Registered as a Newspaper at the General Post Office.]

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

SOUTH KENSINGTON, LONDON, S.W.

VISITOR—H.M. The KING.

ROYAL COLLEGE OF SCIENCE.

The Royal College of Science forms an integral part of the Imperial College and provides the highest specialised instruction in Science and Technology for Day Students. The courses are designed (*a*) as a preparation for positions of importance in the industrial world either as Chemists, Physicists, Economic Botanists, Entomologists, Zoologists, Geologists or Experts and Scientific Investigators generally; and (*b*) to meet the needs of those already following a professional career but who desire to take up more advanced training and research in Science or Technology, especially in relation to the particular industry or industries concerned.

The departments are as follows:

BIOLOGY

GENERAL BOTANY	Prof. FARMER, F.R.S.
Plant Physiology and Pathology ...	Prof. BLACKMAN, F.R.S.
The Technology of Woods and Fibres	Prof. GROOM.
GENERAL ZOOLOGY	Prof. MACBRIDE, F.R.S.
Entomology	Prof. MAXWELL LEFROY.
CHEMISTRY	Prof. H. BRERETON BAKER, F.R.S.
CHEMICAL TECHNOLOGY (Fuel and Refractory Materials)	Prof. BONE, F.R.S. Associate Prof. Dr. M. G. CHRISTIE.
GEOLOGY (including the Technology of Oil)	Prof. WATTS, F.R.S.
MATHEMATICS & MECHANICS	Prof. FORSYTH, F.R.S.
PHYSICS	Prof. CALLENDAR, F.R.S. Prof. the Hon. R. J. STRUTT, F.R.S.

On satisfactorily completing courses of study extending over two, three or four years the Governing Body awards (*a*) The Diploma of the Imperial College (D.I.C.); and (*b*) The Associateship of the Royal College of Science (A.R.C.S.).

For further information the Prospectus of the College should be consulted, which may be obtained on application to the SECRETARY, Imperial College, South Kensington, S.W.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

SOUTH KENSINGTON, LONDON, S.W.

AERONAUTICS SCHOLARSHIPS.

The Governors are prepared to AWARD TWO RESEARCH SCHOLARSHIPS to advanced students desirous of undertaking research work in scientific problems connected with Aeronautics. The Scholarships will consist of exemption from fees, together with a maintenance allowance at rates fixed with regard to the circumstances of the case. In suitable cases provision will be made for part of the work to be undertaken at the National Physical Laboratory, Teddington.

Full particulars may be had on application to the SECRETARY.

SESSION OPENS 29th SEPTEMBER, 1913.

EAST LONDON COLLEGE

(UNIVERSITY OF LONDON).

FACULTIES OF ARTS, SCIENCE, AND ENGINEERING.

FEES: TEN GUINEAS PER ANNUM.
NO ENTRY FEE AND NO REGISTRATION CHARGES.

Special fees and facilities for Post Graduate and Research Students in all Faculties.

M.A. CLASSES FOR MATHEMATICS.

Calendar, with lists of Graduates, University and College Scholarships, Academic and other distinctions, post free on application to the Registrar, or the Principal,

J. L. S. HATTON, M.A.

Telephone No.: East 3384.

UNIVERSITY OF LONDON, UNIVERSITY COLLEGE.

(University Centre for Medical Sciences.)

Provost ... T. GREGORY FOSTER, Ph.D.

FACULTY OF MEDICAL SCIENCES.

The SESSION 1913–14 begins on TUESDAY, SEPTEMBER 30, 1913.

Chemistry	J. NORMAN COLLIE, LL.D., Ph.D., F.R.S. F. G. DONNAN, M.A., Ph.D., F.R.S. R. H. PLIMMER, D.Sc. W. B. TUCK, D.Sc. PAUL HAAS, Ph.D.
Physics	F. T. TROUTON, M.A., Sc.D., F.R.S.
Botany	F. W. OLIVER, M.A., D.Sc., F.R.S.
Zoology and Biology ...	J. P. HILL, D.Sc., F.R.S.
Anatomy	G. D. THANE, LL.D., Sc.D., F.R.C.S. (Dean).
Physiology	E. H. STARLING, M.D., B.S., Sc.D., F.R.C.P., F.R.S. W. M. BAYLISS, M.A., D.Sc., F.R.S.
Pharmacology	A. R. CUSHNY, M.A., M.D., LL.D., F.R.S. (Vice-Dean).
Hygiene	H. R. KENWOOD, M.B., D.P.H., F.C.S., F.R.S.E.
Pathological Chemistry ...	VAUGHAN HARLEY, M.D., M.R.C.P.

Courses of instruction are arranged for the First Medical and the Second Medical Examination of the University, as well as for the corresponding Examinations of the Examining Board of the Royal Colleges of Physicians and Surgeons and other Licensing Bodies.

Post-graduate and Research Work is provided for in all Departments.

Fees: For the First Medical Course, 26 guineas, and for the Second Medical Course, 58 guineas, both including subscription to the Union Society, which entitles to the use of the Gymnasium and of the Athletic Ground.

University College Hall, Ealing (Warden: Walter W. Seton, M.A.), provides residence for Students.

For Prospectus and other information apply to the undersigned.

WALTER W. SETON, M.A., Secretary.

University College, London
(Gower Street).

THE SIR JOHN CASS TECHNICAL INSTITUTE,

JEWRY STREET, ALDGATE, E.C.

Principal—CHARLES A. KEANE, D.Sc., Ph.D., F.I.C.

EVENING CLASSES in CHEMISTRY, PHYSICS, and MATHEMATICS designed to meet the requirements of those engaged in CHEMICAL and ELECTRICAL INDUSTRIES and in trades associated therewith.

Also preparation for the **B.Sc., Examination of London University** and for **Honours B.Sc., in Physics.**

Chemistry	CHARLES A. KEANE, D.Sc., Ph.D., F.I.C. H. BURROWS, A.R.C.S., Ph.D., F.I.C. G. F. MORRELL, B.Sc., Ph.D.
Physics	R. S. WILLOWS, M.A., D.Sc. F. J. HARLOW, A.R.C.S, B.Sc. S. E. HILL, B.Sc.
Mathematics	E. C. SNOW, M.A., D.Sc.

Every facility for **Advanced Practical Work** and **Research** in well-equipped Laboratories both in the afternoon and evening.

NEW SESSION BEGINS MONDAY, SEPTEMBER 22.

For details of the Courses apply at the Office of the Institute, or by letter to the Principal.

CITY OF LONDON COLLEGE.

ACTING IN CONJUNCTION WITH THE LONDON CHAMBER OF COMMERCE.

WHITE ST., and ROPEMAKER ST., MOORFIELDS, E.C.

(Near Moorgate and Liverpool Street Stations).

PRINCIPAL: SIDNEY HUMPHRIES, B.A., LL.B. (Cantab.)

Michaelmas Term begins Monday, September 29th.

EVENING CLASSES in SCIENCE. Well-equipped **LABORATORIES** for Practical Work in **CHEMISTRY, BOTANY, GEOLOGY.**

Special Courses for Pharmaceutical and other examinations. Classes are also held in all Commercial Subjects, in Languages, and Literature. Art Studio. All Classes are open to both sexes.

DAY SCHOOL OF COMMERCE. Preparation for a COMMERCIAL or BUSINESS career.

Prospectuses, and all other information, gratis on application.

DAVID SAVAGE, *Secretary.*

For other Official Advertisements, see pages iii, iv, *and* v.

THURSDAY, SEPTEMBER 4, 1913.

NOTES ON THE ABORIGINES OF SOUTH AMERICA.

Aborigines of South America. By the late Colonel G. E. Church. Edited by an Old Friend, Clements R. Markham, K.C.B. Pp. xix + 314. (London: Chapman & Hall, Ltd., 1912.) Price 10*s.* 6*d.* net.

THE author of this posthumous work was a descendant of the earliest New England colonists. Born in 1835, he became a surveying engineer, and his first introduction to South America was of a kind sufficient to shape his whole career. As a member of an expedition sent out by the Government of Buenos Aires in 1859 to explore the south-western frontiers, he partook of severe fighting with the then still unsubdued Araucanians and Patagones. Then he served through the whole of the Civil War in the United States, and next he joined the General Staff of Juarez against Maximilian. After that episode we find him in Bolivia, which he reached once by Buenos Aires, another time by Peru, busy with concessions of the navigation of Bolivian and Brazilian rivers. A political mission to Ecuador, the building of an Argentine railway, business in Panama, Costa Rica, and elsewhere afforded him well-nigh unrivalled opportunities of studying land and peoples of South America before he settled down in London, where he devoted much time to his favourite geographical and ethnological studies.

The author's intention to write a comprehensive work on the aborigines of South America was frustrated by his death in 1910, and only the less incomplete chapters have been edited by his friend, Sir C. R. Markham, himself a traveller in those parts of the world. They are apparently not so much notes by the experienced, observant traveller as critical, carefully sifted extracts from the numerous accounts of previous explorers, whose accounts alone can bear upon the "history" of these wild, roaming, barbaric tribes. In many cases the bewildering number of names, mostly nicknames bestowed upon each other by the various clans and muddled by the Europeans, have been reduced to synonymic order. Presumably all the aborigines of the whole continent are of one stock, but time and separation and environment have diversified them. One of the most vigorous were the Caraios, Caraibes, Guaranis, or Tupis, with their origin in Paraguay, whence this dominant race made its influence felt from La Plata to Orinoco and spread even to the Antilles. Several chapters are devoted to the unravelling of the resulting dislodgment of the coast-tribes of Brazil and those of Amazonia, and to the troubles brought upon them by the Portuguese and Spaniards. The scanty notes made by the white man, not always well educated, be he soldier, trader, or missionary, about customs, arms, and ornaments, are often the only facts known about many a so-called tribe.

Within late Tertiary periods the whole continent seems to have been divided into an eastern and a western half, from Uruguay to the Orinoco, by a system of enormous lakes. Our author evidently believed that such a division still existed when man already inhabited South America, before the Pampean and Amazonian inland seas and other lakes, of which Titicaca is a remnant, had yet been drained by the present great river systems. This somewhat rash idea is on a par with the suggestion that South America may have been connected with Africa or Australia via Antarctica at a period when climatic conditions made these dreamlands a pleasant abode for man and thus account for the puzzling origin of the Patagonians.

HYDRAULIC MACHINERY.

Modern Pumping and Hydraulic Machinery: Being a Practical Handbook for Engineers, Designers, and Others. By E. Butler, Pp. xvi + 473. (London: C. Griffin and Co., Ltd., 1913.) Price 18*s.* net.

AN examination of this important work brings home to the reader some idea of the enormous extent and ever-increasing variety of machinery that is used in connection with hydraulics; for, although this treatise is devoted to the consideration of the wide range of machinery and appliances connected with almost every known type used in pumping operations, the amount of other classes of hydraulic machinery which the exigencies of space excluded would well fill the pages of another volume. For this reason the subtitle is too comprehensive and rather misleading, as the book does not deal with hydraulic machinery "as applied to all purposes"; but, it is fair to say, the author has wisely restricted its scope to enable him to deal comprehensively with the sections selected, and in a broad way included in the title "pumping machinery." The ground chosen has been covered in an exhaustive and systematic way, and a glance at the contents shows how varied is the machinery dealt with, for it embraces machinery used for water-supply, wells, mines, drainage, irrigation, dredging, reclamation work, and for raising petroleum from deep wells, and a chapter is devoted to hydraulic power wheels and turbines.

There is no lack of admirable books on the theory of hydraulics and of hydraulic machines, but the many important developments and improvements made in hydraulic machinery in recent years have doubtless created a demand for just such a book as Mr. Butler has so ably produced, and the information it contains cannot fail to be of use to the practical engineer and others engaged either in the construction or application of hydraulic machinery, to say nothing of its educational value to the engineering student. The designer will also appreciate the book, as it contains a wealth of detail and descriptive matter, but his requirements as to the proportioning of parts have not received the attention they might with advantage have had given to them here and there in a treatise of this type. No better work than Seaton's "Marine Engineering" can be cited as an example of what can be done in this direction to help the designer. The Humphrey gas-displacement pump, the most important invention in pumping machinery made in recent years, is fully described, and the author gives some particulars of previous inventions of this type, but omits to mention that the first-known internal combustion pump was Tatham's, patented about 1894, and referred to in the discussion on the Humphrey pump at the Institution of Mechanical Engineers.

The illustrations are extremely well reproduced, with few exceptions; for instance, the longitudinal sections on p. 387 look rather too confusing to be easily read, owing to their coarse section lining. On the other hand, the diagram on p. 377, showing development of vane curvature in an impeller wheel, is admirable.

The book is a notable addition to the literature of the subject, and should be well received.

H. J. S.

MIND, HEALTH AND PURPOSE.

(1) *The Game of Mind: A Study in Psychological Disillusionment.* By Percy M. Campbell. Pp. iii + 80. (New York: Baker and Taylor Co., 1913.) Price 75 cents net.

(2) *Mind and Health. With an Examination of some Systems of Divine Healing.* By Dr. E. E. Weaver. With an Introduction by Dr. G. Stanley Hall. Pp. xv + 500. (New York: The Macmillan Company; London: Macmillan & Co., Ltd., 1913.) Price 8*s.* 6*d.* net.

(3) *Development and Purpose: An Essay towards a Philosophy of Evolution.* By Prof. L. T. Hobhouse. Pp. xxix + 383. (London: Macmillan & Co., Ltd., 1913.) Price 10*s.* net.

(1) IN "The Game of Mind" Mr. Campbell puts the question: "To what extent does the mere reiteration, by the possessor of a toothache, of the complaint that he is indeed feeling pain, influence or *constitute* that pain? In other words, If the victim were so organised that he need not perforce tell himself each instant that he is being hurt, would the hurt exist as such at all?" And Mr. Campbell replies: "We are convinced that it would not." Mr. Campbell, of course, discusses many other questions; but his method of argument displays the same degree of cogency throughout.

(2) In "Mind and Health" Mr. Weaver discusses "some of the distinctive religious and philosophical systems of healing," and lays down "the plan of a valid system of healing on religious ground." The first element of "a valid religious psychotherapy" he declares to be that "sickness comes from want of goodness." "Goodness" is, of course, an ambiguous term; and Mr. Weaver very properly describes the sense in which he uses it: "A goodness that starts in the spiritual and will be allowed to work unfettered and unhindered in the intellectual, emotional, and physical life will not be sick. It knows no sickness." If goodness of this kind—a goodness which knows no sickness—is to be pro-

duced in the patient, then it must first be possessed by the practitioner: "The power of healing released through a religious psychotherapy should be mediated by the minister of religion." If so, then, Mr. Weaver argues, the Christian Church must carry on the ministry of religious psychotherapy. Mr. Weaver's fundamental assumption, then, is: Be good (or get someone to make you good) and you won't be ill. It is a defect of his book, however, that he does not convince the reader of the truth of the assumption.

(3) Mr. Hobhouse's "Development and Purpose" is a contribution to philosophy, serious, solid, and certainly heavy. "The book completes a scheme which has occupied the writer for twenty-six years, and has been carried through successive stages in three previous works." But the scheme has come to be completed in a way which a quarter of a century ago Mr. Hobhouse did not foresee or intend. He has come to hold that in the process of evolution both mechanical causation and teleological causation are at work; and, what is more, that mechanical causation involves teleological causation—hence, according to Mr. Hobhouse, the "organic harmony" of the world process.

Intelligent action is truly purposive, that is to say it is teleological causation and is not resolvable into mechanical laws. The actual order of reality, he tells us, is determined by the impulse to realise the future: what we do now is determined by what we want to be or do in the future. But, if that is so, it seems to the reader as though no place were left for mechanical causation, no need for causes prior in time to their effects. Mr. Hobhouse, however, holds that mechanical causation involves teleological causation, *i.e.* apparently that there could be no cause prior in time to the effects unless there were causes which, being teleological, are not prior in time to their effects. From this it would seem that the source of the trouble lies in the assumption that causes must be in time; on that assumption causes must both be and not be prior in time to their effects.

Mr. Hobhouse, though he sees and says that in the more ultimate sense Reality is not in time, but time is in Reality, does not devote more than this single sentence to the way in which, as it seems to us, the notion of time refracts causation into mechanical and teleological causes. However, Mr. Hobhouse's services to the cause of philosophy are recognised by all interested in philosophy; and all will be glad that the University of Durham has, in recognition of those services, conferred upon him the honorary degree of D.Litt.

IRON AND STEEL METALLURGY.

(1) *Iron Making in Alabama.* Third Edition. By W. B. Phillips. Pp. 254+xxxi plates. (Alabama: The University, 1912.)

(2) *Iron and Steel: An Introductory Text-book for Engineers and Metallurgists.* By O. F. Hudson and Dr. G. D. Bengough. Pp. x+173. (London: Constable and Co., Ltd. 1913.) Price 6*s.* net.

IT would be difficult to find a better illustration of the wide range of subjects involved in the study of iron and steel than these two books. Whereas one deals mainly with the extraction of iron from its ores, the other is largely concerned with the properties of the recovered metal, and the subjects range from the mining of the ore and the washing of coal on the one hand, to the constitution of steel and the electrolytic theory of corrosion on the other.

(1) The book by Mr. Phillips is published by the Geological Survey of Alabama, and is of necessity somewhat statistical. It is seldom, however, that one finds statistics dealt with in such an interesting manner. The title of the book might more accurately and with advantage be described as "Iron and Steel Making in Alabama," for it includes an excellent account of the steel-works of the State, which are responsible for an annual output of nearly half a million tons of steel in all sections, from rails to wire.

The first part of the book deals exhaustively with the iron ores of Alabama, and a chapter is devoted to experimental work on concentration. Fluxes and fuels are then considered, and much useful information is given on coking practice and the employment of by-product coke ovens. Blast-furnace practice, as regards both coke and charcoal furnaces, is considered in detail, and the growth and development of the modern blast-furnace is traced from the year 1894 to 1910. This is followed by an excellent account of the steel-works and rolling-mills of the State, and finally there is a chapter on coal-washing. Not the least useful feature of the book is the large number of tables of statistics, and some reference must be made to the excellent series of illustrations, thirty in number, which are reproduced from photographs.

The extent of the iron and steel industry in Alabama may be gauged from the fact that in the year 1910 nearly five million tons of ore were mined and sixteen million tons of coal, of which five million tons were converted into coke. The production of pig-iron amounted to two million tons, and of steel half a million tons. Such an industry is of more than local importance, and

Mr. Phillips's volume will be greatly appreciated not only by those who are connected with Alabama, but by all who are interested in the manufacture of iron and steel wherever it may be carried on.

(2) Mr. Hudson's book is one of a series of text-books which are described as "introductory to the chemistry of the national industries." It is written in a clear and concise manner, and deals very ably with recent scientific investigations and theories regarding the constitution of iron and steel. The principles underlying the smelting of iron, the manufacture of wrought iron and steel, foundry practice, and such processes as case-hardening, welding, &c., are reviewed very briefly, but no attempt is made to treat these subjects from the manufacturing point of view, and this part of the book can scarcely be regarded as an introduction to the metallurgy of iron and steel, except for very elementary students. The book is intended primarily for those interested in the physico-chemical rather than the practical aspects of the subject, and this is clearly the intention of the author, who states in his preface that "practical details of the methods of production have been avoided almost entirely, in order that more attention may be devoted to such matters as an explanation of the constitution of steel and cast-iron, and the effects of mechanical and heat treatment on the properties of these alloys." In the later chapters these subjects have been very completely dealt with, and, together with the chapter on corrosion by Dr. Bengough, will be welcomed by many students of metallurgy.

OUR BOOKSHELF.

Ueber kausale und konditionale Weltanschauung und deren Stellung zur Entwicklungsmechanik. By Wilhelm Roux. Pp. 66. (Leipzig: W. Engelmann, 1913.) Price 1.50 marks.

PROF. ROUX makes game of Prof. Verworn's recent essay on the causal and the conditional outlook on the world, which was, we think, reviewed some months ago in NATURE. What is true in Verworn's essay is not new, and what is new is not true. The causal outlook, which has been in vogue "from the Stone age down to Verworn," is not to be superseded by a crude "conditionism." What is sound in Verworn's emphasis that the scientific task is to inquire into all the antecedent conditions is recognised by all investigators. The change proposed is verbal, for as soon as a process is set a-going, its conditions become active factors or causes. The complete conditions *are* the complete causes. Verworn lays great stress on what he calls the "effective equivalence" of the conditions of any process or result, but Roux cannot accept the phrase. Equally necessary the factors are, but certainly not equivalent.

In the study of development the *specifitas potentiae* of each of the various factors is well known. In vital processes the internal and the external conditions cannot be spoken of as equivalent, as Verworn proposes. The constitution of an ovum includes factors which determine a certain, within limits, typical result; the external conditions of oxygen, warmth, moisture, and so on, activate and sustain the development. Thus Roux distinguishes between "determining" and "realising" factors, and says that it is nonsense to speak of their "equivalence."

From time to time in his brilliant series of studies in "developmental mechanics" Roux has given a causal analysis of the known factors involved, distinguishing, for instance, between internal and external, determining and realising, necessary and "not necessary" factors; and he is entirely opposed to the false simplicity which Verworn's "conditionism" would suggest. There has been hard hitting on both sides, but perhaps it is instructive to remember that Verworn's life has been largely spent in the study of metabolism, and Roux's in the study of development—which is for him an "autophænesis," "a becoming-visible of manifoldness by the proper activity of the germ." J. A. T.

Brazil in 1912. By J. C. Oakenfull. Pp. viii + 498. (London: Robert Atkinson, Ltd., 1913.) Price 5*s*.

THIS is the fourth annual edition of an excellent handbook on Brazil. As usual, it is well and profusely illustrated, the large map of the country and the coloured frontispiece showing the precious stones of Brazil being especially good. The book deals in an interesting manner with the history and geography of Brazil; but the chapters on the anthropology and ethnography, the geology and palæontology, the mineralogy, and the agriculture of Brazil will appeal more directly to scientific readers.

The book is intended for free distribution, but duplicate and trade copies can be obtained at the price stated.

Teachers of geography will find it an interesting and valuable work of reference in the school library.

The Theory and Design of Structures. A Textbook for the Use of Students, Draughtsmen, and Engineers engaged in Constructional Work. By E. S. Andrews. Third edition. Pp. xii + 618. (London: Chapman and Hall, Ltd., 1913.) Price 9s. net.

THE first edition of this book was reviewed at some length in the issue of NATURE for March 18, 1909 (vol. lxxx., p. 64). The additions made to the present edition are incorporated in an appendix of some twenty-seven pages, and these include a note on Dr. Stanton's experiments on wind pressure. The notation in the chapter on reinforced concrete has been made to agree with that proposed by the Concrete Institute, and numerous exercises have been added to the volume.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Spectra of Helium and Hydrogen.

THE spectra of helium and hydrogen have acquired considerable importance in view of the recent experimental researches of Prof. Fowler and the theoretical investigations of Dr. Bohr. Before the appearance of Fowler's investigation the only hydrogen series known terrestrially were the diffuse series, consisting of the Hα, Hβ, &c., lines, and the infra-red series predicted by Ritz, two members of which (18751·3 and 12817·6) were observed by Paschen. However, by passing a strong condensed discharge through mixtures of helium and hydrogen, Fowler was able to photograph four members of the principal series, the strongest line of which is at 4686.

