent the heat from dispersing too rapidly. This wood may be of about 1 in. thick, which is sufficient generally, though there is no reason why it should not be of any greater dimensions, beyond the fact that any excess, being unnecessary, means waste. A good deal, of course, depends on the way the caul is clamped down and on its size. For the material nothing is more suitable than good sound pine.

Such a piece of wood used alone—without zinc—is a plain wooden caul, so that there is nothing very elaborate in the special preparations required to lay veneers with. Perhaps before leaving this part of the subject, it may be as well to state that wooden cauls are more old-fashioned than zinc, and that in well-appointed workshops they are now generally discarded.

In addition to these things a toothing plane is also desirable to roughen the surface to be glued, but this can hardly be regarded as a tool required only for veneering purposes any more than the hand-screws which are used to hold the cauls down with. Something may now be said about the comparative merits of hammer and caul-laying, though it is quite conceivable that some may altogether object to the word merit in connection with hammer-laid work, and deny that there is any merit in it. On the other hand, some workers will also be found to assert that it is "good enough," and no doubt it is so for some purposes or for very small work. The general concensus of opinion, however, among those who have devoted sufficient attention to the subject is that caul-veneering is out and away the better method, especially when anything but a mere strip of veneer has to be laid. Even then the pressure maintained till the glue has set renders it preferable. When laid with the hammer there are more likely to be blisters than when cauls are used, and besides this there is less shrinking with the latter. For "slop" work the hammer has everything in its favour; the caul for such is not to be compared with it. For ordinary thin knife-cut veneers the hammer does very well, especially if the veneers are of a light-coloured wood. Indeed, some go the length of saying that all light-coloured veneers are best laid with hammer, the reason being that the glue is not so likely to discolour them as when laid in a caul. With care, however, in the selection and use of the glue, there is no reason why the lightest veneer should be stained. With regard to this I suppose it will be understood that the heat of the caul causes the veneer to absorb some of the glue, and this if of dark colour naturally destroys the purity of a light-coloured veneer, though it is not observable in the darker kinds, such as mahogany and walnut. All things considered, it may be said that veneers should be laid with a caul, and that the hammer should only be had recourse to as a substitute, or when experience shows that it can be used without detriment. It must not be forgotten that a practised worker may often violate general principles of construction with good results, while a less skilful man would only court failure by venturing to do so.

Let therefore the *modus operandi* with a caul be considered first, reserving any slight differences when a hammer is used for subsequent mention.

First of all, the wood to be veneered on must be properly prepared by smoothing it down as carefully as if it were to be left uncovered. All saw marks must be removed, and if it is pine, take care to select a piece as free from knots as possible. The surface should be gone over with a toothing plane, though this is not always considered necessary. In addition to planing and cleaning up generally, further preparation is required whenever a panel or anything wider than a mere strip, such as part of a door frame, is being veneered, in order that the board when dry may be flat. The action of the water contained in the glue must be taken into account, and counteracted, otherwise the glue and veneer in drying will pull the wood out of shape. Care must further be taken to veneer on the right side of the wood, for if not, the board or panel will have a tendency to become concave or hollow. This is by no means desirable, and when seen at once shows something wrong. Where absolute flatness cannot be obtained, and it often cannot be, it is better for the panel to be convex or rounded outwards, as the appearance is far better than the reverse way. From this those who are acquainted with wood working will see that when at all practicable the "heart side" of a board should be veneered on, as other circumstances being equal, this is the one which becomes convex. To some novices the fact that there is any difference between the two sides of a board may be a new idea, in which case the term "heart side" will not convey any meaning probably. Well, for them let it be said that though the term is a technical one its meaning must be taken literally.

The "heart side" simply means that it is the side of the wood which was nearest the heart or centre of the log. It can easily be determined by looking at the end grain, and noticing which way the segments of the annular rings turn. These, of course, are more or less regular, but there is seldom any difficulty in discerning them on taking a shaving off one end of a plank with a plane. As it is a matter of considerable importance, not only in veneered work but also in other constructions, that the difference between "heart side" and the other should be known, the diagram, Fig. 3, is given in order that there may be no misapprehension. From what has been said there will be no difficulty in recognising that the upper part of the section there represented is the "heart side." This is the one which should almost invariably be selected for the outer surface not only for veneered but for plain work. Sometimes it may make very little difference which side is veneered on, but no instance occurs to me when it would be wrong to do so on the "heart side," though it would be very easy to state instances to the contrary. It may, therefore, be said that the novice will do well not to veneer except on the "heart-side" till he has sufficient experience to enable him to decide when he may do so on the other without detriment. Even then, unless he has some good reason for veneering on the other side, he will do well to be cautious in disregarding the rule to lay veneer on the "heart side." If he attends to this he will never be vexed by having his panels turn hollow, due attention naturally being given to other details of the work, for it must not be imagined that care on one point will make up for negligence in others. Perhaps for the sake of simplicity it will, instead of generalising, be well to imagine some particular piece of work as being required to be veneered. Let us suppose it to be a drawer front, for this is not only a very usual piece of work, but the wood is generally of a convenient size to be easily handled, so that it offers fewer difficulties than others might do. What the wood, both foundation and the veneer, is does not much matter, but we will assume the former to be pine and the latter mahogany or plain walnut—not burr, which, requiring a somewhat different treatment, will be dealt with later on. Mahogany, however, may be taken as a typical veneer requiring no exceptional preparation, and presenting no great difficulty in laying it. In fact, it may almost be regarded as the easiest to work.

The ground wood or foundation being ready, the next thing is to cut the veneer to the size required. This should be a little greater than that of the wood to be covered—not much, but just enough to let it project over the edges a little to allow of its being trimmed off neatly afterwards. I am presuming that the veneer is saw-cut and of the usual thickness, which may be roughly stated as being from 10 to 14 to the inch. If the veneer is very rough, that is to say, if the marks of the saw used in cutting it, or any other inequalities, are very decided they must be removed. The toothing plane will do this, but it is unlikely that any great amount of smoothing will be necessary, as most modern veneers are so well cut that they require very little preparation in this way, presenting a marked improvement upon those of comparatively few years ago, which were frequently what we should now call very badly cut. However, we may take it for granted that the veneer is smooth either direct from the saw, or has been made so subsequently. The side to be glued down must be gone over with the toothing plane finely set to roughen it slightly, and afford a firm hold for the glue. Doing this with a thin substance like veneer requires delicate and careful manipulation. Unless quite dry the veneer should be made so by laying between hot cauls previous to using it, but this precaution is not so important with mahogany as with some other kinds. With some it is absolutely necessary, and even with mahogany it may often be of advantage, so that as a general rule the novice will do well to adopt it. With practice he will be able to do without it sometimes. Nothing has been said about the way the grain in the veneer should run, as I presume this will be understood. In case it is not, let it be said that in both the foundation and the veneer the grain should be coincident. Sometimes they are used transversely or at right angles to each other, ut not in such a piece of work as we are onsidering. When it does occur, it is so arely that the exception may be said to prove the rule. Now, having said all that needs to be at present about the veneer, let attention be directed to the wood to which the veneer is to be glued. As has been stated, the action of the gluing must be taken into account, but without concerning ourselves with theory it will be enough to lay down the principle that the wood must be damped on the back. I have heard of the wood being soaked for a day or two previously to use, but I believe this plan is now altogether obsolete, as it is unnecessarily cumbersome and open to many objections. Still it shows that much variation in practice may exist, and that it is more a matter of how the work is done than what course is adopted. There is perhaps no detail connected with veneering on which experts differ so much as on the preparation of the groundwork to which the veneer is to be attached, and one is almost forced to the conclusion that when a man has become thoroughly conversant with any particular method and practises it intelligently, good results are obtainable. This does not, however, prevent one method having advantages over another, and without discussing them all in their various bearings it will suffice to mention one course which is applicable to almost all kinds of work, and one which can hardly fail in being satisfactory. It is this.

Damp the back of the wood to be veneered, say, from half an hour to an hour before using, by rubbing it over with a wet sponge or cloth. The wood will then become slightly rounded on this side. On the amount of moisture and consequent swelling a good deal depends, but it is impossible to give any minute directions, as so much depends on surrounding circumstances. The most that can be done here is to say that the surface of the wood should be fairly wet, and that the water must not be allowed to collect in pools on its surface. It is to be damped, not saturated. Sometimes the plan of placing a layer of damp sawdust on the wood to be veneered and leaving it overnight is adopted, but the slight disadvantage attending this is that the wood may get too much damped while waiting, and that the time required may not be always convenient.

When the wood is sufficiently swollen, it is ready for gluing. The glue, it goes without saying, should be of good quality and properly made. It must be of medium consistency, and, of course, be quite hot. Rub it smoothly on the wood, taking care that the whole surface is covered. No glue is to be rubbed on the veneer, which is simply laid on the glued foundation. Then, without delay, get the caul, which should, in the meantime, have been getting warmed, and put it above the veneer. If the caul be zinc, lay the board already mentioned above it, apply the hand-screws till the glue oozes out at the edges, and let it stand till the glue has set. This will be when the caul has become cold, which will be in the course of an hour or two. With a zinc caul, only the metal is heated, the wood backing being applied cold. The heat for the caul cannot be learnt except from experience, though it may assist novices to say that it must not be so great that it cannot be comfortably handled. *Per contra*, neither must it merely have the chill taken off. The object of the caul, it must be remembered, is to partially melt the glue again after the veneer has been laid on it, at least, that is what the heat does. The pressure on the caul forces the liquid glue, to some extent, into both the foundation and the veneer, air bubbles and excess being at the same time got rid of. All this in theory is very simple. In practice, it is not quite the same thing, and the following hints will be of service.

If the caul is too cold, the glue is not sufficiently melted to flow freely between the two contiguous surfaces of the veneer and foundation. Pressure, therefore, is only partially effectual, the excess of glue and confined air will not be expelled. Blisters and imperfect cohesion will be the result. On the other hand, if the caul be too hot, there is the danger of overmelting the glue, and together with excessive pressure of forcing too much of it out at the edges, as well as into the wood. These directions may seem vague and unsatisfactory, but it will be better to caution the novice about risks to be avoided than to tell him exactly what to do, even if it were possible to supplant his judgment by giving definite rules. Not only is the right degree of heat advisable, but it must be evenly diffused over the whole caul, for it will require only a moment's consideration to show that it would never do to have any parts nearly cold, or others overheated. The pressure also must be regulated, but with small hand-screws there is not much danger of this being excessive. Take care that the jaws of the hand-screws press evenly, and do not let them merely grip the edges, while leaving the caul and the veneer only slightly in contact towards the centre. This may occur if the caul is too thin, or if from any cause it is hollow in the middle. As it is quite possible that some of the glue may be forced through the veneer, a sheet of paper should be laid between it and the caul. This should also be slightly greased, though with mahogany veneer it is not so necessary as with one of a more porous nature, such as burr walnut. The paper will stick to the veneer, or perhaps, I should say, may do so, but it will be of no consequence, as it can easily be cleaned off, and is only mentioned as the dirty appearance might cause the novice, at first, to think that the work had been spoiled. One other little matter I must put the worker on his guard against, viz., the necessity of seeing that the veneer does not slip from its place when laying it in the caul. To prevent this happening, veneer pins are sometimes used, but with care they may very well be dispensed with. Any small nail or tack will do for the purpose, and it will not be necessary to do more than say that in many circumstances their use is objectionable. After all these cautions it seems hardly possible for the merest tyro to go very far wrong in laying a plain mahogany veneer on one side of a panel or drawer front, but the subject of veneering is far from exhausted. After the work has been removed from the caul, it should be placed so that the air does not get to the veneer, say, leaning against a wall, and then left till the glue has become thoroughly hard. If everything has been properly done, the board will then be slightly hollow on the back, and rounded on the veneered or face side. From this it will not alter, or, if it does, it will be to such a trifling extent as to be almost imperceptible. After the glue is thoroughly hard, the surface may be cleaned off by first using the smoothing plane, which it is almost needless to say must be very finely set, then the scraper, and finally glass-paper. Of course, it must be left for the worker to say whether the use of a plane is necessary. If not, by all means do without it, as it is by no means a case of cut and come again with a thin veneer. Although the cleaning must not be done before the glue has become quite hard, there is no occasion to do so as soon as it has. The work may suffer by being cleaned off too soon, but it hardly can by delay in cleaning. It may almost be said that the longer it is left the better; the risk being with premature cleaning that ridges through inequalities of glue may subsequently show themselves, and also that the heat caused by scraping and papering may melt or soften the partially dried glue to such an extent that its hold may be considerably lessened. If this occurs to any great extent, blisters, the *bêtes noires* of the veneerer, may make themselves unpleasantly obtrusive. How these, when they occur, may be recognised and reduced will be stated later on.

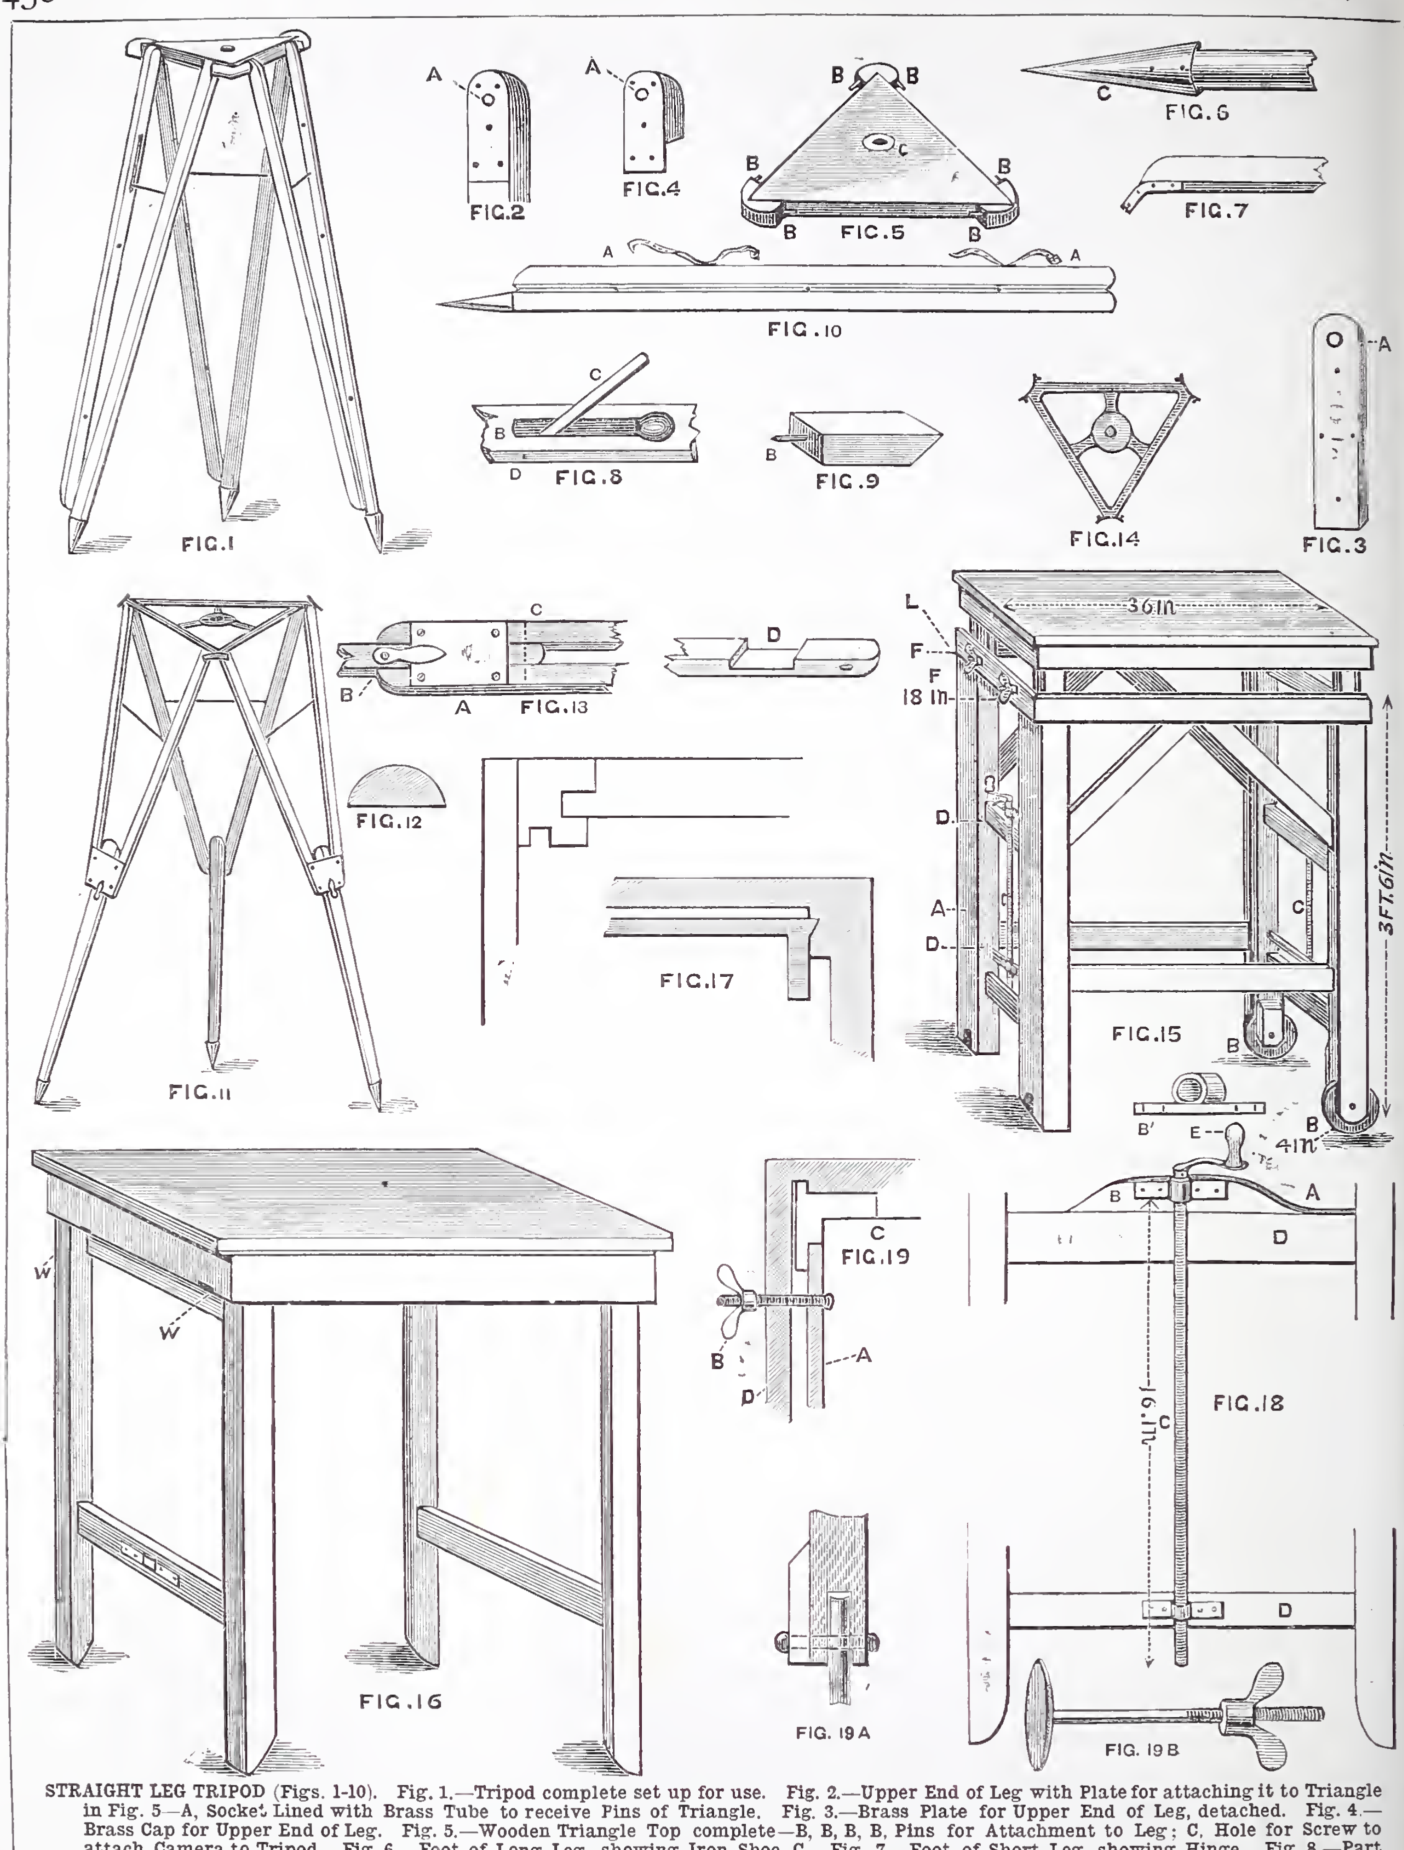
TRIPODS AND STANDS FOR CAMERAS.

BY AN OLD HAND.

THE STRAIGHT LEG TRIPOD—THE FOLDING TRIPOD—THE TABLE STAND—THE STUDIO STAND.

NEXT in order of importance to the camera is the tripod or stand, so designated according to its form, the tripod being almost exclusively used for outdoor work, and the stand for indoor or studio work. The tripod consists essentially of three legs, from which it takes its name, supporting a small platform. These legs may be each in one length or made to fold in several joints. In all cases it is imperative that the apparatus should be perfectly firm when set up and free from vibration. These qualities are the most important of any, for with a rickety or vibrating stand no good work need be expected. Whatever form is chosen it must be one that may be depended on as free from these particular drawbacks. It goes without saying that long, light, and slender legs, especially if jointed, are unreliable. The fashion of making everything so light in weight for outdoor work has unfortunately, in many instances, been at the sacrifice of rigidity; and many stands now in the market are not worth the wood they are made of, if good sharp pictures are looked for as a *sine quâ non*. Many apparently strong stands will vibrate with the lightest touch, and the tremor continue for some seconds; a gust of wind will have the same effect, and when the time of exposure for the plates is calculated in seconds or fractions of them, the result may be anticipated. Blurred, unsatisfactory pictures are generally all that can be made on such stands, except by the merest chance. It will be as well to bear this in mind in their construction, and never let the idea of extra portability trench in the least on this quality of firmness.