It should be noted that the 4686 line appeared on the photograph of the spectrum of a helium tube, which had been taken at the Solar Physics Observatory at South Kensington several years ago. Sir Norman Lockyer and Baxandall in their paper pointed out that the terrestrial line was very probably identical in origin with the chromospheric line of nearly the same wave-length photographed during the eclipse of January, 1898. They also noticed that the 4685·90 chromospheric line is of the same nature as the helium eclipse lines, being long and sharply defined. They concluded that the line is probably due to a gas, which is associated in some way with helium. The 4686 line has also been observed in the spectra of stars of the fifth type, and in the spectra of certain nebulæ, and had been attributed to hydrogen in accordance with Rydberg's calculations, which depend on the numerical relations existing between the different series.

In addition to the series having the 4686 line as first member, Fowler was able to photograph three members of the sharp series, which are found in the spectrum of ξ Puppis, and three members of a new ultra-violet series, which he calls the second principal series of hydrogen. According to the theory put forward by Dr. Bohr, the two principal series and the sharp series are given by helium. Also it should be possible to obtain the diffuse series from helium containing no hydrogen when the sharp series appears.

For some time I have been investigating the origin of the 4686 line, and the experiments already carried out support Bohr's theory. The chief difficulty consisted in driving out hydrogen from the poles of the helium spectrum tube, but this was accomplished so far as spectroscopic evidence goes. No hydrogen could be detected in the bulbs and capillary when heavy discharges from a coil capable of giving a 20-in. spark were passed through the tube. The 4686 line was strong in the capillary and fairly strong in the bulbs. The pressure of helium employed in these experiments varied from about 0·25 mm. to 1 mm. The capillary, in addition to the helium spectrum and the 4686 line, showed impurity lines due to oxygen.

Photographs I. and II. show the spectra obtained when a strong condensed discharge is passed through helium at pressures of 1 mm. and 0·3 mm. respectively. In the first photograph the 4686 line is of nearly the same intensity as the 4713 helium line, and the two are scarcely separated in the reproduction. The low-pressure photograph (Fig. 2) shows the 4686 line much stronger than the 4713 line. In both cases the hydrogen lines at 6563 and 4861 are not seen. The 4686 line could not be obtained from an ordinary hydrogen tube, nor from a neon tube containing a small amount of hydrogen as impurity. A tube containing a mixture of hydrogen and purified argon was also prepared, but the line was not visible when heavy condensed discharges were passed through the mixture.

Coloured Organisms on Sea-Sand.

A VARIED and interesting field of investigation awaits the microscopist who will make a detailed examination of the minute fauna and flora of apparently barren sands on the seashore. To-day, on landing at the island of Oronsay at low tide, the otherwise pure white sand was seen to be coloured pink in one area, for an extent of several yards, green a little further up the beach, and golden-brown in small patches here and there. On examining samples with the microscope the brown colour was found to be due to living diatoms (*not* dinoflagellates in this case), naviculoid forms like Caloneis; the pink is formed of amorphous masses of fine granules in a jelly loosely adhering to the sand-grains, and may perhaps prove to be bacteria in a zoogloea state, while the green is caused by patches of a very simple alga (? a Coccophycid) made up of groups of rounded green cells in a single layer on the sand-grains. I have kept samples of all the organisms and will submit them to a botanist for more precise identification. No Amphidinium patches were present so far as I could see. The variety of organisms present in the one little bay, the extraordinary abundance in each patch, and the brightness of the colour produced on the white sand were very striking, and seemed worthy of note.

The colour was not in any of these cases due to the sand-grains themselves, which are mostly clear quartz with, as usual, a few black specks and some white shell fragments. Nor was there apparently any fresh-water on the beach, and certainly not any sewage or other source of impurity. It is a lonely, sandy bay, inhabited only by sea-birds and seals, and the nearest house is on the opposite side of the island at least four miles away by the coast. The sea-water seemed very clear, of salinity 26·5, and the sandy bottom could be seen from the yacht anchored in five fathoms.

Diatom patches are no doubt abundant in many places; probably the simple green alga encrusting the sand-grains is known to botanists, and I have certainly seen the pink organism elsewhere. Probably other coloured patches due to micro-organisms are present on many beaches. It would be interesting to have them more thoroughly investigated—biochemically, if possible—by someone living on the spot, and able to study their changes day by day.

S.Y. *Runa*, Sound of Islay, August 27.

Physiological Factors of Consciousness.

MR. ABDUL MAJID (NATURE, August 28) asks: "What is the true explanation of the fact that stimuli sufficiently strong to arouse vivid sensations in a subject while he is wide awake apparently fail to arouse any sensations at all in a state of unconsciousness?" But is there any evidence that stimuli do not arouse identical sensations in the waking and the sleeping states? As a medical man, I am frequently "rung up." As far as I am able to judge, I am invariably awakened out of a dream. I am never dreamless. My consciousness never sleeps.

But, in proportion to the depth of slumber, memory appears to be abolished. Memory is ample in proportion as it is clear and coherent—in proportion as it links the present with the past and so fulfils its function of affording a guide for the future. In dreams, since it is so much in abeyance, we live almost wholly in the "immediate present," taking little thought of the past or the future. Absurd or improbable happenings do not then surprise us; for these do not then contradict stored experience. On that account, also, we seldom remember our dreams unless they occur in light slumber (half-wakefulness), or unless our attention is called to them immediately on waking while our minds are still tingling with them. I am sure, if anyone tries the experiment of having himself awakened for a few occasions by the insistent question, "What are you dreaming about?"—if his attention is immediately fixed on his dream—he will soon be convinced that there is no such thing as dreamless sleep.

By way of illustration; I remember a terrible dream. An enemy had his hand on my mouth and was suffocating me. I awoke to find the tail of my friend the cat, who had come on his morning visit, laid across my lips. The dreams of ill-health, and especially of indigestion, are usually unpleasant and sometimes fearful.

I take it, then, that sensations are the stuff that dreams are made of. They are the same sensations that we feel in our waking states, but, when woven into our dreams, they are wrongly interpreted.

G. ARCHDALL REID.

Netherby, Victoria Road, S. Southsea, August 29.

The Elephant Trench at Dewlish—Was it Dug?

THE question of the brain capacity of the Piltdown and other fossil skulls must be decided by anatomists; but a sidelight may be thrown on the subject of the intelligence of early man by a consideration of the works of which he was capable. The most indestructible of these, and consequently the most frequently referred to, are worked flints. Upon their testimony Mr. Moir, and those who agree with him, would carry man's work back to the Pliocene period of the Suffolk Crag. Mr. Moir kindly allowed me to see a few of his specimens, and I am inclined to think that some of them show artificial chipping. The deposit in which the Piltdown skull was found is said to be early Pleistocene. Have we any indication of man's work between this and the Crag period? In my opinion we have. I refer to the remarkable trench at Dewlish, Dorset,[1] which before it was excavated contained abundant remains of *Elephas meridionalis* and no other fossils, though Mr. Grist has found eoliths.[2] It is difficult to account for the formation of this peculiar trench in chalk by any natural process. Mr. Clement Reid, who spent four days to examine it, tells us that "the fissure, or rather trough, ended abruptly without any trace of a continuing joint. It was not a fault, for the lines of flint nodules corresponded on each side. [3] Mr. Reid, at the British Association at Cambridge, described the termination of the trench as "apse-like." It opened out diagonally at one end on to the steep slope of the side of a valley. It was 103 ft. long and 12 ft. deep. The width, as the photographs show, was not quite uniform, and Mr. Reid said that in the narrow place he could just get along. It is remarkable that here the walls approach from each side—a feature apparently incompatible with any natural causation. After the trench had been refilled, I met with a description and photograph of a pitfall for elephants in Africa; and that led me to believe that this trench was artificial, and dug out for the same purpose.

If this view is correct, it shows that man existed in Pliocene times, and was already a social being capable of a great undertaking, for no one individual could have effected such a work.

My hope is that this trench may be reopened for the express purpose of testing this question. It has never been bottomed except at the end where it opened on the valley. Elsewhere two or three feet remain undisturbed. If it was artificial, some indication of the tools used might possibly be found at the bottom. The expense could not be great, and my object in writing this is to endeavour to excite such interest in the subject as may perhaps lead to a proper investigation. But a competent geologist, whose verdict would carry weight, ought to undertake it.

Graveley, Huntingdon. O. FISHER.

Note on the Dicynodont Vomer.

IN 1898 I directed attention to the fact that the paired elements in the front of the palate of lizards and snakes seem in all their relations to agree with the pair of bones in Ornithorhynchus, which afterwards fuse to form the dumb-bell bone, and that they cannot be homologous with the median unpaired vomer of mammals, and must have another name, and I proposed to call them *prevomers*. While the embryological evidence seems conclusive, the palæontological testimony has not hitherto been so satisfactory as one could desire. Cynodont reptiles appear to have a single median vomer, very like that of the mammal, and one specimen of Gomphognathus shows what appear to be a pair of elements in front. Dicynodon appears to have also a single median vomer, and no paired elements. The Therocephalians, on the other hand, have a pair of large anterior elements, and apparently no median element. With the palæontological

1 See paper by the writer with two photographic views, *Quart. Journ. Geol. Soc.*, 1905.

2 Journ. Roy. Anthropological Institute, vol. xl., 1910.

3 See "Geological Survey Memoirs," 1899, p. 54.

evidence in this condition, it is not surprising that the theory, though fully accepted by a few, and hesitatingly by others, has failed so far to be generally adopted.

For the last ten or twelve years I have constantly been on the look-out for a specimen which, while possessing a large median true vomer has also a pair of large distinct paired prevomers. Mr. D. M. S. Watson believes he has discovered in the British Museum a specimen of Lycosuchus showing a median vomer between the pterygoids, and certainly a pair of large prevomers in front. Unfortunately, though the specimen is satisfactory enough for those who believe the median vomer to be quite a different element from the reptilian paired "vomers," it is not convincing enough for the doubter.

In two species of the small Upper Permian Therocephalian genus Ictidognathus, I find a peculiarly complicated but single median vomerine bone, but in a third species, closely allied, I find clear evidence that the apparently single bone is composed of the paired prevomers anchylosed. Further, the anchylosed prevomers have exactly similar relations to the palatines and pterygoids that the median bone in Dicynodon has, and at first it looked as though the theory had received a severe blow.

Fortunately a specimen of a large species of Dicynodon has just been discovered that clears up all the confusion. The median bone, which lies between the posterior pairs in Dicynodon is the anchylosed prevomers. Above it, and completely concealed by it, is a large, well-developed, typically mammalian median vomer extending from the basisphenoid behind to the premaxilla in front. Along its upper side the vomer is grooved for the large basal and ethmoidal cartilages. Posteriorly it is closely united to the basisphenoid. The bone completely confirms the view I expressed in 1898 that the mammalian vomer is the reptilian parasphenoid, and quite a different element from the prevomers.

THE TWELFTH INTERNATIONAL GEOLOGICAL CONGRESS.

The first meeting of the International Geological Congress in Canada, and the third in the western continent, held its session in Toronto from August 7 to August 14, under the presidency of Dr. F. D. Adams, of McGill University. Altogether 1152 members were enrolled, about half of whom attended the meeting; and forty-six countries were represented by their leading geologists. Probably never before had Canada entertained a gathering so distinctively international, and great interest was manifested in the work of the congress, not only in Toronto, but throughout the Dominion. The honorary president of the congress, H.R.H. the Duke of Connaught, who was unable to attend, was represented at the opening session by the Right Hon. Sir Charles Fitzpatrick, Chief Justice of the Supreme Court of Canada, and by him a warm welcome to the Dominion was extended to the visiting delegates in a graceful speech in French, the official language of the congress. Ontario was represented by the Hon. W. H. Hearst, Minister of Mines for that province, Toronto by Alderman Church, and the University of Toronto by President Falconer, to whom the congress was indebted for the use of several of the university buildings during the meetings.

The chief work delegated to the twelfth congress had been the preparation of a monograph on the coal resources of the world, to serve as a companion work to the iron resources of the world, prepared for the eleventh congress at Stockholm. The general secretary of the congress, Director Brock, of the Canadian Geological Survey, presented the monograph, and summarised its main features. It consists of three quarto volumes, accompanied by a 68-page atlas, and contains reports from sixty-four different countries. The editing has been in the hands of a committee of the Geological Survey of Canada, consisting of Messrs. McInnes, Leach, and Dowling. Mr. Brock contributes the preface, Mr. Dowling an introduction summarising the main reports, while contributions by experts from the various countries of the world form the major part of the work. The total coal resources of the world are estimated at 7,397,533 million tons, of which 4,000,000 million tons are bituminous, 3,000,000 million tons brown coal, and the remainder anthracite. As the world's production in 1910 was 1,145 million tons, the exhaustion of our coal supplies is by no means an immediate problem. Approximate reserves of some of the chief countries are as follows:—Canada, 1,234,269 million tons; United States, 3,214,174 million tons; United Kingdom, 189,535 million tons; France, 17,585 million tons; Germany, 85,551 million tons; Russia, 233,997 million tons. In Switzerland only 4500 tons of coal remain. The preparation of the monograph involved a large amount of special investigation in several of the countries from which reports were submitted; and the three volumes, with the atlas of beautifully executed maps, will serve as a fitting companion volume to the iron resources of the world.

In order to facilitate business, the congress resolved itself into three sections, which met concurrently. Over eighty papers were presented, the majority of which had direct bearing on the topics which had been suggested for the consideration of the congress. On the subject of the differentiation of rock magmas the session was interesting, rather because of the variety of hypotheses than because of any distinct contribution to views already propounded elsewhere. Daly advocated stoping and gravitational movement, Harker fractional crystallisation, Lœwinson-Lessing differentiation in liquid state, Evans immiscible liquid phases, while Bergent emphasised recurrent basic and acid succession in its bearing on the problem. Iddings and Washington pointed out from different points of view the necessity of sufficient analyses within petrographical provinces. Hobbs referred to the relationship between certain petrographical provinces and clay states, and Cross discussed Hawaiian lavas from the point of view of the Atlantic-Pacific classification. Báckström, in summing up the discussion, advocated the conservative attitude until experimental work was sufficiently advanced to justify broad conclusions.

The theme "The Influence of Depth on the

Character of Metalliferous Deposits" was of special interest to economic geologists and mining engineers. Kemp dealt generally with primary and secondary precipitation; Krusch with colloidal precipitation of primary and secondary ores; Emmons with experimental evidence bearing on the precipitation of gold, silver, and copper, and the effect of the primary ores; Fermor with the action of oxygen and carbonic acid at considerable depths; Fanning with ore occurrences in the Phillipines. In the general discussion, in which Lindgren, Winchell, Lawson, Kitson, and others took part, the question of the formation of veins consequent on mineral crystallisation, and that of secondary gold deposition from placers, were taken up.

What were perhaps the most interesting discussions to the majority of the members of the congress were those on the sedimentation and the correlation of the Precambrian. The excursions provided to the vast Precambrian areas of Canada had attracted to the congress authorities from the Precambrian fields in all other countries; and the discussions were illuminating in that they focussed the experience of work in many fields on the intricate problems presented. The succession in Finland was given by Sederholm, who also illustrated by slides some clear instances of granitisation on a regional scale. Cole explained the intrusive relationships in north-west Ireland. The difficulties encountered by Scottish geologists in correlating the Precambrian of the Highlands were explained by Horne. An outline of the Precambrian of the British Isles was given by Strahan. Holland pointed out the broad similarities between the series in India and in North America. Coleman and Collins dealt more particularly with the area east of Lake Superior. A rather keen discussion took place when the classification submitted by Lawson as based on work in the Rainy Lake area was questioned by Leith and Lane. Altogether the session was illuminative of the difficulties in the way of any attempt to correlate the Precambrian in widely separated areas.[1]

Other topics considered can only be mentioned in brief. On the physical and faunal characteristics of Palæozoic seas papers were presented by Chamberlin, Schuchert, Ulrich, Frech, and Holtedahl. To the topic of interglacial periods Lamplugh, Coleman, Upham, Alden, Tyrrell, Wolff, and Holst contributed; while at a special session on tectonics papers were given by Paulcke, Dahlblom, Mess, and Smith, McDonald, Howe and Hovey. Numerous miscellaneous papers were also submitted dealing with subjects of geological and mineralogical interest.

During the session of the congress two popular lectures were delivered, to which the Toronto public were invited. The first was by M. Emmanuel de Margerie on the geological map of the world. The lecturer gave some very practical suggestions to the committee in charge of the preparation of the map. He advocated the continental as opposed to the world map, and the discrimination by colour between marine and lacustrine sediments, and between folded and unfolded areas. The continental areas were discussed seriatim, with practical hints as to map-construction. Of more interest to the general public was a lecture by Dr. W. F. Hume on desert phenomena in Egypt. The lecture, which was illustrated by slides, presented a clear picture of the geological conditions, and in particular of the effects of sand erosion on the exposed rocks. Much could be inferred from the slides as to the actual conditions under which work is carried on in desert countries.

Notwithstanding the interest evinced in papers and discussions, the value of the twelfth congress to the visiting delegates lay mainly in the excursions which they were enabled to undertake to many points of geological and mining interest throughout the Dominion. Elaborate preparations had been made by the Geological Survey of Canada to ensure the success of this feature of the meeting, and the total length of line covered by the guide books considerably exceeded 20,000 miles. From July 13 to September 23 excursions practically without a break were arranged for —frequently three, or even more, concurrently. The maritime provinces were visited, before the session, under the guidance of Dr. G. A. Young; Sudbury, Cobalt, and Porcupine before and after the session, the excursions being led by Dr. W. G. Miller; while two transcontinental excursions, the first of more particular interest to petrologists and stratigraphers, the second to economic geologists and mining engineers, had as leaders Dr. Adams and Mr. Brock respectively. An excursion of particular interest, of which many would have gladly availed themselves had time permitted, was that to the Yukon and Alaska boundary, led by Mr. McConnell. Besides these longer excursions numerous field-trips were made, both before and during the session in Toronto. To the localities in the vicinity of Toronto Dr. Coleman and Dr. Parks acted as guides.

For the excursions a series of guide-books was prepared by the Geological Survey of Canada, which contained besides the reading matter numerous coloured maps, topographical maps, and photographs. Apart from the immediate value to the members of the congress, the guide-books represent an important contribution to Canadian geology. They summarise a large amount of investigation accessible only in the reports of the survey, and contribute as well a considerable proportion of new material. They cover the main routes of travel, and will prove valuable books of reference, not only to geologists and engineers, but also to any travellers who may be interested in the resources and rock formations of the country. The interest which the excursions had aroused in Canadian geology was shown by the eagerness with which the literature supplied by the Geological Survey and mines branches was sought after. From this point of view the con-

[1] The discussion had at least one permanent result. A resolution proposed by Dr. Sederholm was passed by the Congress to the effect that geological surveys of countries which have contiguous areas of Precambrian rocks form international committees to include representatives of the geological surveys of all the countries concerned, for the purpose of correlating the Precambrian formations in the different countries.

gress has served as an excellent distributing agency for the literature on the geology and mineral resources of the Dominion.

While the delegates were in Ottawa occasion was taken to do honour to the memory of the first director of the Geological Survey of Canada. Affixed to a block of Laurentian rock, in which formation Sir William Logan did pioneer work, a tablet has been placed in the Victoria Memorial Museum. The tablet, which was unveiled in the presence of the visiting delegates, bears the following inscription:—"William Logan, K.T., LL.D., F.R.S., 1798–1875, the Father of Canadian Geology, Founder and First Director Geological Survey of Canada, 1842–1869. Erected by the International Geological Congress (Canada), 1913." Two of the Canadian universities took advantage of the opportunity afforded them to honour some of the visiting members of the congress. On August 1, McGill University conferred the degree of LL.D. on J. F. Kemp, U.S.A.; H. Bäckström, Sweden; A. Lacroix, France; A. Bergent, Germany; and A. Harker, England. On August 14, the last day of the congress, the University of Toronto paid a similar honour to P. M. Termier, France; T. C. Chamberlin, U.S.A.; R. Beck, Germany; J. J. Sederholm, Finland; T. Tschermyschev, Russia; A. Strahan, England; and W. G. Miller, Canada. A ceremony very different in character—though no less dignified—was performed when the delegates visited Montreal. At the old Indian reservation of Caughnawga the visitors were treated to a short exhibition of the Indian national game, to an Indian play depicting the courtship of former times, and finally four of the party were selected to become chiefs of the tribe. They were:—I. P. Tolmatchew, Russia; W. Paulcke, Germany; H. M. Cadell, Scotland; and F. D. Adams, Canada. After going through the dance of adoption they were given Indian names, and were received as full members of the tribe.

No account of the twelfth congress would be complete without reference to the kindnesses showered on the delegates during their visit to Toronto. The local committee and ladies' committee, aided by the executive committee of the congress, had made very extensive and thorough arrangements, and the people of Toronto responded in a most whole-hearted manner. Receptions, banquets, garden-parties, and afternoon teas were prominent features in the proceedings; automobiles were at the disposal of the members; and several of the clubs in town were thrown open while the congress was in session. If one may judge from the appreciative remarks to be heard on every side, the visiting delegates carried away with them very pleasant memories of Toronto and its people.

On the invitation of M. A. Renier, who represented the Government of Belgium, it was decided to hold the thirteenth congress in Belgium four years hence. The subject on which a special monograph shall be issued by the executive committee of the congress of 1917 was left to the discretion of the new committee. R. C. W.

THE OIL-FIELDS OF BURMA.[1]

THE appearance of this memoir will be welcomed equally by those who are engaged in the study of petroleum from a purely scientific point of view, and by those who are merely concerned with its profitable exploitation in Burma and other parts of the Indian Empire; not only because the author possesses a special knowledge of the subject in both aspects, but also because he has brought together, and arranged in a concise and readable manner, a mass of information that has hitherto been scattered through the pages of a voluminous literature, not always readily accessible.

For close upon a century after Michael Symes and Hiram Cox, in the course of their journeys up the "Erai-Wuddey" to the court of Ava, had visited the earth-oil wells of "Yanangheoum," the great oil-belt of Burma remained almost unexplored by Europeans. The virtues of "Rangoon oil" as a lubricant, especially for small arms, became well known; and following on Dr. Christison's discovery, in 1836, that it contained a large proportion of solid paraffin, considerable quantities of the crude oil were imported into this country for the manufacture of candles. But no further developments took place until, within a year of the annexation of Upper Burma, in 1886, exploitation on modern lines began to supersede the antiquated methods of the Burmese, and a systematic investigation of the conditions under which the oil occurred was taken in hand.

As a result of these investigations, carried on not only by officers of the Geological Survey, but also by geologists employed by the several oil companies, it has become apparent that the petroleum is practically confined to certain horizons—whether one or more has not yet been definitely ascertained—in the upper portion of the enormous accumulation of clays and incoherent sandstones known as the Pegu system, corresponding fairly closely with the Miocene of Europe. These beds, according to Mr. Pascoe, were deposited in a great gulf some 400 miles in length, occupying the greater portion of the present Irrawaddy valley. Orogenic folding, proceeding, in part, simultaneously with the deposition of the beds, has thrown them into a series of elongated domes, beneath which the oil has accumulated. The second and third parts of the memoir are devoted to a discussion of the structure of each of the anticlines so far examined, and of its capabilities as a producer of oil.

The most productive of these anticlines as yet discovered is that of Yenangyaung, where Dr. Oldham first recognised, in 1855, the connection between anticlinal structure and the accumulation of petroleum. Here the oil is confined within an area of less than one-and-a-half square miles, and yet, since the year 1888, this little field has produced more than a thousand million gallons. Nothing like this has been discovered elsewhere in

[1] "The Oil-fields of Burma." By E. H. Pascoe. Pp. xxxix+269+54 plates. Memoirs of the Geological Survey of India. (Calcutta: Geological Survey; London: Kegan Paul, Trench, Trübner and Co., Ltd., 1912.) Price 6s. 8d.

Burma, though many an anticline, apparently as well fitted for the storage of petroleum, has been examined and tested. Meanwhile no fewer than nine companies are engaged in a race for the deeper and richer oil-sands in the Yenangyaung field, and it would appear that the end cannot be far off. One may, perhaps, be allowed to express regret that steps were not taken by Government to regulate this competition until it had seriously affected the resources of the field; especially in view of the fact that Burma is the only country directly under Imperial control which is known to possess large stores of petroleum, and that an adequate supply of fuel oil may become, in the near future, of vital importance to the national existence.

Yenangyaung—Native well-digger in diving dress. (The man on his right is holding the mirror used to illuminate the bottom of the well.) From Memoirs of the Geological Survey of India, vol. xl., part i., "The Oil-fields of Burma."

In the final chapters of the work will be found an able discussion of the origin of petroleum, and of its relations to geotectonic structure. The difficulty of accounting for the presence of oil-sands above a water-bearing stratum (a by no means uncommon occurrence at Yenangyaung) on any theory of inorganic origin, which would entail an upward migration of the oil from a deep-seated source, seems to be insuperable; while, on the other hand, the arguments brought forward in favour of an organic origin, at least in Burma, Assam, and other similar areas, seem no less convincing. Though any direct genetic relation between coal and oil is expressly disclaimed, their close juxtaposition in those countries is highly suggestive, as well as the affinity shown to exist between petroleum gas and such admittedly organic products as marsh-gas and firedamp, in respect of the proportion of methane that they contain. The solution of the problem is one of great practical importance, for upon it depends the question whether an oil-sand, once drained of its petroleum, might ever recover its productiveness.

T. H. D. L.

OCEANOGRAPHY OF THE MEDITERRANEAN.[1]

THE Mediterranean Sea has always been an attractive field for oceanographical investigation, since it presents many features which contrast strongly with those of the other enclosed seas. Italy, Sicily, and a submarine ridge over which the greatest depth of water is about 400 metres, separate the whole area into two sea-basins. The western one, comprising the Balearic and Tyrrhenian Seas, is, for the most part, about 2000–3000 metres in depth; while the eastern basin, which includes all the seas to the east of Italy and Sicily, is rather deeper on the average, and soundings of more than 4000 metres have been made. Large coastal areas, like the North Sea, with depths of less than 200 metres do not

[1] Report on the Danish Oceanographical Expeditions of 1908–10 to the Mediterranean and Adjacent Seas. Edited by Joh. Schmidt. Vol. i., Introduction, Hydrography, and Sen-bottom Deposits. (Copenhagen, 1912.) Pp. 270+xx plates.

exist, and because of this absence of extensive tracts of sea-bottom of moderate depth, fisheries on the scale of those of the North Atlantic enclosed seas are non-existent. Because of this relative unimportance of the sea-fisheries, the fauna of the Mediterranean is not nearly so well known as, for instance, that of the North Sea and Baltic; and the remainder of the reports of the Danish expeditions, dealing with the biological investigations, promise to be of exceptional interest on this account.

The sea-bottom deposits are of relatively little interest. Over by far the greater part of the Mediterranean the bottom is covered by terrigenous materials. These contain far less volcanic débris than might have been suspected. Siliceous materials are also relatively rare, and the chief calcareous deposits are to be found over relatively small areas, and contain Pteropod shells.

The hydrographic conditions in the Mediterranean depend mainly on the fact that this water area is one of high concentration. The amount of water received from the rainfall over the land area which it drains is far less (less than a quarter, it is said) than the amount of water removed by evaporation. The temperature of the superficial strata of water is relatively high: even at a depth of 1000 metres it is uniformly 13° C., while the salinity is also relatively high, being everywhere about 38 per mille in the bottom and intermediate strata. This excess of evaporation over precipitation would lead, of course, to a reduction of water-level, were it not compensated by the strong inflow from the Atlantic through the Straits of Gibraltar. But this inflow tends, of course, to raise the hydrostatic pressure of the water in the sea, and therefore a counter-current sets out from the Mediterranean into the open Atlantic Ocean. The inflowing current is superficial, has a velocity of from one to three knots, a temperature which is that of the Atlantic water in the Spanish Bay, and a salinity of about 36 per mille. The outflowing current is a deep one, its velocity varies from one-half to about five knots, its temperature is uniformly about 13° C., and its salinity is about 38 per mille. The variations in velocity are due to the tidal streams in the straits.

The volume of relatively warm and dense water flowing out from the Mediterranean is very considerable. This water is so highly saline that it flows on as a bottom or intermediate current in spite of its high temperature. Although its direction is nearly east to west as it emerges from the straits, it soon becomes deflected to the north and east as the result of the earth's rotation, and it approaches the coasts of the British Islands. Normally it flows to the west of Ireland, and Dickson has shown that it may be present even so far north as the channel between Rockall and Scotland, but as a rule the current must flow along deep depressions of the sea-bottom. If, however, it is unusually strong it may enter the shallower sea-basins, and Bassett has recently suggested that unusually high salinities in such enclosed sea areas as the English Channel or Irish Sea may be due, not to an unusually strong Gulf Stream drift, but more probably to the presence of this highly saline Mediterranean water. This indeed, appears to have been the case in the summer of 1912 in the Irish Sea and adjacent waters.

Precisely the opposite conditions exist in relation to the Black Sea and the Sea of Marmora. The latter basin has a depth of 1000 to 2000 metres, and the Black Sea has a maximum depth of about 2200 metres. The Black Sea is an area of excess of precipitation over evaporation, so that the superficial strata of water are of low salinity. From the surface down to about 20 metres the salinity is about 17·5 per mille, and it is nearly constant at this limiting depth, increasing towards the bottom. The temperature appears to be nearly constant at about 80 metres depth, and also increases slightly towards the bottom. Because of the excess of precipitation over evaporation the water-level of the Black Sea tends to rise, but this is prevented, of course, by an outflow of relatively light water through the Bosporus into the Sea of Marmora, and from the latter basin through the Dardanelles into the Mediterranean. But since this outflow reduces the hydrostatic pressure of the communicating water masses, a counter-current of relatively dense Mediterranean water enters the Sea of Marmora, and then the Black Sea through the Bosporus. The water flowing out from the Black Sea is a surface current, that flowing in a deep one. The depth of water at the entrance to the Black Sea is, however, very small, and the existence of this "sill" prevents the complete renewal or ventilation of the deeper strata of water, a condition which also exists, on a much smaller scale, in some of the Norwegian fjords. The absence of renewal of water leads to the stagnation of most of the water of the Black Sea: not only is oxygen absent in the deeper layers, but its place is actually taken by sulphuretted hydrogen, and except for some forms of bacteria this water-mass is lifeless.

The horizontal water circulation in the Mediterranean depends on the Atlantic inflow. This is at first west to east in direction, but, becoming deflected to the right in consequence of the rotation of the earth, it flows along the coast of Africa. The direction of flow of surface-water then follows the general scheme of that in the northern hemisphere. Two cyclonic circulations are set up in the western basin—one in the Balearic Sea to the west of Sardinia and Corsica, and another in the Tyrrhenian Sea. The main stream enters the eastern basin through the channel between Sicily and Tunis, and then becomes deflected, forming another cyclonic circulation. There is also an intermediate level water circulation which depends for its direction on a complex resultant of superficial horizontal circulation and vertical circulations due to concentration and cooling of superficial waters. This intermediate circulation is difficult to explain, and, indeed, is still imperfectly known. It is, of course, the origin of the westerly flowing deep current in the straits, and seems to result from the junction of two main streams flowing to the south of Sardinia and the north of Corsica respectively.

Many disputed questions are discussed by the authors of the papers in this report, and we await with interest the results of the biological investigations. There is no doubt that the fishes and other groups of animals inhabiting the Mediterranean area are still imperfectly known; while the investigation of the pelagic microscopic life of these seas is one which is full of interest. A good deal of such work has, of course, already been done, but the results of investigators thoroughly familiar with deep-sea work of this kind in the northern seas are sure to be interesting, and the comparisons which we may expect they will attempt ought to throw new light on many questions of general biological interest. J. J.

THE GUM TREES OF AUSTRALIA.[1]

MR. T. H. MAIDEN, the director of the Botanic Gardens, Sydney, N.S.W., published the first part of his great work on the characteristic Australian genus Eucalyptus in 1903, and it has now reached the seventeenth part. There is no other country of the same extent as Australia in which one genus of trees largely predominates throughout and, at the same time, has few extensions beyond. It has been estimated that three-fourths of the forest vegetation of Australia consists of gum trees and bushes, yet the genus is not represented in the native flora of New Zealand, New Caledonia, Lord Howe Island, and other contiguous countries, including, I believe, New Guinea, though *E. alba* is a native of Timor.

But, like Baeckia and Melaleuca, other myrtaceous genera, Eucalyptus has a considerable northward extension in eastern Asia, limited, however, to one species the present distribution of which is peculiar. Mr. Maiden has succeeded in showing that this species, *E. naudiniana,* abundant in Neu Pommern (New Britain), is the same as that discovered in Mindanao, Philippines, by the United States Exploring Expedition (1838–42), and described under the name multiflora—a name previously occupied. These two localities are separated by about 13° of latitude and 25° of longitude, or, approximately, 1500 miles, and hitherto *E. naudiniana* has not been recorded from any intermediate locality. Its presence in the Philippines is an interesting fact in phytogeography, and the question arises, Is it a straggler of a southern migration, or is it, and similar outliers, a northward extension of a type of southern origin? But this is not the place to discuss the point.

So far Mr. Maiden has described and figured ninety-four species of Eucalyptus, and given all details available of their distribution, based on practically all the important herbarium material in existence, and a very wide personal experience in the forests of all parts of the country. Upwards of one-third of these ninety-four species are of later date than Bentham's "Flora Australiensis," or were not given specific rank by Bentham. From a rough calculation the number of valid species of Eucalyptus will not be fewer than 150; some generally dispersed, though the western species are mostly different from the eastern, and many of them bear more conspicuous flowers than the eastern. Others are very rare and near extinction, notably the very large-flowered, shrubby *E. macrocarpa.* It is to be hoped that Mr. Maiden's health and official duties will permit him to bring this valuable monograph to a relatively early conclusion, as it is only in the complete form that it can be fully useful.

W. BOTTING HEMSLEY.

[1] "A Critical Revision of the Genus Eucalyptus." By J. H. Maiden, Government Botanist of New South Wales. Parts xii–xvii. Plates 50–76. with descriptive letterpress. (Published by Authority of the Government of the State of New South Wales, 1910–13.) Price 2s. 6d. each part.

NOTES.

WE are informed by Dr. H. Mohn that he has resigned the professorship of meteorology in the University of Christiania and the directorship of the Meteorological Institute of Norway. Mr. Aksel S. Steen has been appointed to succeed him in these positions.

AT the time of going to press with our issue of last week, the race by Mr. H. G. Hawker in an all-British waterplane for the 5000*l.* prize offered by *The Daily Mail* was in progress. The distance to be covered was 1540 miles, and of this 1043 had been accomplished on Wednesday when, according to the aviator, his foot slipping off the rudder bar, he lost control of the machine, which fell into the water of Lough Shinny, Ireland, and was wrecked. Mr. Hawker and his companion, Mr. Kauper, were rescued, the first-named uninjured, but the latter with a broken arm and other injuries. Although the task set him to accomplish was not fulfilled, the aviator must be congratulated upon having made a very satisfactory series of flights. The machine, fitted with a Green engine, was built by the Sopwith Aviation Company, and was a biplane with a span between the wing tips of 50 ft., and a length of 31 ft. 6 in. It had two main floats, with single hydroplane step, each weighing 170 lb., and also a small torpedo float under the tail. The total weight of the machine and passengers was estimated at 2400 lb.

THE next International Conference on Cancer (the fourth) is to be held at Copenhagen in 1916.

ACCORDING to the *New York Medical Journal,* an International Exposition of Safety and Sanitation will take place in New York in December next. It will include exhibits devoted to safety, health, sanitation, the prevention of accidents, the welfare of the public and the individual, and the advancement of the science of industry. Exhibits from foreign countries will, by a special Act of Congress, be admitted free of duty.

A REPORT from Vienna states that a ship has been purchased for an Austrian expedition to the South Polar regions, and that funds are being collected in aid of the object. The expedition is to be under the leadership of Dr. F. König, of Graz, and the proposal is that it shall leave Trieste in May next. A large donation to the funds has been given by the Austrian Academy of Science, and the Austrian Geographical Society has promised an annual subsidy towards the cost of the undertaking.

Mr. D. A. Bannerman has returned from a zoological mission to the eastern islands of the Canary group, undertaken with the object of procuring examples of the birds of these islands for the Natural History Museum. The islands visited were Fuerteventura, Lanzarote, Graciosa, Montana Clara, Roque de l'Oueste, and Alegranza, several of which had not previously been visited by a collector. Mr. Bannerman succeeded in obtaining a number of rare and interesting species peculiar to the islands, while the fact that the birds were collected in their breeding plumage renders them of special value to the museum bird room. On Alegranza a new species of chat was discovered.

Reference was made in our last issue to the three educational museums which were founded and equipped by the late Sir Jonathan Hutchinson. We regret to learn from *The Times* that the future of these institutions is in an uncertain state and causing anxiety to those who have been privileged to make use of them. So far as the museum of Haslemere is concerned, there is a strong feeling in the town that everything should be done to retain the institution, and it is understood that the family are willing to hand it over to a responsible committee or body of trustees so that the museum may be placed on a permanent and public basis. The annual cost of maintenance on the present lines is about 400*l*., and an appeal will shortly be issued with the hope of securing this sum for five years at least, it being thought that by that time those who are interested in the matter will have had an opportunity of deciding what are the best steps to be taken for the permanent control and maintenance of the museum.

As was stated in our issue of July 3 last, plans are being prepared for the new buildings to be erected at the Rothamsted experiment station in commemoration of the centenary of the birth of Sir John Lawes and Sir Henry Gilbert. We now learn from the *Journal* of the Royal Society of Arts that strong committees are being formed to raise the necessary funds for the memorial. It is stated that the sum of 12,000*l*. is required, and of this amount half will have to be raised by public subscription, the remaining half being obtainable from the development fund.

A tablet was unveiled on Sunday last at Primiero, Southern Tyrol, on the house in which Alois Negrelli was born, to commemorate Negrelli's work as surveyor of the Suez Canal. He began his investigations in 1847, completed his plans in 1855–6, and in 1858 was appointed inspector-general of the Suez Canal works. He died on October 1 of the latter year.

We note, with regret, the death, at the age of sixty-six, from typhoid fever, while on his voyage home from the Philippines, of Dr. Tempest Anderson, who for a time lectured on volcanoes at the Royal Institution. He was joint author of the report to the Royal Society on the seismic disturbances in the West Indies in 1902 and 1907, and had filled, among other positions, those of president of the Yorkshire Philosophical Society and the Museums Association.

The death is announced, at the age of sixty-six, of Col. Andrew Clark, a gold medallist of the British Medical Association, lecturer on surgery at the Middlesex Hospital Medical School, and author of the "Middlesex Hospital Surgical Reports, 1872–4," and of "Ambulance Lectures." He also edited the fourth edition of "Fairlie Clark's Manual of Surgery."

It is stated in *The Allahabad Pioneer Mail* that the Maharaja Scindia of Gwalior is giving special attention to the valuable archæological relics and treasures in his State, and is taking steps to create an archæological department in Gwalior. In furtherance of this object he has sought the advice and cooperation of the Director-General of Archæology in India.

According to *The Scientific American*, a large naval radio station is shortly to be constructed by the United States at Caimeto, Panama, to be known as the Darien Radio Station. It will consist of three towers, each 600 ft. in height. The bases of the towers will be 180 ft. above sea-level, and they will be arranged in a triangle measuring 900 ft. on each side. The sending and receiving radius will be about 3000 miles direct reach to the Arlington Station, to San Francisco, and to Valdivia, 420 miles south of Valparaiso, on the Pacific, and Buenos Aires on the Atlantic. It will cover a vessel anywhere on the east coast of the United States, and communicate with St. Vincent. The system to be used is the Poulsen.

New lightning conductors have been installed on St. Paul's Cathedral. In the course of the operations part of one of the original iron bar conductors erected more than 140 years ago under the supervision of Benjamin Franklin was discovered. This bar, having been inside one of the towers and so not exposed to the weather, was still in a good state of preservation. *The Times* recalls that the fixing of these "Franklin rods," as they were called, led to a heated controversy as to whether lightning conductors should have points or balls as terminals. The president of the Royal Society, who advocated points, had to resign. King George III. was a strong adherent to ball terminals.

It is announced in *The Times* that a discovery of oil shale has been made in the island of Skye by Dr. G. W. Lee, a member of the scientific staff of the Scottish Geological Survey and Museum, Edinburgh, who was examining the geological structure of the east coast of Skye. The extent and value of the deposits are not yet fully known, but it is stated that the seam discovered is about 11 ft. in thickness, that it extends over a considerable area, and that, although not of first-class quality or so good as the seams worked in the Lothians, it is likely to prove sufficiently good to be worked successfully, in view of the improved methods of operation now followed by the leading shale oil firms.

THE droughty summer has closed with some exceptionally heavy rainfalls over the south-eastern portion of England, where the rains for the last two or three days of August have materially modified the aggregate measurements for the season. At Greenwich the rainfall for the three days, August 29 to 31, was 1·22 in., which is more than the total for the preceding part of the month. Without the rainfall for the last three days of summer the total for the three months at Greenwich would have been more than an inch less than for the corresponding season in the abnormally fine year 1911. The total rainfall for the summer at Greenwich is 4·69 in., whilst in 1912 it was 7·86 in., and in 1911 it was 3·72 in. The driest summer of the last seventy years occurred in 1864 with 2·50 in., and in the last fifty years there have been fourteen summers drier than the one which has just closed. At Greenwich the summer rains this year are 70 per cent. of the average. In places the recent rains have not had much influence on the total for the summer. At Jersey the summer rains, June, July, and August, are only 28 per cent. of the average; at Leith, 40 per cent., where until August 28 they were only 28 per cent.; at Valencia, 51 per cent.; and at Liverpool, 66 per cent. The mean temperature for the three months at Greenwich was 61°, which is in precise agreement with 1912, and 5° cooler than 1911. The sunshine this summer was 442 hours, in 1912 it was 497 hours, and in 1911 it was 819 hours.

THE proceedings of the third meeting of the General Malarial Committee of the Government of India, held at Madras during November, 1912, have been published recently as a substantial volume, which contains much interesting reading and affords evidence of a great deal of energetic and enthusiastic research upon the etiology of disease in India. The papers and discussions reported cover a wider field than the title indicates. Several papers deal with the question of *Stegomyia fasciata*, the mosquito known to be the carrier of yellow fever in the New World; in view of the approaching opening of the Panama Canal, when the endemic home of yellow fever will be brought into closer communication with the Far East than it is at present, the degree of prevalence of this mosquito in the ports of India is likely to become a matter of urgent practical sanitary importance. Other papers read dealt with the vexed question of the transmission of Kala Azar. Capt. Patton, who regards the parasite causing this disease as a member of a group of Flagellates primarily parasitic in insects, has observed developmental stages of the parasite in the common bed-bug, but as yet no satisfactory experimental proof that the bed-bug transmits Kala Azar has been brought forward, nor has the existence of any "reservoir" of the disease in domestic or wild animals be demonstrated. The problem of Kala Azar is, however, under investigation by a number of competent workers, and its solution in the near future may be confidently expected.

THE Australian Institute of Tropical Medicine has issued its report for the year 1911 (more correctly for the year ending March, 1912). The bulk of the report is written by the director, Dr. Anton Breinl, and contains important investigations dealing chiefly with parasitic worms and Protozoa, illustrated by eleven excellent lithographed plates. Especially noteworthy amongst these researches is an investigation into the morphology and life-history of *Onchocerca gibsoni*, the nematode parasite which causes the so-called worm-nodules in Australian cattle. A number of experiments were recorded which were directed towards solving the problem of the transmission of this parasite, but up to the present these experiments have not led to any conclusive results as to the intermediary host of the worm. Appended to the director's report is that of the entomologist, Mr. Frank H. Taylor, and a report on the Cestoda and Acanthocephala of North Queensland, by Dr. T. Harvey Johnston. The entire report makes a quarto volume of 96 pp. and 17 plates, neatly bound in cloth, but having one defect from the point of view of the bibliographer, namely, that there is nowhere any indication to be found of the date of publication, whether 1912 or 1913. This is an unfortunate omission in a work which describes numerous new species of animals, including even a new species of Cyclops.

IN a recent number of the Annals of Tropical Medicine and Parasitology (vol. vii., No. 3A), Dr. J. W. Scott Macfie gives an account of a new species of trypanosome observed in human beings in Nigeria. It occurs most commonly in young people, and produces a mild form of sleeping sickness in which the trypanosomes cannot be found in the peripheral blood, but are present in the lymphatic glands. To the smaller experimental animals of the laboratory the trypanosome appears to be but slightly pathogenic. In the blood of the guinea-pig the trypanosome is smaller than *Trypanosoma gambiense;* like that species it is polymorphic, with long and slender, short and stumpy, and intermediate forms, and a few minute trypanosomes, measuring as little as 8 μ in length, appear constantly in the blood-films. Some of the short, stumpy forms have the principal nucleus situated far forwards at the anterior (flagellar) end of the body. Forms in which the flagellum appears to be free from the body for its whole length are also found. The Nigerian trypanosome is regarded by Dr. Macfie as a species distinct from *T. gambiense*, and is given the name *T. nigeriense*.

IN part 6, vol. iii., of the Journal of the East Africa and Uganda Natural History Society, Mr. C. W. Hobley discusses, from an examination of weapons used by the Pygmy and other neighbouring tribes, the question of the evolution of the arrow. He comes to the conclusion that the use of the stone point is later than that of the thorn; hence, that the use of poison applied to the tip is probably older than is commonly supposed; the lateral barbs were suggested by some of the many thorny-stemmed plants which flourish in the bush in which the hunter lived. He suggests that the aboriginal tribes of the centre of the continent passed direct from the use of natural thorns to the use of iron points, but the people east of Lake Victoria began with natural thorn points, passed through an age in which stone arrow-points were used, and eventually passed into an iron age, the variation in development depending on the absence or presence of suitable stone for making arrow-points. The wooden point still survives, but only sporadically; the stone point has disappeared, but the leaf-shaped iron point used by some of the Kavirondo, Nandi, and also found among the Tharaka, is undoubtedly a copy of the leaf-shaped stone arrow-head, of which good examples are now coming to light.