For indoor or studio work, the heavier in reason the stand is the better. The framework is always massive in character in those patterns used especially for portraiture. A kind of stand for studio work of a varied kind is called a table stand, as it somewhat resembles this article of furniture, and for real practical usefulness nothing can be better. All ordinary stands may be classed under one or other of these heads, the difference being merely in pattern or unimportant detail. Almost every maker affects some particular design, and the variety is legion. In the present paper I give working designs for each of these leading patterns, choosing as simple ones as I conveniently can, and I would call



STRAIGHT LEG TRIPOD (Figs. 1-10). Fig. 1.—Tripod complete set up for use. Fig. 2.—Upper End of Leg with Plate for attaching it to Triangle in Fig. 5—A, Socket Lined with Brass Tube to receive Pins of Triangle. Fig. 3.—Brass Plate for Upper End of Leg, detached. Fig. 4.—Brass Cap for Upper End of Leg. Fig. 5.—Wooden Triangle Top complete—B, B, B, B, Pins for Attachment to Leg; C, Hole for Screw to attach Camera to Tripod. Fig. 6.—Foot of Long Leg, showing Iron Shoe, C. Fig. 7.—Foot of Short Leg, showing Hinge. Fig. 8.—Part of Leg, showing Strut, C; B, Hollow to receive Strut when Legs are closed for Carriage; D, Pin to act as Pivot and secure Strut to Leg. Fig. 9.—Wooden Block with Pin for Point of Triangle. Fig. 10.—The Leg complete and folded—A, A, Straps. THE FOLDING TRIPOD (Figs. 11-14). Fig. 11.—Folding Tripod set up ready for use. Fig. 12.—Transverse Section of Leg. Fig. 13.—Part of Legs, showing how they are fastened together—A, Brass Plate; B, Button; C, Screw; D, Part of Lower Leg cut away to receive Plate when extended, so that Leg and Plate come flush and allow Button (B) to act. Fig. 14.—Brass Triangle, Top. (*For Continuation of Inscription, see next page.*)

the attention of the constructor to the illustrations given in manufacturers' price lists for any additional modification that may take their fancy, and which by the exercise of a little skill they will be able to add to the designs here given.

The Straight Leg Tripod.—The material of which tripods of this form are made is usually ash, although deal, mahogany, and other woods have been used. Ash combines the qualities of toughness and rigidity, and is heavier than some other woods; but this is overbalanced by its lasting qualities and its power of withstanding a deal of hard usage without becoming disabled. Very useful tripods have been made of bamboo exactly, without any play; the holes may be drilled almost through the thickness of the wood, and lined with a short metal tube. The fitting of the head determines the rigidity of the apparatus when it is set up, so it is as well not to err on the side of lightness in the metal used. If a plate is considered sufficient, it should be made of brass $\frac{3}{16}$ in. thick, as Fig. 3. If a cap, it can be cast in one piece, as Fig. 4, or by bending a piece of brass round the top in addition to the plate, and securing it with screws on each side; but whatever plan is selected the brass-work must be sunk flush with the surface of the wood. The longer laths are then shoed, Fig. 6 being tapered to fit the iron whole may be made into a compact parcel when travelling. A leather strap handle is preferred by some; this can be also screwed to one of the legs centrally, so that a proper balance is secured when carrying it. The head of tripod may be purchased of metal as in Fig. 14, or made of wood as in Fig. 5. It is important that there should be no warping in this part, to prevent which three layers of $\frac{1}{4}$ in. mahogany, placed in different directions of grain, are glued together and dried under pressure. A triangular piece thus built up must be cut 8 in. on each side.

Now make six blocks, as Fig. 9, $1\frac{1}{2}$ in. long, mitred and rounded off afterwards, in which the pins, B, are fixed, and from

jointed together fishing-rod fashion. Deal is a very rigid wood, but not suitable for hard, rough usage, as it is liable to snap short off if subjected to sudden strain. Fig. 1 shows a complete tripod of the simplest possible form, and for practical usefulness not to be superseded by any other.

To construct a tripod, as in Fig. 1, procure some good seasoned wood, free from knots or shakes, cut out three laths 4 ft. 8 in. long, and three 4 ft. 6 in. long, 1 in. in width, and $\frac{3}{4}$ in. in thickness; round off the edges, and smooth them. One end of each lath is shaped like Fig. 2, and strengthened by a plate (Fig. 3) or cap of brass (Fig. 4); this strengthening is absolutely necessary, as the wood at this point is subjected to severe strain. The holes, A, are drilled to admit the pins, attached to the head (B, B, B, B, B, B, Fig. 5), fitting into them sockets (Fig. 6, C), which consist of sheet iron bent into a conical shape, and brazed or welded, with holes drilled so that they can be securely riveted to the wood. The shorter legs are finished as in Fig. 7, a strong hinge being affixed thereto; the hinge is then screwed to the longer end, so that the upper ends of the legs are perfectly level. At six inches from the top of the shorter leg a groove is hollowed out $4\frac{1}{2}$ in. in length (Fig. 8), in which an iron or brass rod 4 in. long (C) working on a pivot (D) at the lower end can be embedded in B flush with the surface of the wood. This is the strut or stretcher, which, when the tripod is set up, fits into a hole in the opposite leg to which it is attached, in order to keep them in close and firm connection with the top. The legs can now be well oiled and polished, two small leather straps, A A, being screwed on to one of the legs (Fig. 10), so that the which they should project 1 in., and screw and glue one on each side of each point of the triangle (Fig. 5) and round off the points. The exact position of the pins should be such that when attached to the legs the ends of the legs should be level with, or rather below, the surface of the triangle. A quarter inch hole is now drilled through the centre of the triangle, strengthened on one or both sides by a circular brass plate (Fig. 5, C); the under part of the triangle, for about an inch on each side of the screw hole, may be slightly hollowed. This acts as a guide in screwing on the camera. It can now be polished, and it is a good plan to cover the upper surface with a piece of cloth or velvet; it gives a firmer bed for the camera, and prevents scratching, and altogether works more pleasantly than bare wood. This completes the ordinary single tripod.

The Folding Tripod.—Fig. 11 is one of the folding kinds, a thoroughly useful pattern, and for travelling its compactness is a great recommendation.

This kind of tripod varies from the straight leg tripod in the construction of the legs, the attachment to the head and the head itself being the same. Proceed to cut six pieces of ash, ¾ in. square and 31½ in. long; round off two corners; a section of the rod will be as Fig. 12. Round off the ends, and drill and cap as in the other case. Cut out three pieces of ash, 1 in. by ¾ in. in thickness and 27½ in. long; make them slightly taper for three parts of their length and shoe. To fix them together place one long piece on each side of the shorter one, overlapping 5 in., as in Fig. 13, and put a stout screw (C) through all of them an inch from the end of shorter leg; file off the point of the screw level with the wood. This acts as a pivot, and permits the legs to be folded. A plate of brass (A), 2¼ in. in length and 2 in. in width, is attached by screws to the outer legs, the wood in the shorter leg being cut away the depth of the thickness of the plate, as at D, so that when the legs are opened out the plate will be flush with the surface of the wood, in order to permit a button (B) on the shorter leg being turned to keep the whole rigid and firm. The measurements for this stand are suitable for working with a whole-plate camera or lens. A six-inch triangle in brass (Fig. 14) is rather to be preferred to wood, as being more easily carried. If it is elected to make a wooden one, it can be made the same as already described, no alteration being required except that the space between the ends of the pins must be reduced to 4½ in., by shortening the sides of triangle and the pins themselves projecting ⅝ of an inch. The struts may be made of strips of brass 4 in. long and ⅛ in. in thickness, let into the wood edgeways. The cell to contain them is best hollowed out somewhat above the end of the strut, to permit the more easy grasp of the brass by the finger end, as in Fig. 8. The same applies to the larger tripod. The usual polishing and straps complete the arrangements.

The Table Stand.—The table stand, shown complete in Fig. 15, is a much more elaborate piece of apparatus, and is especially useful for all kinds of copying work, and for portraiture, although for portraiture alone a smaller stand, and one that can be moved in all directions with facility, is to be preferred. The outside framework of this table is made of 2 in. stuff, the inner sliding frame (Fig. 16) of ¾ in. stuff. Deal answers every purpose. The outer frame (Fig. 15, A) is first made of the dimensions shown on diagram. The method of joining and grooving the corners is shown in Fig. 17; the two front legs are provided with 4 in. iron grooved wheels, B B, working in slots. The back legs are merely grooved at the bottom, to run on rails, for copying purposes. Two half-round iron rails are screwed to the floor of the studio, on which the table is pushed to and fro, the rails always keeping the stand in the same direction when moved backwards or forwards, an important point in copying; by slightly raising the back legs, the stand, even with a heavy camera on it, is easily moved. If no rails are used, good strong castors may be fixed to each leg; then the table may be moved in any direction with facility. The inner or sliding frame to which the table top is attached by hinges (Fig. 16) is constructed as shown, and is raised or lowered by endless screws working in collars attached to the end bars (Fig. 15 D). The screws, C C, are 16 inches long, which gives sufficient elevation for all practical purposes. The lower ends of the screws work through nuts on the lower bars, raising or lowering the table. A winch handle (E, Fig. 18) on the upper bar effects the movement; two stout pins, with screw threads (Fig. 19), only one shown in diagram (also see Fig. 15, F F), are attached to a bar pinching the inner sliding frame to the outer one at each end of the table, and passing through the outer frame, where by means of winged nuts the table may be steadied at any height. In order that either end of the table top may be raised at will, the top is hinged with two stout book hinges at each end to the framework supporting it (Fig. 16, W W). The upper part of the outer frame is braced together by two cross bars, not shown in drawing, made of ½ in. wood, and let into the lower side of the top frame (Fig. 15). This may now be stained and varnished, and the apparatus is complete. The advantage of having wheels only on the front legs is that the stand cannot be accidentally moved, it being necessary to raise the back legs before altering its position, the flat foot giving considerable grip of the floor. Both ends of the table are made precisely alike, with the exception of wheels. The clamping-bar, which is merely a piece of wood (Fig. 19, A) ¾ in. thick and 2½ in. wide, is retained in its place at the back of the upper bar of the outer frame (Fig. 15, L) by the screw, and when screwed up presses firmly against the legs of the sliding frame, Fig. 19 being a sectional diagram, C, frame of sliding table, B, winged nut pressing clamping bar A and D into close contact.

The Studio Stand.—The ordinary studio stand (Fig. 20) combines in a certain degree the movability, to coin a word for the occasion, of the tripod, with the solidity and firmness of the table stand. It is supported on three stout legs supplied with castors, so that it can be moved readily in any direction on the studio floor. The top, C, is considerably less than the table stand, and double—15 in. by 11 in.; and the wood ¾ in. thick. The double arrangement is in order to tilt the camera; the upper platform is supplied with a ledge, D, to prevent the camera slipping off when tilted. The lower part is supported on a bracket, G, whose shape is shown in an enlarged form in Fig 20 A. The upper circular platform (A) and lower circular platform (B) are shown separately in Fig. 23. E is the handle by which the pillar on which the top rests is raised or lowered. Fig. 22 shows the double top, hinged in front, and raised or lowered by a wooden hand-screw or a winch and screw; a 5-in. screw is sufficiently long, as it very seldom happens that more angle than can be obtained by this length is required. The screw should be a stout metal one, say ½ in. in diameter; each half of the top should be clamped to prevent warping. For legs cut out three pieces of wood, 2½ by 2 in., as in Fig. 21; they might be straight as far as utility is concerned, but the curves make them of more presentable appearance. The length from above the castors to the top is 3 ft. 4 in., and the height of the first circular platform from the ground is 18 in. The upper circular platform, Fig. 23, A, is made of 2 in. wood, and is 8 inches in diameter. The lower one, Fig. 23, B, is 2½ in. wood, and 15 in. in diameter, both nicely shaped at the edges, and with square apertures cut through the centre, just large enough to allow easy passage of a solid pillar of wood (Fig. 24), 2½ in. square and 3 ft. long; this is firmly screwed to the lower part of the top, into which it is let in about ¼ in. One side is provided with a strong iron rack about 20 in. long from the bottom of the pillar, which, when fixed in place, engages with cog wheels attached to winch handle, E, on outer case (Fig. 25) for the purpose of raising or lowering the table. In order to prevent movement after the table has been raised to the required height, by the weight of the apparatus, a strong wooden hand-screw or spring catch (Fig. 26) is fixed on the inside of the thin casing, which, engaging with the rack, prevents any downward movement. By merely pulling the knob F the rack is set at liberty, and may be lowered by the winch. The casing is made of ¾ in. wood, neatly joined, and extending between the upper and lower platforms, increasing the firmness and rigidity of the stand, and of just sufficient internal diameter to permit the pillar moving easily through it, not forgetting to allow sufficient space for the cog wheels and winding arrangements. As this entirely depends on the size of the castings, it cannot be definitely stated; three of the sides can, at any rate, be flush with the apertures in the platforms. A small bracket, Fig. 20, A, attached to the pillar under the table is an advantage, as there is considerable strain on this part when using heavy apparatus. With the exception of the pillar and casing, all sharp edges should be taken off the work. How much roundness shall be given to the legs depends entirely on the taste of the workman. The whole should be well polished, and the castors attached. The stand is then complete.

BLACKLEAD AND BLACKLEADING.

BY GEORGE EDWINSON BONNEY.

Blacklead.—The common and well-known name for *Graphite* or *Plumbago*. The black powder, known by the name of "blacklead," has no relation to lead, but probably received this name because pencils made of it caused a mark on paper resembling that made by lead, only blacker. This similarity, together with its metallic appearance, also gave it the name of plumbago, from the Latin *plumbum*, meaning lead. The name graphite is derived from a Greek source, and bears a reference to its use as a writing material. It is really a crystalline form of carbon found in the oldest sedimentary rocks. It is sometimes found associated with iron in its ores, and in some districts is found in the form of veins in the rocks. Its specific gravity varies from 2·15 to 2·35. This material is of great use to the electrotyper, since it enables him to coat a non-conducting surface of a mould with a conducting substance capable of reproducing the finest lines impressed thereon. For this purpose the very best graphite should be employed.

As there may be several opinions as to what constitutes the best, let me say that the best material for the electrotyper is that which rubs into a very fine powder of a dead-black appearance when undisturbed, but having a metallic lustre when rubbed or brushed on a surface. Coarse graphite is useless, however much it may be lauded by the vendor as being "pure as it comes from the mines." Much of this native graphite is too impure to be used for blackleading moulds.

"Coarse impure graphite may be purified by heating the powder with sulphuric acid and potassium chlorate; a compound is thus obtained which, on being strongly lated, decomposes, leaving pure graphite a bulky, finely divided powder." (Roscoe.) ectrotyper's graphite may have its con-ducting power improved by mixing with it me tin or copper-bronze powder. Mr. att gives the following recipe for improving c conductivity of plumbago. "Dissolve part of chloride of gold in 100 parts of lphuric ether; this is then to be mixed ith 50 parts of plumbago, and the mixture exposed to sunlight, being frequently irred until quite dry."

Blackleading or *Plumbagoing*.—The pro-ss of applying plumbago or graphite to oulds to render their surfaces conductors of ectricity. Small moulds of coins and edallions are blackleaded by brushing in e fine plumbago dust with a sable or mel-hair brush or pencil. Larger moulds quire larger brushes, which should always e soft; whilst those of printing electro-ypes are blackleaded by machinery, the ould being fixed to a travelling carriage nd caused to move to and fro under a ibrating brush. Every part of the mould ust be coated with the conducting aterial, and the coat must be nicely olished to produce good results. Some lectrotypists, it should be said, dispense ith the dry blackleading process and dopt Knight's wet process. By this ethod the mould is coated with a thin ash of plumbago in water squirted on to it rom a rose nozzle.

OUR GUIDE TO GOOD THINGS.

**** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

91.—One Hundred Photographic Dodges.

This is a brechure which the publishers, Messrs. Piper & Carter, 5, Furnival Street, Holborn, offer te the public for 6d. It contains "One Hundred Photographic Dodges" collected, classified, and arranged by Mr. W. Inglis Rogers, with a number of interesting experiments with the camera, etc. The publishers assert on the wrapper that it is "the book you want," and a glance through it shows that it contains much that is useful and interesting. Here is one of the dodges—a telescope dodge, which runs thus:—"By fixing an ordinary telescope to the flange of the camera, pretty circular views may be taken of objects that would be too distant for the usual process, provided the camera is provided with a bellows that suits the focus of the telescope." Here is another—the sand dodge, a mode of vignetting, which is thus described:—"Make a shallow wooden box with a ground glass bottom (ground side downwards) with a rim below it to fit loosely over a printing frame. Having adjusted it over the frame, pour into it a quantity of fine sand, just enough to render the glass bottom opaque. Then with the finger form an oval of the required size and shape, and give the box one or two taps to equalise the sand. When required to examine the prints, lift the box off bodily. By piling up the sand on the centre of the plate, the margin may be tinted to any desired extent." The production of head on plate is thus described:—"This curious phenomenon is produced by getting the sitter to hold half a plate against his throat above his collar and covering the remainder of his body, including the hands, by hanging a black cloth in front. Then cover the face, get the sitter to hold out his right arm, as if in the act of holding something, and take another plate *without shifting the camera*. In printing, superpose, so as to get the bodiless head with plate beneath exactly over the outstretched hand." I have given in the above a fair sample of the nature of the "dodges," and I must now leave it to my readers who are also photographers to decide whether or not it seems desirable to purchase the book.

92.—Lansdell's Improved T-Squares and Set Squares.

I have received from Mr. Mark J. Lansdell, A.R.I.B.A., Architect and Surveyor, of Bedford Row House, Bedford Row, London, W.C., a specimen in the form of a set-square of his improvement in the manufacture of T-squares, set-squares, and other analogous appliances. These improvements are embodied and described in Mr. Lansdell's Specification of June 28th, 1888, No. 9442, which is now before me; they may be applied not only in the construction of the appliances already named, but to centrolineads, flat rulers, and all similar appliances and apparatus used by draughtsmen and others in setting out and drawing on cloth or paper representations of architectural, mechanical, and other objects of like character. Mr. Lansdell shows that "as at present manufactured, such appliances are made with flat sides, the whole surface of each of which, or of each part of which, as in French curves, lies in the same plane, and, consequently, rests on the paper or other material on which it is used, causing an unnecessary amount of frictional contact therewith at each movement, and soiling the same by rubbing thereover tho detached particles of pencil dust and other matter which adhere to its under surface. Such disadvantages are especially apparent in those of such appliances which are used indiscriminately with either side as the underside, as the moisture from the hands which adheres to the top side for the time being stains the same, and, when the appliance is turned over, causes particles of pencil dust and other matter to be liable to be attracted and to closely adhere thereto, and in the movement of the appliance over the paper such particles are rubbed in contact with the paper or material, and necessarily soil the same and injure any fine work thereon."

I have myself frequently experienced the detrimental effects of the continuous contact of the paper and the appliance placed upon it for the purpose of drawing or setting-out lines, throughout the entire superficial area of the latter, caused mainly by the drawing of particles of lead pencil dust over the surface of the paper when set-square, T-square, ruler, or curve has been moved, and I have also learnt that the removal of such blemishes is a very difficult matter. The great object, therefore, is to prevent contact between the opposing surfaces of paper and appliance. This, at first sight, may seem an insuperable matter, but Mr. Lansdell has been able to show us that the remedy is, after all, but a simple one, but none the less ingenious because marked with simplicity. Briefly described, his plan is to recess the sides of the instrument, be it what it may, so that a narrow strip along its edge or edges is the only part which comes into immediate contact with the material, whether cloth, paper, or cardboard, on which it is placed. Thus the contact is reduced to a minimum, and although the danger of defacement as the instrument passes over and along the surface of the material is not entirely obviated, yet it is reduced to a minimum. In the set-square sent to me as a sample, the piece of thin mahogany is barely $\frac{1}{16}$ inch in thickness, and it is edged on each side with what has the appearance of being a very thin piece of veneer about the thickness of ordinary cardboard and rather more than $\frac{1}{8}$ inch in breadth. The thickness of the mahogany itself and the edgings laid upon it on both sides is less than $\frac{1}{8}$ inch in thickness. To prevent any objection that might be raised to the effect that the substance of the mahogany being so very slight, and the edging itself extremely thin, the central part of the appliance might be brought in contact with the material on which it is placed under pressure of the hand, two small studs of the same height above the surface of the set-square as the edge itself are placed on the mahogany on each side. Of course, there are other modes of effecting the recessing, and notably that of hollowing out the surface of the appliance on both sides, leaving only the extreme edge to rest on the paper, the section of depression from edge to edge being a curved line. I am not aware that rulers and appliances made on Mr. Lansdell's principle are yet on sale; if so, I daresay he will kindly tell us where they may be had, as, doubtless, many readers of Work would wish to become possessed of them. That they are made in vulcanite I learn from Mr. Lansdell's letter to me, in which he says:—"Vulcanite set-squares of the ordinary thickness would be moulded with recessed body part, and I have had several in vulcanite distributed for a long time in different architects' offices, all of which, from letters received, appear to have given the most complete satisfaction." I cordially agree with such expressions of approval of Mr. Lansdell's invention, which I regard as being a most useful one, and this, I think, will be the opinion of all who are induced to make trial of it.

93.—"Laundry Management."

"Laundry Management" is the title of a useful and comprehensive work on the laundry, the work done in it and the appliances that are used in it, written by the editor of the *Laundry Journal*, and published by Messrs. Crosby Lockwood & Son, 7, Stationers' Hall Court, Ludgate Hill, London, E.C. It purports to be a handbook for use in public and private laundries, and includes descriptive accounts of modern machinery and the apparatus necessary for laundry work. "Laundry Management" is divided into two parts, the first of which deals *seriatim* with the operations and processes generally carried on in the best English laundries. Thus, sorting and marking linen, disinfecting by various means, including chemical agents, fumigation, hot air, and steam, and water and water softening, a subject of the utmost importance, are first treated, and the writer then proceeds to soaking and the removal of stains, washing, rinsing, wringing and drying, blueing, starching, mangling, ironing, completing this branch of his subject with instructions on washing flannels and blankets, curtain and lace cleaning and ironing, and cleaning generally with regard to textile fabrics, leather, and numerous articles that cannot be subjected to the operation of washing. This portion of the work will be found especially useful to those who are about to commence business as laundrymen, and will also show many who are already in the trade, as well as those housewives and housekeepers who desire the highest results, how to set about the business of dressing and washing linen in the best and most economical way.

The second part deals with the planning and installation of laundries, and the machinery to be used therein. Here the writer passes over in review first the laundry buildings with the arrangement of the different departments and the means of securing proper ventilation. After this, machines for washing, hand-power, automatic, and steam power, are brought under the reader's notice; then machines for rinsing and the extraction of moisture, such as wringing machines. Drying machines, box and roller mangles, and ironing machines are next considered, and the book is brought to a close with a chapter on carpet-beating, and with another on some appliances and apparatus connected with the laundry and laundry work that have not found notice in previous chapters. Books likely to prove of service to laundrymen form the subject of the last paragraph: "A Treatise on Steam Boilers," by R. Wilson, C.E.; "A Text-Book on the Steam Engine, with a Supplement on Gas Engines," by T. W. Goodeve, M.A.; "Stationary Engine Driving," by Michael Reynolds; and "The Safe Use of Steam," by an Engineer. To the value of the last brief, but comprehensive, little pamphlet, I can bear ready testimony.

The Editor.

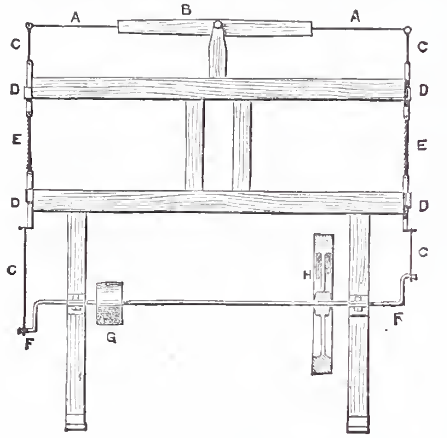
SHOP:

A Corner for Those who Want to Talk It.

, Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Double Scroll Saw.—Artist in Wood writes:—"I forward a sketch of a double scroll saw for coarse and fine work, that I think would run very steady at high speed, one saw to move up when the other is moving down; the springs are to pull



Double Scroll Saw.

A, A, Springs. B, Rocking Beam. C, C, Rods. D, D, Slides. E, E, Saws. F, F, Cranks. G, Driving Pulley. H, Balance Wheel.

the saws tight, and will not bend much when the saw is in use. The plan is a new one, and no machine has been made like it."

Ebonising Door Knobs.—E. P. W. (*Warrington*) writes:—"I notice in 'Means, Modes, and Methods,' instructions showing how to ebonise door knobs, and it has put me in mind of something that would answer the same purpose. We used to stain mouldings for picture frames to imitate rosewood when I was an apprentice. Put a good handful of logwood into a saucepan, cover it well with water, and boil it until it stains a red. Drop in a little pearlash, and dry it on a piece of wood until it gets a rich colour: then put on with a brush while hot. When it is dry put the same stuff on the fire, and add a little bichromate of potash, and you have the black. To make the dark grain get a large feather, and cut it so that it will make three or four streaks at once, and you can grain rosewood like fun. I think the same would answer for door knobs. I am waiting patiently to see articles on violin making."—[Your patience will soon be rewarded.—Ed.]

Subjects in Work.—F. M. (*Glasgow*) writes:—"I am highly pleased with your paper Work, and I anxiously wait on it every Thursday morning. I am much annoyed to see the way you are attacked by some of your readers regarding the subjects which are treated from week to week. Some of the readers appear to me to think that you should give them a paper with an article on every subject under the sun every week. The idea, I think, is preposterous. What I write this letter for is to ask you when I may expect an article on the building of small cottages, etc. I have seen several anxious inquiries about this subject, and I think it would take well. I do not wish to push you too hard, for I see every man wants to see his own trade treated first, and of course some article must stand back. An answer through the columns of your valuable paper will much oblige."—[Pray do not be annoyed at the onslaughts on editorial work and arrangements, as I can assure you they do not trouble me in the least. Once on a time there was a big burly blacksmith, whose wife—an exceedingly small woman—was afflicted with a waspish temper to such a degree, that at times, utterly ignoring her marriage vows, she would assault him with a broomstick. One day a friend asked him how it was that he permitted such a little specimen of the gentler sex to treat him in so ignominious a manner. "Well," said the good-tempered fellow, "you see, it pleases her, and it doesn't hurt me," with which answer the friend was doubtless satisfied. I hope the moral to be gathered from this storiette will be equally satisfactory to you. The papers on building will appear in due course; but I never commit myself to specific promises, lest anything unforeseen should prevent me from coming up to time.—Ed.]

II.—Questions Answered by Editor and Staff.

Photography.—Greenhorn (*Greenock*).—If by "American photos" ferrotypes are meant, it is merely the wet collodion process on ferrotype metal plates instead of on glass. Any treatise on wet collodion will give instructions. A very good shilling hand-book is published by J. Werge, Berners Street, Oxford Street, W., fully treating on positive work, and may be had of him; and there is Hepworth's "Photography for Amateurs" (1s.). In fact, any elementary book on glass positives will afford the information sought.—E. D.

Camera.—M. J. M. (*Aberdeen*).—The plan of folding and making a camera bellows will be found in Work, No. 23, page 359, as simple a form as possible, in the article on "A Whole Plate Camera." Instructions with regard to camera are also therein contained.—E. D.

Electro-gilding.—Aqua Regia (*York*).—I have never seen any gilding that will match the green gold used in some of the French work. I know how to make the gold that colour, but I doubt that gilding can produce it. As to oxidising, I used to use a solution of hydrosulphate of ammonia, but it made such an unpleasant smell, that I now send both oxidising and gilding to my gilder. However, I should use it again if necessary, and for that purpose the work, if of silver, would have to be quite clean, and if of brass, it would have to be electro-plated. The solution should be made with warm water—about one part of hydrosulphate to ten of warm water. Immerse the work until it gets the colour desired, either black, or dark brown, or bluish. Then rinse it in clean water, and dry it in boxwood dust. It will be improved by a final rub with a soft chamois leather.—H. S. G.

Glazing Fretwork Photo Frame.—J. W. L. (*Middlesborough*).—The easiest way by which you can secure glass to your oval fretwork frame is to cut an oval rim, with an opening slightly smaller than that in the frame, and glue it on to this. You will see by this arrangement that the rim forms a rebate, into which the glass will fit, and that it will require no fixing beyond the support afforded by the backing which you will naturally put in behind the photograph. The rim, of course, can be moulded instead of being left with plain edges, but from your inquiry, I judge this will be more than you can accomplish. You will, however, experience very little difficulty in rounding the edges off with any convenient cutting tool, and then smoothing down with glasspaper. The accompanying diagram,

Section of Photo Frame.

showing part of your frame with rim attached, will make everything clear to you: A, the fretwork frame; B, rim; C, glass; D, back cover. Yes, certainly, French polish can be applied to Canadian oak, though oiling or waxing will be easier.—D. A.

Polishing Gunstock, Pear-tree Wood, Gasoline, and Marks on Carpet.—J. McW. Iernus (*Tarbert*).—If your gun is a common one, varnish may have been used, but oil polishing will be preferable if it is a good one. All you have to do is to rub some raw linseed oil into the wood, which, however, must not be saturated. A little oil and much dry friction produce the best results. The more you rub the better the polish will be. Pear-tree wood is suitable for any of the purposes you name, and for furniture generally. It is an admirable material for carving. I am sorry I cannot help you about "gasoline," as, not knowing what it is, I am unable to tell you where it can be got. I may be familiar with it, but under some other name. The "silvery marks" you ask about can only be formed by snails or slugs; at least, none of the carpets I have ever seen have been subject to silvery marks in the morning unless they had been gone over by snails, etc. As you say it could not possibly be these in your case, I am afraid you must endeavour to find some unique cause with which I am not acquainted.—D. A.

Sundial.—Joe Spivens.—A paper or two on the construction of the sundial shall be given as soon as room can be found for them.

Soldering as treated in Work.—D. C. B. (*Reading*).—It is a matter of satisfaction to all who are concerned in the production of Work to find that the papers that appear in it are generally liked and valued by those for whom they are written. With respect to Mr. R. Alexander's paper on "Soldering," which appeared in No. 17, page 257, you write:—"I am glad to say that the first of the articles on tin work has quite come up to, in fact has gone beyond, my expectations. I must say that the article is clearly and explicitly written, so that no one can fail to thoroughly understand how to proceed in this branch of work." I hope, with yourself, that Work will supply the lack of a Technical Institute in many places, or, what is better, pave the way to the establishment of technical institutes. I am obliged to you for your efforts to increase the circulation of Work by introducing it to your friends.

Taxidermy.—E. R. (*Swansea*).—The art of stuffing and mounting birds and animals generally, and the preparation of the skins, will be taken in hand eventually, but it is not possible to commence them yet a while.

Metal Engraving.—R. E. B. (*South Petherton*)—Some excellent papers, well and efficiently illustrated, on this subject are in the hands of the printer and engraver, and will be commenced shortly.

Circular Saw.—Circular Saw (*Clapton*) has a saw 16 in. diameter driven by a 5 ft. 6 in. driving wheel, the proportions of the driving wheel and saw pulley being ten to one; and being turned by hand, it is both hard and slow work. Here double gear must be used to get up speed. A circular saw should properly be speeded to run at about 6,000 feet per minute at the periphery. Your saw being 16 in. in diameter, its circumference is $50\frac{1}{4}$ inches, or, say, approximately 4·16 feet in circumference. Then $\frac{6000}{4 \cdot 16} = 1442$ revolutions of saw per minute. The driving pulley is 5 ft. 6 in. diameter, and the saw pulley, in the proportion of ten to one, is 6·6 in. Say you leave this 5 ft. 6 in. pulley, as at present, on the first motion shaft, and drive thence to a pulley on an intermediate spindle, and on this same spindle drive from another pulley to the saw. Then assume that you turn your 5 ft. 6 in. pulley at 40 revolutions a minute, and speed your intermediate shaft at five times $40 = 200$ revolutions. Then $\frac{66 \text{ in.} \times 40}{200} = 13{\cdot}2$ in.; that is a pulley $13\frac{1}{4}$ in. diameter should go on the intermediate shaft. Then $\frac{1442 \times 6{\cdot}6 \text{ in.}}{200} = 47\frac{1}{2}$ in., the proper diameter of the pulley driving from the intermediate shaft to the saw. So that you will have your first motion pulley turning at 40 revolutions per minute, driving on to a $13\frac{1}{4}$ in. pulley, and on the same shaft as the latter, a $47\frac{1}{4}$ in. pulley driving on to the $6\frac{5}{8}$ in. pulley on the saw spindle, so running at 1,442 revolutions per minute, or 6,000 feet peripheral speed. Though I give 6,000 feet per minute, some saws run at less, others at greater speed, and you can modify your sizes of pulleys if you so desire. If you have the pulleys too close together, the belts will slip with heavy cutting, so put them as far apart as you conveniently can. If your space is contracted, then a good device is to cover the pulleys with leather to increase the bite of the belts. —J.

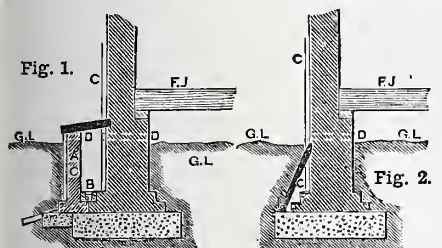
Medical Coil.—Bernhard writes:—"I thank G. E. B. for his reply to my query, battery for medical coil, in Work, June 22nd. I have tried the coil with plates exposed to solution, $3\frac{1}{2} \times 2\frac{1}{2}$, and the carbon full $\frac{3}{8}$ in. from the zinc. Every section works well, giving powerful currents. The contact breaker works well—very brisk; but I wish to know if the positive electrode must be smaller than the negative."—In a small pamphlet I have on the subject, directions are given for the treatment of over fifty diseases, but no mention is made of any required difference in size between the two electrodes, except where necessary for the application of the current to particular parts of the body, as, for instance, to the inside of the mouth. This pamphlet I had with a magneto-electric machine some years since, but it lacks the name of author and publisher. Some of the information is unfit for publication in Work. Perhaps some of our readers can oblige Bernhard with the title and price of a book giving full directions for the treatment of diseases by means of a medical coil.—G. E. B.

Newspaper Rack.—T. A. C. (*Maidstone*).—Unless you are familiar with the work, it is impossible in the limited space of "Shop" to give you sufficient directions to enable you to make newspaper racks. Papers on cane (bamboo) work are in hand, and among the articles will be a newspaper rack which will probably be of use to you. Owing to the pressure of more important subjects, it is, however, impossible for much attention to be devoted to this one at present. Rest assured, though, that in due course full particulars will appear. Meanwhile, if you like to send a rough sketch of the thing you contemplate making, we will see what assistance can be given you in these columns. —D. A.

Pearl for Inlaying.—W. C. M. (*Barrow-in-Furness*).—Messrs. McCallum & Hodson, Summer Row, Birmingham, prepare pearl of the various sorts for inlaying papier-mâché. The same pearl is, we imagine, what W. C. M. requires for his glass work.—S. W.

Bedroom Suite.—J. C. B. (*London*).—For size of 4 ft. 6 in. bedroom suite, those I have given here will be found as convenient and useful as any. I do not say that they are the exact dimensions to which makers in the trade generally work, as they have to economise their wood, in a great many instances, for certain reasons. The extreme outside measurements of the wardrobe would be: height, 6 ft. 6 in.; width on the front of the plinth, 4 ft. 6 in.; width on the side of the plinth, 20 in. The toilet table should be 29 in. from the floor to the top, 4 ft. wide, and 20 in. from back to front, the jewel boxes 13 in. wide along the top, 10 in. at the side, and $5\frac{1}{2}$ in. high. The glass frame ought to be 24 in. by 20 in. without the top moulding. The top of the table should overlap the framing by $\frac{3}{4}$ in. all round. As the legs are turned out of $2\frac{1}{2}$ in. stuff, this will bring the drawer to $20\frac{1}{2}$ in. by 5 in., divided by $\frac{1}{2}$ in. partition. The total depth from the table top to the bottom of the under framing should be 7 in. The jewel drawers will each be 11 in. by 4 in. The sizes of the pedestal pot-cupboard are: height from floor to top, 25 in.; width along the front of plinth, 14 in.; along the sides of the plinth, 12 in. The washstand will be made according to the table measurements. Th ack, if one row of 6 in. tiles is used, should be 47 in. ide and 9 in. high; for every other row of tiles, in-ease 6 in. Chair and towel-rail it is unnecessary give sizes of, as I do not suppose that J. C. B. or ny one else would wish to make them, as they can e bought at very reasonable prices; and, moreover, man may be able to make a firm solid job with oards, but it requires a different kind of skill to make chairs and towel-rails to preserve their en-irety for any length of time without "squeaking." -J. S.

Dry Area.—E. T. (*Blackheath*).—The two sections nnexed give the details of dry areas. You will at nce see that there is a certain amount of work to e done underground. In any case, it is necessary o dig out the ground until you expose the footings nd concrete foundations (it is assumed that they xist). In section in Fig. 1 you will notice a retaining wall, A, of sufficient strength to keep back the ground, built on a concrete foundation, which may e from 6 in. to 14 in. (or more if you have room) rom external wall of house, and covered at the top with stone slabs built into existing wall, one or two of which should be left loose for the purpose of examination from time to time. The floor of area hus formed should be covered with cement con-crete, and a gully, B, let into same at the lowest level, and connected with drain pipes carried through retaining wall, A, into loose earth beyond, to carry off any moisture that might accumulate. Both the walls on the faces marked C should be



Details of Dry Areas—F.J., Floor Joist; G.L., Ground Line.

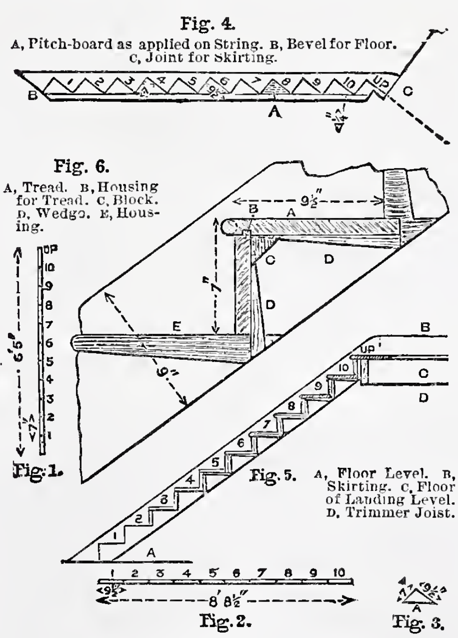
rendered with cement, or, better still, with asphalte. At the point marked D insert air bricks here and there along the length of walls for ventilation. The area could be left open at the top, but that would necessitate more care being given to clearing out same. As to the drainage at B, section in Fig. 2 shows a method sometimes adopted, which is simply slabs of stone leant against the building and the earth filled in, but the former method is recommended, unless you are confined for room. If cheapness is a considera-tion, after digging out the ground, the external face of existing wall may be left with the face, C, ren-dered as described for section in Fig. 1, or covered with slates or damp proof felt nailed to wall and the ground filled in. Whichever plan you adopt, I should at least carry it round the corner of dining-room, for I have frequently noticed that moisture travels by capillary attraction some distance along a wall before showing itself inside. And on no account disturb the slate damp proof course which you notice, for although it is a method open to a great many objections, I have no doubt but that it was originally put there with the best intentions.—E. D.

Paper Replicas and Picture-Frame Compo, etc.—A. E. (*Liverpool*).—For a reply to the first part of your letter I must refer you to the answer given to a similar inquiry by G. M. in No. 13, page 206. With regard to your other questions, I do not quite under-stand whether you require a receipt for making the picture-frame "compo" or not. However, I give the best I know of:—Melt 7 lbs. of best glue in 3 pints of water; melt 3 lbs. of resin in 3 pints of linseed oil. While hot, mix all together and boil for half an hour, being careful to avoid boiling over. Then mix in gradually finest whiting until of the con-sistency of dough; knead well, and press into moulds while hot. If the lump of "compo" be-comes cold and therefore hard, it must be well beated before a hot fire, or in an oven, etc., when it will become workable. The moulds used are gener-ally of boxwood, and the making of them affords scope for any amount of skill in carving, their nega-tive character rendering them rather difficult.—Opifex.

Bell Telephone.—Iernus (*Tarbert*).—Any kind of hard-grained wood will do for the body of a bell telephone; mahogany is commonly used. I made mine with this wood, and I find that after years of use they are still perfect. The magnets should be almost the entire length of the case or body. If you make your case 6 in. long, which is about the usual size, make the magnets 5¾ in. long by ⅜ in. diameter. The diaphragm and coils will depend upon the dimensions of the case for their size also. Assum-ing the case to be the size mentioned above, let the diaphragm be made 2⅜ in. in diameter. Make the space in the case to hold the coil 2⅜ in. by ¼ in.; then the coil bobbin should be 1½ in. by ¾ in. On the bobbins wind ½ oz. of No. 36 silk-covered copper wire; I cannot give you the quantity in yards, as this fine wire is always weighed instead of mea-sured by the yard. There should be no difficulty in getting the materials. I do not know the address of any firm in Ireland where you could get them; but if you write to Messrs. King, Mendham, & Co., manufacturing electricians, Narrow Wine Street, Bristol, I am sure you will be able to get all you want. But I thought you were going to make your telephones. You can do this nicely if you have a turning lathe; all you will require to buy ready made is the wire for the coils. If you want further details, write again.—W. D.

Pattern-Making Book.—Tom Smith.—Has-luck's "Pattern Maker's Handy-book" (2s.), Sta-tioners' Hall Court, London, may answer your purpose. Your other questions will be answered in due course.—F. J. C.

Flight of Stairs.—A Reader of Work (*Ac-crington*).—As you do not mention what kind of stairs you want, or give any particulars as to position, size, etc., I take it that you mean a plain straight flight of stairs, so I have purposely omitted any mention of newels, winders, etc. First, take the distance from floor to floor, and cut off a rod to this length; then divide it into as many equal parts as near 7 in. as possible (Fig. 1); this is called the height rod. You will notice I give the height at 6 ft. 5 in., which gives you eleven steps, or, practi-cally speaking, ten and up. Now determine how far you can allow the stairs to spread out, and divide this into ten equal parts, each part being as near 9½ in. as possible (Fig. 2). I have taken this at 8 ft. 8½ in. Of course I only take the height at 6 ft. 5 in., and the length or going at 8 ft. 8½ in., for the purpose of simplifying the explanation. But the 7 in. rise is about the general height for this class of stair. There are several ways of determining why the going should be about 9½ in. if the rise is 7 in., but it is quite unnecessary to go into this now. Now take a piece of any hard wood about ⅜ in. thick, and shoot one side and one end perfectly square and true, just as if you were going to make a plain set square, and on one side set off the going, which we have determined shall be 9½ in., and on the other 7 in., which is the rise. Connect these two as Fig. 3, and this will give what is called the pitch-board. Great care should be taken in making this, for the pitch-board is the principal, or, I might say, the secret of staircase making; for, unless it is perfectly square and true, the tread of your stairs will not be level when you get them into position, if you get them into position at all. The staircase I am describing is called a housed string stair, so called because the treads and risers are housed or grooved into the strings. I need hardly say that the strings are the pieces which reach from floor to floor, and into which the treads and risers are housed; the one next the wall is called the wall string, and the other the outer string. The next step is to plane up a piece of 1½ ft. 9 in., about 13 ft. long on one side, perfectly straight and out of winding, and gauge it to a width as wide as it will go for the wall string. Then draw a line along the entire length 1½ in. from one edge, place the longest side of the pitch-board (marked A in Fig. 3) on this line, and starting about 9 in. from the left-hand end, mark off as many triangles or steps as you require (Fig. 4). You will notice that you will want ten and one extra (or what is called up), the riser of step 11 or up giving the line of joint between top of wall string and the skirting on floor or landing above, and the line of going or tread giving the bevel of floor below. The same bevels give the notching out of string to fit over



Construction of Flight of Stairs.

trimming joist (Fig. 5), which string is now ready for marking and cutting the housings. If you look at Fig. 5, which shows the string in position, you will see that steps 1 and 2 are simply marked as in Fig. 4; but steps 3 and 4 have the thick-ness of treads and risers marked on. The treads and risers in this case may be out of 1 in. stuff, which will be about ⅞ in. finished. The next two steps (5 and 6) have the wedging shown, Nos. 7 and 8 show the complete housing with nosings bored out, and 9 and 10 show the treads and risers in place and wedged. Fig. 6 is ¼ full size section, showing more plainly how the stairs are put together, and with the size of wedges, etc., marked. After marking the string as in Fig. 4, set off below the line of treads and behind the line of risers ⅞ in. the thickness of same, then slide the pitch-board along the line before mentioned, and draw this thickness parallel to the existing face line of treads and risers. Now allow for wedging, and this will give the exact size or width of housings, which should be ½ in. deep. Cut out the housings for the treads within ½ in. of the face line of risers, as shown at B, Fig. 6, then bore with a ⅞ centre bit a hole the same depth as housing, and this will give a sharp curve for the nosings to fit up to, which would have been destroyed by the saw if done before the rest was cut out. Now follow with the housing for the risers, taking care that the front of the saw does not knock against top edge of tread housing, which would look very unworkmanlike when your stairs were finished. The outer string should be now planed on both sides and treated in the same manner, care being taken that it is marked so that it will pair with the wall string, and they will now be ready for the steps. Now prepare your treads and risers as shown in section Fig. 6, cutting them to the exact length you require the width of stairs to be, allowing for thickness of strings after deducting depth of housings. You will notice that the treads are wider by the thick-ness of risers and projection of nosings than the 9½ in. going, and the risers are less the thickness of treads plus the tongue, which is fitted into treads. One tread and one riser should now be glued together as shown (Fig. 6) and blocked, keeping the blocks 1½ in. away from ends, to allow for going into housings, and for points of wedges in fixing to strings. When the ten steps are glued up and dry, the nosings should be worked. It is better to leave this till now, because there is less likelihood of the round edges getting damaged, and you are sure of not making the mistake of rounding the nosings before you have ploughed for the risers. If you now lay the wall string on the bench or floor, and place the steps in the housings, and lay the outer string on top, taking care that the steps fit, and strut the whole together from the ceiling, or in any other convenient manner, you will at once see if you are all right, and all that remains is to wedge the tread of one step and the riser of the next, working upwards and cutting off the projecting end of wedge of riser or step, as the case may be, and so on to the end. Screw the back edges of treads up to risers, using plenty of glue with the wedging, and you will be all ready for fixing when the whole is dry. The strings might with advantage be 11 in. wide instead of 9 in. if strength is required, and in that case the line on which you set the pitch-board should be about 2 in. from the edge.—E. D.