THE possibility of the existence of some hitherto unidentified animals in Central Africa is again raised in a communication by Mr. C. W. Hobley, published in part 6, vol. iii., of the Journal of the East Africa and Uganda Natural History Society. One of them is described as possessing "thick, reddish-brown hair, with a slight streak of white down the hindquarters, rather long from hock to foot, rather bigger than a hyena, with largish ears." Some naturalists are inclined to identify it with the hairy ant-bear, Orycteropus; but most of those who have seen it are well acquainted with the ant-bear, and it is an almost unique phenomenon for an ant-bear to be seen abroad in daylight. The natives, again, have tales of a lake monster which the Baganda call Lukwata. Europeans have seen a strange beast swimming in the Napoleon Gulf, which was apparently not a crocodile. An American sportsman, E. B. Bronson, saw on the Gori River, Lake Victoria, a beast "14 to 15 feet long, head as big as a lioness but shaped and marked as a leopard, two long white fangs sticking down straight out of his upper jaw, scaled like an armadillo, back broad as a hippo, spotted like a leopard, and a broad, fine tail; the imprints of its feet were as large as that of a hippo but clawed like a reptile." Another monster has been seen by natives "as large as a man, sometimes going on four legs, sometimes on two, in general appearance like a huge baboon, and very fierce." Naturalists will await with interest the discovery of specimens of these strange animals.

BEFORE the publication, in *The Philippine Journal of Science* for April last, of Mr. H. O. Beyer's paper on origin myths among the mountain peoples of the Philippines, no representative collection of Philippine myths had been made. Until recent years it was believed that all ancient records written in the syllabic alphabets which the Filipinos possessed at the time of the Spanish conquest had been lost; but two of these alphabets are now found in use by wild tribes of Palawan and Mindoro, and ancient manuscripts written in the old Bisaya character have recently been discovered in a cave in the island of Negros. These still await publication. Mr. Beyer's paper is based on oral tradition and gives a large collection of interesting legends, including an underground death-land, a story of the Atlas type, in which the world is supported by a post created by the chief deity and near which he dwells, and a remarkable flood myth current among the Central Ifugaos. It may be hoped that Mr. Beyer will continue his researches in the new folklore area.

MR. T. SHEPPARD, curator of the Municipal Museum, Hull, has issued a fourth edition of his catalogue of the collections under his charge. This is rendered necessary by the process of rearrangement which followed important additions to the collections, and the establishment of the new Wilberforce House Museum and the Pickering Museum of Fisheries and Shipping, which has done much to remove the pressure on the original buildings. Wilberforce House, built for the Lister family, about the end of Queen Elizabeth's reign, a beautiful old residence with numerous relics, was the birthplace of the philanthropist, William Wilberforce, born here in 1759, and has now become the repository of collections illustrating his life, and of the general history of Kingston-upon-Hull. The Pickering Museum is largely devoted to collections illustrating the whaling, fishing, and shipping industries, the nucleus being the specimens collected by a public-spirited citizen, Mr. C. Pickering. Hull is to be congratulated on the activity displayed by its municipality and residents on the establishment of these museums, and the curator, Mr. T. Sheppard, on the valuable series of catalogues issued at a nominal price.

DR. W. S. HUNTER'S "The Delayed Reaction in Animals and Children," affords an interesting contribution to the "Behavior Monograph Series." A release box is employed leading to three different compartments, any one of which can be illuminated by the experimenter. The compartment which is illuminated can be opened and entered by the subject, whereas the other compartments are closed. Food is obtained by entering the illuminated compartment. Rats, dogs, raccoons, and children were used as subjects. After a clear association had been established between the movements leading to food and the light which might appear in any one of the three boxes, experiments were begun in which the light was turned off *before* the subject had made the appropriate reaction. The research consisted in determining the maximal length of this delay-period which is compatible with a correct response, and in ascertaining the psychological factors at work permitting of the correct response after the delay-period. The author lays stress on the importance of what he terms "sensory thought."

THE current number of *The Psychological Review* contains an important paper on association and inhibition, by Prof. J. F. Shepard and Mr. H. M. Fogelsonge, based on the learning of nonsense-syllables. In the first series of experiments these were learnt in pairs, and subsequently the subject was tested by being shown the first syllable of a pair either alone or in different combinations. These combinations of first syllables were either shown successively or simultaneously. Where two first syllables were shown successively, the second was shown at such an interval that the association set up by the former was not already completed in the subject. In a second series of experiments, three, instead of two, syllables were learnt together, and, in testing, the first two of the three syllables were shown simultaneously; these might belong to the same or to different three-syllable groups. In other series of experiments two different syllables were each separately learnt in conjunction with one and the same syllable; the two syllables were subsequently presented successively to the subject when tested. The resulting reproduction-times, as measured by the chronoscope, convince the authors that the inhibition or facilitation thus experimentally produced is one "which cannot be . . . explained neurologically as a division of energy, or drainage." They believe that "an association cannot be explained as a mere path of lowered resistance," but that it "involves other processes which prevent any other stimulus from using the same neuroses at the same time . . . and which block any other association that is tending to operate at the same time, even though both will lead to the same end result."

IN vol. viii., Section D, No. 3, of *The Philippine Journal of Science*, Mr. A. E. W. Salt gives an elaborate account of the endowment provided by Francisco de Carriedo y Peredo, the greatest benefactor of the city of Manila, who died in 1743. From the funds received under his will, a water supply was provided for the city until the American occupation. A new system to supplement the ancient supply was opened in 1908. Water is now brought from an almost virgin watershed of one hundred square miles in area, and thence carried to a storage reservoir with a capacity of 210,000,000 gallons. The city, however, is so rapidly developing that this system is barely adequate to the needs of the population. Mr. Salt has done good service in directing attention to the benevolence of a citizen who, at a time when sanitation occupied little public attention, devoted his wealth to this excellent purpose.

IN Professional Paper No. 79 of the United States Geological Survey, Mr. H. S. Williams discusses the recurrent Tropidoleptus zones of the Upper Devonian in New York. In preparing the data for the Watkins Glen-Catatonk folio (No. 169 Geol. Atlas USUS, Geol. Survey, 1909) the occasional discovery of *Tripodolpetus carinatus* (Conrad) in strata far above the supposed range of the species or of the fauna with which the species is normally associated led the writer to undertake an examination of the sections and sequence of fauna where they appeared. The result throws important light upon the regional geography. The departure and return of the fauna must have been due to diastrophic changes which produced recurring favourable or unfavourable conditions for the existence of the fauna. Those changes of conditions may have resulted from the alternate closing and reopening of an actual passage-way which obstructed or admitted the access of the fauna and of waters favourable to them, or from changes that affected the direction, character, or volume of the existing ocean currents.

THE insect food of Canadian fresh-water fishes forms the subject of an article by Dr. Gordon Hewitt, the Dominion entomologist, published in the fourth annual report of the Commision of [Fish] Conservation of Ottawa. Attention is directed by the author to the futility of attempting to restock depleted rivers, or to introduce new kinds of fish into Canadian rivers, without taking measures to ensure an abundant supply of suitable insect food. In Europe it has been demonstrated that the artificial cultivation of many kinds of insects constituting the chief food of fishes is perfectly practicable; and in many rivers an insect hatchery is almost as necessary and important as a fish-hatchery. Before such insectaria can be introduced with satisfactory results in Canada, a close investigation into the nature of the food of native or introduced fishes is absolutely essential.

A RECENT number of the *Zeitschrift für wissenschaftliche Zoologie* (Bd. cv., Heft 3) is entirely devoted to a memoir on the chemical composition of the hæmolymph of insects and its significance as regards sexual differentiation. According to the author, Herr Kurt Geyer, the hæmolymph in caterpillars and pupæ of Lepidoptera is usually green in females and pale yellow or colourless in males. The green pigment is, as Poulton has already shown, slightly altered chlorophyll in solution, derived from the food-plant; it constitutes a protective coloration, and it is improbable that it has any assimilatory function. The yellow colour of the male hæmolymph is due to the yellow constituents of chlorophyll (xanthophyll). The hæmolymph of non-phytophagous insects shows no such colour difference. When the male and female hæmolymph are mixed a heavy precipitate is at once formed, and this reaction can only be distinguished quantitatively from that which takes place between different species. The author concludes that in insects the entire soma is sexually differentiated in male and female.

DR. C. H. OSTENFELD'S account of the biology and distribution of the phytoplankton of Danish seas (De Danske Farvandes Plankton i aarene 1898–1901. Phytoplankton og Protozoer. D. Kgl. Danske, Vidensk. Selsk. Skrifter. 7. Raekke, Naturvidensk og Mathem. Afd. ix. 2. 1913) is of more than local interest. The main work is written in the Danish language, but there is a *résumé* in French, extending to 65 pp., which in itself constitutes one of the best summary accounts which we possess of the present state of our knowledge of the general problems of the biology of plankton organisms. The Danish seas, extending as they do from the Baltic through the deep waters of the Skager Rak to the North Sea, furnish such wide variations in salinity, temperature, and chemical constitution, that they offer exceptional opportunities for studying the effects of physical conditions on the distribution of the plankton, and this aspect of the subject receives a full consideration in the report. A good bibliography will be found on pp. 346–352.

FROM the Kommissionen for Havundersögelser in Copenhagen we have received three further reports dealing with the investigations which have been carried out under the direction of Dr. Johs. Schmidt into the life-histories of eels. These are: Danish researches in the Atlantic and Mediterranean on the life-history of the freshwater-eel (*Anguilla vulgaris*, Turt.), with notes on other species, by Johs. Schmidt (*Internat. Revue Hydrobiologie und Hydrographie*, 1912); on the identification of murænoid larvæ in their early (preleptocephaline) stages, by Johs. Schmidt (*Meddel. Komm. Havunders. Fiskeri Bd.* iv. 2); and the metamorphosis of elvers as influenced by outward conditions—some experiments, by A. Strubberg (*Meddel. Komm. Havunders. Fiskeri Bd.* iv. 3). In NATURE, vol. lxxxix., pp. 633–636, Dr. Schmidt himself gave a brief account of these researches, and those interested in the subject will no doubt welcome the more detailed reports.

In his presidential address to the Quekett Microscopical Club for this year, Prof. Dendy dealt with the subject of "By-products of Evolution," illustrating his theme by the spicules, more particularly the microscleres of siliceous sponges. After pointing out that these minute spicules exhibit constant specific characters, and have undoubtedly arisen by some process of evolution, since one form leads on to another, just as in the case of any other characters, it is argued that natural selection cannot be directly responsible for their origin, on the ground that the minute differences in the form of the microscleres cannot be of any importance to the sponge in the soft tissues of which they are scattered without order or arrangement. By the principle of correlation non-adaptive characters of this kind may be linked inseparably with other characters which being adaptive, are directly influenced by natural selection, in such a way that any variation in the one must be accompanied by a corresponding variation in the other. Thus, a non-adaptive character may undergo a progressive evolution indirectly controlled by the action of natural selection. The principle of correlation cannot, however, be invoked to explain the specific forms assumed by the microscleres; it can only help to explain why such characters exist at all and why they should undergo progressive evolution. The specific form of the microsclere must be produced by chemical and physical causes involved in, and controlled by, the hereditary constitution of the mother-cell.

Sir F. W. Moore contributes a useful paper on hardy water-lilies to *Irish Gardening* (vol. viii. May, 1913), including not merely cultural hints and lists of species suitable for ponds of different depths, but also some interesting remarks on the general biology and mode of growth of these plants. For instance, the author lays stress on the importance of the study of roots to the gardener; observation of water-lilies shows that from early April to June new roots are developed rapidly as the new leaves and flower-buds are formed and the rhizome elongates, while the older roots largely die away after having served as collectors of food reserves during previous years and as anchors during the winter. It is also noted that while, as a rule, the flowers close on bright days between three and four o'clock in the afternoon, if after noon the day becomes wet and gloomy the flowers usually remain open until dark.

In continuation of his investigations into "Southern Hemisphere Seasonal Correlations" (Nature, August 7), Mr. R. C. Mossman contributed a fourth article to *Symons's Meteorological Magazine* for August. He pointed out an interesting instance of the temporary character of many correlations. The example chosen was the comparison of April to September rainfall at Trinidad (West Indies) with that at Azo (Argentine Republic) for the following six months. Dealing with the fifty years, 1862–1911, it was found that from 1862 to 1877 and from 1895 to 1911 there was no relation between the rainfall of the six-monthly periods; but during the seventeen years 1878–94 the curves showing the rainfall departure from normal are the reverse of each other. The author observes that these results are of importance, as they show that the physical processes that produced a given precipitation at Trinidad during the period under discussion were associated during the six months following by an opposite effect in the south temperate zone, some 2850 geographical miles distant. Mr. Mossman also refers to one or two interesting correlations in other regions, especially one between the rainfall of Java and Trinidad.

The Meteorological Office chart of the North Atlantic and Mediterranean for September (first issue) shows that the last report from the scout-ship *Scotia* was dated August 7 in 54° 45′ N., 49° 30′ W.; no ice in sight. It is pointed out that the full scope and value of the work accomplished cannot be estimated until the reports of the captain and scientific staff have been submitted. The ice notices which may prove to have been of most value are those relating to the comparatively small quantities that have been seen drifting south in the polar current. An important feature this year is the fact that the ice has been held up, for the most part, north of latitude 43°. The special reports above mentioned will, it is thought, no doubt decide whether this was due to abnormal strength of the Gulf Stream, to unusual weakness of the Labrador current, or to both causes.

A circular headed "Road Dangers" has been widely circulated by the editor of *The Automotor Journal*. It suggests that the dangers both of vehicular and foot-passenger traffic might be greatly minimised if at crossings the traffic of one street were arbitrarily given a right of way and the traffic of the other street which crosses it were made to go dead slow by a sign that must be obeyed. The writer of the circular considers that not only would the accidents that occur from collisions of vehicles at crossings be greatly reduced, but the noisy use of the horn would be no longer necessary. It is difficult to see how the suggestion can be carried out without some enactment giving to a street authority a power to make bye-laws controlling the traffic in the less important streets and which can be enforced by the police. It would be easy for the Chief Commissioner, through his advisers in Scotland Yard, to decide which streets are to be of primary and which are to be of secondary importance, but short of keeping a constable on traffic duty at every crossing it is difficult to see how, with his existing powers, he can instruct them to summon drivers disobeying notices informing them that they must give way to traffic in the preferred streets.

We have received a copy of the third edition of Merck's "Reagenzien-Verzeichnis." It is a volume of 446 pages, and all the commoner reagents, tests, hardening and preservative fluids, and the like are given alphabetically under authors' names, some 5000 formulæ being thus detailed, with references to the literature. There is further a valuable list of the substances for which the tests are employed, and a similar one for those used in microscopic work. Finally, there is an index of the preparations employed for the various tests, with authors' names attached; thus we find that "arbutin" was recommended by Reichard as a test for nitric acid. The lists are most complete, and so far as we have been able to refer to them are accurate, and are not confined to recent work; *e.g.* Beale's carmine stain and injection fluids are given. The volume will be of the greatest service in the chemical and the biological laboratory.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR SEPTEMBER:—

Sept. 8. 20h. 46m. Jupiter in conjunction with the Moon (Jupiter 4° 56′ N.).

10. 17h. 0m. Saturn at quadrature to the Sun (90° distant).

,, 20h. 0m. Venus in the ascending node.

,, 22h. 14m. Uranus in conjunction with the Moon (Uranus 3° 35′ N.).

14. 20h. 0m. Juno in conjunction with the Moon (Juno 0° 20′ N.).

15. 0h. 48m. Moon eclipsed, invisible at Greenwich.

16. 3h. 0m. Mercury in superior conjunction with the Sun.

22. 4h. 2m. Saturn in conjunction with the Moon (Saturn 6° 59′ S.).

23. 3h. 53m. Sun enters Sign of Libra; autumn commences.

,, 8h. 22m. Mars in conjunction with the Moon (Mars 5° 6′ S.).

THE SPECTRA OF THE STARS.—After many years of patient labour by such pioneers as Rutherfurd, Secchi, Huggins, Vogel, Pickering and his co-workers, Lockyer and McClean, the subject of stellar spectra has attracted during the last decade the attention of an ever-increasing number of students in astronomy, astrophysics, physics, and chemistry. This is no doubt thanks in a great measure to the enormous number of spectra classified in connection with the Draper catalogue, but also largely to the simple nomenclature developed by Miss A. J. Cannon, further simplified by the suggestions of Dr. Hertzsprung. Although classification merely has received a great amount of attention of recent years, perhaps partly due to the prominence given to the matter by the Solar Union making it the work of a special committee, yet many important pieces of work have been accomplished beyond. Such are Campbell's and Kapteyn's work on the relations between radial velocities and type of spectrum, the similar work of Lewis Boss on the relation between proper motion and type, the work of Pickering and others on the distribution of stars of particular type of spectrum with reference to the Milky Way, &c. It is perhaps fitting that the importance of the subject should have led to the publication of a summary in the Memoirs of the Society of Italian Spectroscopists, No. 6, from the pen of Signor G. Abetti. It is, however, passing strange that this writer makes no mention of the work of Rutherfurd, Huggins, Lockyer, or McClean, except perhaps that some of them may be referred to in an "&c." Signor Abetti does not deal at all adequately with the literature on the chemical constitution of the stars. He does state, however, that titanium stars are on a level nearer to the helium stars than are the iron stars—a statement for which we know no justification.

EXHIBITION OF THE ROYAL PHOTOGRAPHIC SOCIETY.

THE Royal Photographic Society's annual exhibition at the Gallery of the Royal Society of British Artists, Suffolk Street, Haymarket, is well worth a visit by anyone interested in photography and its applications before it closes on October 4. Besides an excellent collection of works that are notable for their pictorial quality, and that will be examined by technicians as illustrations of the possibilities of the processes that they represent, there is a larger than usual number of colour transparencies, and also exhibits that are of specially scientific interest. The colour transparencies are chiefly autochromes, but there are many on the new Paget plate and a few "Dufays," both of which latter will quite well bear comparison with the autochromes for the quality of their colour and detail. In the scientific section, Lt.-Col. J. W. Gifford shows a large number of original photographs of spectra of the metals taken with a quartz optical train of large aperture. Mr. G. Reboul shows that cuprous chloride, produced by exposing a polished copper plate to chlorine gas, will furnish photographs by treatment somewhat similar to that employed in the production of daguerreotypes. The insecurity of intaglio plate printing for monetary documents is again demonstrated by Mr. A. E. Bawtree in his copies of stamps, the genuine stamp and the forgeries being indistinguishable. The photo-micrographic section is particularly strong. The method of discovering a difference in the colloids present in jams, and of detecting various adulterations, is excellently shown in a series of low-power photo-micrographs by Mr. E. Marriage. Of other series, the "Histology of the Optic Nerve of Sheep," by Mr. J. T. Holder; the "Corpuscular Elements of Human Blood," by Dr. D. H. Hutchinson; and Mr. J. M. Offord's "Diatoms under High Power," deserve special notice. There is a fine collection of radiographs by Dr. Bela Alexander, Dr. G. H. Rodman, Dr. Gilbert Scott, Dr. Robert Knox, and Dr. Thurstan Holland, some taken in a small fraction of a second. In this direction the most novel work is by M. Pierre Goby, who by the use of ultrasoft rays secures quite full details in the most delicate transparent membranes, such as insects' wings, at the same time as showing the internal structure of the insect. But more wonderful are his micro-radiographs, made by using the fine pencil of Röntgen rays that passes through a small hole in a lead screen. The detail in parts of small vertebrates only a fraction of an inch in length, is so well reproduced that a fifteen or seventeen times enlargement would be considered excellently sharp for a direct radiograph. M. Goby applies his method to foraminifera and other minute objects with similar success. Among the other exhibits there are a process with examples of a method of producing colour transparencies by the absorption of dyes in fish-glue, by Mr. Bawtree, and good collections of natural history photographs, lantern slides, and stereoscopic transparencies.

THE ARCHÆOLOGICAL INVESTIGATIONS IN THE MISSISSIPPI REGION.[1]

IN the publication referred to below Mr. Clarence B. Moore gives us another of his very careful descriptions of the systematic excavations he is undertaking in the Mississippi valley, and, as usual, it is profusely illustrated with most excellent photographs and coloured plates. By these investigations and the superb way in which he publishes his results, Mr. Moore is laying a sure foundation for future general-

[1] "Some Aboriginal Sites on Red River." By Clarence B. Moore. Journ. Acad. Nat. Sci., Philadelphia, xiv., 1912.

isations. The last year's work covered 519 miles of the Red River from its confluence with the Mississippi. Few burial places were found in Louisiana, as these were mainly in the often flooded level ground, and the artificial mounds were erected for places of residence; since most of the finds are obtained from graves the spoil was not very large, and as many of the mounds are now utilised they could not be satisfactorily investigated.

Along the Red River in Arkansas the conditions in the main are different; mounds containing burials, some of them richly endowed with artifacts, are fairly abundant, and further northward the lavish use of pottery with burials has often been described. It seems probable that the Arkansas mound burials were those of people of consequence. The pottery of Arkansas is as a rule tempered with fine gravel or sand, or with small bits of pottery, though kitchen vessels are often shell-tempered. The ware is thin and carefully modelled. There are few unusual shapes, grotesque or life forms were very rarely attempted, though they occur in the region to the north. Many vessels bear a high polish, and nearly all have incised designs filled in with red or white pigment. Circles, often series of concentric circles (probably sun-symbols), form a frequently recurring design. Decoration in polychrome was very exceptional, though common more to the north. A remarkable feature—indeed, it is unique—in connection with some of the mounds is the depth of the grave-pits; one reached 15·5 ft. in depth. Among several interesting pipes, two types have not been met with hitherto. One form, from Haley Place, is of earthenware, the truncate conical bowl of which occurs at some distance from the end, the terminal continuation of the stem being hollow; one is nearly 23 in. long. The other, from Gahagan, is moulded to represent a kneeling man; there is a communication between the bowl and the open mouth of the figure, so that smoke can be made to emerge from it when the pipe is in use (Fig. 1). A number of beautiful useful and ceremonial stone implements were found, and various interesting pendants, some of which have the form of a lizard; one was formerly coated with sheet copper, as were also the large circular ear-plugs of limestone. It is, however, impossible to point out all the items of interest in this memoir.

FIG. 1.

Dr. Hrdlička adds a notice on the human remains. He says the skeletons from Haley Place and the McClure mounds probably may be safely ascribed to an extension of the Natchez people; the skulls exhibited deformation of the "Flathead" variety.

A. C. HADDON.

MAGNETIC STORMS AND SOLAR PHENOMENA.[1]

IN the publication referred to below only the first thesis is printed. It deals with the relations between magnetic storms and solar phenomena. The thesis shows the nimbleness of mind one hopes to see in those who have taken high mathematical degrees at Cambridge, accompanied by a knowledge of terrestrial magnetism most unusual in British seats of learning. There are, it is true, researches bearing on the subjects investigated of which the author seems unaware, but his knowledge of foreign writings, including theoretical work by Kelvin, Larmor, Birkeland, Störmer, and Schuster, and observational work by Walker, Airy, Ellis, Maunder, Hale, and many others, is highly commendable. Also the attitude he adopts towards the work he criticises is generally philosophical. Thus, taking Kelvin's attempted demonstration that solar action cannot be the proximate cause of magnetic storms, Bosler points out that there are possibilities not considered by Kelvin making much smaller demands on the sun's stores of energy, and that in the light of modern knowledge no one can say what is a reasonable limit to solar expenditure. On the other hand, he recognises that Kelvin's work directed attention to a point apt to be overlooked.

Dr. Bosler regards his countryman Marchand (1887) as the first to claim a connection between the occurrence of magnetic storms and the presence of individual sun-spots or faculæ near the sun's central meridian, but he regards Maunder's observations on the recurrence of storms in the solar rotation period as the strongest evidence yet advanced in favour of this view. He seems to be unaware of Broun's early work. He apparently accepts Sabine's deduction of an eleven-year period—corresponding to the solar period—in magnetic disturbances, but while recognising the strength of the evidence adduced—especially that of Maunder—in favour of solar jet theories, he considers Dr. Schuster to have demonstrated the impossibility of swarms of any kind of electrified particles sticking together all the way from the sun to the earth. The view he inclines to is that earth currents are the immediate cause of most, if not all, magnetic disturbances. The evidence he advances in favour of this view is derived from comparisons of records of magnetic storms at Parc St. Maur and Greenwich—especially those known as "sudden commencements"—with corresponding records of earth currents. This from an observational point of view is probably the most important part of the thesis, though only partly novel.

The author thinks earth currents may be produced by movements of electrified matter—associated with protuberances, spots, or faculæ—on the sun. Taking the case of a cable of 0·25 cm.^{2} section, made of copper of resistivity 1600, enclosing a circle 8000 km. in perimeter, he calculates that the current induced in the cable by a magnetic field of amplitude 10γ and period 10 sec., normal to the plane of the circle, would at a distance of one metre from the wire produce an alternating magnetic field of amplitude 1250γ. This is adduced as an illustration of how a small field originating in the sun might be amplified on the earth. The idea may be worth considering, but the problem treated seems somewhat too remote from actuality. The magnetician will find a variety of other interesting matter in the thesis.

C. CHREE.

THE LIFE-HISTORY OF A WATER-BEETLE.[1]

THE life-history of a water-beetle can be outlined in a very few words. An egg is laid by the mother-beetle: an aquatic larva hatches out which feeds and grows, and, during the process of growth, moults several times. When full grown it leaves the water and burrows into the earth, forming a "cell," in which it changes to a pupa. After a time the pupal skin is cast off, and the perfect insect makes its way out of the cell and resumes its life in the water.

There are, however, all sorts of interesting details in the life-history, and these details often differ considerably in different types. There are differences in the egg-laying habits; differences in the method of development of the embryo; differences in the way the larva gets out of the egg; differences in the way it feeds and in the nature of its food, and so on; and it is these differences which are of importance to each species in enabling it to fit in among other species in the life of the community.

Although there are a number of widely separated species of beetles which inhabit the water, there are two groups which are usually referred to as "water-beetles," and these may be broadly distinguished as the swimming carnivorous group—the Hydradephaga—and the creeping herbivorous group—the Palpicornia, or Hydrophilidæ. The description of this second group is not strictly accurate, as the larvæ are, apparently without exception, carnivorous, and the perfect insects, although capable of subsisting upon a vegetable diet, in at least many cases enjoy animal food; and although they are somewhat differently constructed from the swimming water-beetles, some of them are very fair swimmers.

I propose to outline the life-history of a type of the Hydradephaga, and then to compare with it a type of the Palpicornia; and as a type of the former group I will describe a species of Dytiscus, *D. lapponicus*, the life-history of which I worked out during last summer.

The male and female differ in general appearance, the former having smooth wing-cases, the latter having these grooved or fluted. The male has also a pad on each of the front legs, while the female has quite simple front legs. The slide also shows a full-grown larva, and thus gives an idea of the relative sizes of these two stages of the species.

This species is extremely local in the British Islands, only having been found in a few localities in Scotland, and in one in north-west Ireland. It inhabits lochs, usually mere lochans, at altitudes of from 800 ft. upward, and there are certain characteristics about its habitat which make it possible generally to tell at a glance whether a particular lochan is or is not likely to hold the species.

As a rule the habitat is a bare stony lochan, with very little vegetation; it has no stream flowing into or out of it, and trout and *lapponicus* are mutually exclusive. There are usually newts and fresh-water shrimps (*gammarus*), but otherwise there is always a marked scarcity of animal life. Very few other water-beetles are associated with *lapponicus*, which usually is abundant where it occurs.

The only place I have found the species in great abundance is in a lochan 950 ft. above sea-level on the island of Eigg. Along its eastern side this lochan is strewn with large stones, and under these the beetle is to be found, often as many as four or five under one stone. It occurs in other lochans on Eigg, and has been found also in Rhum, Skye, Mull, and Arran, but otherwise it is only known from Inverness-shire.

One place in Mull where it used to occur abundantly is a peculiar loch, situated in the top of a hill, about 800 ft. behind Tobermory. The place looks like the crater of a volcano, but I believe is not so described by geologists. The species has apparently quite disappeared from this loch; it is probably slowly disappearing from our islands, being a remnant of the fauna which abounded when our climate was much colder than it is at present.

All my specimens came from the one lochan on Eigg, and they were placed in large tubs in my garden in the north of Ireland. The tubs are filled with water, but the bottom is covered by a thick layer of soil, and in the soil a few species of water plants thrive, chiefly the common water-grass, *Glyceria aquatica*. The tubs are covered with wire-gauze to prevent the beetles escaping.

Now the Dytiscus possesses a small apparatus capable of piercing the tissues of the water-plants, and each time this borer makes a hole in the water-plant one egg is deposited. In my tubs the *lapponicus* chose the water-grass as the receptacle for its eggs. In its native home this grass does not grow, the only water-plants being a common rush, a species of *juncus*, and the club rush *eleocharis*, both possessing round stems. Now, the grass possesses a round stem surrounded by leaves, each leaf consisting of a long sheathing base and a free lamina or blade. The sheath is keeled, and in every case the mother-beetle pierced the leaf-sheath, and always in the line of the keel, depositing the egg in the tissues of the sheath, and this shows the peculiar instinct possessed by the mother in the deposition of her eggs and the extreme sensitiveness of the borer or ovipositor. Although I examined very carefully the plants in the tubs, only twice did I find that the ovipositor had passed right through the sheath and dropped the egg between that and the stem.

Lapponicus, unlike our other species of Dytiscus has a very definite egg-laying period, commencing in March and ending in June. From two of the British species I have had eggs in October, December, and February, as well as in the summer months.

I collected a number of the eggs, dissecting them out of the leaf-sheaths, and placed them on wet cotton wool in tumblers and watched their development.

I do not intend to weary you with the details of the development of the embryo, but I wish to point out that the embryo first appears on a part of one side of the mass of yolk—it does not at first occupy the whole length of the egg—and it then extends first backwards and then forwards, and the sides grow up around the yolk until the embryo ultimately encloses it. The nerve-chord does not increase in length with the embryo, and consequently appears to shorten as the embryo extends in the egg.

The development of the embryo occupies about three weeks in June, but temperature affects the length of this embryonic period. In the case of another species, an egg laid in April matured in three weeks, while one laid in winter took six weeks to hatch.

Towards the end of the embryonic period the pressure of the embryo in the shell is very great. I accidentally punctured an egg with a needle when turning it over, and immediately a portion of the embryo bulged through, just as the inner tube of a pneumatic tyre tends to bulge through a tear in the outer cover. The pressure is also indicated by the changed shape of the egg during the final stages.

During the latter part of the egg-period, there are various slight movements of the embryo, but during the last few hours certain very definite movements

[1] Discourse delivered at the Royal Institution on Friday, May 9, by F. Balfour Browne.

become noticeable. In the first place, inside the head a spasmodic pulsation is visible, at first at long intervals, but later more or less continuously. I have observed this pulsation in eggs of other water-beetles, and also in those of the dragon-fly, and although I am not sure that the interpretation is the same in dragon-fly and water-beetle, I am satisfied in the latter case the pulsation is really a swallowing process.

The larvæ of all the water-beetles I have examined possess a special sucking apparatus known as a "pharyngeal pump," the use of which I shall describe directly, and in the embryo this pump apparently comes into use to absorb the fluid which surrounds the embryo in the shell; the embryo merely drinks this up.

After this sucking-pump begins to work, various other movements of the internal organs can be observed, including peristalsis, and also at infrequent intervals the whole body moves slightly in the shell, the tendency being to push the head into the end. One other movement is to be noted, and that is an up-and-down motion of the head, at first very slight, but later becoming very marked.

On either side of the head is a small papilla, at the apex of which is a minute, slightly curved spine. When the embryo is at rest, this papilla lies in a slight depression, but when the sucking-pump is at work the papilla bulges outward, so that the spine touches the shell. Thus when the head moves up and down and the sucking-pump works at the same time, the two spines scrape along the inside of the shell and ultimately burst it open. They are, therefore, "hatching spines," and similar instruments differently situated have been observed in a few insect embryos of other orders.

You see, therefore, that the shell bursts open at the head end; immediately it bursts the compressed larva bulges out, and by slight writhing movements works its way clear of the shell, the whole operation taking less than two minutes. As soon as the larva is clear of the shell the tail straightens out, and the legs and mouth parts assume their natural position. In the embryo there is a peculiar fold in the upper part of each jaw, but within two or three minutes of the larva's escape this fold has completely disappeared.

From the moment the larva escapes it begins to grow in length and breadth. The long air-tubes in the body are flat, but have a bright silvery appearance, suggesting that some gas has been secreted in them; but the larva is heavier than the water, and therefore sinks to the bottom. For a time, half an hour or more, it rests quietly and shows no desire to get to the surface, but sooner or later it gets restless and swims to the surface, using its feathered legs as oars, and raises its tail to the surface film and remains suspended for a few minutes. After this the newly hatched larva is buoyant, and cannot remain away from the surface without holding on to the submerged vegetation. The buoyancy is, however, only temporary, as older larvæ frequently require to swim to the surface to renew their air-supply.

In the insect, breathing and blood-circulation are normally not intimately associated as in other animals. In a human being or a fish, or even in a snail, air is taken into special organs—lungs or gills—where the blood takes up the oxygen and carries it through the whole body. In the insect the blood has usually nothing to do with the aëration of the different organs, the whole body being permeated by innumerable air-tubes.

In all the water-beetle larvæ which come to the surface to obtain their air, these innumerable air-tubes communicate with two large air-tubes which run the length of the body, one on each side, and these open on the last segment. Hence, when a larva requires to renew its air-supply it comes up tail first, bringing the openings of the two lateral tracheæ into communication with the air, and by contracting and expanding the body it exhales the used-up air and inhales fresh air.

For a day or so after hatching the larva is soft and is not hungry, but once its skin and jaws have hardened it begins to look about for food. I found that tadpoles and pieces of chopped worm were suitable food, but under natural conditions small newts, water-shrimps, and insect larvæ—including brothers and sisters—constitute the normal diet. It is impossible to keep two larvæ together in one small vessel, as one invariably attacks and kills the other within a few hours. Even when I gave a tub to four specimens only one survived after a few weeks, so that in a small loch, where at least some thousands of these larvæ hatch out, the death-rate must be enormous.

The method of feeding of the larva is peculiar. The two long sharply pointed jaws are each pierced with a fine tube, of which one end opens on the inner side just below the apex, and the other end opens on the upper side just near the base. When the jaws are closed the inner ends of these tubes communicate with the corners of the mouth, but when the jaws are open the inner ends of these tubes do not communicate with the mouth at all. The mouth itself is also peculiar. In a front view of the head it is visible as a long narrow slit between the bases of the jaws, but if this slit is examined it is found that across the lower side of it is a raised ridge which fits into a groove running across the upper side of it. When the jaws are wide apart the ridge and groove are separated, and the mouth is open, but as soon as the jaws come together the ridge fits into the groove, and the mouth is closed. As soon, therefore, as the larva seizes its prey its mouth is closed, and the only communication into it is through the tubes in the jaws, the basal ends of which now open into the corners of the mouth.

Immediately behind the mouth is the powerful sucking-pump, the pharynx, which I mentioned in connection with the embryo. By expansion and contraction of its muscles it sucks in the juices of the prey through the tubes in the jaws. But if this were the whole process of feeding there would be a considerable waste, as a worm or a tadpole consists of a large amount of solid material; and yet, if one watches one of these larvæ feeding, one will find that almost nothing is left of the prey except the skin. This is due to the fact that at short intervals the sucking-pump stops working and saliva is poured into the prey. This saliva digests and dissolves away the solid parts of the food, which are then sucked in by the larva. The process of digestion, which in most animals takes place internally, is carried on in these larvæ outside the body.

With regard to the *duration of the larval period*, in my examples this varied from six to nine weeks. This period is divided into three stages, there being two moults prior to the final one which produces the pupa. Each of the first two stages only lasts about ten days, so that the last stage is a very long one, as it is in all other insects.

This last stage is also divisible into two parts, the first occupying four or five weeks, during which the larva feeds and grows as in the previous stages, the second occupying two to four weeks, being spent out of the water making a cell in the earth, and resting preparatory to becoming a pupa.

In the few cases which I had the opportunity of observing, the full-grown larva always left the water in the morning between eight and ten o'clock; but whether this is the rule with this species, or whether it was connected with the artificial conditions in which my larvæ were reared, I do not know.

Once the larva leaves the water it crawls about very actively, seeking a suitable place to enter the earth. If left to itself it usually selected a stone and burrowed underneath it, but I found that if I made an artificial burrow—with a pencil, for instance—the larva could be made to crawl into this, and as a rule would make its "cell" in it. By making such a burrow against the glass side of a box filled with earth, I was able to watch the process of the formation of the pupal cell.

Once the larva has entered and adopted the burrow, it straightway begins to prepare its cell, and this is done by enlarging part of the burrow. The jaws are now used for transporting pellets of soil from one position to another, and for breaking up the pellets into their separate particles. Very little earth is actually pushed into the unused part of the burrow, the cell being formed almost entirely by breaking up the pellets of soil and battering the fine particles against the sides. The vertex of the head is the main battering-ram, but the larva, which during the whole process of making the cell lies with its tail bent over its head, also flattens out the earth with its body.

The actual making of the cell occupies about twelve hours, and during that time the larva does not rest for a moment. At the end of that time it is apparently tired out, and rests in any position, often stretched across the cell, its head pressed against one side and its curved body against the other. It thus rests for about twenty-four hours, after which it bends its tail underneath it and usually adopts a sitting-up position—reminding one of Tenniel's illustration in "Alice in Wonderland" of the caterpillar sitting on the mushroom. It is, however, very restless, and frequently changes its position, tossing from side to side.

The pupa appears, after the larva has been thus resting for a fortnight or more, by the larval skin splitting along the back and being cast off at the tail end. On its back are to be seen a number of short projecting spines, and Lyonnet suggested in the case of another pupa, similarly though better equipped, that these are for the purpose of raising it off the damp soil of the cell. This may be true, but in my experience the pupa most usually lies, so to speak, on its face rather than on its back.

The pupal stage lasts about three weeks, and the only change noticeable during that time is a slight pigmentation of what is at first a perfectly white pupa. At the end of the pupal stage the skin ruptures along the back, and the perfect insect comes forth at first white and soft, but in the course of two or three days it assumes its normal coloration, and after a longer period its normal hardness. After a week or so it makes its way out of the pupal cell by biting and scraping, and at once goes to the water.

In its native haunts it spends most of its time amongst the stones and mud at the bottom, occasionally coming up to renew its air-supply, and in my tubs also it was seldom to be seen.

With regard to its winter habits, it apparently buries itself at the bottom of the loch as soon as the cold weather begins, and sleeps until the following spring. In my tubs it disappeared completely in October or November, burrowing deep into the soft oozy mud at the bottom, and there it remained until the following March. During all this time the metabolic processes must be practically at a standstill, as otherwise the insect would require to renew its air-supply at frequent intervals.

Having now outlined the life-history of this type of the swimming carnivorous water-beetles, I will take an example of the other group, and the one I have chosen goes by the name of *Hydrocharis caraboides*. There is only one species of Hydrocharis in the British Islands, and it is practically confined to the south-east of England, only very occasionally having been found anywhere else in the country. It inhabits stagnant ponds and drains, and is not uncommon in a few places in Surrey, Essex, and Middlesex.

I began to experiment with it five years ago in the north-east of Ireland, having obtained my specimens from Surrey. Each year I obtained eggs, reared the larvæ, and renewed and increased my stock, so that it is obviously not the climate of north-eastern Ireland which prevents this species from being a native there.

The conditions in my tubs were just such as are to be found in any pond or drain in the country, and apparently the only reason why this species is confined to the south-east of England is that competing species prevent it from extending its range.

Whereas Dytiscus lays its eggs singly in holes pierced by it in the living vegetation, Hydrocharis builds an elaborate silken cocoon which floats in the water, and in which about fifty eggs are deposited.

The spinning of the cocoon is a wonderful process. The beetle carries on its underside a film of air, which is part of its supply for breathing. The cocoon is actually spun on a part of this film of air, which is then detached from the rest of the film as a bubble enclosed in silk. The egg-laying commences soon after the cocoon is begun, and the eggs are arranged side by side in the cocoon standing upon one end, being fastened in position by silken threads. A space above the eggs is filled with very loosely woven silk.

In closing up the cocoon a peculiar plate-like structure is formed of very closely woven silk, and this ends in an upward projection known as the "mast." The purpose of this "mast" is not known. It is not a tubular structure, but merely a band of silk. It has been stated that if it is cut off the eggs die, but in the case of another species I have hatched eggs removed from the cocoon and submerged, so that the suggestion that the mast is necessary for keeping up the air-supply is without foundation.

I shall not weary you with details of the development of the embryo beyond mentioning that, unlike Dytiscus, the embryo from the first occupies the whole length of the egg, and that the nerve chord, again unlike Dytiscus, grows with the embryo as it develops. The only other point I need mention is that in the cocoon all the embryos develop head downwards.

The egg-laying period of Hydrocharis extends from about the middle of May until about the middle of July in my tubs, but it may perhaps be rather longer in the south-eastern parts of England. The incubation of the egg occupies nine or ten days, and, as in the case of Dytiscus, towards the end the embryo is very tightly packed within the shell. There is, however, no special hatching apparatus that I have been able to find. The pulsating organ or sucking-pump in the head is visible, and there are also movements of the embryo, but at the end the skin splits along the back and the larva treads it off, giving a peculiar backward wriggle.

Now, under normal conditions the newly hatched larva does not at once leave the cocoon; in fact, it does not appear for one or even two days after hatching. As soon as it bursts the egg-shell it wriggles backwards out of the egg into the space above all the eggs, and it is interesting to note that the hairs on the body of the newly hatched larva all point forwards. As the larvæ hatch, the empty shell and the silk bindings become broken down—I think they are chewed by the larvæ—and the whole cocoon ultimately becomes filled with the larvæ.

In those cases where I dissected the eggs out of the cocoon and allowed them to develop on the wet cotton wool, the newly hatched larvæ congregated into a mass and remained so for a day or two, after which they became active in search of food.

You will notice that the larva possesses on each body segment a pair of lateral processes, and on the last segment a pair of ventrally placed processes of a different kind. These latter, which are possessed by all water-beetle larvæ which come to the surface for their air, have probably some connection with raising the tail to the surface for breathing, but the hairy lateral processes have been called gills. Many larvæ of the Palpicornia have lateral processes, usually smaller than those of Hydrocharis, but in no case are they really gills, and the larvæ quickly drown if prevented from bringing their tails to the surface to renew their air-supply.

The larvæ of Hydrocharis, like those of Dytiscus, will eat almost any kind of animal matter, and hence they are easily supplied. I fed them mostly upon chopped worms, but their method of feeding is very different from that of Dytiscus. They seize their food with the jaws, antennæ, and the other mouth parts, and they then come to the surface, and raising their heads and part of the body out of the water, they proceed to chew up the food by opening and closing the jaws, turning it from time to time with the other mouth parts. The jaws are not perforated, nor is there any mouth-lock as in Dytiscus, and they suck in the juices of the prey by the mouth, spitting up saliva at intervals, which actually froths over the food and digests it, the dissolved material then being sucked down. The external digestion is so complete that in the case of a thick piece of worm all that is ultimately rejected is the thin transparent outer pellicle.

In the mouth parts of the larva I want to direct your attention to a curious want of bilateral symmetry, noticeable not only in the jaws—one of which, the left, has a small extra tooth near its base—but also in the upper lip. In many species there is an absence of bilateral symmetry where a pair of organs are complementary. Thus in the jaws of the beetle itself, the base of the left one is hollowed out to receive the base of the right one, which is convex, the two being related as pestle and mortar for grinding up the food. The larva of another species of the same group also shows asymmetry of the jaws, but here again it is definitely associated with the method of feeding. This species feeds upon pond snails, and the left jaw holds the shell while the right jaw with its large double tooth cuts through it.

The asymmetry of the upper lip, however, is at present inexplicable, and, curiously enough, it occurs in several other species.

The larva of Hydrocharis, like that of Dytiscus, passes through three stages, the first two of which occupy from five to eight days, and the third stage, up to the time the larva is full grown, occupies about four weeks. It then leaves the water and burrows into the earth, forming a cell, just as the Dytiscus larva did. I had many specimens of these larvæ, and so made many experiments with them, and one curious fact about them is that the instinct which leads them to burrow into the ground and make a pupal cell only lasts for one or, at most, two days. In no case, where I removed a larva even immediately after the completion of its cell, did it make any attempt to form another one, and if left on the surface of the soil it moved about listlessly and ultimately died, apparently of drought, since if placed in a damp position, for instance, in an artificial cell, it survived and pupated. If a cell was damaged before completion the larva often completely destroyed it, apparently in the attempt to repair the damage, and would be found sitting amongst the ruins.

Once the cell is completed the larva rests for about three weeks, at the end of which time the skin is cast off and a greenish-white pupa appears. This is more spinose than that of Dytiscus; but it also prefers to lie upon its face, resting upon the two small tail projections and upon the "collar" of the prothorax.

The perfect insect appears after about ten days, so that the whole life-cycle occupies about nine or ten weeks from the laying of the egg to the appearance of the perfect insect. This time, however, may be greatly prolonged under less favourable conditions. Thus, the later egg-cocoons produce larvæ which take twelve or fourteen weeks to grow up, and the cocoons built in July produce beetles which do not leave the pupal cell for six or seven months. The larvæ leave the water in September and even in October, and after three or four weeks turn into pupæ. These pupæ turn into beetles in late October or November, but the beetles remain, apparently torpid, until the following March or April, when they make their way out and to the water.

I have mentioned that the larvæ of both Dytiscus and Hydrocharis breathe in the same manner by raising the tail to the surface. The perfect insects, however, assume very different positions when taking in their air-supply.

Dytiscus floats up to the surface tail first, taking in air between the body and the great wing-cases which cover it, and it is in this cavity under the wing-cases that the whole reserve of air is carried.

On either side of the body under the wing-cases is a row of pits, spiracles; the last pair of these are much larger than the others. When the insect rises tail first to the surface, the tubes connected with this last pair contract and expand, just as in the larva, renewing the air-supply in the whole tube system, while at the same time the body contracts and expands, renewing the reserve supply under the wing-cases.

Hydrocharis, on the other hand, comes to the surface head first, turns its head on one side, and pushes its short, club-like antenna through the surface-film. Now a large part of the under side of this beetle is covered with fine velvety hair, which retains a thin film of air upon it, just as a piece of velvet does when gently pushed under water. When the beetle raises its antenna above the water it brings this film of air into communication with the air above the water. It also has a reserve supply under its wing-cases, and this communicates at the sides with the ventral film, and by expansion and contraction of the body the used-up air is expelled above the water and fresh air is taken in. In Hydrocharis the most important spiracles are situated well forward, and thus the used air from the air-tubes is expelled and fresh air taken in at the front end of the body instead of the tail end.