Sal-Ammoniac.—S. J. (*Birmingham*).—Your query is rather vague. You ask, What is the sal-ammoniac that tinners use to get the bright flush on their work, such as saucepan handles? and so on. Well, there is but one kind of sal-ammoniac that I know of; that is the ordinary sal-ammoniac or chloride of ammonium of commerce, the same as is used for electric bell. The articles to be tinned are pickled in a bath of hot acid till sufficiently clean, then run through killed spirits, in which a lump or so of sal-ammoniac has been dissolved, and then into the tin bath, which is kept well supplied with sal-ammoniac. When thoroughly tinned they are lifted out, and the superfluous tin shook off or wiped with tow, according to the necessities of the case, and cleaned in sawdust. Copper moulds are, of course, not done in a bath. The tin is poured on to them, swilled round and out again till properly tinned, then drained, cleaned, and polished. I should think that in your town you would have no trouble in getting practical illustrations of what you want to know.—R. A.

Bookcase.—Frisby.—Your sketch, though rough, is quite sufficient for the purpose, as it shows better than words alone could do what your idea is. I pre-sume you intend it to stand in a recess, in which case the 1½ in. you have allowed is ample—too much, in fact, if you want to make a close fit. You, how-ever, give the dimensions on the bottom where it is to stand on the cabinet on which you intend to place it; and in setting out the width you must take into account the skirting board, if any, which runs round the walls. I am also not clear whether you intend to put a cornice or moulding on the top, and, of course, if you do you must allow for this. As re-gards thickness of wood, 1¼ in. stuff ought to be sufficient for ends and shelves, while a little less may be used if preferred for the other parts; pine will do very well. Your best plan will be to make the two drawer boxes separate from the upper part or case, which should be complete in itself. Fasten this to the drawer boxes by screws, as may easily be done by removing one of the drawers for the purpose. Fasten all tops and bottoms to ends by means of the ordinary lap dovetail, unless you prefer to adopt the simpler method of nailing the parts together, as suggested in the articles on "Artistic Furniture." A perusal of these will, no doubt, be of assistance to you, not only so far as construction is concerned, but by indicating how you may improve the appearance of your bookcase.

I may also say that an article or two will shortly be devoted to the construction of a bookcase as one of the pieces of easily made artistic furniture; and, unless you are in a hurry, it may be advisable for you to wait till they appear. Unless I am very much mistaken, you will find all the points on which you may now be in doubt thoroughly elucidated. The pieces between the drawers—the bearers—may either be nailed or grooved into the ends. Read the remarks about drawers in the articles on the bureau which have appeared in these pages. No, the back need not be panelled, though, of course, this is the best form of construction. For such a piece of furniture as yours I should, however, advise you to use a munted back, or even match boarding. We shall be happy to help you on any other point you may require advice about.—D. A.

Prospects for Young Workman.—CABINET MAKER.—Yes, I can certainly tell you of one publication of special advantage to young cabinet makers, and I know many experienced hands who take it regularly with benefit to themselves. Its name is WORK, and though, as you are aware, it does not confine itself solely to the cabinet-making craft, I do not think you will find the same amount of useful information, both of a theoretical and practical kind, elsewhere. With regard to other books, much must depend on whether you want to be thoroughly well read on all that pertains to your trade, or are content with having a good general knowledge of the joinery part of it. In connection with the former intention, you will find no book treating of decoration or applied art beneath your notice. Read everything you can get hold of in which woodwork is referred to, and a good many where it is not will be of service, for example, Ruskin's "Stones of Venice," "Seven Lamps of Architecture," etc. Pay special attention to works, both historical and practical, treating of carving, turning, marquetry cutting, polishing, and similar correlated trades. The works of Chippendale, Heppelwhite, Sheraton, and other noted cabinet makers of the last century, will be of use to you. Books on architectural matters sometimes contain hints, though in knowledge of the practical details of cabinet making you will often, if not generally, find architects very deficient. For a general insight into the principles of "art" furniture, I cannot do better than recommend Eastlake's "Hints on Household Taste." There are also the two trade papers—*The Cabinet Maker* and *The Furniture Gazette*. As there is nothing in your inquiry to indicate where you live, I am unable to say whether the information that you will find all the books named, and dozens of others equally useful, in the South Kensington Museum Library. You need never expect to master the whole subject, but you may vastly improve your knowledge by attention to the foregoing hints. I have been studying the literature of furniture for the last twenty-five years, and though I may, in consequence, know a little more than would otherwise have been the case, the subject widens yearly, monthly, daily. There is always something more to learn, so if you want to be a thorough student of furniture you see what you have before you. Your other questions are somewhat difficult to answer definitely, as so much depends on your personal ability, habits, and other circumstances of which I am ignorant, and which you yourself cannot foresee. With exceptional skill and business ability, you may, of course, greatly improve your position, but assuming you are a good average worker, steady, and obliging, I think it may fairly be said that the prospects are as good as in any other trade. If you remain at the bench, you may take it that the wages will be from 27s. to 40s. 6d. per week; at least, that is what they now range from under "Society" rules, and, of course, they may alter. They are, however, not likely to go lower. The rates vary according to the locality. Thus in London 40s. 6d. is now the figure, 27s. being for districts where expenses of living are less, so that, taking all things into consideration, it is a question whether the cabinet maker earning 27s., say, in the Isle of Man is not as well off as the cockney with his 40s. Perhaps the average rate may be given as about 34s. One great advantage a good workman has over others is that he is more likely to be constantly employed. No; on the whole I don't think it can be said that one branch pays better than another. A good deal depends on fashion. For example, when "turned spindles" were all the rage, the turners to the trade had a good time. Later on fret and marquetry cutters had their innings, but things all round soon get equalised. Ability to turn your hand to anything connected with the trade, such as the above arts, carving, polishing, upholstery, would make you more valuable, especially in country towns, but you must distinctly understand that you cannot hope to become so proficient in more than one branch as to compete successfully in large towns with those who have made it their speciality. As "fitter" you might command increased wages, but only experienced and thoroughly reliable men are able to fulfil the duties, so you must wait some years. The same may be said of foremanship. A knowledge of drawing will be of service, if not of actual necessity, to you. You should be able to make and understand a working drawing, and if you can also manage a small sketch so much the better. Of course you stand a chance of getting into a good firm. Why not? It depends principally on yourself. Without having the slightest idea where you are serving your time, what work you have been at, or anything else about you, how can I possibly say what wages you would have at first starting? I have known lads who, as improvers, have been well worth within a very few shillings of men's wages. These, however, are the exceptions. Others, perhaps the majority, are certainly not worth 20s. per week, while many of them would be dear at half that amount in a good general furniture factory. It really is a pity you have not given more particulars, as I might have helped you more. As it is, I have written at length in order to assist you, though I have done so a good deal in the dark, as you give so few of the necessary particulars. These are not wanted from motives of curiosity, as so many inquirers seem to think, if one may judge from the remarkable reticence displayed, but are positively necessary in most instances, if helpful answers are to be given. If the Editor and members of the staff are willing to give their best services, and take time and trouble in helping inquirers, surely these might respond by being a little more explicit than is sometimes the case. Speaking for myself, it is really mortifying not to be able to advise readers who inquire in "Shop" simply because, like you, the questions, though requiring a personal answer, are made in the most general terms.—D. A.

Quick Drying of Photo Negatives.—W. L. D. (*Louisville, U.S.A.*).—Yes, benzine may be used instead of methylated spirit, but I do not like it so much. For one thing, the smell is objectionable. As you say, however, it is inexpensive, and does not injure the negative, so that it may be convenient as an alternative. For the same reason ether may be mentioned as effectual for the purpose. Your other suggestion of placing the negative in the receiver of an air-pump, and then exhausting the air, seems a roundabout way of doing what is wanted, and not nearly so simple as drying with spirit. I have not tried your second plan, so cannot offer any further opinion about it. Glad, nevertheless, to receive your hints, which may be of use, and would have been attended to before but for the fact of your being at one side of the "ferry" and I at the other.—L. I. P.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Machine for Current of Air.—YOUNG ENGINEER (*Newcastle-on-Tyne*) writes in reply to BELLOWS (see page 190):—"I think a small fan would give a powerful and steady current of air. I enclose you a sketch illustrating my idea. BELLOWS

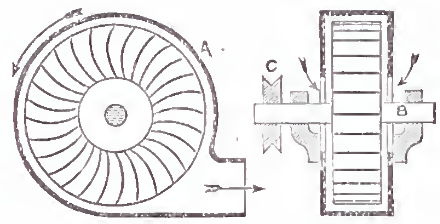


Fig. 1. Fig. 2.

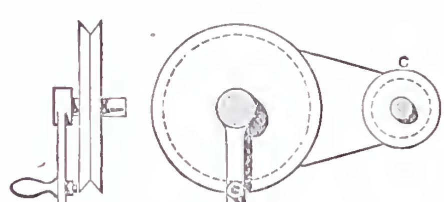

Fig 3.

Fig. 4.

Figs. 1 and 2 show Section of Fan or Blower—A being a Sheet Iron Casing; B, Spindle on which the Wings revolve; C, Small Driving Wheel on Spindle. Fig. 3 shows Speed Arrangement. Fig. 4 shows method of attaching Wings to Plate—E being Wing; D, a small Angle Iron.

could make one if he is a professional, or even a good amateur, or any smith would make him one, at a small cost. Should BELLOWS want more particulars, I should be glad to give him any assistance I can."

Repairing Ivory Stick.—B. A. B. (*Hampstead*) writes in reply to W. A. (*Hanley*) (see page 270):—"You had better try to mend your ivory stick with Marshall's Giant Cement, or Kay's Coaguline. There is also a new fish glue, of which good reports are abroad."

PRIZE COMPETITION.

THE Editor of WORK has the pleasure of informing his readers that the Examiners of the Drawings sent in by One Hundred and Fifty-two Competitors for the Prizes offered by MESSRS. CASSELL & COMPANY, LIMITED, for the Three Best Designs for a small Bookcase to contain 208 volumes of

CASSELL'S NATIONAL LIBRARY,

have awarded the First Prize of *One Guinea and a Half* to

Mr. P. L. SMITH, 7, Albert Terrace, Etherley Road, West Green, Tottenham, London, N.;

the Second Prize of *One Guinea* to

Mr. ROBERT BELLAMY, 48, Albert Street, Barnsbury Road, Islington, London, N.;

and the Third Prize of *Half a Guinea* to

Mr. S. J. SPELLER, Bay Cottage, Broadway, Frome, Somerset.

The Drawing sent in by Mr. J. H. WOOLFITT 4, Crooke Road, Lower Road, Deptford, is highly commended.

*** The Designs by the successful Competitors will shortly appear in WORK, and each Design will be accompanied by a brief paper explaining its construction, with hints and suggestions with regard to materials, finish, &c. Many of the drawings submitted gave evidence of originality of conception ability of expression, and considerable skill and proficiency in drawing in those who executed them, and the Editor of WORK sincerely hopes that disappointment in the present instance will tend to stimulate those who have failed to fresh efforts in the future, which, through perseverance and steadiness of purpose, will not fail to produce the ever welcome fruits of success. Indeed, the Editor regrets that there were not more prizes at his disposal, as a great number of drawings, though not so good as the successful designs, were well worthy of pecuniary reward.

WORK

is published at La Belle Sauvage, Ludgate Hill, London, at 9 o'clock every Wednesday morning, and should be obtainable everywhere throughout the United Kingdom on Friday at the latest.

MELLIN'S FOOD

For Infants and Invalids.

TRADE MARK **NOT FARINACEOUS. Rich in Flesh, Nerve, Brain, and Bone Formers.**

IT is a fact that farinaceous foods cannot be digested by Infants. This is **the only food** in which the starch has been wholly changed into **soluble substances,** which can at once be converted in the body into **living blood.** This remarkable result is attained outside the body, by imitating exactly, in the process of manufacture, the natural conditions of healthy and perfect digestion.

MELLIN'S FOOD has been examined physiologically by the highest Medical Authorities, and tested chemically by the most distinguished Analysts, and has always been classed by them A 1. It has gained many awards of the highest merit at Public Exhibitions.

No Food in the market can show such a vast collection of *bonâ-fide* testimonials, and many of these allude in an emotional yet sincere manner to the fact that **"MELLIN'S FOOD has saved Baby from Death."**

USED IN ALL CHILDREN'S HOSPITALS.

*Prospectus, Pamphlet and Sample, post free on application to the **Inventor and Manufacturer,***

NERVOUSNESS IN MEN

IT is extraordinary how many men suffer now-a-days both in mind and body from a multitude of ailments resulting simply from weak nerves, consequent upon over-work, worry, and other debilitating causes. Doctors have tried for years past, and are still trying, to find some drug which will cure the distressing symptoms of nervous exhaustion, but the best they have been able to do in this direction up to the present is to afford slight temporary relief in some simple forms of the disease. The Consulting Physician and Electrician at St. Bartholomew's Hospital has, we are glad to say, made a move in the right direction. After finding that physic is practically useless for the relief of nervous sufferers, he says:—

"There is no doubt Electricity is one of the most powerful nerve tonics we possess. No agent so quickly restores the depressed condition of the system resulting from illness. In all states of nervous depression, as from long mental strain or overtaxed bodily powers, general galvanism has proved a refreshing and most invigorating tonic."

The next point, therefore, to be considered is, as to the best method of pleasantly applying these currents to the system, and for this purpose we cannot do better than strongly recommend all nervous sufferers to wear one of Harness' Electropathic Belts.

They have stood the test of nearly twenty-five years, have restored thousands of sufferers to health and vigour, are guaranteed to be perfectly genuine, and are constructed on sound scientific principles. The Medical Battery Co., Limited, are the Sole Proprietors and Manufacturers of this now world-famed curative appliance, and should any of our readers still have the least doubt as to its *boná-fide* character, they are invited to call at the Company's Electropathic and Zander Institute, 52, Oxford Street, London, W. (at the corner of Rathbone Place), where they can see the Electropathic Belts scientifically tested, and can personally examine the thousands of unsolicited testimonials and Press reports that have been received from all parts of the World. Sufferers from Nervous or Rheumatic Affections, Liver or Kidney Diseases, &c., who are unable to call and who desire further particulars regarding the curative powers of Harness' Electropathic Belt, should send at once for Descriptive Pamphlet and Book of Testimonials, which will be forwarded to any address free on application to Mr. C. B. Harness, President of the Medical Battery Company, Limited, 52, Oxford Street, London, W. The Consulting Physician, Surgeon, Medical Electrician, Electro-Masseurs, and other officers, are in daily attendance, and give advice free of charge, either personally or by letter. We may add that all communications are regarded as strictly private and confidential.

THE MAIL CART.

HOW TO BUILD IT AND FINISH IT.

BY W. P.

THE mail cart (Figs. 3 and 4) which I am about to describe is so simple of construction that any of my readers could make and put one together in an incredible short time. I have been asked which is the better for wear, wood or the rubber tyre wheels? Well, my experience of wheels is that a wood wheel will last fully three times as long as a rubber tyre wheel will. A wooden wheel after it has been in use a couple of years the hoop will become slack, so that the hoop will have to be made smaller by shrinking it up and rehooping the wheel with it again, the wheels afterwards lasting for a dozen years or more. The spider wheels last a long time, and wear very well if used carefully. The rims of these wheels are without the rubber, and are made stronger than the ordinary rubber tyre wheel. The rims are of two different shapes; one is quite round, whilst the other is flat at the outside, or nearly so. The rubber tyre wheel is at present a general favourite, and has superseded all other wheels, both for bassinettes, mail carts, etc. On account of the rubber it runs along easy and noiselessly, and looks light and elegant in appearance. With a continuous pressure upon the rubber it causes it to flatten out, gets cut up with sharp stones, etc., and is a continuous source of trouble after it has once been "started." Some object to wooden wheels because they look heavy and make a grating noise when wheeled on the flags. A list of the wheels and the prices will be found below.

Wood wheels, a pair 22 or 24 inches high, from 4s. to 4s. 6d.
Spider wheels without rubber, springs, and axle, from 7s. to 7s. 6d.
Rubber tyre wheels a pair, with axle only, from 5s. 6d. to 6s. 6d.

In almost every town will be found tradesmen from whom the reader can buy his requirements, but the above-named articles he may purchase at any cyclist's shop, or any place where bassinettes are made or sold, or at any large toy dealer's. The size of the wheel which I am describing is 24 in. high, or the largest size they make for mail carts. The axle is ½ in. square, and measuring across from cap to cap of the wheels will be 22½ in.

We will now consider the kind of wood we are to make our cart of. In the ordinary cheap mail cart it is of stained deal, whilst the better sort are of pitch pine or ash; either of these two will do, but I prefer ash. We can either buy the wood in a piece and saw it into required lengths, or buy it ready for working. Ash is sold at threepence per foot of 1 in. thick, 2 in. thick sixpence, 3 in. thick ninepence per foot, etc., or threepence for every additional inch per foot. Ash can be bought off any English timber dealer, coach builder, or wheelwright. The measurements enumerated below are as they will be when sawn, planed, and finished off, so therefore allow for sawing and planing.

1 Pair of Shafts	52½	in. long,	2	in. wide	1¼	in. thick.
4 Standards	18	,,	1¾	,,	¾	,,
2 Bottom Side Rails	24	,,	1½	,,	¾	,,
2 Top Side Rails	22¼	,,	1½	,,	¾	,,
Board for the Seat	13	,,	14¾	,,	½	,,
2 Steps or Footboards	12	,,	3½	,,	¾	,,
Back Rest	16¾	,,	3½	,,	½	,,

In planing the pieces always get two sides of the piece true to work from. Mark with pencil to show which is the true side, as one must be at the top and the other at the outside. When finished planing, we round the ends of the shafts a little, also the ends of the rails, and at one end of the standards only, which is to be at the top. We now dress the handles off on the shafts, measure 6 in. from the end of the shaft, draw with the pencil, and dress the handle off same as Fig. 5. Do not dress too much out with your spokeshave, but file it a little. The sides of the handles are left square, the average only taken off and slightly rounded.

If possible a large drawing, full size, should be made upon a blackboard, wall, or floor in chalk, or with a crayon if on a white wall; by placing our work upon the drawing it would enable us to work quicker. We lay the shaft upon the bench or floor with the true side towards us. Place the standards in their right position slanting towards each other at the top. The measurement from the top of the shaft to the top of the standard is 10 in.; measuring from across the top of the standards from the ends it will be 21 in., and at the bottom 28½ in.; measuring from underneath the shaft to the end of the standard it will be 8½ in. Get your pencil or steel scriber and mark each side of the standards on the shaft, press the standard down to keep it from shifting, and mark the standards from the sides of the shaft; when marked, number the standards, and the places marked on the shafts to correspond.

Get your shaft and square across the underneath side from the lines we marked where the standard was. Next set your gauge ¼ of an inch, and mark from the true side just across where we have squared it; this marking is only done at the bottom side of the shaft, recollect, as the top end is not touched at all. When all four have been marked we get our tenon saw, and saw within the lines, and down to the gauge mark; pare this out with your paring chisel, beginning at the gauge line, and slanting up to a feather edge at the top.

We now fix a standard into this rebate. Fix all the standards on the shafts; measure from the top of the standard to the top of the shafts to be certain that it is 10 in. before boring a ¼ in. hole through the centre of the standard and shaft. Fasten together with a cup-head bolt 2½ in. by ¼ in. thick, let the bolt head be at the outside of the standard, and be sure to put an iron washer under the nut when screwing up.

When all the standards are fixed, we next fasten our side rails upon the outside of the standards. Get your short rail and place it an inch from the top; let the ends of the rails stand over the end of the standards. Screw this rail to the standards with a couple of stout screws 1¼ in. long, the head countersunk level with the rail; the screws can be either brass or the common sort, the points being dipped in oil before screwing up.

Next get the other rail and place it under the other, leaving a space between of 2¾ in.; screw this rail upon the standards, and when both the sides are finished like this we commence to fix our springs under the shafts. As there is such a variety of springs, I think it best to keep to the simplest in design and make. The oval-shaped one (Fig. 9) as seen on the cart is made of 1 in. spring steel, ¼ in. thick, and measures across the inside 12 in.; from the axle to the shaft 6½ in.; the other spring (Fig. 10), though a different pattern, will be the same in length and height as the above mentioned.

If we are to have our mail cart to run true we must be particular in fixing our axle on right. If you notice on the spring which fits the axle you will see a bolt hole. Now this hole must be in the centre between the standards. When we have got it so, get your lead pencil and mark the holes which are in the springs on to the shaft, bore through the shaft with ¼ in. bit, and put 4 bolts 2½ in. by ¼ in. thick, screwing the nuts up underneath the top of the springs. Now measure from the bolt hole to the end of the shaft to enable you to set the other spring right. When the other spring is fixed, we fix the axle upon the springs, place a leather washer between the spring and axle, and put a cheese-head bolt through 1¼ in. by ¼ in. thick, and rivet the bolt end, holding a heavy hammer on the bolt head whilst you rivet the end to keep the nut tight.

We are now ready for fixing our seat. We saw this piece 13 in. by 14¾ in. into five pieces, two 5 in. wide, and three 1½ in. wide; when planed and finished off get one of the small pieces and screw it down in the centre of the cart just over the axle; put the other two pieces, each to be near the standard, then screw the two larger pieces between the smaller pieces, as in Fig. 7.

In sawing, countersink the heads level with the seat. The seat can be fitted up if desired with one board instead of the pieces.

We now get our steps or footboards (Fig. 1). Measure from across the bottom of the standards; this we suppose to be 12 in. Get a piece this length by 3½ in. wide, hold the piece, letting the sides come flush with the sides of the standards, and mark with the pencil; get your saw and saw this piece out where marked 1¾ of an inch. At the outer ends near the standards we round the step; serve both steps exactly alike, and put a screw through the standards into the footboard.

We are now ready for our back rest (this with the seat can be made of deal). Measure across the inside of the top rail, which we will suppose is 16¾ in. Get a piece this length and 3½ in. wide by ½ in. thick; fit this within the rails; then mark each side of the rail on the edge of the back rest; take out and round the end to the pencil mark; fix this back rest right in the centre and over the axle, and screw from the outside of the top rail. We now get four small blocks 1½ in. long and 1 in. square; the average is planed off one edge and the top; these are glued in the angle of the back rest and the rail; also put a screw in the block from the outside of the rail.

We next procure our ironwork for the feet. These are of the same width and thickness as the springs; these cranked stays and feet are in two parts (Fig. 2). The part which fits under the seat and running in the direction of the shafts is 7 in. long; from the end of the seat down to the step it is 8½ in.; from this underneath the step 3½ in. We now have a leg to fasten on this plate or stay; for the front it will be 9½ in. with the end twisted up, measuring from the footboard altogether 13½ in. long, as 4 in. of the leg are bolted on the other ironwork; the legs at the back are 6 in. from the footboard, also 4 in. bolted to the other ironwork. These plates should be fixed under the seat 1½ in. from the side of the shafts.

We have now finished making our mail cart as shown in Figs. 3 and 4; when we have bolted the ironwork together, the woodwork can be stained and varnished over with oak varnish. To make the ash a pretty colour, get some old dark gold size;

give it a coat when dry; wash it well and give another coat, stopping the screw holes up with putty, and finish off with some old oak varnish.