Anyone who examines Hydrocharis and compares it with Dytiscus will at once see great structural differences. In a ventral view of the two types, comparing the heads, the most noticeable difference is in the antennæ, which are filamentous in the former and clubbed in the latter, and the maxillary palpi, which are short in the former and long in the latter, in which they are used under water as feelers, just as are the antennæ of Dytiscus.

Passing over other less remarkable differences in the heads of the two types and coming to the body, one at once notices the different disposition of the legs: in Dytiscus the first two pairs are close together, in Hydrocharis the three pairs are about equidistant. In Dytiscus the basal segment of each hind leg—the coxa marked 3* on the screen is large, and the two coxæ are fused into a single piece which is firmly fixed into the body. In Hydrocharis the coxa is long and narrow; the two coxæ are separate, and each is hinged on to the body. The firm fixing in Dytiscus gives it a much more powerful leg-drive than the hinging gives to Hydrocharis, and hence Dytiscus is a more efficient swimmer.

These differences between the two types are therefore connected with differences in function. The antennæ of Dytiscus are feelers, while those of Hydrocharis are connected with breathing, and the disposition of the legs and their methods of attachment to the body are connected with differences in mode of progression, Dytiscus being a "swimmer," and Hydrocharis chiefly a "creeper" on the submerged vegetation.

In these two groups of water-beetles, the Hydradephaga represented by Dytiscus and the Palpicornia represented by Hydrocharis, we have two types of adaptation to an aquatic existence. Each type has originated independently of the other—that is, they are not descended from a common aquatic ancestor. Each represents a part of a large terrestrial family, and each has probably developed an aquatic habit as a result of competition, stronger land forms having driven the weaker off the land and into the water.

Just as each group has originated under the stimulus of competition, so, within each group, competition has moulded the different forms, and the peculiar details in the life-history of any one form are just those which enable it to retain its place in the community to which it belongs, and to hold its own in the great struggle for existence.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE announcement is made of the resignation of Dr. A. L. Bowley of the professorship of mathematics and economics at University College, Reading.

PROF. J. S. KINGSLEY, of Tufts College, has been appointed professor of zoology, in charge of vertebrates, in the University of Illinois.

DR. K. F. MEYER, director of the laboratories of the Pennsylvania State Livestock Sanitary Board, has vacated that position to fill the chair of bacteriology at the University of California. Dr. J. B. Hardenbergh has been appointed to succeed Dr. Meyer in the first-named post.

PROF. HERBERT V. NEAL, who has held the chair of biology at Knox College, Illinois, since 1897, has accepted an appointment to a similar post at Tufts College, Massachusetts. He has already had some acquaintance with the work of that college, having been for the last five years an associate director of the Tufts biological laboratory at S. Harpswell, Maine.

IT is announced in *The Indian Medical Gazette* that the scheme for the establishment of a School of Tropical Medicine in Calcutta is now so far advanced towards fulfilment that there is every reason to hope that it will be opened in the autumn of next year. Already valuable work on cholera, epidemic dropsy, dysentery, and other diseases has been done by a few workers in Calcutta. What is now wanted is money. Our Indian contemporary asks for substantial endowments of three or four lakhs for several additional research chairs, or annual subscriptions of 20,000 rupees for each.

AN effort is about to be made to raise a fund of 20,000*l*. for the foundation of a chair of engineering chemistry at Princeton University. This campaign will be undertaken mainly by members of the federation of Pinceton clubs of New Jersey, with the object of the advancement of chemical industries in that State. The course of instruction to be given by the occupant of the proposed chair will supply engineering students with a knowledge of the commonest construction materials of the chemical industries, and of various materials that now take the place of the direct products of the soil.

A COURSE of lectures on tuberculosis, for general practitioners and especially for candidates as tuberculosis officers, has been arranged by the Royal Institute of Public Health. The introductory lecture will be delivered by Prof. G. Sims Woodhead on October 10. Subsequent discourses will be given by Dr. C. Porter ("The problem of Tuberculosis in relation to Insurance and Public Health"), by Prof. Woodhead ("The Spread of Tuberculosis"), by Dr. J. E. Squire ("Diagnosis"), by Dr. T. N. Kelynack ("Tuberculosis in Childhood"), by Dr. C. Wall ("General Treatment"), by Dr. C. Riviere ("Specific Treatment," &c.), by Dr. T. D. Lister ("Sanatorium Treatment"), by Dr. A. Greenwood ("The Prevention of Tuberculosis"), and Dr. H. O. West will outline a co-ordinated scheme for dealing with the malady.

THE medical schools of London and the provinces are beginning to announce the opening functions of their winter session. Prof. Sir William Osler, Bart., F.R.S., is to distribute the prizes and deliver an address at St. George's Hospital on October 1; at St. Mary's Hospital, Paddington, the prizes will be presented and an address given by Sir John Prescott Hewett, K.C.S.I., on the same date; Mr. W. Sampson Handley will deliver an address and Sir Squire Bancroft distribute the prizes at the Middlesex Hospital on October 1, on which date also Sir Charles Pardey Lukis, K.C.S.I., will give an address at the London School of Medicine for Women. On October 7 a lecture will be delivered at the University of Birmingham by Prof. Arthur Keith, F.R.S., on "The Present Problems relating to the Antiquity of Man"

MUCH interesting information as to the progress of secondary education in England is contained in the recently published Blue-book (Cd. 6934), "Statistics of Public Education in England and Wales, Part i. Educational Statistics, 1911–12." During the school year dealt with, there were in England 885 efficient secondary schools receiving grants from the Board of Education; of these 358 were for boys, 311 for girls, and 216 admitted both boys and girls. The teaching in these schools was in the hands of 9126 full-time teachers, of whom 4584 were men and 4542 women; and they were assisted by 3082 part-time instructors. The schools were attended by 150,605 pupils 81,383 boys and 69,222 girls. Of the total number of pupils 30,427 were under twelve years of age, 98,623 were between twelve and sixteen years of age, 11,553 between sixteen and eighteen years of age, and 0·6 more than eighteen years of age. As regards the management of the schools, it may be pointed out that 328 were provided by local education authorities, 427 were foundation and other schools, 48 were Roman Catholic schools, and 28 Girls' Public Day School Trust schools.

THE prospectus for the session 1913–14 of the Day and Evening College for Men and Women at the South-Western Polytechnic Institute, Chelsea, has been received. The day college is intended for students above the age of sixteen, and the courses of study are suited for technological and university purposes. The prospectus, we observe, points out that those who enter for technical instruction should have received previously a sound English education and should have acquired an elementary knowledge of mathematics and, if possible, of physics and chemistry. The courses are arranged to occupy three years.

On entering the student is asked to state whether he wishes to be trained as a mechanical or electrical engineer, or as a consulting or industrial chemist. In any of these cases he will find mapped out for him a complete course of study, involving laboratory instruction, tutorial work, attendance at lectures, exercises in mathematics, geometrical, mechanical, and architectural drawing, and instruction in the workshops. Evening courses in almost every branch of pure and applied science have been arranged at very moderate fees, and in their anxiety that no properly qualified person should be debarred from attending classes through inability to pay fees, the governors have arranged that apprentices, learners, and improvers, under the age of twenty-one years, may be admitted to all classes and courses at half-fees, on production of their employer's certificate.

The prospectus of the Belfast Municipal Technical Institute for next session has been received. The object of the institute is to provide instruction in the principles of those arts and sciences which bear upon the industries of Belfast, and to show by experiment how these principles may be applied to their advancement. A day technical course has been established to give instruction in mechanical engineering, electrical engineering, the textile industries, and pure and applied chemistry. The course provides a sound training for youths who aim at filling positions of responsibility in various industries. A trade preparatory school, which constitutes a junior section of the day technical department, provides a specialised training for boys who are intended for industrial occupations. The evening classes are suitable for persons engaged during the day who desire to supplement the knowledge and experience gained in the workshop or warehouse. The needs of women are catered for in the same complete manner as those for men. It is not possible here to enumerate all the interesting ways in which the technical instruction committee has endeavoured to assist local industries, but mention may be made of the public textile testing and conditioning house which has been opened in the institute. It undertakes the examination of textile materials with the view of ascertaining their true weight, length, strength, and so on; and it carries out such other investigations as manufacturers and others may desire.

Pamphlets giving full particulars in connection with the faculty of medical sciences and with the faculty of engineering for the coming session have been published by University College, London. The college faculty of medical sciences comprises the departments of physics, chemistry, botany, and zoology (the preliminary medical sciences), also the departments of anatomy, physiology, and pharmacology (the intermediate medical sciences), and the departments of hygiene and public health, and of pathological chemistry (post-graduate study). Full preliminary and intermediate courses of study are provided for students desirous of obtaining the medical degrees of the University of London, as well as for students seeking the qualifications of other universities and licensing bodies. Each of the departments is also equipped for more advanced work, and provides facilities for research. The faculty of engineering, including the departments of mechanical, heating and ventilating, electrical, civil and municipal engineering, is intended to provide for students wishing to devote themselves to engineering a systematic training in the application of scientific principles to industrial purposes. The courses are also suited to the requirements of students who intend to enter for appointments in the Indian Public Works Department, Engineering Department of the General Post Office, Department of the Director of Engineering and Architectural Works in the Admiralty, Patent Office, and other similar services, or of those who intend to become patent agents, technical teachers, and chemical engineers. The engineering departments have been recognised by the Board of Trade as providing suitable technical training for marine engineers. Facilities are provided for post-graduate and research work in all the subjects.

The Yorkshire Summer School of Geography, organised this year by the University of Leeds, completed a successful inaugural session on August 23. More than a hundred students were in residence for three weeks at and near Whitby, the headquarters being in the new buildings of the County School, which were kindly lent for the purpose by the governors. Systematic instruction in the methods of modern geographical study was aimed at by choosing Yorkshire as a representative area, and studying as exhaustively as possible all the factors and relationships connected with its structure and location. A course of five lectures on the physical geography and special geological features of the district was given by Prof. P. F. Kendall, together with lectures on the North Sea, and on meteorology by Mr. A. Gilligan. This led to the study of special topics of industrial or historical character, including plant distribution and agriculture (Dr. W. G. Smith), metalliferous and coal mining (Mr. A. Gilligan), the textile and metallurgical industries, ports, fisheries and communications (Mr. Ll. Rodwell Jones), prehistoric Yorkshire (Prof. P. F. Kendall), the Roman occupation (Mr. P. W. Dodd), Saxon and Danish Yorkshire (Mr. W. G. Collingwood), mediæval Yorkshire (Mr. H. B. McCall), architecture (Mr. S. D. Kitson), place-names and language (Prof. Moorman), Old Whitby as a port (Mr. E. H. Chapman), and river development (Prof. Kendall). The course concluded with two lectures on the teaching of geography by Mr. W. P. Welpton. The practical work included the reading and enlargement of topographical maps, the examination of typical rocks, the making of models and microscope sections, field surveys, and the reading and construction of meteorological charts. Frequent excursions were made to places of geological and industrial interest in the neighbourhood, and an afternoon was devoted to the study of a typical Yorkshire farm, with large-scale plans showing the rotation of crops on each field for the past four years.

SOCIETIES AND ACADEMIES.

Calcutta.

Asiatic Society of Bengal, August 6.—E. Digby. Nor'-westers and monsoon prediction. Nor'-westers have hitherto received little scientific attention. The entire literature is covered by a monograph by Sir John Eliot in 1876 and certain observations in a paper of his in 1910 on the anemographic records of Saugor Island. His observations and deductions are summarised. The structure of a typical nor'-wester is analysed. Its form and motion appear to show it is not a cyclonic eddy but a rectilinear splitting of the still-air layer between the lower southerly and upper northerly wind, which takes place transversely to the direction of motion of the storm mass. The absence of hail and the rapidity of the motion support this theory. A typically complete nor'-wester indicates a strong northerly upper current, and therefore the probability that the advance of the monsoon will be delayed. Weak or ill-formed nor'-westers indicate a weak upper current and little opposition to the monsoon. The factors that require study are briefly enumerated and divided into those which can be noted by individual observers and those which require co-ordinated effort.

THE STATE MYCOLOGIST IN THE COLONIES.

Handbook of Fungus Diseases of the Potato in Australia and their Treatment. By D. McAlpine, Department of Agriculture, Victoria. Pp. iii+215+1 map. (Melbourne: J. Kemp, Government Printer, 1912.)

THIS handbook records matters of scientific interest to economic mycologists in all countries, while, at the same time, it is written with the aim (which is certainly achieved) of giving valuable information and assistance in practical matters to the Australian farmer. In the latter direction Dr. McAlpine has performed, indeed, a public service.

The book deals in detail with *Phytophthora infestans, Alternaria solani,* Rhizoctonia, "scab," *Fusarium solani,* and *Bacillus solanacearum,* and is illustrated with 158 excellent photographs. In a very instructive appendix are given the various legislative "orders" relating to potato diseases which have been put into force under the "Vegetation Diseases Acts" and "Quarantine Act" of Australia.

The author states that in Australia the annual value of the crop is more than one-and-a-half million pounds sterling. He rightly insists on the economic importance of all steps being taken by the State, and by the individual, to safeguard the health of the crop, and remarks:—"Some of the worst diseases with which the [potato] grower has to contend in Britain and elsewhere are not known here, simply because the fungi causing them have not been introduced, and with a Quarantine Act in existence they are not likely to be."

The *educational* value of the legislation against plant-diseases is shown by the following observation:—

"There is a widespread desire on the part of growers to know more about the diseases of the potato, for the ignorance of the past can no longer be tolerated, since there is a rigid system of inspection to prevent diseased tubers passing from one State to another."

With regard to all the diseases mentioned, a number of highly interesting experiments and observations are recorded. In the case of *Phytophthora infestans* it is shown that sporangia can infect the unbroken skin of healthy tubers; and that the mycelium can remain living in a dried-up tuber ("as dead as a mummy," to quote the author's words) for more than four months. Interesting facts are given as to the different characteristics the disease shows in Australia, as compared with Great Britain and particularly Ireland; while the tubers are attacked in Australia, there is, generally speaking—owing to the prevailing hotter weather—no sudden blackening and decay of the tops. This difference not unnaturally led potato-growers in Australia, particularly those who had had experience of the "blight" in Ireland, to the error of supposing that the two diseases were distinct. (The speculation naturally suggests itself whether a distinct form of *P. infestans* may not arise in Australia, specialised to these new conditions of temperature and humidity.) It is found that the "kangaroo apple" (*Solanum aviculare*) serves as a host-plant; while it is stated that *S. nigrum,* a common weed in Australia, appears to be immune. Another very interesting fact which has been ascertained is the undoubted connection of the severity of the disease with the rainfall in different districts.

A full discussion is given of the life-history of *P. infestans.* Here, as with so many common fungous diseases, there are important gaps in our knowledge waiting to be filled; it is necessary to take every opportunity to point out that in no department of botany is research needed more than in economic mycology. The author remarks: "probably the mycelium remains dormant in the [potato] stalks"; such statements are to be deprecated—it is better to admit the absence of definite knowledge.

A series of experiments showed that the Fusarium of the potato and tomato are transferable; excellent photomicrographs are given of the life-history and stages of development of this fungus.

E. S. S.

PHYSICAL TRAINING.

Ma Leçon-Type d'entraînement complet et utilitaire. By Lieut. G. Hébert. Pp. 208. (Paris: Librairie Vuibert, 1913.) Price 1.75 francs.

ON reading this book most people interested in physical training will agree that although the training it describes may be *utilitaire,* it is certainly not *complet.* The training aims at the acquirement of strength and endurance, as do all forms of physical training and many forms of sport. But M. Hébert's system lacks the completeness and variety of the Swedish system, which is the system now used in our Army and Navy and in an increasing number of schools in this country. There is nothing M. Hébert claims for his method which is not equally true of the Swedish method.

M. Hébert divides exercises into seven classes: (1) marching; (2) running; (3) jumping; (4) climbing; (5) lifting; (6) throwing; (7) exercises of defence—boxing and wrestling. What are called balance movements in the Swedish system, as well as abdominal movements, are included in a truly "utilitarian" manner in climbing exercises. So far as abdominal movements are concerned, this does not allow graduation of resistance, which is a matter of importance. There is little variety of limb exercises, and the group of back exercises, so valuable for their corrective effect in regard to the faulty positions assumed in most occupations, are entirely omitted. Head and neck exercises are also omitted, while lateral trunk movements are only used as applied movements, and are therefore not graduated.

The more definite grouping of movements in the Swedish system allows of a more graduated and equal training for each part of the muscular system, each group of muscles, and, therefore, of the body as a whole. Free trunk movements, lateral and otherwise, are obviously of value in acquiring strength, flexibility, and complete coordination. Free arm movements are of greater value for the normal development of the arms and chest than movements of lifting and throwing.

In a Swedish gymnastic lesson the hardest work is performed in the middle of the lesson, the amount of exertion being graduated throughout. M. Hébert also graduates the amount of work, but leaves the hardest work to be performed towards the end of the lesson. The effect of the former method on circulation and respiration, and on the distribution of blood in the body, is more desirable physiologically.

M. Hébert lays due stress on the importance of deep breathing, and of complete expiration as well as inspiration. On the other hand, he recommends as an exercise slow marching, breathing in during four to six steps, breathing out during four to six steps, either with or without an intermediate respiratory pause with expanded chest for one or two steps. This method of breathing would undoubtedly tend to produce over-expansion of the chest, with loss of elasticity and accompanying emphysema. Marching with the hands crossed behind the back (Fig. 18) also tends to fix the chest and hinder complete expiration, besides producing a bad position of the shoulders and often hollow back. Sun and air baths and gymnastics in the open air are recommended, the body being uncovered except for a short pair of drawers, unless the weather is specially inclement, or the sun very hot, when a protective covering for the head and back of the neck is added.

The illustrations as a whole are excellent, although some of those which illustrate jumping appear to show that the height of the jump is considered more than the correctness of the attitude in jumping (Fig. 94).

The book is arranged clearly, and is much more readable than the more severe and "complete" gymnastic treatises.

MINA L. DOBBIE.

OUR BOOKSHELF.

L'Aviation. By Prof. P. Painlevé, Prof. E. Borel, and Ch. Maurain. Sixième edition. Pp. viii+298. (Paris: Librairie Felix Alcan, 1913.) Price 3 francs 50 centimes.

WRITTEN by well-known members of the French aeronautical professions, the book provides a simple and interesting account of the position of aviation at the present time. The text rarely deals quantitatively with the problems connected with the construction or motion of an aeroplane, calculations being left to notes at the end of the book; the notes occupy about one-third of the whole, and refer to investigations many of which are the original work of the authors.

Only a very short historical portion is provided as introduction, but it is interesting to find that the work of Sir George Cayley, as a pioneer in the development of the theory of the aeroplane, is prominently referred to. The "coming of the aeroplane" is dated from the autumn of 1908, when the flights of Farman, Delagrange, Blériot, and the striking achievements of the Wright Brothers began to attract attention; the subsequent rapid development of aviation and its causes are referred to and illustrated by means of a record of the best results obtained at successive stages.

A discussion of the flight of birds in winds, on the lines of Langley's "Internal work of the Wind," is used to illustrate the possibility of extracting energy from the wind, and so flying without the use of an engine.

Aeroplanes of various types, made in the period 1908–10, are illustrated, and the organs described in some detail. The use of the elevator and rudder in manœuvring is referred to under gliders, but stability, longitudinal and lateral, is referred to power-driven machines. Lateral stability is subdivided into "stability of gyration," that is, stability of direction relative to the wind and "lateral stability" in the limited sense of keeping an even keel. Bryan has shown that the subdivision may be misleading as the two are not independent, and should be treated together.

The book has the advantage of a very complete index, which makes reference a simple matter.

Household Bacteriology: For Students in Domestic Science. By Estelle D. Buchanan and Prof. R. E. Buchanan. Pp. xv+536. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 10*s*. net.

"DOMESTIC science" is rightly coming to the fore, and in any course of instruction devoted to this subject, some amount of bacteriology, or "microbiology," as it may preferably be termed, must be included. The present volume practically covers the ground of such knowledge of micro-organisms as is desirable for the domestic science student. It is divided into five sections, dealing respectively with (a) morphology and classification; (b) cultivation and methods of investigation; (c) physiology; (d) fermentation; and (e) micro-organisms in relation to health and disease. The bacteria, yeasts, and moulds are considered at some length, and a chapter on parasitic Protozoa is included.

The chapters on general morphology and classification are particularly good, and a clear account is furnished of the distinguishing features of the various groups. In an appendix an illustrated key is given of the families and genera of the common moulds; this will be found most useful in the laboratory by other than domestic science students.

The brief description of the optics of the immersion system of lenses is correct, so far as it goes, but a paragraph should have been inserted pointing out that the great advantage of this system is the increased resoluion obtained thereby.

The chapter on food preservation is a useful summary of the subject, but might have been extended with advantage.

The chapters on the nitrogen cycle in nature, alcoholic and other fermentations, enzyme action, and the ripening of certain foods are all satisfactory and convey a considerable amount of coordinated information on these important aspects of microbiology.

Much space (140 pages) is devoted to a consideration of disease and disease-producing micro-organisms, vegetable and protozoal. We think this section could have been somewhat curtailed with advantage, having regard to the avowed limitation of the book; and the space so gained might then have been devoted to a fuller consideration of certain aspects of household microbiology. Such criticisms as have been offered are those of detail, but the book as a whole is an excellent one. It is profusely and well illustrated, and can be strongly recommended not only to the domestic science student, but to a wider public.

R. T. Hewlett.

Aus Süd-Brasilien. Erinnerungen und Aufzeichnungen. By Dr. W. Breitenbach. Pp. xvi+251. (Brackwede i. W.: Dr. W. Breitenbach, 1913.) Price 3 marks.

The author has lived in southern Brazil for several years in order to observe the land and the people, especially the German colonies, and beginning in the year 1884, he has since described his observations in more than thirty newspaper articles, essays, and separate pamphlets. Considering the changes which have come about in Brazil within the last thirty years, this book does not pretend to deal with present-day questions of commerce, industry, and general development, or with the colonisation scheme, which, of course, has undergone complete modifications. His personal experiences, narratives of various journeys, are also omitted, having been described elsewhere. It is, therefore, not very obvious why these "reminiscences and notes" should be published now.

The fragmentary chapters on minerals, fauna, and flora are poor. Others, written in the easy, fluent style of feuilletons or causeries, deal with the life in towns, chiefly Porto Alegre, the capital of South Brazilian Germans, whose customs, modes of assimilation, ideals, and successes are compared with those of the Brazilians.

Branch Product in Actinium C.

It is now well established that the atoms of radium C and thorium C can break up in two distinct ways, *i.e.*, with the expulsion of either an α or a β particle. It is to be expected from the close analogy between the C products of the various radio-active families that actinium C should also show abnormal disintegration, and, further, it might be anticipated that one of the branch products would emit an α particle with great velocity and corresponding long range. We have made experiments to test this point. A source of actinium active deposit was covered with a sheet of mica equivalent to about 5 cm. air in stopping power of α particles, and the whole placed in an exhausted chamber with a zinc sulphide screen about 2 cm. from the source. The numbers of scintillations appearing on the screen per minute for different pressures of the air inside the apparatus were counted, and thus the falling off of the α particles with "range" determined. The results showed that in addition to the α particles of actinium C with range 5·4 cm., a small number, about 1 in 600, can penetrate as far as about 6·45 cm. Special experiments showed that the long-range α particles could not be due to radium or thorium impurity, and they must therefore be attributed to the expected new branch product.