The mail cart which I have described is the easiest to make, and all the others of whatever shape or design are made upon this principle. The iron legs can be dispensed with by letting the standards be longer, according to the height of the wheel—9 in. longer—and below the footboard, and 6 in. for the back standard, if the wheels are 24 in. high. Fig. 6 has a footboard 8 or 9 in. long at the back and front to allow the riders to stand up when desired, the seats lifting, or as a sort of lid resting upon the shafts, and screwed with brass hinges to a piece fastened under the back rest. Fig. 8 has a box under the seat; the lid of this can be in the centre of the seat, and should have a few holes bored in the side of the box to allow air to enter. Observe the springs; these are half a circle, 1 in. by $\frac{1}{4}$ in. thick, and 5 in. high, fastened under the shaft and on to a cross-bar of ash or oak 1 in. square, and upon which the axle and footboards are fixed.

SIGN WRITING AND LETTERING.

BY HENRY L. BENWELL.

The Manufacture and Preparation of Signboards.

The manufacture of signboards is, of course, the work of the carpenter, but as the sign writer has often to give orders for their construction, it is just as well to give the proper and necessary instructions to the carpenter at the outset, in order to ensure a good article being made. A few remarks on this subject can therefore be hardly out of place in these articles, so it is my intention to give some simple directions as to making a signboard, and painting and preparing the surface ready for receiving the sign writer's inscription thereon.

Before I proceed further, however, I may perhaps be allowed to explain that the one object these articles have in view is in lending a helping hand to the novice and apprentice who is taking up this particular branch of decorative art. To all those, therefore, who have already a full knowledge of the art, and are past teaching and even learning, my advice—as far as these articles are concerned—is to pass them over.

These words from me have been called forth by the remarks of correspondents who have complained about the elementary character of these articles. Therefore, I repeat they are meant to be elementary, and that I do not profess to write for the skilled workman. For my own part, I cannot understand a man who knows every trick and wrinkle in his trade wasting his time in reading these pages; but in my past experience I have always found this to be the case, that those people who are so learned, so well up in their work, and, in fact, boast so much about their knowledge, and consider themselves above any further instruction, are generally those very workmen who know next to nothing of their particular trade, especially in its best departments. No sensible person, however clever and skilled a workman he may be, need consider it derogatory on his part to peruse an elementary treatise on the handicraft at which he gets his living; in fact, the oftener he recommences at the beginning, the more proficient he is likely to be, as a workman, in his adopted calling.

The wood used in the manufacture of signboards must be well seasoned and perfectly dry when being worked, and as far as possible free from knots. The wood mostly used is the best pitch pine, free from knots. Oak is sometimes used, but it is harder to work, and more expensive.

A signboard should contain as few joints as possible, so it is advisable to have the boards used in its construction as wide as possible. Neither must they be too thin—at least, $1\frac{1}{2}$ or 2 in. thick—or a very flimsy article will be the result. The boards must first of all be planed up smooth and perfectly true, and tongued and grooved, which, the better to prevent them opening, should be done in dovetail manner. The boards are now laid face to face dowwards, and close together upon some level surface, and are secured at the back with ledges or cross pieces firmly attached with plenty of strong screws. These cross pieces should not be more than two feet six inches apart. Now a good many people will at once say that the boards should be "clamped up" before having the cross pieces affixed, but to do this would be a great mistake, for signboards are exposed to all weathers, hot and cold, wet and dry, consequently they undergo a large amount of expansion and contraction. Consequently, if the boards were "clamped up," which they frequently are, no allowance is made for this expansion, and therefore, on the first appearance of wet or damp weather, the boards, naturally expanding, exert a tremendous force against each other, which causes the whole signboard to warp and twist in all directions; nor is this the worst, for the whole structure having been now pushed apart in this way, the boards, contracting with the first dry weather, will have glaring cracks in place of the previous almost invisible joints. It therefore devolves on the carpenter to use his utmost skill and knowledge to obviate and allow for this swelling and shrinking when making a signboard. There is a much more scientific way of making signboards than the one described herewith, with the special view of doing away with all these defects, but the writer is not sufficiently acquainted with the method to describe it in this place.

A signboard is "finished off" by having an ornamental moulding placed around it. This moulding should be rebated, mitred at the corners, and placed around the signboard, exactly as a picture is framed, and screwed thereto at the edges, and not from the front.

These few remarks may assist the young sign writer in giving his orders to the carpenter; in fact, he should write out a short specification in order to avoid disputes. A carpenter who is in the habit of making signboards a speciality can generally be relied upon to turn out a good article without receiving special instructions; but that there is a lot of bad and scamped work turned out in this direction can easily be seen on noticing the cracked, warped, and twisted signboards which one discovers on all hands, totally destroying all the labour and art which has been bestowed upon them by the aspiring and painstaking sign writer.

The carpenter having delivered the board properly glass-papered and perfectly smooth, we now proceed to prepare the surface ready for lettering. This job is generally handed over to the ordinary house painter, or an apprentice, and they are allowed to do the work in their own way, with the very natural consequence that the sign soon after completion is one mass of blisters, or the colour fades or cracks all over. It may not pay the sign writer—especially if he be a clever man and fully employed—to do this work himself, but whenever and wherever possible, he should always have it done under his immediate supervision, for on the lasting result of the signs he paints rests his reputation; and if at any time a sign does go wrong, he will not only get the whole of the blame, but in nine cases out of ten will lose any future work from the same customer. It behoves him therefore to see that great care is taken in preparing the groundwork of his signboards.

In good firms men are kept who understand the whole process thoroughly, and in such cases I need hardly say the "writer" need give himself no trouble; but when one works for the trade generally, and especially for men in a small way of business, he must see to these things if he wishes to keep up his connection.

There are, again, a good many ways of preparing signboards, all of which have their advocates and detractors alike, so it will perhaps be best to describe more than one process.

But it is no matter what method the workman may adopt, he must, *if there are any*, effectually destroy the damaging power of any knots. These must therefore be carefully coated with patent knotting, glass-papered, and again carefully coated. The panel is now primed with red and white lead, half and half, raw linseed oil, and a little dryers (not liquid dryers); a little turpentine may be added, and the priming should be thoroughly strained. When the first coat is perfectly dry, it may again receive a second coat of the same composition, but both must be laid on very thin and sparingly, especially if the panel is made of oak or mahogany. This priming must be allowed to get quite dry and hard, and then it may be well rubbed down with glass-paper.

The sign now receives a sparing coat of the ground colour mixed in the ordinary way, allowed to get dry and hard and glass-papered. This process is repeated, but this time it is glass-papered with extra care. It next receives a good round coat of "flatting" of the same colour, and if this does not sufficiently cover, it must be lightly rubbed down with some fine glass-paper and again "flatted." It must now be decided whether the panel is to be varnished before or after lettering; if the former, it now receives two good coats of copal or amber varnish; if the latter, it is ready for the writer without any further work.

In Spon's "Workshop Receipts," the following method is described:—

"Brush the board over back and front with equal quantities of linseed oil, japanner's gold size, and turpentine, to which add a little ground white lead, driving or rubbing out the colour well. For the second coat take equal quantities of white lead, common spruce ochre, and whiting, all well dried and ground fine and stiff separately with raw oil; mix the whole together; add sufficient gold size to cause it to dry quickly, firm, and hard; dilute with turpentine to a proper consistency, and apply two or three coats of the above colour.

"When dry and hard rub the surface smooth with either sand-paper or pumice stone and water, then grind equal portions of spruce ochre, whiting, bath brick, and white lead with two parts oil and one part turpentine, adding a little gold size diluted with turpentine, and apply one, two, or three coats if necessary, taking care to rub down and wash off the panel between each coat, repeating rubbing and colouring until the surface is as smooth and level as plate glass. It is then fit to receive the last coat to write, marble, or grain upon."

The finishing application, whether it be a plain ground, landscape, figures, or letters, ought to stand until thoroughly dry and hard; it should be finally varnished twice over with the best body copal or amber varnish, as the delicacy of the painting will admit.

HOME-MADE TOOLS.

BY J. H.

Miscellaneous Planes.

Fig. 19 shows a section through a bull-nose rebate plane. The use of such a plane is similar to that of a bull-nose smoothing plane, only that the one is used for working rebates close up to a shoulder, while the other is for plain surfaces simply. Such planes cannot well be made in wood because of the weakness of the nose in that material, but in iron they are strong as well as serviceable. Fig. 20 shows a plan view of the iron. It is shouldered and extended to the full width of the outside faces of the plane, and the flat face is downwards and the bevelled facet upwards, as in all planes whose irons are set at a low angle.

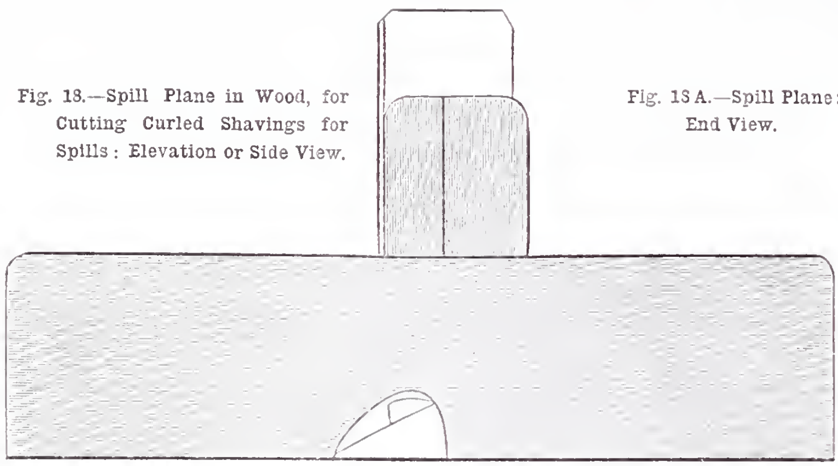

Fig. 18.—Spill Plane in Wood, for Cutting Curled Shavings for Spills: Elevation or Side View.

Fig. 18 A.—Spill Plane: End View.

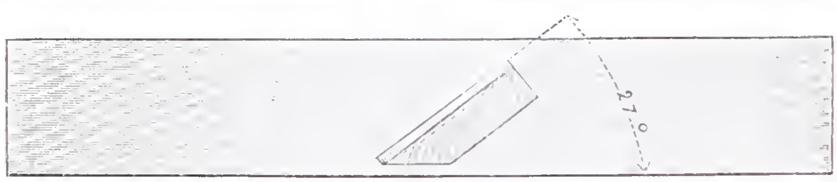

Fig. 18 B.—Spill Plane: Plan.

Figs. 21 and 21A show the patterns of the plane in elevation and plan, Figs. 22 and 22A the core box, also in elevation and plan. The mutual correspondence of these will be evident on comparison. The core outline is dotted in Figs. 21 and 22, and the print, A, is seen to correspond with the width, B, in Fig. 22A. In this example the sides, C, of the plane (Fig. 22) are put in the core box, and the hole, D, for the escape of the shavings is also made in the box, so that nearly the whole of the plane is formed in the core. This is an alternative of the method described in the previous article.

This may be cast either in iron or in gun-metal, it matters not which, and sizes may vary. The bedding of the iron on its face, and the good fitting of the wedge against the under face of the bridge piece, are to be particularly attended to. In this, as in other matters, the instructions already given in reference to previous examples will hold good, and need not, of course, be repeated.

A screw may be tapped into the hinder end of the plane to receive the hammer blows for the loosening of the iron, as noted in a previous example.

Round and hollow planes cost about 2s. 3d. each, and a workman wants a large number. I have seen very many planes made by workmen to supplant the shop-purchased ones, and they answer every whit as well. Figs. 23 and 23A show one of these wooden "rounds" in section and plan.

In making wooden planes there is not much difficulty, but a little care is necessary. In the first place, the stuff for the plane body is squared to width, depth, and length, the silver grain running vertically, or at right angles with the face; and the opening for the escape of the shavings, the seat for the iron, and for the wedge, are carefully marked with a scriber. Then bore holes with a small bit into the mouth. Bore other holes into the opening above, not too deep, but only sufficient to ease the work of the chisel and mallet in cutting out. Do not cut too much out of the mouth at the commencement. This is where a beginner is apt to err and to spoil his work. If the full width of mouth is cut away at once, then when the bedding of the iron, and easing off, and finishing comes to be done, the chances are that the mouth is at once widened as much as it would be if the plane had been in use for a long period.

In cutting out the opening, the chisels used must be as sharp as possible, and, with a flat piece of wood whitened with chalk, check from time to time the truth of the faces which are being cut. A new and coarse flat cut file may be used at the finish to remove the chisel marks and impart a smooth surface.

There is a risk of starting a shake in the angle where the front edges of the wedge fit. Hard driving of the wedge will do this, even if the wood of the plane is perfectly sound at the commencement. For this reason the front edge of the wedge should make perfect contact with its groove, and not be touching on one corner or opposite corners only. Also the chamfer should not start off at too sharp an angle, because that will weaken the wood just where the greatest driving stress occurs.

The surface of the plane should be saturated with boiled oil, which will afford a hard protective coating and gloss to the wood. Over this, when dry, a coat of varnish may be employed with advantage, protecting the wood from the weather and improving its appearance.

Every workman can make for himself small thumb planes—that is, miniature smoothing planes. They are very useful tools. They may range in length from four to seven inches. Single irons for these, from about $\frac{3}{4}$ in. in width, are obtainable in the shops.

It is often the case that pattern makers, carpenters, and joiners, want to work out mouldings, plain, hollow, or ogee around curves. Of course, much of this work can be, and is, done by machine, but not in all shops. In such cases I have seen planes something like that shown in elevation, plan, and section, in Figs. 24, 24A, and 24B, improvised in the space of a few minutes out of a bit of deal worked to the radius of the moulding transversely, and to its curve longitudinally.

They may, for a temporary purpose, be cut from a bit of deal, and they will, for temporary service, answer every whit as well as planes made of hard wood. To lessen the labour still more, I have seen the place for the iron and wedge cut clean out through one of the sides, as in Fig. 24, with a tenon saw. A rough plane like this, cut out for its iron and wedges, and sweeped in two directions, can easily be improvised in half an hour, and will save that small amount of time over and over again, by comparison with the time occupied in working a circular moulding laboriously with an outside gouge.

When its purpose is fulfilled, the plane may be thrown away if its rough appearance is an eyesore, or put away on a top shelf for possible future service.

It is impossible to work long flat sweeps true with a spokeshave, because the base or sole of this tool being so short permits it to rock and roll about, and so to follow, to some extent, the rough contour of the stuff as originally prepared with saw or gouge. To prevent this waviness, and to properly obliterate all lumps, a plane having a sole of considerable length is required. This then rides over the minor projections, and adapts itself to the general or average curvature of the sweep, and so produces true work.

Sometimes workmen make a tool somewhat resembling a spokeshave, but having an iron like a plane iron, and a sole about twice or three times as long as that of the spokeshave. In this way fairly good sweeps can be worked. But still the plane is the best tool for the purpose, and to one of this type the term "compass plane" is applied.

Compass planes, Figs. 25 and 25A, are, therefore, those whose curvature is in the transverse direction to that in Fig. 23, that is in the longitudinal direction of the work. A common smoothing plane is often utilised thus as a compass plane by having a suitable amount of curvature imparted to its sole. But obviously it is not possible to work sweeps accurately with a plane whose

Fig. 24 A.—Plan of Rough Plane for Temporary Use.

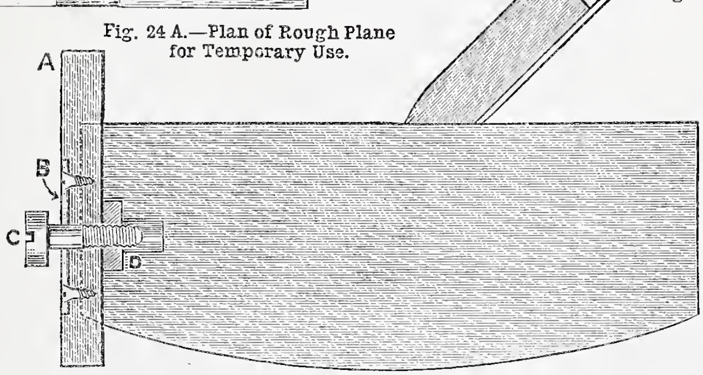

Fig. 25.—Compass Plane: Elevation.

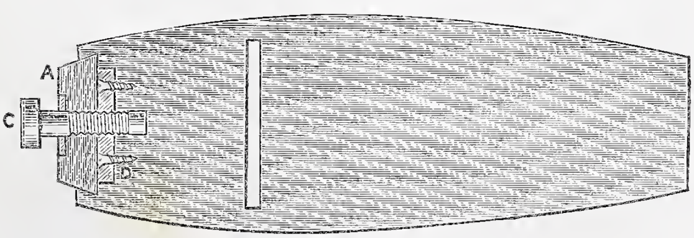

Fig. 25 A.—Compass Plane: Plan.

curvature is very much quicker than that of the sweep which is being worked, while, further, it is impossible to cut a sweep that is at all quicker than the curvature of the plane itself. Hence we want properly a separate plane for nearly every separate sweep, manifestly inconvenient on the score of expense. Hence the great utility of those American sweeped or circular planes having an elastic sole of steel, and a screw, and double lever arrangement with interlocking teeth by which any curvature, either convex or concave, can be imparted to the sole. But these are costly, hardly within the range of amateur work, and are not so well adapted to the rougher kinds of work as a plane of wood. Fig. 25, therefore, shows a device for making a compass plane adaptable to any reasonable range of curvature.

In this a dovetailed adjustable slip, A, is fitted into the front end of the plane with a vertical range of about $\frac{3}{4}$ in. A brass slotted plate, B, is let into and fastened with a couple of screws into the outer face of the slip to take the pressure of the set screw, C. A bit of brass or iron plate, D, tapped to take the set screw, is let into and screwed to the end of the plane, as shown, the set screw being tapped into this, and the loosely dovetailed and slotted piece sliding over the screw body, therefore the turning of the latter with a screwdriver pinches the adjustable slip, A, in any required position, rendering it suitable to a flatter or quicker sweep, according as it is set more or less away from the sole of the plane.

Fig. 18 shows a spill plane made in wood, one of those little articles by which the curling of the shavings used for pipe and cigar lights is effected. These spills look rather pretty on the mantelpiece; the worst of it is that the ashes drop off them as they burn. Gluing thin pine and mahogany together before planing off the spills gives them a pretty variegated appearance.

The important point in these planes is to get the precise angles required; a very slight departure therefrom will prevent that close curling together of the shavings which is essential to good appearance. Both the angle of the iron and of the sole of the plane are of equal importance.

Figs. 18, 18A, and 18B show the plane in side, end, and plan views. A block of wood is planed rectangular to the dimensions shown, and then the hole marked and cut for the wedge and iron, the iron standing vertically. Afterwards the bottom of the plane is rebated through to coincide with the transverse angle to which the iron is ground; the angle of the iron in plan is 65°.

I scarcely think it worth while to occupy valuable space with any detailed description of the mode of construction of the ploughs, filisters, routers, and various bead and moulding and sash planes used by carpenters and joiners. They are very common, and many are made by workmen themselves, many are bought second-hand. In any case, there is no difficulty in their mode of construction. Perhaps the most difficult to many would be the plough, because of the bit of metal work involved. But if the body were described and made, a set of irons would have to be bought, and then it would be cheaper to buy a second-hand plough and irons in good condition. The same remarks apply in the main to the other planes mentioned. The examples which I have selected have been mostly those of planes involving the employment of cast-iron bodies, in whose construction I think most of my readers might be expected to have less acquaintance than with the working of wood. Hence, although I have not by any means exhausted the stock of useful planes, my instructions have embraced all, except some of the most elaborate types which few could undertake with hope of success, and those common planes in wood which are better bought than made. I shall pass on in future papers to the description of some other classes of tools, of which there are many kinds awaiting notice.

The value of these and other home-made tools does not consist altogether in the saving in cost effected over those which are purchased ready made, although that is in some cases very considerable. But they have a much wider value, common to all work undertaken in leisure hours by amateur and professional mechanicians. These are the acquisition of that practical skill which can come only of experiences of failure and success, the intimate knowledge gained thereby of processes and operations, the pride begotten of the successful accomplishment of tasks more or less difficult, the useful and happy employment of hours which might otherwise be given to idleness or to positive vice, the keen interest which grows with devotion to pet hobbies, and the satisfaction of contemplating time past well spent and tasks well done. The stress of life would overwhelm many a man but for his pet hobbies, and it matters little what those hobbies are so that they are innocent. They ever serve the happy purpose of keeping us from brooding over life's worries, and breaking down under its cares, an end which all must desire.

VENEERING PANELS, ETC.

WITH REMARKS ON THE TREATMENT OF LIGHT VENEERS AND BURRS.

BY DAVID ADAMSON.

Let us now suppose that two drawer fronts or panels of the same size have to be veneered. The general work will be exactly as before, but it will be more convenient to place them together with a couple of cauls, the backs of the panels being in contact. This is mentioned as I consider it a better plan than placing the veneered sides together, or, rather, with one caul (metal) between them, though this is done by such very good workers sometimes that I feel loth even to insinuate that it is not altogether desirable, and I certainly would not go the length of saying that it is wrong. If pairs of panels are done, on taking them out of the caul instead of placing them separately against a wall, put the veneered surfaces in contact, and leave the work undisturbed for a few hours in a warm place, when all that has been said applies equally to their after treatment. Perhaps before leaving this part of the subject it should be said that many people before gluing the ground wood size it over with weak glue, just to fill the grain. This may be advisable when the wood is soft, and can never do any harm even with hard woods. A good deal, however, depends on the consistency of the glue, so that whether sizing is necessary or not must to a great extent be left an open question.

It may sometimes happen that both sides of a board must be veneered, and from what has been said about heart side and damping the back the novice may possibly put a few questions to himself which he will find difficult to answer. To save him from any perplexity, he may be told that when both sides of a piece of wood are to be veneered the wood does not require swelling, and that the rest of the work is exactly the same as when only one side is to be veneered. The wood, when ready, is placed between two cauls.

Let us now suppose similar pieces of wood are to be hammer-laid, and the caul dispensed with. The veneer will still be laid on the heart side of the ground wood, which will be glued as before, but not swelled on the back. As the work must proceed without delay in order to prevent the glue setting, everything required should be ready to hand. If the surface is at all large, a warm iron or two should be regarded as among the indispensables. Some warm water, say that from the outer glue kettle—but it must be clean—and a rag or sponge will also be wanted. If necessary, the surface of the wood may be slightly warmed. When all is ready, brush the glue on as usual, and as quickly as possible lay the veneer in position, pressing it down with the hands. Then with the damped rag wet the face of the veneer and squeeze it down with the hammer. To use this with the utmost force which is sometimes required, take hold of the end of the handle with the right hand, pressing with the left on the top of the head, and work the iron edge all over the surface. The moisture on the surface of the veneer should not be excessive, though it must be sufficient to cause the hammer to slip freely over it. Where it can be done without injury to the veneer it is not a bad plan to have a small quantity of glue mixed up with the water to damp the rag. Sufficient will be got by wiping up that which exudes from the edges. The amount of pressure will depend to some extent on the thickness and stubbornness of the veneer, and to prevent this slipping it may be necessary to fasten it down with a pin or two. Blisters should be pressed down as much as possible, and if the glue seems inclined to set too soon, it must be softened either by the application of a warm iron, or, if only locally, by a heated hammer head. Sometimes the inner glue pot laid on any particular spot will do all that is required.

With all veneers the process is very much the same as that which has been described, but some of them want special preparation, and details vary.

Let us suppose, for instance, that a white or light-coloured veneer has to be laid. It would at once be apparent that if put down with a caul, the glue striking through would cause an irreparable blemish. This may be prevented to a certain extent by the use of light-coloured glue, but this is not always obtainable easily, so that it is satisfactory to know that the ordinary kind will do very well when mixed with some white material such as powdered chalk, plaster of Paris, whiting, etc., any of which, it is almost needless to say, must be quite free from lumps or grittiness. One very good plan is to mix some of the white with size or very thin glue, and lightly smear the veneer with it on the side to be glued down. Put the veneer aside till dry, then lay as usual, the only difference, if any, being that the glue should be as thick as it can conveniently be. Another method is not to prepare the veneer by coating it with whitened size, but simply to mix the glue with white before laying. Sometimes it is sufficient to rub the veneer over with ordinary chalk dry; but so much depends on the colour of the veneer that it is almost impossible to lay down hard and fast rules. For example, though oak and satinwood are both light woods, it is evident that the latter is much the more delicately tinted of the two, and consequently more liable to injury. Among the lighter woods commonly met with in veneers requiring care in this respect may be mentioned the following:—Birch, bird's-eye maple, wainscot oak, satinwood, American ash, Hungarian ash.

In connection with these and similar veneers, attention may be called to the fact that the glue is not so apt to strike through when they are laid with the hammer as when the caul is used.

The advisability of thoroughly drying all veneers, and the absolute necessity of doing so with others, has already been alluded to; but, so far, it has inferentially been presumed that they are all of a flat, smooth kind. Burrs, however, are so much wrinkled and crumpled as to require special treatment before they can be successfully flattened out. Among these may be reckoned burr walnut, Amboyna, pollard oak, etc. If they lie flat, well and good; but if not, they must be damped slightly to render them limp and flexible. They should then be placed separately, or in a pile, between hot cauls, and left till they are dry, when they will be flat enough. Be careful, however, that they are thoroughly dry before laying them. All burrs are more or less faulty, and this remark specially applies to walnut, which is frequently full of great flaws and rents. These must be carefully pieced up, and on the way this is done a great deal of the effect depends. Of course, when skilfully patched, the pieces let in should hardly show, and on the finished surface they sometimes require a good deal of looking for before they ca discovered. As I have known amateurs, nply because they could not find any places hich had been thus patched, fancy that ey had got hold of a very superior piece veneer, and cast a doubt on their informer's racity, I may say to those who read this, d have similar notions, that it is almost impossibility to get hold of a very fine ece of burr which has no holes in it. In ct, it may almost be said that the finer the arkings the looser the veneer will be in is respect, so that in veneering with burr is not only necessary to estimate the cost the material, but of the time required to nder it presentable. This is just one of ose points in which the amateur valuer of rniture is apt to go altogether astray, and hich lead him to fancy that he is being imosed on, while in reality he is trying, doubtss unwittingly, to drive a hard bargain. He gues much in this way. A walnut panel the solid is worth so much. He is not to e had, and he knows the value of a burr eneer, large enough to cover it, to be, say, alf-a-crown. Add this to the solid, and -well, yes, not to be unreasonable, a little ore for sticking it to the wood, but that on't take long, as it's only a matter of a ttle glue and sticking the two pieces toether—say 3s. for veneer and laying. The ery important items of time and skill reuired to prepare the burr are altogether eft out of consideration, though it is quite onceivable that they might be worth coniderably more than the cost of the veneer. o show this in its unprepared condition to person of such vast knowledge and expeience would be useless, or worse than useess, for he would think it very poor, comnon stuff, and would much prefer to have a iece as smooth and perfect as a piece of ardboard.

And, without doubt, "so say all of us," only, nfortunately, it is not obtainable. Burrs won't grow according to pattern, and the wood from which they are cut is not machinenade. Uniformity in irregularity is all hat can be expected from natural producions, and where they are not perfect for urposes of manufacture, skill and intelligence are required to make them so. We avail ourselves of the works of nature so far as they can go, and then by art we make them fit for the use we intend for them. This in the case of veneers is that they shall present a smooth, unbroken surface. Every piece of burr, therefore, must be carefully examined before laying, and the larger holes filled with bits cut to fit them. Small cracks and minute holes will be filled up by the glue when laying, so they need no special attention. To fill the others, it should not be deemed sufficient just to fill them up, though this, in any case, could hardly be done generally with pieces cut to fit. It is mostly necessary to trim away the rough edges, and in doing so the hole is enlarged. The aim should be to let in a piece so that it and the join harmonise with the rest of the marking.

In order that this may be achieved it will be seen that it would not do to cut the hole and piece fitted in to a regular outline, such as a square, circle, or oval. This would be too conspicuous, but with a small amount of discretion the joint should be almost imperceptible. The two pieces can easily be made to fit by cutting them both out at the same time. This may easily be managed either with an ordinary fret saw or with the point of a knife, as the veneer, especially if damp, is not difficult to cut. In using the fret saw for this species of inlay it is not necessary to cut on the bevel. The glue will fill up the saw kerf sufficiently. As the pieces are let in, a piece of paper should be glued over them and the surrounding veneer to keep them in place. Any odd scrap of paper will answer the purpose, and I suppose it is unnecessary to do more than state that it must be applied to the face side—*i.e.*, the one which is afterwards to be cleaned off.

In much the same manner burrs which are to be jointed to cover a larger surface must be treated, the edges being cut to fit each other in an irregular line, and then attached by glued strips of paper. As the thickness of different pieces of veneer may vary, they should be reduced as nearly as possible to an equality before laying by going over them with the toothing plane. This is necessary, as it stands to reason that otherwise the caul would not press them down all equally, and surplus glue or confined air would not be driven out to the same extent from under the thinner as from the thick portions. If an unusually large surface has to be veneered, it will be convenient to cut all the different pieces before joining any of them together. This is the general treatment to be adopted with burrs of all kinds, and they should, when at all practicable, be laid with a caul. The hammer does not do for them. Owing to the porosity of most burrs, the sheet of paper between the caul and the veneer must on no account be omitted, and be sure that the caul is either soaped or greased, otherwise the chances are that the glue will not only adhere to the base, but to the caul, and be injured. Nothing more need be said about burrs, of which the walnut variety is that most commonly met with. It must not be confused with plain walnut, though possibly this designation may be confusing to some, as implying that it is without figure. It frequently has plenty of this, but may be distinguished by its presenting much the same markings as a plank instead of a mass of involved figuring such as is seen in burrs.

Rosewood, from its resinous nature, requires somewhat different treatment from any of the veneers which have been considered. Instead of damping it like twisted burrs before pressing flat in the caul, it should be heated at the fire till the oil or gum exudes, and care must be taken that it is equally warmed all over. When the gum has apparently all come out, the veneer is then pressed till cold, after which it is ready for use. It should be said that some of the "bastard" rosewoods which are so often met with now, do not seem to require this special manipulation, but may be treated as if they were mahogany. As a rule they do not emit the peculiar fragrance of rosewood, but in case of doubt they may all be heated. If they contain no oil, of course heat won't bring it out, so that there need be no room for doubt. I believe it is not usual to heat knife-cut rosewood.

Many kinds of veneer have necessarily not been mentioned by name in these directions, but by noticing the leading features of any others which he may come across, the learner will have little difficulty in knowing how to treat them properly and lay them satisfactorily, and we may proceed to consider other matters connected with the art of veneering.

These, however, through want of space, I must defer for another paper, in which I shall consider for the benefit of all workmen, but more especially for the benefit of the improver, such things as blistering and other things connected with the art.

A MAURESQUE COFFEE TABLE.

BY E. BONNEY STEYNE.

How well-to-do folks pass the tempting windows of the warehouses of the Liberty type without buying half their contents is a wonder to poor amateurs. We (not you, my reader, of course) never have those pleasant spare guineas which are required to possess the delightful medley of china, brasses, hangings, and furniture, brought from the spicy East. The very scent of one of these shops is intoxicating, and almost sends prudence to the winds, and leaves one reckless to buy all that is so captivating, with no thought of payment. But although poverty has its pains, it has its pleasures, and the make-shift that does duty in home-made fashion for coveted but unobtainable reality, has a charm of its own in the eyes of its maker, who can trace it back to the first germ, if the idea of it be his own design, or can recall the pleasant sensation of being at last within reach of the long-admired original when some technical journal gives the recipe for cooking a substitute.

The pretty coffee tables sent over from Turkish possessions (it is kinder to be vague, for they may be made in Whitechapel for all I know) are extremely decorative little things, with a squat stability that suggests strength without ugliness. If you examine their detail, it is rarely, save in the very best examples of a high order of art, but they answer their purpose admirably, and know the important point "when to leave off." Yet inlaying with mother-of-pearl would probably be a more costly operation than buying the real thing outright.

To take a suitable design and paint it in set conventional Oriental patterns, with colours in the key those self-taught Eastern folk use so cunningly, would be better than the plan followed in the table hereby set forth. But colour is a hard thing to describe in words. My idea of blue and yours may differ as the sky at midday and Reckitt's advertisements. My notion of purple may be a sort of claret stain, yours the dazzling brilliancy of the aniline so-called violet. Yet I do not say that my notion of each colour is artistic and yours commercial, still less that there are "art colours" any more than art notes in music. Colour and notes are the common material of each artist, and if one makes a beautiful colour harmony, and the other a rare melody, while his rival creates only garish discords and vulgar comic songs, it is purely the merit or fault of the worker who spoils his material, not of the tints or sounds themselves.

Therefore, in lieu of inlay or colour, I have dared to modify the shape, and add some fretwork, of no style in particular, to give a decorative quality.

The necessity of compression (within one page of WORK) of full size working patterns has rendered it important to describe the whole rather fully and with frequent reference to the diagrams.

As this "oddment," to use a dealer's word for the endless variety of small tables and stools, is for the weaker brother to make, its very infantile joinery must be apologised for in advance. In the columns of WORK the correct way is pointed out by many capable leaders, and should any reader wish to make this table, and disdain every word of my suggestions for its fitting, so much the better. But if some unskilled workman would fain try his hand on such a thing, I think the course suggested will keep the structure together until some weighty visitor

A Mauresque Coffee Table.

FULL-SIZE DRAWINGS FOR THE FRETWORK ORNAMENT AND PLAN OF THE CONSTRUCTION.

BY

E. Bonney Steyne.

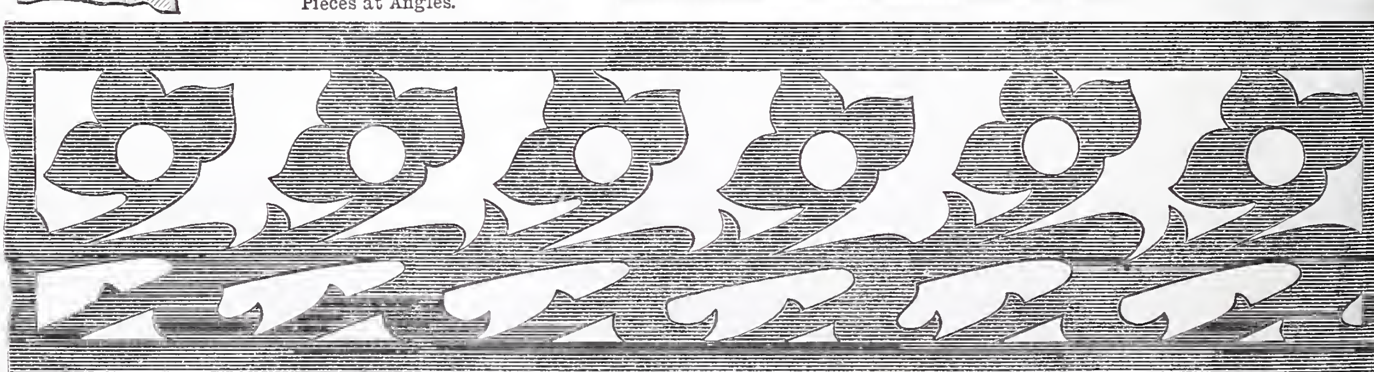

Fig. 3.—The Borders. Cut Eight.

mistakes it for a seat. It is not guaranteed to carry hundredweights or tons, yet if fixed as indicated, will not be more nervous and quaking than I am at venturing to introduce such a bungling piece of joinery into the pages of a paper devoted to serious work.

To begin, take a piece of wood, or pieces, tongued and glued to the requisite width ($19\frac{1}{4}$ inches); on it draw a perfect octagon. For those who have forgotten their Euclid, it will suffice to draw a series of lines in Union Jack fashion—that is, a cross bisected with another at the angle of 45° from the centre; mark each radiating line at 10 inches from the central point; connect these marks with straight lines, and the octagon, from which I propose to evolve the table, is ready to cut. Work two of these in inch stuff, taking care that they are geometrically accurate, and facsimiles of each other; then take eight pieces of deal (or other wood) 2 feet long by 8 inches wide; these may be of half-inch stuff; bevel the edges until they fit exactly round the two octagons, making, as it were, a box, not unlike a concertina (which is usually a hexagon, however), with the bottom placed at the point *a* of Fig. 1. Having fitted them, trace upon them the *outlines* of the two arches within the fretwork, at the distances indicated by diagram. With a keyhole saw cut these as there shown, and smooth the edges to a good finish. If you can rabbet the arches to let in the fretwork from the back, do so by all means, having, say, $\frac{1}{4}$ inch rabbet, and leaving on the fretwork a quarter of an inch to fit therein. The fretwork pieces in Fig. 4 are to be copied in full for the upper arches, and those in Fig. 5 which show pieces for the lower ones. The pieces Fig. 3 may also be provided for in the same way; they form a balustrade to the shelf, and hide the rough edge of the sawn straight line across the grain, which is difficult to finish neatly. Having worked the fretwork either with its $\frac{1}{4}$ inch border for the rabbet, or to the full size as drawn, as the case may be, if the fitting of the structure has been previously completed, the final fixing may be attained by screwing each piece to the octagonal shelf and top, gluing the bevelled edges, and securing them with key-pieces, put in at the angles, as in Fig. 6. Of course, it may be found, in spite of all care, that the table wobbles; if so the fault may be left until the last thing, when all is firm and set; then the feet must be shaved down until the table is both level and firm.

The top (Fig. 2) is an octagon of 24 inches from point to point. Whether this is plain wood with a bead, or with the balustrade Fig. 3 added; whether it is worked with a moulded edge or formed of eight isosceles triangles tongued together, with their grain parallel to the base of each, is just as the workman can or will have it.

The finish of the whole may be ebonised, "Aspinalled," or as you like it. If desired, the top may be painted with a design, the plain spandrels of the arches relieved with patterns, and so on. I think ebonised wood, with neatly painted conventional design in cream colour enamel, to simulate inlaid ivory, would be as little objectionable as any sham can be.

The stability of the structure would be increased by angle pieces or blocks, such as any actual table will show.

So with apology I offer the coffee table, which, may, I hope, give pleasure to some, even if the purist and thorough person look askance at it, and condemn the wilfulness of the writer in venturing to offer such an unorthodox variety of what has hitherto borne an unimpeachable and blameless character.

HOW I MADE A VERTICAL CYLINDER.

BY ELECTRON.

A SHORT time since, I wanted a vertical engine cylinder of a certain size, and not being able to get a casting without making a set of patterns, I set about it in the following manner.

I got a piece of locomotive boiler tube about 3 inches longer than the length of cylinder. The tube was of brass $\frac{3}{16}$ inch thick; the inside was bored in an ordinary wood-turner's lathe, in the following

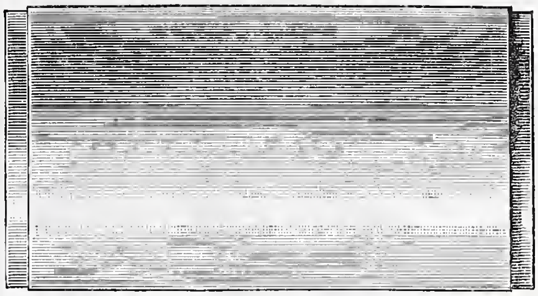

Fig. 2.—Tube for Cylinder.

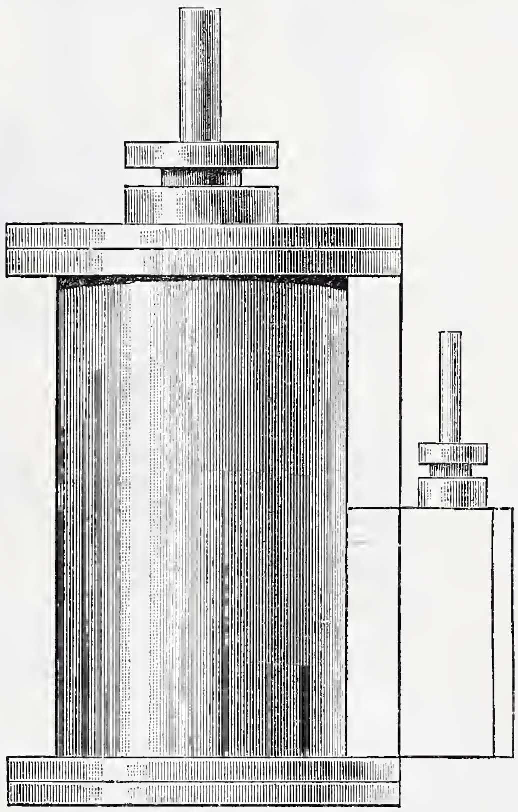

Fig. 3.—Completed Cylinder.

manner:—A boring bar was fixed between the centres of the lathe, and the part at the outer or right-hand end of the cutter was turned true; two discs of wood were turned to fit into the end of tube with a central hole in them to fit the turned part of bar; the tube was then packed up with wood till at the right height, and two strips nailed on the top of packing, to keep the tube parallel to centres; the turned part of bar was then put through the two discs, one being at each end of tube; the tube was pushed forward by hand, the two discs and the packing keeping it parallel. As soon as sufficient length was bored for the cylinder, the tube was cut to the length, fixed on a mandrel, and the ends and outside turned up; each

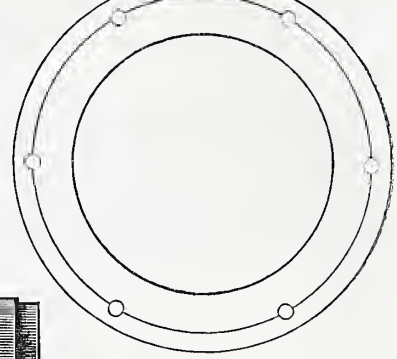

Fig. 1.—Flange for End of Tube.

end was also reduced a little for $\frac{1}{8}$ inch, as shown in Fig. 2.

Two pieces of sheet brass $\frac{1}{8}$ inch thick were fixed on face plate of lathe, and a piece cut out of the centre to fit the end of tube, and the outside cut off $\frac{1}{4}$ inch larger than the outside of tube. Fig. 1 shows one of these. The inside of the holes in these pieces and each end of tube were tinned by a soldering bit, and each piece was then soldered to the ends of tube to form the flanges, and turned up true.

The cylinder bottom was made from brass plate $\frac{1}{8}$ inch thick, and was filed up square; in the centre of this a piece of plate, rather larger than the bore of cylinder, was soldered, then fixed on the face plate and turned to fit the bore of cylinder. Fig. 4 shows cylinder bottom.

The top cover was formed in a similar manner, except that it was circular, and had a piece of brass $\frac{3}{8}$ inch thick soldered on the top side to form the stuffing box. This was turned and bored in the usual way; the gland was also formed in the same manner, a piece of $\frac{1}{8}$ inch brass plate being soldered on a short rod of brass, turned to fit stuffing box, and bored for piston rod. Fig. 3 shows complete cylinder with top cover and gland.

The piston was also formed in the same way, three pieces of brass plate soldered together, and turned to fit cylinder, the centre plate being turned down to receive the packing.

The plates were soldered in the following manner:—Each piece

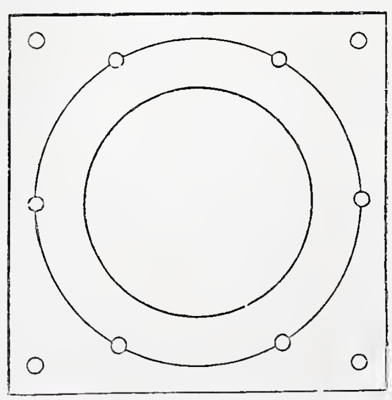

Fig. 4.—Cylinder Bottom.

was tinned all over with the soldering bit; they were then put between two pieces of red-hot iron, and screwed up tight in the vice, and left till cool, when they were quite fast.

A piece of brass the size of steam chest, and ½ inch thick, was filed up and squared, and one side made hollow to fit on the outside of eylinder; the steam and exhaust ports were cut in it, and a hole drilled from one side into the exhaust port, and tapped for the exhaust pipe; a hole was also cut at the lower end of cylinder, corresponding to the steam port: this piece was then tinned on the hollow side, and the outside of cylinder being tinned, the two were sweated together.

A piece of brass about ½ inch square was filed up to form the top steam passage; a groove was cut in the underside of this; a hole was also cut from the top steam port, and into the top of cylinder; the piece of brass was then tinned on the underside and the ends, and the side of the cylinder being tinned, this piece was sweated into its place. The steam chest was cut out of a piece of solid brass ⅝ inch thick, holes were drilled round, and the centre cut out by a small chisel. A stuffing box was formed on the top, and a gland fitted to it; the cover for steam chest was made from a piece of brass plate. The steam chest had a hole drilled and tapped in one side for steam pipe; the cover and steam chest were fixed by four long screws.

The piston rod and valve rod were turned and fitted in the usual manner. The slide valve was made from a solid piece of brass, with a groove in the back, through which the valve rod passed, fixed by a nut at each end. The covers were each fixed by six set screws with canted heads.

The surplus solder at the edges of the joints was all scraped off, and the outside cleaned up with emery cloth.

BINDING SCREWS.

BY GEORGE EDWINSON BONNEY.

Binding Screws.—These are small clamps made of brass, and cast or turned in various forms to suit their requirements. They are used as convenient means of connecting one part of an electric circuit with the rest of the circuit. This has given to them the name of "connectors." When made in the form of a pillar or post and fixed by screwing or soldering to a base, they are named "binding posts." When fixed to the two wires proceeding from a generator of electricity so as to form the two poles of the generator, they are named "terminals." The accompanying illustrations will show at a glance several types of binding screws.