In connection with this question, it should be noticed that Mme. Blanquies, in 1910, inferred the existence of two α-ray products in the active deposit of actinium from the shape of the Bragg ionisation curve. The small fraction of long-range α particles found in our experiments, viz., 1 in 600, is, however, quite insufficient to be reconciled with her results. We are therefore repeating her experiments.

The Terrestrial Distribution of the Radio-elements and the Origin of the Earth.

In Nature of June 19 and August 7, 1913, Mr. Holmes, in two interesting letters, shows on the basis of the planetesimal hypothesis how a concentration of the radio-elements might possibly take place in the earth's crust with their absence at depth to satisfactorily account for the observed temperature gradient of the earth; and in his latest communication he indicates how the inhibition of radio-activity by pressure might bring about the same result. But the terrestrial distribution of these elements seems to be of further importance in that it may enable us to determine whether our earth had a stellar or a planetesimal origin.

On the stellar hypothesis, the earth would be partly developed by a process of oxidation—practically the same as that by which we manufacture steel from impure cast-iron at the present day—and whereby all the impurities would be removed to the surface to form the primal crust. The first of this primal crust would be the most acidic, and the last the most basic; and in the metallic core left, even the oxygen which had been the means of removing all the impurities would itself be undetectable. Thorium is but a higher member of the silicon (carbon) family as uranium is of the oxygen family, and the conditions which remove the lower members should be effective in removing the higher ones also. So, too, it seems only natural that the most acidic rocks—that is, the rocks containing the greatest proportions of silicon and of oxygen—should at the same time be associated with the greatest proportions of thorium and of uranium, which are but the highest members of the silicon and oxygen families.

On the planetesimal hypothesis a similar distribution of the radio-elements can hardly be imagined. To get a metallic core that shall be free from thorium and uranium, we have to imagine the planetesimals undergoing individually the oxidation process which has just been sketched, unless the planetesimals happened to be fragments of a preformed stellar mass. Provided all went well, when these planetesimals were piling themselves together to form the earth, the result would be a metallic core free from thorium and uranium, but surrounded by a crust in which these elements would be uniformly distributed. As the acidic rocks differ only in degree from the basic rocks, it would be impossible for the former to rise up through miles of a mixture of both to form an acidic layer, as happens in the case of a stellar earth. Subsequent aqueous action is relatively negligible in both cases.

It is probably the exigencies of the planetesimal hypothesis that constrain Mr. Holmes to state that there is "clearly a marked antipathy between the radio-elements and native iron, for in all the terrestrial examples which have been examined uranium and thorium are barely detectable." As a matter of fact, these elements alloy with iron and nickel, which are the constituents of native iron; and their marked absence is a proof that native iron had undergone an oxidation process at one time in its history, and so had its thorium and uranium removed.

95 Bath Street, Glasgow. GEORGE CRAIG.

THE INTERNATIONAL UNION FOR SOLAR RESEARCH.

THE fifth conference of the International Union for Cooperation in Solar Research was held at Bonn, by invitation of Prof. Kayser, from July 31 to August 5. The attendance was about 100, including delegates from nearly every country in Europe, and a large contingent from America. In the absence of Prof. Hale and Dr. Schuster, through sickness, the executive committee was ably represented by Prof. Turner. As on former occasions, the chief business at the general meetings was to receive and discuss the reports of the various committees appointed for the organisation of observations and methods of reduction.

An important part of the work of the union has been that relating to standards of wave-length. At the last meeting, held at Mount Wilson, California, in 1910, it was believed that a final set of standards was well within sight, but further investigations have revealed unexpected difficulties. It has, in fact, been found by Goos and others that the wave-lengths of many of the iron lines vary slightly with the length of the arc and the portion of the arc observed. Fortunately, most of the lines already adopted as secondary standards, from interferometer determinations, preserve their positions under a variety of circumstances, but they are not sufficient in number. Hence, it has become necessary to attempt the definition of a standard iron arc for determinations of further standards, and for the production of reference spectra to be used in the determination of wave-lengths by interpolation. The committee recommended the following specification for the iron arc: (1) Length of arc, 6 mm. (2) For lines of wave-length greater than 4000, current to be 6 amperes, and for lines of shorter wave-length 4 amperes, or possibly less. (3) Direct current, positive pole above negative, P.D. of 220 volts, electrodes being iron rods of 7 mm. diameter. (4) An axial portion of the arc, at its middle, about 2 mm. in length, to be used as the source of light. Cooperation in the determination of tertiary standards is desired from all who possess concave gratings, plane gratings, or prisms of sufficient dispersion and resolving power, and to this end it is recommended that additional secondary standards be determined with the interformeter, so that the interpolation method may be used with greater exactness.

At the Mount Wilson meeting a committee on the determination of the solar rotation by means of the displacements of lines was formally organised, and a programme of research agreed upon. Each cooperating observer undertook observations, at specified latitudes, in a definite region of the spectrum, in addition to a control region common to all the observers, and lines were to be selected so as to include elements of widely different atomic weights. It now appears that different observers may obtain results differing systematically by as much as 10 per cent. from one another, and that serious discrepancies have also been found in the results obtained by different observers from measurements of the same photographs. The committee accordingly recommended that, before proceeding further, investigations of these sources of error should be made by determinations of velocity at the solar equator by as many different methods as possible.

Satisfactory progress in work with the spectroheliograph was reported, but the Committee hoped that additional observatories would install instruments of high dispersion, in order that filaments and alignments in the upper atmosphere might be more completely recorded. As the result of representations made by Prof. Ricco and by the Royal Astronomical Society, the title of the spectroheliograph committee was changed to "Committee on Solar Atmosphere," so as to include and unify all the observations on the solar atmosphere, visual and photographic, except those associated with eclipses. The organisation directed by Prof. Ricco, and other observers of prominences, were thus given the opportunity of closer connection with the union. After some discussion, a subcommittee for visual observations of prominences and related phenomena was appointed, with Prof.

Ricco as chairman and Father Cortie as secretary. The chief recommendations subsequently made by the sub-committee were that the limiting height of prominences for general statistical purposes should be 30″, and that results should be expressed as profile areas, the conventional "prominence unit" being defined as the area covered by an arc of 1 degree along the sun's limb and 1 second of arc of the celestial sphere in height. It is hoped that by this means it may be possible to combine more successfully the records made at different observatories.

From the report presented by the committee on the spectra of sun spots, it appears that spots observed during the recent minimum did not differ appreciably from those observed at maximum, so far as could be determined with instruments of moderate dispersion. It is, however, considered desirable that the systematic visual observations initiated by the committee should be continued at least until 1916, so as to include a complete cycle of eleven years. The organisation of photographic investigations of spot spectra has been undertaken, and several observers have already agreed to cooperate in preparing a much-needed catalogue of lines affected in spots, and also in other investigations.

An important outcome of the Mount Wilson meeting was the extension of the scope of the union so as to include astrophysics in general. The committee then appointed to consider the possibility of securing uniformity in the classification of stellar spectra has collected opinions from a great number of workers, and reports that a provisional preference for the Draper classification is nearly unanimous. At the same time, the general feeling is opposed to immediate committal to any system, and an effort will be made to secure the material necessary for the establishment of a classification that can be recommended for permanent and universal adoption.

The formal proceedings were varied by addresses and papers on subjects coming within the scope of the union, and by several interesting social gatherings. The receptions by the municipalities of Bonn and Cologne, and by Prof. and Frau Küstner at the Bonn Observatory, will long remain a pleasant memory to those who were privileged to be present, as will also the excursion on the Rhine generously provided by Prof. Kayser. The success of the conference as a whole was largely due to the admirable arrangements made by Profs. Kayser and Pflüger.

The next conference will be held at Rome in 1916.

A. Fowler.

THE BRITISH ASSOCIATION.

Arrangements for the Birmingham Meeting.

The meeting, which began on September 10 in Birmingham under the presidency of Sir Oliver Lodge, F.R.S., promises to be a large and important one. The number, both of local and of visiting members and associates, amounts at the time of writing to about 2600.

Among the corresponding and foreign representatives are:—Sir H. Angst (Consul-General, Zurich); Prof. Svante Arrhenius (Stockholm); Prof. Bemmelen (Groningen); Prof. H. Braus (Heidelberg); Prof. Capitan (Paris); Prof. Chodat (Geneva); Madame Curie (Paris); Dr. Dollo (Brussels); Prof. Lorentz (Leiden); Prof. Reinke (Kiel); Prof. Keibel (Freiburg); Dr. Versluys (Giessen); Dr. Gregory (New York); Prof. Pringsheim (Breslau); Prof. Sörensen (Copenhagen); and Prof. R. W. Wood (Baltimore). It is hoped that others may be able to attend the meeting.

A new procedure has been adopted this year with a view to reducing the pressure on the reception room during the first day or two of the meeting. To each intending visitor a "Selection Circular" has been addressed, giving a list of the various functions (addresses, discourses, entertainments, and excursions), which have been arranged, with a request that the functions selected should be indicated on the returned half of the circular. The response to this appeal has been very gratifying, as over fifteen hundred replies have already been received. Nevertheless, the work of the reception room officials has been very heavy.

The usual business meetings were held on Wednesday last. At the general committee a deputation from the Corporation and University of Manchester invited the Association to visit that city in 1915. The representatives present were: the Deputy Lord Mayor of Manchester, the Town Clerk, the Vice-Chancellor, Prof. Horace Lamb, F.R.S., Prof. H. B. Dixon, F.R.S., and Mr. Maxwell Garnett. In the evening the President delivered his long-expected address, the contents of which will now have become known.

On Thursday evening (September 11) the Lord Mayor and Lady Mayoress of Birmingham are holding a reception in the Council House Buildings, in which the new art gallery and natural history museum are lodged. Special loan collections have been deposited in the museum during the association week.

The University Degree Congregation takes place on the afternoon of September 11, and a fuller account will be given in our next issue. The list of graduands has been limited to a few distinguished men of science from abroad, representative mainly of the chief European nations. The following is the list of recipients of honorary degrees:—Madame Curie (Sorbonne. Paris), Prof. H. A. Lorentz (Leyden), Prof. Keibel (Freiburg), Prof. R. W. Wood (Baltimore), Prof. Svante Arrhenius (Stockholm). In the unavoidable absence of the chancellor, Mr. Joseph Chamberlain, Vice-Chancellor Barling conferred the honorary degree of LL.D. on the graduands, the ceremony in each case being prefaced by a presentation and speech made by the principal (Sir Oliver Lodge). After the ceremony the various departments of the New University Buildings were visited.

Entertainments and Excursions.

With regard to the entertainments: at the garden party given by Messrs. Cadbury Brothers at Bourneville on Friday, September 12, there will be a masque, folk-dancing, and choral singing by village children and workpeople. On Saturday a long list of excursions fills the bill, and an "Excursion Guide" giving full information of the route followed in each case, together with a full description of the several places to be visited, has been compiled by the chairman and secretary of the Excursions sub-committee (Mr. John Humphreys and Mr. F. B. Andrews), and is obtainable at the reception room; Stratford-on-Avon and Warwick, Coventry and Kenilworth, Worcester; Malvern; Banbury and Compton Wynyates; Lichfield and Wall; Droitwich and Hartlebury Castle, and the Arden villages are some of the chief points. In addition to the general excursions, some of the sections are arranging special visits for their members, particulars of which can be obtained in the reception room. On Saturday evening there will be a military concert and torchlight tattoo in the Botanical Gardens, Edgbaston.

On Sunday (September 14) there will be special services at the principal places of worship in the city. The Bishop of Birmingham is to preach in the Pro-Cathedral.

On Monday evening there will be three entertainments given by the local committee. The Prince of Wales Theatre will present the opera *Orpheus*, under the management of Herr Denhof. The Repertory Theatre will give St. John Hankin's *Return of the Prodigal*, and the New Street Picture House will exhibit films of historical and scientific interest.

Lectures.

The evening discourses take place on September 12 and September 16. The first will be given by Sir Henry Cunynghame, of the Home Office, and will deal experimentally with "Coal Dust Explosions and the Means of Preventing Them." The second—by Dr. Smith Woodward, F.R.S., of the British Museum (Natural History)—will be an illustrated exposition of "Missing Links among Extinct Animals." Both of these lectures will be delivered in the new Central Hall.

This year five "Citizens' Lectures" are to be given to (mainly) working-class audiences at the Digbeth Institute, Birmingham. They are not intended for members, but form an altogether independent scheme, provided partly by the association and partly by the local committee, with a view of interesting those members of the community who cannot join the association. The first lecture will be given by Dr. A. C. Haddon, F.R.S., on the decorative art of Savages. The other lectures are "The Panama Canal," by Dr. Vaughan Cornish, F.R.G.S.; "Recent Work on Heredity, and its Application to Man," by Dr. Leonard Doncaster; "Metals under the Microscope," by Dr. Walter Rosenhain, F.R.S.; and "The Evolution of Matter," by Mr. F. Soddy, F.R.S. The arrangements for these lectures have been entrusted to a committee, on which the Workers' Educational Association, the Birmingham Trades Council, the City Council, and other kindred bodies are represented. The demand for tickets has been very encouraging.

Sectional Proceedings.

A general statement of the addresses and of the chief papers to be delivered during the meeting has already been made public, and it is now only necessary to mention a few of the main topics of interest.

Section A (Physics and Mathematics) is naturally very strong this year, both from the fact that the president is a leading physicist, and also from the support which has been given to the sectional president, Dr. Baker, by the presence of distinguished colleagues, both from this country and from abroad. Among these may be mentioned Lord Rayleigh, Sir J. J. Thomson, Sir Joseph Larmor, Prof. Rutherford, and Prof. Bragg. Attention will be devoted especially to the subjects of radiation, radio-active emanations, and the structure of the atom. Prof. H. H. Turner will demonstrate a seismograph (which was one of the late Dr. Milne's instruments) to be erected in the basement of the University (Mason College). There will be a joint meeting with the Geographical Section on geodetic problems to be held on Tuesday morning, September 16.

The Chemical Section (B) meets in the Technical School. In addition to the usual programme, there will be a discussion on coal and coal-fuels on Monday morning (September 15), and another on radio-active elements and the periodic law on Tuesday, September 16; whilst on Friday morning (September 12) the two divisions of the section will discuss respectively the significance of optical properties of substances and certain problems in metallurgy.

The Geological Section (C) has a full programme, both of papers and excursions dealing with local problems in coal-mining, and in stratigraphical and palæontological geology. Special interest is exhibited in the address by Prof. Lapworth on the geology of the country round Birmingham.

The Zoological Section (Section D) is devoting Friday morning to a discussion on mimicry, the inheritance of melanism, and other problems of especial interest to entomologists, whilst on Monday morning the subject of "Convergence in the Mammalia" will be attractive to geologists, as well as to those distinguished zoologists who are to take a foremost part in the discussion. Many other papers of interest are promised, and on Monday afternoon at 3 p.m. Prof. Minchin is to give a special address on some aspects of sleeping sickness. We may here mention what promises to be one of the most important demonstrations and papers, namely, Prof. Benjamin Moore's "Synthesis of Organic Matter by Inorganic Colloids." This subject will be given jointly to Section D, Section K (Botany), and Section I (Physiology) on Tuesday morning at 10.45. Prof. Braus (of Heidelberg) will give a kinematograph exhibition that morning in the Picture House, New Street, of the development of the heart, and on Thursday afternoon there will be a joint excursion by a limited number (twenty-five) of members of each of the sections of Zoology, Botany, and Agriculture, respectively, to the Burbage Experimental

Station, when Major Hurst will demonstrate his Mendelian experiments.

The Economic Section has a well-organised discussion on inland waterways, to be opened by Lord Shuttleworth on Friday, September 12, and another on prices and the cost of living, on the Monday following. The subject of the "Panama Canal" will be discussed from many points of view, both by this section in the Queen's College, Paradise Street, and by the Engineering Section in the Technical School.

A large number of photographs of the Canal will be shown in the latter meeting room.

The Engineering Section has a full programme. In the Mechanical Sub-section Prof. Burstall has a paper on fuels that should attract attention; in the Electrical one there are contributions to the study of wireless telegraphy, and a paper on electric cooking. The transport and settlement of sand and sand-bars, and the re-construction of Snow Hill Station, Birmingham, are among the topics for discussion by the Mechanical Engineers. A gyroscope will be exhibited by Mr. J. W. Gordon.

Anthropology (Section H) has a long and interesting programme for each day, including Wednesday, September 17. The subject-matter, indeed, is so large and varied that in addition to the large meeting room in the Temperance Hall, Temple Street, a sub-section has been arranged to meet in the University (Mason College), Edmund Street. For details of the work of this section the daily programme must be consulted, and mention here can only be made of the joint discussion with the Education Section on the value of museums, to the report by Dr. Fleure and Mr. T. C. Jones on the ethnology of Wales; the papers by Dr. Flinders Petrie on Egyptian exploration; and to the paper on Palæolithic cave-paintings by Dr. Capitan, of Paris.

Section I (Physiology) suffers to some extent from the meeting during the past week of the International Congress of Physiologists at Groningen; but though many prominent men will thereby be prevented from attending the Birmingham meeting, an interesting debate on the physiology of reproduction is assured, and the psychologists have such a strong programme that their work is to form the basis for an independent sub-section, the problems of which are so closely allied to those of education that the meeting room of the sub-section is placed close to that of Education in the University (Mason College). A joint meeting of their two bodies will discuss "Research in Education" on Monday morning, September 15.

In the Botanical Section there will be, in addition to the usual programme of single papers (which include such interesting topics as "The Preservation of the British Flora" and "The Colours and Pigments of Flowers"), one or more joint discussions. On Friday morning, September 12, there will be a conference with the Agricultural Section on barley production, and probably a second on the fruit industry. The agriculturists are offering a paper on German forestry methods, by Prof. Fraser Storey, that is sure to appeal equally strongly to the Botanical Section.

Meetings devoted to topics of general interest form a distinctive feature of the Education Section. "The Educational Use of Museums" is the title of a discussion, which is strongly supported by the leading directors of our museums, whilst "The Function of the Modern University" is the subject for Friday's discussion. As this is introduced by Sir Alfred Hopkinson, and supported by such speakers as Lord Kenyon, Sir H. Reichel, Sir George Kenrick, Sir James Yoxall, and Miss Burstall, there is sure to be a large attendance.

Lastly, Agriculture (Section M) has a paper of outstanding interest, "The Partial Sterilisation of Soil by means of Caustic Lime," by Dr. Hutchinson and Mr. M. MacLennan, and gives the results of some striking experiments recently carried out at the Rothamsted Laboratory, Harpenden. Contributions from the same laboratory are: "The Relations between Protozoa and Soil-Problems," by Mr. T. Goodey (protozoologist to the University of Birmingham), and "The Weeds of Arable Land," by Dr. Brenchley. Prof. Sörensen will give an account of his recent investigations on cereals, whilst the economic side of agriculture will be represented by Sir Richard Paget's address on the possibilities of partnership between landlord and tenant.

Inaugural Address by Sir Oliver J. Lodge, D.Sc., LL.D., F.R.S., President.

Continuity.

Natura non vincitur nisi parendo.

First let me lament the catastrophe which has led to my occupying the chair here in this city. Sir William White was a personal friend of many here present, and I would that the citizens of Birmingham could have become acquainted with his attractive personality, and heard at first hand of the strenuous work which he accomplished in carrying out the behests of the Empire in the construction of its first line of defence.

Although a British Association address is hardly an annual stocktaking, it would be improper to begin this year of office without referring to three more of our losses: one that cultured gentleman, amateur of science in the best sense, who was chosen to preside over our jubilee meeting at York thirty-two years ago. Sir John Lubbock, first Baron Avebury, cultivated science in a spirit of pure enjoyment, treating it almost as one of the arts; and he devoted social and political energy to the welfare of the multitude of his fellows less fortunately situated than himself.

Through the untimely death of Sir George Darwin the world has lost a mathematical astronomer whose work on the tides and allied phenomena is a monument of power and achievement. So recently as our visit to South Africa he occupied the presidential chair.

By the third of our major losses, I mean the death of that brilliant mathematician of a neighbouring nation who took so comprehensive and philosophic a grasp of the intricacies of physics, and whose eloquent though sceptical exposition of our laws and processes, and of the modifications entailed in them by recent advances, will be sure to attract still more widespread attention among all to whom the rather abstruse subject-matter is sufficiently familiar. I cannot say that I find myself in agreement with all that Henri Poincaré wrote or spoke in the domain of physics, but no physicist can help being interested in his mode of presentation, and I may have occasion to refer, in passing, to some of the topics with which he dealt.

And now, eliminating from our purview, as is always necessary, a great mass of human activity, and limiting ourselves to a scrutiny on the side of pure science alone, let us ask what, in the main, is the characteristic of the promising though perturbing period in which we live. Different persons would give different answers, but the answer I venture to give is—rapid progress, combined with fundamental scepticism.

Rapid progress was not characteristic of the latter half of the nineteenth century—at least, not in physics. Fine solid dynamical foundations were laid, and the edifice of knowledge was consolidated; but wholly fresh ground was not being opened up, and totally new buildings were not expected.

"In many cases the student was led to believe that the main facts of nature were all known, that the chances of any great discovery being made by experiment were vanishingly small, and that therefore the experimentalist's work consisted in deciding between rival theories, or in finding some small residual effect, which might add a more or less important detail to the theory."—*Schuster.*

With the realisation of predicted æther waves in 1888, the discovery of X-rays in 1895, spontaneous radio-activity in 1896, and the isolation of the electron in 1898, expectation of further achievement became vivid; and novelties, experimental, theoretical, and speculative, have been showered upon us ever since this century began. That is why I speak of rapid progress.

Of the progress I shall say little; there must always be some uncertainty as to which particular achievement permanently contributes to it; but I will speak about the fundamental scepticism.

Let me hasten to explain that I do not mean the well-worn and almost antique theme of theological scepticism: that controversy is practically in abeyance just now. At any rate, the major conflict is suspended; the forts behind which the enemy has retreated do not invite attack; the territory now occupied by him is little more than his legitimate province. It is the scientific allies, now, who are waging a more or less invigorating conflict among themselves, with philosophers joining in. Meanwhile the ancient foe is biding his time and hoping that from the struggle something will emerge of benefit to himself. Some positions, he feels, were too hastily abandoned and may perhaps be retrieved; or, to put it without metaphor, it seems possible that a few of the things prematurely denied, because asserted on inconclusive evidence, may after all, in some form or other, have really happened. Thus the old theological bitterness is mitigated, and a temporising policy is either advocated or instinctively adopted.

To illustrate the nature of the fundamental scientific or philosophic controversies to which I do refer, would require almost as many addresses as there are sections of the British Association, or, at any rate as many as there are chief cities in Australia; and perhaps my successor in the chair will continue the theme; but, to exhibit my meaning very briefly, I may cite the kind of dominating controversies now extant, employing as far as possible only a single word in each case so as to emphasise the necessary brevity and insufficiency of the reference.

In physiology the conflict ranges round *Vitalism.* (My immediate predecessor dealt with the subject at Dundee.)

In chemistry the debate concerns *Atomic structure.* (My penultimate predecessor is well aware of pugnacity in that region.)

In biology the dispute is on the laws of *Inheritance.* (My nominated successor is likely to deal with this subject; probably in a way not deficient in liveliness.)

And besides these major controversies, debate is active in other sections:—

In education, *Curricula* generally are being overhauled or fundamentally criticised, and revolutionary ideas are promulgated concerning the advantages of freedom for infants.