Fig. 1 shows a binding post as used for the terminal poles of dynamo machines. When used for this purpose the post should be massive, the threads on the screws well cut, and the hole for the wire left large. If these posts are nickel-plated, they enhance the appearance of the machine, and require less care to keep them clean. Some makers taper the post from the base upward, whilst others round off the tops. This is merely a matter of taste. The wires from the machine are twined around the tang of the post and secured by a nut beneath the base of the machine. Fig. 2 shows a ball pattern binding post used for a similar purpose. Figs. 3 and 4 show two "telegraph pattern" binding posts. These are used for the terminals of telegraph instruments. When made large, they are useful terminals for ammeters and similar instruments. Fig 6 shows a neat modification of the same terminal; and Fig. 7 shows a similar terminal furnished with a butterfly nut. This form of nut enables the workman to take a good grip on the wire connected to the terminal, and also to unscrew it without the aid of pliers. It is a form of nut that finds favour with French workmen, and is used by them instead of the milled head, so commonly met with in binding screws of English makers. Fig. 5 shows a simple nut and pin terminal, as used to insert in the lead tops of carbons

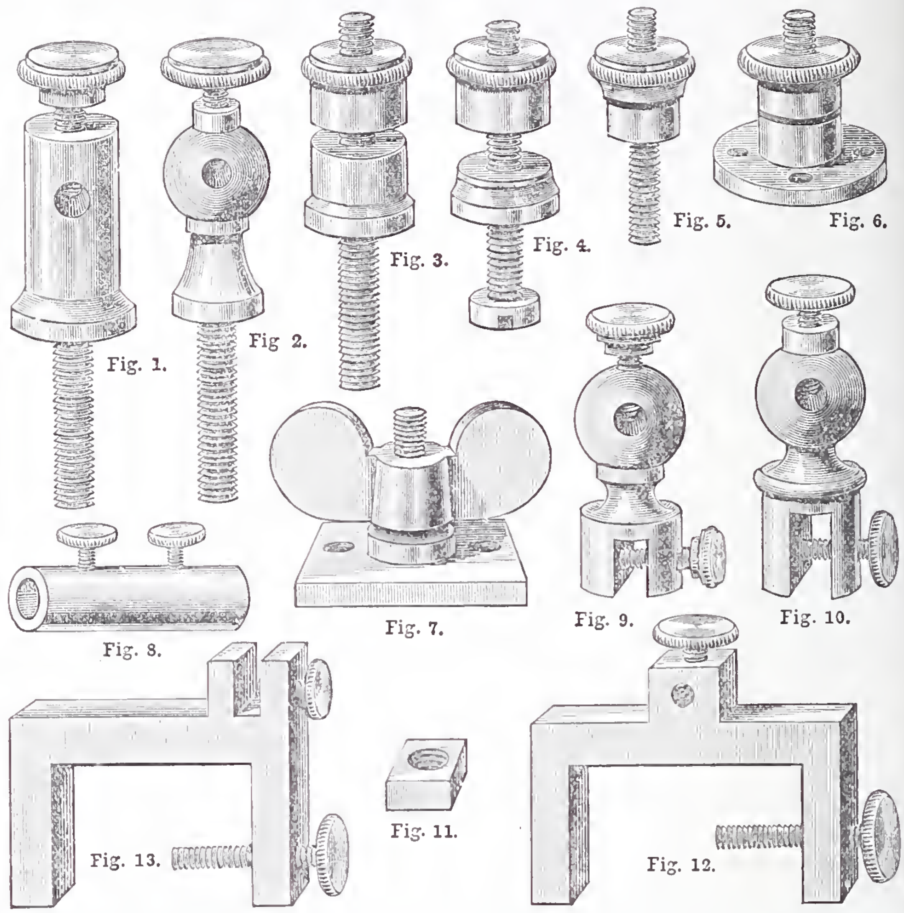

Fig. 1.—Straight Pattern Binding Post. Fig. 2.—Ball Pattern Binding Post. Figs. 3, 4.—Telegraph Pattern Binding Posts. Fig. 5.—Nut and Pin Terminal. Fig. 6.—Flat Base Terminal. Fig. 7.—Butterfly Nut Terminal. Fig. 8.—Wire Connector. Figs. 9, 10.—Binding Screws for Zinc. Fig. 11.—Binding Post Nut. Figs. 12, 13.—Clamps for Carbon Block.

employed in Leclanché batteries. Fig. 8 shows a wire connector made out of a piece of brass tube. Two holes are drilled and tapped in the side of the tube to receive two brass screws as shown in the sketch. These connectors are useful when we wish to connect a broken wire or connect two wires together. Thick brass tube should be used, or else a lug should be soldered to the side to thicken it where the holes have to be made, else the holes will not contain enough screw threads to allow of the screws being tightened on the wires. Figs. 9 and 10 show two forms of binding screws made and sold as clamps for connecting wires to zinc plates and cylinders. These patterns of binding screws are both faulty. The milled heads of the screws hurt the finger and thumb of the workman whilst unscrewing them from the battery. Both forms get weakened at the angle of the jaws by the action of the mercury from the zincs, and then one of the jaws breaks off. The threads on the screws are very fine, and soon wear out. Figs. 12 and 13 show two forms of clamps sold for connecting wires to the carbon blocks of the Bunsen battery. Fig. 12 is a well-formed clamp, but the milled heads of the screws are objectionable. Fig. 13 is only suited to cells connected by strips of copper, or by means of special wires flattened at one end and soldered to a copper strip. They are inconvenient forms of clamps for any purpose.

In No. 1 of WORK, page 4, I show two patterns of clamps made to my order by Messrs. H. Dale and Co. It will be seen that the jaws of the zinc clamp are massive and strong, and the angle of the jaw stands high above the zinc when the clamp is fastened to the plate or cylinder. The top screw passes through a long neck cut with several threads, and this gives it holding power. The threads are also coarser than those in general use, and flat thumb-screws have been substituted for milled heads. The carbon clamps are similarly well made and strong.

The binding screws and clamps of Bunsen cells often get very dirty, and the screw threads become corroded by fumes from the acid. To lessen the labour needed to keep these parts clean and in working condition, have them lacquered whilst new. As the lacquer gets damaged, make the brass warm and dip in melted paraffin; this will cover up bare spots and protect the threads of the screws from being corroded. It is also well to oil the threads of the screws whilst they are dry, before setting the cells up. Clean off all oil and paraffin from the parts to be in actual contact with the battery elements. Should the screws become corroded, soak them first in warm water to loosen the corrosion, then wipe this off with a piece of rag, but be chary of dipping them in acid to clean them, as this will cause the screws to work loose and lose their grip. If binding screws are cleaned and oiled before they are put away, they will always be ready for use and never set fast with corrosion.

Bottles.—Glass bottles stoppered with ground glass stoppers should be the only bottles used by the electro-plater for his acids and solutions. For large quantities of solution the acid-proof stoneware bottles made by Messrs. Doulton, of Lambeth Potteries, will give satisfaction, but common stoneware bottles are untrustworthy, for sooner or later the glazing gives way and the bottles leak. Smaller quantities of acids and solutions are best kept and handled in the tall half-gallon glass bottles known as Winchesters. Bottles holding from 20 to 40 fluid ounces, are handiest for daily use in the laboratory whilst testing and assaying. Strong ammonia, and carbon bisulphide, together with any other highly volatile liquids, should be kept in closely stoppered bottles, with the stoppers tied down. Hydrofluoric acid must be kept in gutta-percha bottles. Should a ground glass stopper become fixed in a bottle, some care and ingenuity must be brought into practice to effect its safe removal. First gently tap the sides of the top of the stopper with a small wooden mallet or the handle of a hammer, then grip the top in the jaws of a stout pair of iron tongs and try to wrench it around. Do not use sufficient force to twist off the neck of the bottle or the top of the stopper, but enough to start the stopper if slightly loosened by tapping. Should this treatment fail to move the stopper, next put a few drops of paraffin oil around it near the rim of the neck and allow this to penetrate the crevice between the stopper and neck. Then try another course of gentle tapping and wrenching. If still stubborn, get an assistant to hold the bottle whilst you twist a towel or piece of flannel around the neck, and work it to and fro rapidly for a few minutes; this will warm the neck by friction and cause the glass to expand. If this fails, the neck should be warmed with flannel soaked in hot water, or with a flame of a spirit lamp, when the glass of the neck will expand and leave the stopper loose. To prevent stoppers from becoming fixed, wipe them with an oily rag before inserting in the neck of the bottle; also wipe the inside of the neck to free it from salts, as these crystallise in the neck and frequently fix the stopper. Do not stopper warm liquids, but allow them to cool before stoppering, as these in cooling create a vacuum and draw the stopper fast. Do not mix sulphuric acid with water in a bottle, as the heat developed is likely to crack the glass. Always label each bottle as filled, and paint them with warm paraffin if intended to be set aside for some time.

Borax.—Sometimes named biborate of soda. This is a compound of boron, sodium, and oxygen, found as a natural salt in India. Its composition is represented by the chemical formula $Na_2 B_4 O_7 + 10H_2 O$. This salt is useful in the workshop and in the laboratory as a flux for brazing operations, a flux for smelting gold, and a vehicle for substances being analysed by the blowpipe. It may also be used as a case-hardening compound, with some success. It also forms an ingredient in mixtures used for colouring gold, and whitening silver. See notes on *Gold Colouring*, and *Silver Whitening*.

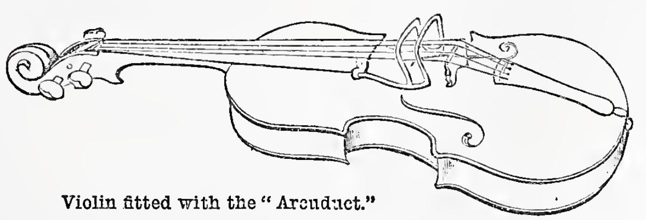
Boxwood.—The seasoned wood of the box tree forms a good substitute for such insulating substances as ebonite and insulite. It is used as insulating rings for the commutators of dynamo electric machines, collars for the insulated pillars of electric bells, and bobbin reels for these and other instruments. The dust from this wood, obtainable from wood engravers and boxwood block-makers, forms the best material for drying electro-plated articles, since it does not stain the pure silver deposit.

OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of any one who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

94.—The "Arcuduct."

The "Arcuduct," or, in plainer English, the bow-guide, is a small but useful little instrument, devised and recently patented by Mr. Sydney J. Pope, Purewell, Christchurch, Hants. It is an appliance that is easily attached to the finger-board of violins and violoncellos, and has for its object the guiding of the bow in the proper position. It is claimed by Mr. Pope that it insures perfect bowing, and if it will accomplish this, it must manifestly be a great boon to all those who are learning and practising on the violin and any instrument of its class, whether small or large. The appliance itself is made of wire bent into the necessary form, and filled at the end with a small clamp, actuated by a screw with a milled head. By this clamp it is attached to the upper right-hand corner of the finger-board of the violin as shown in the accompanying illustration. Starting from the clamp, the wire is bent in such a manner as to form two arches about $\frac{5}{8}$ inch apart in the small size, which cross the strings just midway between the top of the finger-board and the bridge. I am told that in playing the violin, the bow should cross the strings in a direction at right angles to the strings themselves, and midway between the bridge and end of the finger-board. I do not play the violin myself—indeed, I do not play any instrument, though a stray correspondent will sometimes try to convict me of playing the fool, if nothing worse—so in this case, I have been obliged to seek information from those who do. Thus, according to what I have been told, the young violinist when compelled to keep the bow between the two arches of wire is obliged to draw it across the strings just in the right place, and thus is led to acquire a habit of bowing which is never forgotten. The "Arcuduct" may be had in brass or electro-plated. For terms, dealers and those who wish to buy them singly must make application to the patentee.



Violin fitted with the "Arcuduct."

95.—A Useful Boring-Bit.

The accompanying illustrations show from three different points of view the form and construction of a very useful boring-bit which has long been in use in the United States of America, and which was first shown me by an amateur who had been travelling in the States, and had there purchased some of them. I then strongly

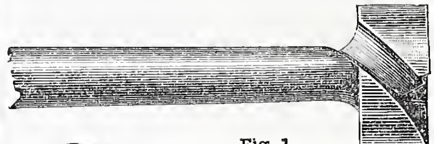


Fig. 1.

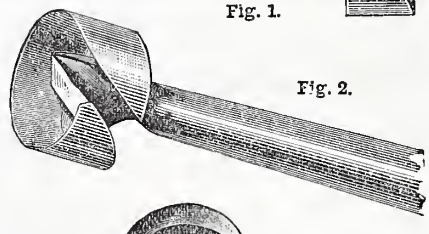

Fig. 2.

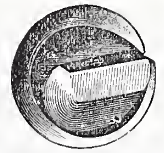

Fig. 3.

Fig. 1.—Boring-Bit, Elevation or Side View. Fig. 2.—View of ditto, showing Form of Interior. Fig. 3.—View of ditto seen as in Plan.

advocated its introduction into this country, but heard no more of until it was brought to me the other day by Mr. Melhuish, of the firm of Richard Melhuish & Sons, 85 and 87, Fetter Lane, London, E.C., and shown to me as a new tool. The nature of the bit will be sufficiently apparent from the illustrations, and it will suffice to say that it does the work of the centre-bit, but does it very much better, for the bottom of any hole that is bored by it is flat and without any mark whatever, while the bottom of a hole made with a centre-bit has in its centre a hole equal in length to the central projecting point of the bit. For this reason, the American boring-bit is especially useful for dowelling, etc. The bits have a long shank, and as they are constructed in a such a manner as to facilitate clearance, holes may be bored to a considerable depth with comparatively little labour. I have a piece of wood before me, in which all that can be done with the bit is shown in a thoroughly practical manner. For example, by boring in two directions at right angles to each other, a square hole may be made which requires but little clearance at the corners with a chisel to make it square at the bottom as well as at the sides. Diagonal holes can be bored with it very readily, and it can be used for boring conical indentations wider at the bottom than at the top by holding the bit in a slanting direction. By means of a series of bits ranging from $\frac{7}{16}$ in. upwards to $1\frac{3}{8}$ in., a set of depressions can be bored, descending by steps, as it were, from the widest to the narrowest diameter named. By moving the bit from point to point round the circumference of a circle, a circular groove of uniform depth may be easily cut. In short, a skilful workman may turn the bit to account in a variety of ways. I do not know the price or the number of bits comprised in a complete set, so readers who wish for information on these points must kindly write to Messrs. Melhuish & Sons, instead of to me. I will, however, when I am myself acquainted with these points, name them in "Shop."

I have no hesitation in recommending this recent introduction from the States as a most useful and desirable addition to the varieties of bits that are used with the brace.

The Editor.

SHOP:

A Corner for Those who Want to Talk It.

_ Notice to Correspondents.—*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

I.—Letters from Correspondents.

Home-made Planes.—E. P. W. (*Warrington*) writes:—"The first thing I look at when I get Work is 'Shop,' and on page 300 I see a moulder approves of my plan. It was a moulder that suggested it to me many years since, and I found it worked well. Some time I will describe a plane that I made myself that will answer for both smoothing plane and rabbet plane, and how to make the pattern, if you think well of it. I know wherever I have worked all hands have used it, and I have had a good price offered for it many a time."—[By all means send me a paper on your plane on approval.—Ed.]

Papers in Work.—D. C. (*Huddersfield*) writes: —"I was very pleased to see my letter appear in a recent number of Work. I was afraid you had thrown it into the waste-paper basket, as it is a few weeks since I wrote to you. I may say I am still looking for the promised article I mentioned in my previous letter, and hope it will not be long before it appears. I may tell you that I have just finished a pattern for an iron smoothing plane, which appeared in Work some few weeks since. I am anxious to have a casting made from it, but do not know how to get it made. I am very much interested in the letters by E. P. W., 'Pattern of Plane for Casting,' and 'Home-made Planes,' by Bert, also the papers by the author of 'Home-made Tools.' I have been thinking it would be a great advantage to many of the readers of Work, who are trying to carry out the instructions of the author of 'Home-made Tools,' if you would try and prevail on Bert to write a few plain instructions telling us how to mould castings for home-made planes. I see, according to his letter, he is a practical man, having made dozens himself. I should also like to repeat the query of G. T. M. (*Liverpool*), with reference to instructions how to make small furnace for melting iron or steel. Also will A. H. (*Wolverhampton*) give us a fuller description of his fan or machine for current of air? I should prefer the fan being of iron or brass, and the sides and top of iron, with detailed instructions how to make the machine complete."—[I daresay Mr. Milnes, lathe and tool maker, of Bradford, would make a casting for you from your pattern if you write to him. I shall be happy to have papers on approval on the subjects named in your letter from the correspondents specified therein, if they will write them and send them to me.—Ed.]

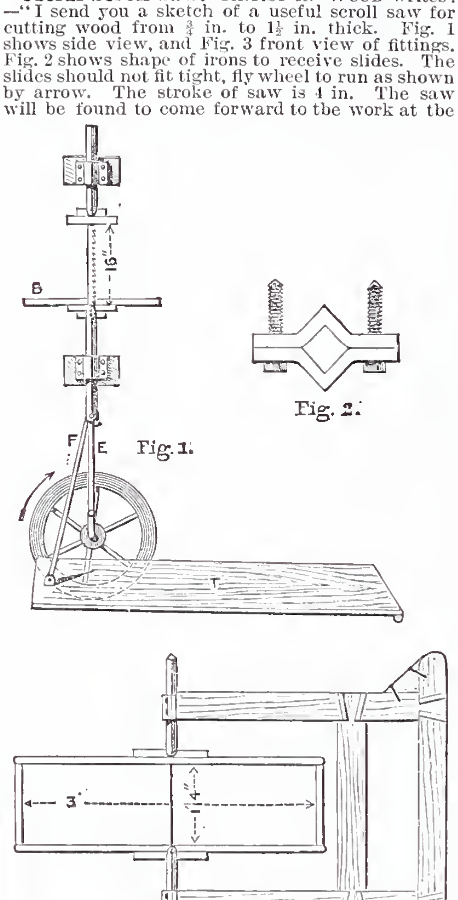
Building Construction.—C. S. (*Newcastle-on-Tyne*) writes:—"Referring to the letters of W. P. and A. E. D. in No. 13 concerning building construction, is it your wish that the various readers of Work who take an interest in the subject should supply plans of various houses to be published in Work, or do you intend, in the course of time, to give a series of articles upon it? If you wish to have plans forwarded by your readers, I would try and do my best to help, as I take an interest in the subject, although I have never before sent to any paper."—[I shall be glad to see any plans you may desire to send.—Ed.]

Overmantel, with Cupboards.—Clerk (*Leytonstone*) writes:—"When I saw and bought the first number of Work, I was not entirely a beginner at woodwork, as I had been through two courses of lessons in carpentry at Toynbee Hall, each course consisting of making various joints, under the instruction of a master, during an hour and a half once a week for three months. In addition to this practice, I had made some Oxford frames out of the top of an old deal table, had knocked up a chicken house with old packing cases, and various other jobs of the same sort, together with a few fretwork frames. But Mr. Adamson's design for an overmantel fired my ambition, and I made up my mind that, at any rate, I would try and make it. Last night I finished it after working for about a couple of hours nearly every evening for the last three months. The wood I used was common ¾ in. floor boarding, together with yellow deal ⅜ in. thick. I took the liberty of altering the design slightly, and instead of making cupboards I put panels covered with Lincrusta Walton at the back, and the open spaces under the side shelves are also filled in in the same way. In the centre, instead of a shelf across the middle, I have inserted an old-fashioned-looking glass, with a wide rosewood frame, which has been in our family for the last century and a half. This is let into rebates, cut in the two middle uprights for the purpose. The woodwork is finished off with two coats of Stephens' satin wood stain, and varnished. The Lincrusta is enamelled sea-green to match the wall paper of the room. Now that it is done, it looks fairly decent, and I don't think any ordinary observer would know that it was done by a nineteen-year-old clerk in his spare time, the total cost (exclusive of the Lincrusta, which was given me) being 6s. 2d. I should like my next job to be an umbrella stand. Could you see your way to giving me a design for one in your valuable columns? The main point with me is that it should be cheap, made of wood, and with as few tools as possible, as I have such a small collection of these. I hope that Work may continue to be as useful to every one as it has been to me; if so, I am sure its circulation will be enormous."—[Yes; you shall have an umbrella stand as soon as I can find room for it.—Ed.]

Swords.—J. C. K. (*Paris*) writes:—"In my article 'Swords' some errors got into print. Page 291, line 25 from bottom of first column, should be 'heating.' Second column, line 32 from bottom, should be 'elliptic.' Page 292, line 34, should be 'play,' not 'plug'; line 63, 'slings,' not 'strings.'"

Swords and Work.—W. E. M. (*Pall Mall*) writes:—"I was pleased with a paper in No. 19, and that was about swords. I showed the article to my master, and he showed it to some more of the workmen, and it has caused three more numbers to be taken in every week. They were so pleased with it; it was the first time they had Work, and they say it is worth recommending to all classes of workmen. For my part, I am satisfied with it, and wish it every success, for I have never before seen such a good specimen of the help-one-another as our little corner 'Shop.'"

Useful Scroll Saw.—Artist in Wood writes: —"I send you a sketch of a useful scroll saw for cutting wood from ⅛ in. to 1½ in. thick. Fig. 1 shows side view, and Fig. 3 front view of fittings. Fig. 2 shows shape of irons to receive slides. The slides should not fit tight, fly wheel to run as shown by arrow. The stroke of saw is 4 in. The saw will be found to come forward to the work at the



Useful Scroll Saw.

B, Table; F, Rod to fit end of Slide and Treadle; E, Rod to fit end of Slide and Crank; T, Treadle Board.

down stroke. It is very easy to work, and will cut wood of the thickness named very quick. Use a saw ⅜ in. wide, ground thin at the back. This saw has been in use fifteen years for trade work."

Moore's Patent Folding Chair.—Mr. J. T. Moore (*Langley, Macclesfield*) writes:—"I note that you have an illustration in No. 23 of Work of a chair, No. 3, that is patented for this country. You are no doubt aware that by the Patent Law of 1883 to make a copy of a patented article, although for personal use, is an infringement, and is actionable at law. Kindly draw attention to the above facts in your next. I am quite sure that your excellent paper will not knowingly encourage injustice in any form."—[Certainly not. Work will never lend itself knowingly to the countenance of anything that is wrong, and therefore I publish your letter with the utmost pleasure. Mr. Lebrun, I am sure, was as ignorant as I was that the form of chair to which you allude was patented in this country, but, you see, none of us can know everything, and hence its appearance. The illustration was derived from an American source. Kindly note that I shall be happy to notice in "Our Guide to Good Things" any speciality you may have or produce, whether patented or otherwise.—Ed.]

Æolian Harp.—G. L. G. writes:—"A detailed description how to make an æolian harp would be an appropriate subject for Work, and welcome to many a subscriber this winter, including myself."—[Will any competent reader oblige?—Ed.]

II.—Questions Answered by Editor and Staff.

Steel Distorting.—G. H. (*St. Helens*).—The reason the steel gets distorted in hardening is, I think, because you make it too hot, and, in dropping it in the oil or water, you let it get horizontal. Just get it a dull red and drop it carefully in perpendicular or endways. I seldom distort anything by going to work this way.—A. B. C.

Wood Pulp.—E. A. (*Liverpool*).—Wood fibre is, we believe, prepared in this country, for the use of paper-makers and others, by crushing withy poles between heavy rollers. Papier-mâché articles made from it in the ordinary way with glue paste would necessarily swell if exposed to wet, but a substance impervious to moisture might be formed by mixing with boiled oil, or some similar medium. As regards procuring pulp, and for further information, E. A. is referred to Messrs. McCallum and Hodson, Summer Row, Birmingham.—S. W.

Silvering Worn Harness Mounts.—B. (*Balsoon, Navan*).—Unless you care to go to the trouble of re-electro-plating your harness mounts, the best thing you can do is to get some silvering solution, and apply to them. I expect you will be able to purchase it at any silversmith's or ironmonger's; if not, here is a recipe:—Nitrate of silver, fifty grains; potassium cyanide, four grains; liquor potash, fifty drops; water, half-ounce (by measure). Mix and bottle. N.B.—This is poison. Apply with a piece of flannel, and use a little plate powder. Polish with chamois leather.—R. A.

Zinc Clock Dial.—Decorator (*London*).—The dials of small circular American times and alarms are printed on paper, and then pasted to the zinc, but the larger American clock dials are, I think, hand-painted. The second query, as to designs on glass doors of clocks, I cannot answer, but I rather think they must be transfers, and then painted over at the back to fix them.—A. B. C.

Photo Camera.—D. M. (*Inverness*).—The size of camera must depend on that of the plate to be exposed. As you will have seen in the article on pin-hole photography to which you refer, the image being always in focus, the length of extension is comparatively unimportant. The further the plate from the hole the larger the image, with indistinctness slightly increasing. Any needle will do. Of course it is only the point that is used, as the hole must be small. Any of the ordinary dry plates, films, etc., may be used. In fact, the only difference in the process consists in having no lens.—L. J. P.

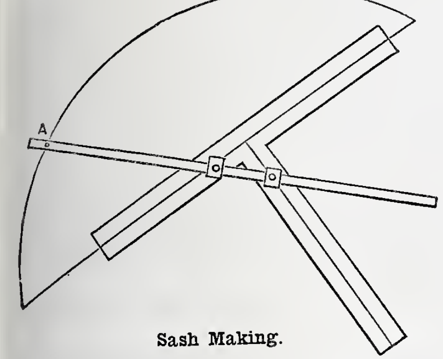
Soldering Aluminium.—G. F. B. (*Dalston*).—(1) On receipt of your letter, I communicated with the secretary of the Aluminium Company, Limited, 115, Cannon Street, E.C. In his reply he says, "The soldering of pure aluminium is a difficulty, and no certain method of doing it is now generally known." The metal has been soldered by Mr. Watts, of 8, Carnaby Street, Regent Street, W., and the soldered articles are exhibited by Messrs. Percy Edwards and Co., 71, Piccadilly, W. Mr. Watts keeps his process of soldering a secret. I *collected* for Rouge Buff all the information obtainable on the subject, and, therefore, gave a guarded reply. I have not soldered the metal myself. (2) The ingredients composing the solder must be melted by fire. I find it best to melt aluminium first, using common salt as a flux, and then add the other metals of the alloy. Granulate and re-melt two or three times. (3) By solid paraffin is meant the pure paraffin wax used by electricians for insulating purposes.—G. E. B.

Electro-gilding in Colours.—Aqua Regia (*York*).—To electro-gild in colours you must have a separate bath for each separate colour, and keep it specially for this purpose. To gild *green*, add silver-plating solution to the gilding solution in very small quantities at a time until the required tint has been obtained; too much silver solution will cause a whitish deposit, known as *white* gold. To gild *red*, add a solution of copper cyanide, or use a copper anode until the desired colour is deposited. To gild *rose pink*, first gild the article and scratch-brush it, then deposit a mere flash of silver on the surface; on this deposit a mere tint of copper from an alkaline copper bath, and then just a blush of gold to tint the copper. The process is a delicate one. To oxidise brass, paint it with a solution of chloride of platinum. To oxidise silver, paint the parts with a fresh solution of ten grains sulphide of potassium dissolved in a wine-glassful of hot water. Apply with a camel-hair brush.—G. E. B.

Electricity from the Earth.—Miller (*Leeds*). —It is quite true that an electric current can be obtained from two plates of dissimilar metals sunk in the earth, such as zinc and copper or zinc and carbon (represented in the case you quote by coke).

I have obtained a current from the gas-pipes and the water-pipes of a house, and a friend of mine has actually done electro-gilding with such a current by way of experiment. At the time you speak of (1844), great things were expected of this discovery (?), but its usefulness is limited by the low pressure of the force thus obtained.—G. E. B.

Sash Making.—JOINER (*Dalston*).—Instructions in sash making would take up more space than could be afforded in a brief reply in "Shop," but a paper dealing with the subject will shortly appear, in which the intricacies of setting out, and the various joints that puzzle the novice, will be clearly shown. The tool you inquire about for drawing ovals is usually called "trammels;" you can buy it



Sash Making.

at a tool shop, but it is usually a home-made thing, and consists of a long piece of wood about ½ in. square, on which are two brass slides with studs on the underside. These studs work in grooves cut in a **T**-square, and the size of the oval is regulated by the distances from the end of the rod and between the studs. The annexed figure will help to show you how the apparatus works. A hole is bored at A for the insertion of a lead pencil.—G. LE B.

Electro-Plating.—MANKTELOW (*Winchett Hill, Kent*).—Plating can be learned by the most inexperienced person, if he will only faithfully follow the directions of his teacher. Amateur plating (such as silvering and gilding alberts, bracelets, brooches, etc., or even spoons and forks) may be easily learnt, and I hope to give some easily understood lessons on this subject in a future number of WORK. If you will take the trouble to read the article on *Anode* in "Notes for Electro-platers," page 123, I think you will fully understand this term; whilst in the first three numbers of WORK you will find illustrated articles on Bunsen cells.—G. E. B.

Accumulator Plates.—D. S. (*Holloway*).—(1) The composition of accumulator plates is lead, coated with red lead, or with lead peroxide. (2) You may make them by the following directions, but you will see that the process is tedious. Procure lead plates of the requisite size, and let the thickness of the lead correspond with the superficial area of the plates, to prevent undue buckling. In cutting each plate, leave a lug 2 in. by 1 in. on the top to form connecting pieces. Perforate each plate with ⅛ in. holes all over. Make a paste of finely-ground red lead with oil of vitriol, and rub this with a lead or pewter spatula all over the plates until each hole has been closely filled and the plates coated with a crust of the paste. Connect the plates in pairs, one on each side of a strip of teak or mahogany (well soaked in hot melted paraffin), by means of short brass screws. See that the screws are not long enough to go through the strips and touch the opposite plate of lead. The plates are now to be placed in their cells (a pair of plates in each cell) to be formed, that is, to be charged and discharged again and again with a strong current of electricity from a dynamo until all the red lead (lead oxide) has been converted into lead peroxide. The cells should be of glass, acid proof stone-ware, or a similar acid proof and insulating substance, and should be charged to near the top of the exposed plates with a solution of one part sulphuric acid to twelve parts of water. Each pair of plates must now be included in an electric circuit, either with a dynamo or a very large battery, if the plates of the accumulator have a large area. If the voltage of the generator (dynamo or battery) is high, several pairs of the plates may be connected in series; but if the current has an E. M. F. of, say, three volts, only one pair of plates may be charged at a time. The E. M. F. of a pair of accumulator plates being two volts when fully charged, we must employ a generator having a higher E. M. F. than the sum total of the plates in series to be charged with it, or the accumulator will discharge itself back through the battery or dynamo, to the injury of either. Charge the plates for half an hour at first, then connect them up to some work, and let them discharge themselves; again charge for a longer period, and again discharge them. Continue this until the plates are formed, that is, until each square foot of positive plate will yield six ampères of current. (3) I should advise you to consult a practical electrician, and abide by his advice respecting the size of accumulators required for your installation, and the other matters connected therewith. (4) If you get the plates from the E. P. S. Co., they will advise you respecting installation, or you may get both plates and advice from Mr. H. Dale, 26, Ludgate Hill, E.C. (5) I must leave this matter to be decided by our Editor. I cannot give professional advice by private letter without a prepaid fee, the amount of which would depend on the work to be done.—G. E. B.

Article for Iron Moulders.—D. J. J. (*Birmingham*).—There is no place in Birmingham, or anywhere else, where you can get your invention registered on credit. The stamp for protection for nine months costs £1. The necessary forms are supplied free at the Chief Post Office, but you must pay for the stamp.—F. C.

Prospectuses of WORK.—E. L. R. (*Oxford*).—These were forwarded to you on receipt of your request for them, and should have reached you long ago. I take the opportunity to thank you for your good opinion of WORK, and your intention "to take it in as long as it continues." That I trust will be beyond my time and yours, too.

Cutting through Paper Tubes.—D. B. (*Glasgow*).—In the papier-mâché trade the approved method of cutting up paper tubing is in the lathe with a keen knife-like chisel, and it is easy to understand how the neatest cuts are to be made in this manner. But paper soon blunts the tool, and thick tubing is frequently merely nicked in the lathe, and then sawn. In default of a lathe, we do not see how D. B. can cut his tubes better than with a fine tenon saw.—S. W.

Covers for WORK.—J. H. (*Wolverhampton*).—The pasteboard covers were suggested as temporary means to keep the numbers clean until binding time comes. Your wish is that the advertisements could be relegated to covers, on the plea that as the numbers are now constituted the advertisement pages must, of necessity, be bound up with them. Well, why not bind up the advertisement pages? In course of time they will prove most useful to the readers of WORK as a record of "What to buy, and where to buy it." Everything, it is said, comes useful once in seven years, but I feel sure that the advertisement pages in WORK, after a time, will prove useful to many, perhaps, once in seven days, if not much oftener.

Book on Paints.—SUBSCRIBER (*Sunderland*) writes:—"Can you inform me of any manuals of technology or any work of chemistry, or colour striking? Also can you tell me where to get 'Trade Secrets,' and the price of the book?"—A work which might suit you is, "Painting and Paint Materials: a book of facts for those who deal in paint materials" (10s. 6d.), Spon & Co., 125, Strand, London.

French Polish.—C. H. W. (*Hastings*).—I am under the impression, from what you now say about not being able to mix the ingredients, that your question was answered in due course for the "Shop" columns. Owing to the length of time which must necessarily elapse between going to press and publication, it is impossible that answers can appear immediately. In case you have not discovered the cause of your want of success, and presuming your inquiry is the one referred to above, I can only advise you not to use so much polish, or to substitute for it methylated spirits. If you had told me exactly how you have mixed the things, I might have been able to discover the cause of your failure; as it is, I cannot do more than I have. The receipt is well known among French polishers, and is always effective.—D. A.

Imitation of Leaded Windows.—SPECTATOR (*Skipton*).—We presume from SPECTATOR'S note that the imitation of leaded lights required is that known as "Patent Glacier." The makers of this are Messrs. M'Caw, Stevenson, & Orr, Belfast. The agents for its sale in Great Britain are Messrs. Perry & Co., Holborn Viaduct, London, who supply a book of designs, with sample, instructions, etc., by post for 1s. It can, doubtless, be procured through any fancy shop.—M. M.

Dressing Skins.—SEALSKIN (*Liverpool*).—To prepare his roughly dressed sealskins for rugs, we do not see that our correspondent can do better than damp them (by rolling in damp cloths), stretch them tightly, and rub down the flesh side, till even and uniform, with pumice stone and powdered chalk. Lumps of flesh or fat will best be removed with a knife. The chalk will clean the hide by combining with and taking up its grease and dirt. Any skin can be made soft and pliant by thoroughly working oil or yolk of egg into its pores. By the last substance the beautiful softness of kid gloves is produced, the skins for making which—like our correspondent's sealskins—have first been roughly cured with alum. After egging, it is usual to draw the skin backwards and forwards across a blunt semi-circular knife fixed upright; this operation is called "staking." In the language of the workmen, "Staking brings the skins to themselves again," *i.e.*, it makes them appear as pliant as when first stripped from the animal.—M. M.

Horsehair Cleaning.—R. J. P. (*Feltham*).—The hair in question is, of course, for use as stuffing in upholstery work. If it is new hair, boiling with a little washing soda will effectually clean it, and remove all smell; and drying afterwards in an oven will tend to make it curl up, which is desirable. If it is old stuffing which has been curled, boiling is not recommended, as it would take out the curl, and so render the hair less elastic. To curl horsehair properly needs appliances which an amateur will not possess. In this latter case, the better plan will be to beat out the dust thoroughly with a pliant stick; to shake the hair in a sieve or riddle, to remove short fragments, foreign matters, etc.; to sprinkle it from a watering-can with dilute Condy's Fluid (this, if done with care, will not destroy the curl); and to dry it, which will best be done in an oven just *not* hot enough to singe it, as this will make sure of destroying any germs of disease or insect life which may have escaped the disinfectant.—M. M.

Tenant's Greenhouse Cost.—A. P. (*Heaton Chapel*).—The cost of material for making the "tenant's greenhouse" will vary according to the locality, as wood is dearer in most inland towns than in places near to a seaport; but I should say that the timber necessary could be bought for, say, £8 to £10. If you want to be economical, use white pine, which is the cheapest, although not so easy or pleasant to work as yellow; and for the sole framing you might procure an old beam at a builder's yard for a few shillings that would suit your purpose quite as well as new wood.—G. LE B.

Carving in Cast Iron.—PIPER (*Manchester*).—I am not quite sure that I understand your meaning. You ask "How to carve in cast iron, etc., such as these sweets we see, fish, raspberry, dolls." Do you mean cast iron moulds or dies? If so, these would not be carved, but cast from a plaster or clay model, and chased up afterwards.—J.

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

Bicycle Repairs Tools.—ANIMO ET FIDE:—"As a practical repairer of cycles, my experience is that there is almost no end to the tools that may be bought for this work, as a great many are to be had that are more ornamental than useful. As to the tools that seem to me absolutely indispensable for cycle repairing as a pursuit, I will mention them as shortly as possible. The lathe and slide rest are all right to begin with, if the heads are not less than 4 in. About the best chuck is a Cushman two-jaw, fitted to the lathe mandrel. This chuck will take in objects from about 2 in. down to ¼ in., and is splendid for holding the larger-sized drills. N.B.—I never use any other than twist drills, except for boring out spoke stumps; for drills under ¼ in. shank down to No. 14 B.W.G. (Birmingham wire gauge) the 'Essex' drill chuck, price 10s. (Britannia Co.), is A 1. It is held by the 'Cushman' in the lathe, and with these you can drill almost anything. A leg vice of, say, 4½ in. jaws, fixed to a firmly fitted-up vice board, you must have, also a good hand vice of, say, 1½ in. jaws, to hold small articles for filing, etc. A strong pair of cutting pliers; an assortment of files; a taper reamer of square section. A ratchet drill stock is indispensable to drill out old spoke stumps. Then as to screwing tackle. A die stock and set of taps, say, from ⅝ in. down to ¼ in., and a screw plate with taps from ¼ in. down to, say, 18 B.W.G., are necessary. The spoke grip is about the first tool taken in hand, and the last to finish the repair of a wheel with. It costs from 1s. 6d. to 2s. When you get a wheel to repair with butted spokes, a difficulty comes in that does not exist with the direct spoke. A head has got to be worked on the spoke after it has been passed through the rim of the wheel. To head the spoke in these circumstances, a somewhat ponderous spoke-heading machine is used. I make use of a simple substitute which does the work very well. It is shown in the annexed cut (Fig. 1). A A are two plates of steel 4 in. by 2 in. by

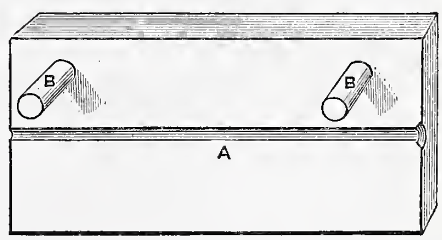


Fig. 2.

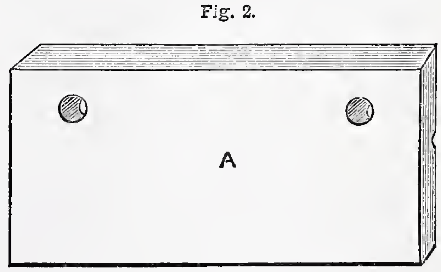

Fig. 1.

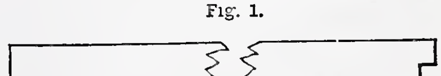


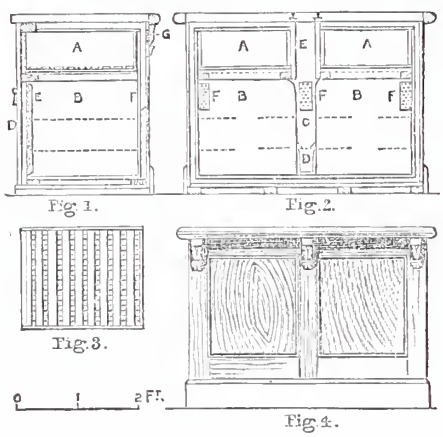
Bicycle Repairs Tools.

½ in. on the upper edges, and $\frac{1}{16}$ in. less on the under edges; in one of the plates are firmly fixed two steel pins, B B, ⅜ in. thick; they fit to slide into two holes in the other plate. Along the centre of both plates is cut a groove, either circular or V-shaped, and somewhat less than the half-section of the spoke. The two plates being placed together, the right-hand end is countersunk to the size of a spoke head. To use this tool the spoke is placed in the groove with the end protruding about $\frac{1}{16}$ in., and the plates fixed firmly in the vice. The head is now staved up cold with a hammer. In the case of butted spokes the wheel is placed in front of bench board, with the rim near the vice, and the spoke having been previously screwed home in the hub and cut to length at the rim, allowing $\frac{1}{16}$ in. to make the head, it is screwed from the hub, pulled through the rim to the vice, when the 'heading block,' just described, being put in vice with the spike, as mentioned, in it, the head is made with ease. The spoke is again screwed into the hub with the grip before mentioned. This heading block I made from two pieces of a heavy file softened to bore in the fire. If your correspondent means to go the length of brazing, he will require a forge with a fan blower or blowpipe. I use a fan blower fitted to a small forge, and it does very well for brazing, the forge being necessary for all kinds of light forgings, tempering drills, heating tyres, cementing rubbers, etc. In fact, it cannot be done without. A grindstone is another necessity. A small one to run in the lathe might serve all purposes, grinding drills and slide rut tools, etc. Now, as to a buckled wheel. If the wheel is badly buckled, the chances are that the rim is cracked at the edges, in which case it had better be put aside altogether, and a new one put on. If the rim is whole, but very much twisted, the best way is to loosen all the spokes with the grip, then see how far the rim has come back to its proper position. If there are still any sharp side bends, place the rim on a block of wood, and hammer the bends straight with a wooden mallet; then proceed to screw up the spokes: some of them may be overhauled—*i.e.*, pulled out of the hub by accident, and the thread spoiled. Where this is the case the hub should be rescrewed with a tap a size larger, in order to work a fresh screw, and a new spoke, a size thicker, screwed to fit. The wheel is now adjusted by screwing in the spokes all round to the depth they were at first. The rubber being removed from the rim, a lath of wood may be used. This lath is as long as to reach from the hub over the rim. A notch is cut on one end of the lath (see Fig. 2); this notch is placed against the hub between the spokes, and a mark is made on the lath at the outer edge of the rim. A truly trained wheel has the outer edge of the rim equidistant from the hub all round, and that on both sides. The lath will at once show which spokes to screw up and which to bring back in order to achieve this result. I have frequently made wheels to run true by simply countersinking the rim every hole the same depth, cutting all the spokes exactly the same length, and screwing them all exactly the same number of threads, and, on putting up the wheel, screwing every spoke exactly the same depth into the hub. Such a wheel will as likely as not run dead true at once, without further adjustment. A buckled wheel is more difficult to put right than building a new one. Sometimes the spokes will not stand the strain necessary to pull the bends out of the rim; hence the necessity of hammering as before mentioned. When your wheel coincides with a mark on the lath at the rim all round, and when applied on both sides, then the hub will be found to project equally from the centre plane of the wheel. Now place the wheel on the axle, and allow it to revolve freely; then holding a piece of chalk steadily, let the parts that may be out of truth touch the chalk for two or three revolutions: do this on both sides. Then at the chalk marks, if the spokes feel tight, loosen them a little, or if the spokes on the opposite side of the chalk feel loose, tighten them up; clean off the chalk, turn the wheel again, and rechalk, repeating the adjustment of the spokes as before; continue this until the last vestige of wobble disappears. The spokes should all now give forth the same sound when twanged like the strings of a harp. There are several firms that send out materials in small parcels: Lloyd & Co., Warman Street, Birmingham; H. Matthews, Snow Hill, Birmingham; Wm. Bown, about the best place to get good things in bearings, etc., 308, Sumner Lane, Birmingham; Thos. Smith & Son, Saltley, Birmingham; Brown Bros., 7, Great Eastern Street, London, E.C. There are several others, but your correspondent would get well served with any of the above, and all of them send out price lists. I shall be happy to give any further information I can on the above subject to ANIMO ET FIDE, or others, by favour of our Editor."—A. S. P.

Broom and Brush Making.—ELECTRICITY (*Camberwell*) writes in reply to T. M. (*Rochdale*) (see page 253):—"I notice the above-named correspondent has a desire to make brushes for his own use. That being the case, I will volunteer (with your kind permission) to add further to the explanation already given respecting this particular handicraft. T. M. must bear in mind that if large quantities of brushes were wanted it would almost be compulsory to have a lathe and brushmaker's bits to bore the holes in the stock (or wooden part of the brush). But for a very limited quantity for household use, and without going to the expense of fitting up a brushmaker's shop, I should say the holes might be made by means of the brace and bit. The holes must be made very clear and placed at a regular distance from each other, but not too wide apart. When advanced so far T. M. must have prepared a hot pan of pitch (but not boiling), which can be kept in a liquid state by means of oil lamp or burning charcoal; then proceed with the stuff (already cut up to a certain length), and knock one end up level in the left hand, and with the right hand pinch off just enough stuff to exactly fill the hole in the stock. Have previously prepared a quantity of hemp (shoemaker's hemp), cut into lengths of about 5 or 6 inches. So when the bunch (or knot) of fibre is dipped into the pitch it must be tied round quickly and tightly with the hemp close to the level end of the stuff, say, within $\frac{1}{2}$ in. When that is so far prepared it must be dipped a second time into the pitch, then into the hole firmly to the bottom, each one in succession, until the broom is completed; trim off the uneven stuff with a pair of shears, then the broom will be finished. Having said so much, it must be understood that the theory of brush making, like everything else, requires practice before any good results can be shown. But still, nothing attempted, nothing done."

Drilling Square Holes.—A. C. O. (*London, E.C.*) writes in reply to A READER (see page 270):—"I notice in No. 17 of WORK, in your questions submitted to correspondents, is the following. A reader states that he noticed in a paper that the scientific method of drilling square holes has been found out and patented in Austro-Hungary. I beg to inform him this method has been discovered in England by Mr. Ainley, and patented (No. 8,688) some months since, in the names of Ainley & Oakes. This machine will shortly be offered to the public."

Refrigerator.—C. F. W. (*Hampstead*) writes in reply to URGENT (see page 174):—"I herewith enclose rough plans of refrigerator counter. I think it possesses one feature not met with in any other—viz., the ice drawers. My former communication gives details of manufacture. Description of plans: Fig. 1, cross section—A, ice drawer; B, cupboard; E, inside door, zinc lined; D, outer door that



Refrigerator.