In economic and political science, or sociology, what is there that is not under discussion? Not property alone, nor land alone, but everything—back to the garden of Eden and the inter-relations of men and women.

Lastly, in the vast group of mathematical and physical sciences, "slurred over rather than summed up as Section A," present-day scepticism concerns what, if I had to express it in one word, I should call *Continuity.* The full meaning of this term will hardly be intelligible without explanation, and I shall discuss it presently.

Still more fundamental and deep-rooted than any of these sectional debates, however, a critical examination of scientific foundations generally is going on; and a kind of philosophic scepticism is in the ascendant, resulting in a mistrust of purely intellectual processes and in a recognition of the limited scope of science.

For science is undoubtedly an affair of the intellect, it examines everything in the cold light of reason; and that is its strength. It is a commonplace to say that science must have no likes or dislikes, must aim only at truth; or as Bertrand Russell well puts it:—

"The kernel of the scientific outlook is the refusal to regard our own desires, tastes, and interests as affording a key to the understanding of the world."

This exclusive, single-eyed attitude of science is its strength; but, if pressed beyond the positive region of usefulness into a field of dogmatic negation and philosophising, it becomes also its weakness. For the nature of man is a large thing, and intellect is only a part of it: a recent part, too, which therefore necessarily, though not consciously, suffers from some of the defects of newness and crudity, and should refrain from imagining itself the whole—perhaps it is not even the best part—of human nature.

The fact is that some of the best things are, by abstraction, excluded from science, though not from literature and poetry; hence perhaps an ancient mistrust or dislike of science, typified by the Promethean legend. Science is systematised and *metrical* knowledge, and in regions where measurement cannot be applied it has small scope; or, as Mr. Balfour said the other day at the opening of a new wing of the National Physical Laboratory:—

"Science depends on measurement, and things not measurable are therefore excluded, or tend to be excluded, from its attention. But life and beauty and happiness are not measurable." And then characteristically he added: "If there could be a unit of happiness, politics might begin to be scientific."

Emotion and intuition and instinct are immensely older than science, and in a comprehensive survey of existence they cannot be ignored. Scientific men may rightly neglect them in order to do their proper work, but philosophers cannot.

So philosophers have begun to question some of the larger generalisations of science, and to ask whether in the effort to be universal and comprehensive we have not extended our laboratory inductions too far. The conservation of energy, for instance: is it always and everywhere valid; or may it under some conditions be disobeyed? It would seem as if the second law of thermodynamics must be somewhere disobeyed—at least, if the age of the universe is both ways infinite—else the final consummation would have already arrived.

Not by philosophers only, but by scientific men also, ancient postulates are being pulled up by the roots. Physicists and mathematicians are beginning to consider whether the long known and well established laws of mechanics hold true everywhere and always, or whether the Newtonian scheme must be replaced by something more modern, something to which Newton's laws of motion are but an approximation.

Indeed, a whole system of non-Newtonian mechanics has been devised, having as its foundation the recently discovered changes which must occur in bodies moving at speeds nearly comparable with that of light. It turns out, in fact, that both shape and mass are functions of velocity. As the speed increases the mass increases and the shape is distorted, though under ordinary conditions only to an infinitesimal extent.

So far I agree; I agree with the statement of fact; but I do not consider it so revolutionary as to overturn Newtonian mechanics. After all, a variation of mass is familiar enough, and it would be a great mistake to say that Newton's second law breaks down merely because mass is not constant. A raindrop is an example of variable mass; or the earth may be, by reason of meteoric dust; or the sun, by reason of radio-activity; or a locomotive, by reason of the emission of steam. In fact, variable masses are the commonest, for friction may abrade any moving body to a microscopic extent.

That mass is constant is only an approximation. That mass is equal to ratio of force and acceleration is a definition, and can be absolutely accurate. It holds perfectly even for an electron with a speed near that of light; and it is by means of Newton's second law that the variation of mass with velocity has been experimentally observed and compared with theory.

I urge that we remain with, or go back to, Newton. I see no reason against retaining all Newton's laws, discarding nothing, but supplementing them in the light of further knowledge.

Even the laws of geometry have been overhauled, and Euclidean geometry is seen to be but a special case of more fundamental generalisations. How far they apply to existing space, and how far time is a reality or an illusion, and whether it can in any sense depend on the motion or the position of an observer: all these things in some form or other are discussed.

The conservation of matter also, that main-mast of nineteenth-century chemistry, and the existence of the æther of space, that sheet-anchor of nineteenth-century physics—do they not sometimes seem to be going by the board?

Prof. Schuster, in his American lectures, commented on the modern receptive attitude as follows:—

"The state of plasticity and flux—a healthy state, in my opinion—in which scientific thought of the present day adapts itself to almost any novelty, is illustrated by the complacency with which the most cherished tenets of our fathers are being abandoned. Though it was never an article of orthodox faith that chemical elements were immutable and would not some day be resolved into simpler constituents, yet the conservation of mass seemed to lie at the very foundation of creation. But nowadays the student finds little to disturb him, perhaps too little, in the idea that mass changes with velocity; and he does not always realise the full meaning of the consequences which are involved."

This readiness to accept and incorporate new facts into the scheme of physics may have led to perhaps an undue amount of scientific scepticism, in order to right the balance.

But a still deeper variety of comprehensive scepticism exists, and it is argued that all our laws of nature, so laboriously ascertained and carefully formulated, are but conventions after all, not truths; that we have no faculty for ascertaining real truth; that our intelligence was not evolved for any such academic purpose; that all we can do is to express things in a form convenient for present purposes and employ that mode of expression as a tentative and pragmatically useful explanation.

Even *explanation*, however, has been discarded as too ambitious by some men of science, who claim only the power to describe. They not only emphasise the *how* rather than the *why*—as is in some sort inevitable, since explanations are never ultimate—but are satisfied with very abstract propositions, and regard mathematical equations as preferable to, because safer than, mechanical analogies or models.

"To use an acute and familiar expression of Gustav Kirchhoff, it is the object of science to *describe* natural phenomena, not to *explain* them. When we have expressed by an equation the correct relationship between different natural phenomena we have gone as far as we safely can, and if we go beyond we are entering on purely speculative ground."

But the modes of statement preferred by those who distrust our power of going directly into detail are far from satisfactory. Prof. Schuster describes and comments on them thus:—

"Vagueness, which used to be recognised as our great enemy, is now being enshrined as an idol to be worshipped. We may never know what constitutes atoms, or what is the real structure of the æther; why trouble, therefore, it is said, to find out more about them. Is it not safer, on the contrary, to confine ourselves to a general talk on entropy, luminiferous vectors, and undefined symbols expressing vaguely certain physical relationships? What really lies at the bottom of the great fascination which these new doctrines exert on the present generation is sheer cowardice; the fear of having its errors brought home to it." . . .

"I believe this doctrine to be fatal to a healthy development of science. Granting the impossibility of penetrating beyond the most superficial layers of observed phenomena, I would put the distinction between the two attitudes of mind in this way: One glorifies our ignorance, while the other accepts it as a regrettable necessity."

In further illustration of the modern sceptical attitude, I quote from Poincaré:—

"Principles are conventions and definitions in disguise. They are, however, deduced from experimental laws, and these laws have, so to speak, been erected into principles to which our mind attributes an absolute value. . . .

"The fundamental propositions of geometry, for instance Euclid's postulate, are only conventions; and it is quite as unreasonable to ask if they are true or false as to ask if the metric system is, true or false. Only, these conventions are convenient. . . .

"Whether the æther exists or not matters little—let us leave that to the metaphysicians; what is essential for us is that everything happens as if it existed, and that this hypothesis is found to be suitable for the explanation of phenomena. After all, have we any other reason for believing in the existence of material objects? That, too, is only a convenient hypothesis."

As an antidote against overpressing these utterances, I quote from Sir J. Larmor's preface:—

"There has been of late a growing trend of opinion, prompted in part by general philosophical views, in the direction that the theoretical constructions of physical science are largely factitious, that instead of presenting a valid image of the relations of things on which further progress can be based, they are still little better than a mirage. . . .

"The best method of abating this scepticism is to become acquainted with the real scope and modes of application of conceptions which, in the popular language of superficial exposition—and even in the unguarded and playful paradox of their authors, intended only for the instructed eye—often look bizarre enough."

One thing is very notable, that it is closer and more exact knowledge that has led to the kind of scientific scepticism now referred to; and that the simple laws on which we used to be working were thus simple and discoverable because the full complexity of existence was tempered to our ken by the roughness of our means of observation.

Kepler's laws are not accurately true, and if he had had before him all the data now available he could hardly have discovered them. A planet does not really move in an ellipse but in a kind of hypocycloid, and not accurately in that either.

So it is also with Boyle's law, and the other simple laws in physical chemistry. Even Van der Waals' generalisation of Boyle's law is only a further approximation.

In most parts of physics simplicity has sooner or later to give place to complexity; though certainly I urge that the simple laws were true, and are still true, as far as they go, their inaccuracy being only detected by further real discovery. The reason they are departed from becomes known to us; the law is not really disobeyed, but is modified through the action of a known additional cause. Hence it is all in the direction of progress.

It is only fair to quote Poincaré again, now that I am able in the main to agree with him:—

"Take, for instance, the laws of reflection. Fresnel established them by a simple and attractive theory which experiment seemed to confirm. Subsequently, more accurate researches have shown that this verification was but approximate; traces of elliptic polarisation were detected everywhere. But it is owing to the first approximation that the cause of these anomalies was found, in the existence of a transition layer; and all the essentials of Fresnel's theory have remained. We cannot help reflecting that all these relations would never have been noted if there had been doubt in the first place as to the complexity of the objects they connect. Long ago it was said: If Tycho had had instruments ten times as precise, we would never have had a Kepler, or a Newton, or astronomy. It is a misfortune for a science to be born too late, when the means of observation have become too perfect. That is what is happening at this moment with respect to physical chemistry; the founders are hampered in their general grasp by third and fourth decimal places; happily they are men of robust faith. As we get to know the properties of matter better we see that continuity reigns. . . . It would be difficult to justify [the belief in continuity] by apodeictic reasoning, but without [it] all science would be impossible."

Here he touches on my own theme, *Continuity*; for if we had to summarise the main trend of physical controversy at present, I feel inclined to urge that it largely turns on the question as to which way ultimate victory lies in the fight between continuity and discontinuity.

On the surface of nature at first we see discontinuity; objects detached and countable. Then we realise the air and other media, and so emphasise continuity and flowing quantities. Then we detect atoms and numerical properties, and discontinuity once more makes its appearance. Then we invent the æther and are impressed with continuity again. But this is not likely to be the end; and what the ultimate end will be, or whether there is an ultimate end, is a question difficult to answer.

The modern tendency is to emphasise the discontinuous or atomic character of everything. Matter has long been atomic, in the same sense as anthropology is atomic; the unit of matter is the atom, as the unit of humanity is the individual.[1] Whether men or women or children—they can be counted as so many "souls." And atoms of matter can be counted too.

Certainly, however, there is an illusion of continuity. We recognise it in the case of water. It appears to be a continuous medium, and yet it is certainly molecular. It is made continuous again, in a sense, by the æther postulated in its pores; for the æther is essentially continuous. Though Osborne Reynolds, it is true, invented a discontinuous or granular æther, on the analogy of the sea-shore. The sands of the sea, the hairs of the head, the descendants of a patriarch, are typical instances of numerable, or rather of innumerable things. The difficulty of enumerating them is not that there is nothing to count, but merely that the things to be counted are very numerous. So are the atoms in a drop of water—they outnumber the drops in an Atlantic Ocean—and, during the briefest time of stating their number, fifty millions or so may have evaporated; but they are as easy to count as the grains of sand on a shore.

The process of counting is evidently a process applicable to discontinuities, *i.e.*, to things with natural units; you can count apples and coins, and days and years, and people and atoms. To apply number to a continuum you must first cut it up into artificial units; and you are always left with incommensurable fractions. Thus only is it that you can deal numerically with such continuous phenomena as the warmth of a room, the speed of a bird, the pull of a rope, or the strength of a current.

But how, it may be asked, does discontinuity apply to number? The natural numbers, 1, 2, 3, &c., are discontinuous enough, but there are fractions to fill up the interstices; how do we know that they are not really connected by these fractions, and so made continuous again?

(By number I always mean commensurable number; incommensurables are not numbers: they are just what cannot be expressed in numbers. The square root of 2 is not a number, though it can be readily indicated by a length. Incommensurables are usual in physics and are frequent in geometry; the conceptions of geometry are essentially continuous. It is clear, as Poincaré says, that "if the points whose coordinates are commensurable were alone regarded as real, the in-circle of a square and the diagonal of the square would not intersect, since the coordinates of the points of intersection are incommensurable.")

I want to explain how commensurable fractions do not connect up numbers, nor remove their discontinuity in the least. The divisions on a foot rule, divided as closely as you please, represent commensurable fractions, but they represent none of the length. No matter how numerous they are, all the length lies between them; the divisions are mere partitions and have consumed none of it; nor do they connect up with each other, they are essentially discontinuous. The interspaces are infinitely more extensive than the barriers which partition them off from one another; they are like a row of compartments with infinitely thin walls. All the incommensurables lie in the inter-

[1] In his recent Canadian address, Lord Haldane emphasised the fact that though humanity is individually discontinuous it possesses a social and national continuity.

spaces; the compartments are full of them, and they are thus infinitely more numerous than the numerically expressible magnitudes. Take any point of the scale at random, that point will certainly lie in an interspace: it will not lie on a division, for the chances are infinity to 1 against it.

Accordingly incommensurable quantities are the rule in physics. Decimals do not in practice terminate or circulate; in other words, vulgar fractions do not accidentally occur in any measurements, for this would mean infinite accuracy. We proceed to as many places of decimals as correspond to the order of accuracy aimed at.

Whenever, then, a commensurable number is really associated with any natural phenomenon, there is necessarily a noteworthy circumstance involved in the fact, and it means something quite definite and ultimately ascertainable. Every discontinuity that can be detected and counted is an addition to knowledge. It not only means the discovery of natural units instead of being dependent on artificial ones, but it throws light also on the nature of phenomena themselves.

For instance:—

The ratio between the velocity of light and the inverted square root of the product of the electric and magnetic constants was discovered by Clerk Maxwell to be 1; and a new volume of physics was by that discovery opened.

Dalton found that chemical combination occurred between quantities of different substances specified by certain whole or fractional numbers; and the atomic theory of matter sprang into substantial though at first infantile existence.

The hypothesis of Prout, which in some modified form seems likely to be substantiated, is that all atomic weights are commensurable numbers; in which case there must be a natural fundamental unit underlying, and in definite groups composing, the atoms of every form of matter.

The small number of degrees of freedom of a molecule, and the subdivision of its total energy into equal parts corresponding thereto, is a theme not indeed without difficulty but full of importance. It is responsible for the suggestion that energy too may be atomic!

Mendelejeff's series again, or the detection of a natural grouping of atomic weights in families of seven, is another example of the significance of number.

Electricity was found by Faraday to be numerically connected with quantity of matter; and the atom of electricity began its hesitating but now brilliant career.

Electricity itself—*i.e.*, electric charge—strangely enough has proved itself to be atomic. There is a natural unit of electric charge, as suspected by Faraday and Maxwell and named by Johnstone Stoney. Some of the electron's visible effects were studied by Crookes in a vacuum; and its weighing and measuring by J. J. Thomson were announced to the British Association meeting at Dover in 1899—a fitting prelude to the twentieth century.

An electron is the natural unit of negative electricity, and it may not be long before the natural unit of positive electricity is found too. But concerning the nature of the positive unit there is at present some division into opposite camps. One school prefers to regard the unit of positive electricity as a homogeneous sphere, the size of an atom, in which electrons revolve in simple harmonic orbits and constitute nearly the whole effective mass. Another school, while appreciative of the simplicity and ingenuity and beauty of the details of this conception, and the skill with which it has been worked out, yet thinks the evidence more in favour of a minute central positive nucleus, or nucleus-group, of practically atomic mass; with electrons, larger—*i.e.* less concentrated—and therefore less massive than itself, revolving round it in astronomical orbits. While from yet another point of view it is insisted that positive and negative electrons can only differ skew-symmetrically, one being like the image of the other in a mirror, and that the mode in which they are grouped to form an atom remains for future discovery. But no one doubts that electricity is ultimately atomic.

Even magnetism has been suspected of being atomic, and its hypothetical unit has been named in advance the *magneton*; but I confess that here I have not been shaken out of the conservative view.

We may express all this as an invasion of number into unsuspected regions.

Biology may be said to be becoming atomic. It has long had natural units in the shape of cells and nuclei, and some discontinuity represented by body-boundaries and cell-walls; but now, in its laws of heredity as studied by Mendel, number and discontinuity are strikingly apparent among the reproductive cells, and the varieties of offspring admit of numerical specification and prediction to a surprising extent; while modification by continuous variation, which seemed to be of the essence of Darwinism, gives place to, or at least is accompanied by, mutation, with finite and considerable and in appearance discontinuous change.

So far from Nature not making jumps, it becomes doubtful if she does anything else. Her hitherto placid course, more closely examined, is beginning to look like a kind of steeplechase.

Yet undoubtedly continuity is the backbone of evolution, as taught by all biologists—no artificial boundaries or demarcations between species—a continuous chain of heredity from far below the amœba up to man. Actual continuity of undying germ-plasm, running through all generations, is taught likewise; though a strange discontinuity between this persistent element and its successive accessory body-plasms—a discontinuity which would convert individual organisms into mere temporary accretions or excretions, with no power of influencing or conveying experience to their generating cells—is advocated by one school.

Discontinuity does not fail to exercise fascination even in pure mathematics. Curves are invented which have no tangent or differential coefficient, curves which consist of a succession of dots or of twists; and the theory of commensurable numbers seems to be exerting a dominance over philosophic mathematical thought as well as over physical problems.

And not only these fairly accepted results are prominent, but some more difficult and unexpected theses in the same direction are being propounded, and the atomic character of *energy* is advocated. We had hoped to be honoured by the presence of Prof. Planck, whose theory of the *quantum*, or indivisible unit or atom of energy, excites the greatest interest, and by some is thought to hold the field.

Then again radiation is showing signs of becoming atomic or discontinuous. The corpuscular theory of radiation is by no means so dead as in my youth we thought it was. Some radiation is certainly corpuscular, and even the ethereal kind shows indications, which may be misleading, that it is spotty, or locally concentrated into points, as if the wave-front consisted of detached specks or patches; or as J. J. Thomson says, "the wave-front must be more analogous to bright specks on a dark ground than to a uniformly illuminated surface," thus suggesting that the æther may be fibrous in structure, and that a wave runs along lines of electric force; as the genius of Faraday surmised might be possible, in his "Thoughts on Ray Vibrations." Indeed, Newton guessed something of the same kind, I fancy, when he superposed ether-pulses on his corpuscles.

Whatever be the truth in this matter, a discussion on radiation, of extreme weight and interest, though likewise of great profundity and technicality, is expected on Friday in Section A. We welcome Prof. Lorentz, Dr. Arrhenius, Prof. Langevin, Prof. Pringsheim, Prof. R. W. Wood, and others, some of whom have been specially invited to England because of the important contributions which they have made to the subject-matter of this discussion.

Why is so much importance attached to radiation? Because it is the best-known and longest-studied link between matter and æther, and the only property we are acquainted with that affects the unmodified great mass of æther alone. Electricity and magnetism are associated with the modifications or singularities called electrons; most phenomena are connected still more directly with matter. Radiation, however, though excited by an accelerated electron, is subsequently let loose in the æther of space, and travels as a definite thing at a measurable and constant pace—a pace independent of everything so long as the æther is free, unmodified and unloaded by matter. Hence radiation has much to teach us, and we have much to learn concerning its nature.

How far can the analogy of granular, corpuscular, countable, atomic, or discontinuous things be pressed? There are those who think it can be pressed very far. But to avoid misunderstanding, let me state, for what it may be worth, that I myself am an upholder of *ultimate* Continuity, and a fervent believer in the æther of space.

We have already learnt something about the æther; and although there may be almost as many varieties of opinion as there are people qualified to form one, in my view we have learnt as follows:

The æther is the universal connecting medium which binds the universe together, and makes it a coherent whole instead of a chaotic collection of independent isolated fragments. It is the vehicle of transmission of all manner of force, from gravitation down to cohesion and chemical affinity; it is therefore the storehouse of potential energy.

Matter moves, but æther is strained.

What we call elasticity of matter is only the result of an alteration of configuration due to movement and readjustment of particles, but all the strain and stress are in the æther. The æther itself does not move, that is to say it does not move in the sense of locomotion, though it is probably in a violent state of rotational or turbulent motion in its smallest parts; and to that motion its exceeding rigidity is due.

As to its density, it must be far greater than that of any form of matter, millions of times denser than lead or platinum. Yet matter moves through it with perfect freedom, without any friction or viscosity. There is nothing paradoxical in this: viscosity is not a function of density; the two are not necessarily connected. When a solid moves through an alien fluid it is true that it acquires a spurious or apparent extra inertia from the fluid it displaces; but, in the case of matter and æther, not only is even the densest matter excessively porous and discontinuous, with vast interspaces in and among the atoms, but the constitution of matter is such that there appears to be no displacement in the ordinary sense at all; the æther is itself so modified as to *constitute* the matter in some way. Of course, that portion moves, its inertia is what we observe, and its amount depends on the potential energy in its associated electric field, but the motion is not like that of a foreign body, it is that of some inherent and merely individualised portion of the stuff itself. Certain it is that the æther exhibits no trace of viscosity.[2]

Matter in motion, æther under strain, constitute the fundamental concrete things we have to do with in physics. The first pair represent kinetic energy, the second potential energy; and all the activities of the material universe are represented by alternations from one of these forms to the other.

Whenever this transference and transformation of energy occur, work is done, and some effect is produced, but the energy is never diminished in quantity: it is merely passed on from one body to another, always from æther to matter, or *vice versâ*—except in the case of radiation, which simulates matter—and from one form to another.

The forms of energy can be classified as either a translation, a rotation, or a vibration of pieces of matter of different sizes, from stars and planets down to atoms and electrons; or else an æthereal strain which in various different ways is manifested by the behaviour of such masses of matter as appeal to our senses.[3]

Some of the facts responsible for the suggestion that energy is atomic seem to me to depend on the discontinuous nature of the structure of a material atom, and on the high velocity of its constituent particles. The apparently discontinuous emission of radiation is, I believe, due to features in the real discontinuity of matter. Disturbances inside an atom appear to be essentially catastrophic; a portion is liable to be ejected with violence. There appears to be a critical velocity below which ejection does not take place; and, when it does, there also occurs a sudden rearrangement of parts which is presumably responsible for some perceptible æthereal radiation. Hence it is, I suppose, that radiation comes off in gushes or bursts; and hence it appears to consist of indivisible units. The occasional phenomenon of new stars, as compared with the steady orbital motion of the millions of recognised bodies, may be suggested as an astronomical analogue.

The hypothesis of *quanta* was devised to reconcile the law that the energy of a group of colliding molecules must in the long run be equally shared among all their degrees of freedom, with the observed fact that the energy is really shared into only a small number of equal parts. For if vibration-possibilities have to be taken into account, the number of degrees of molecular freedom must be very large, and energy shared among them ought soon to be all frittered away; whereas it is not. Hence the idea is suggested that minor degrees of freedom are initially excluded from sharing the energy, because they cannot be supplied with less than one atom of it.

I should prefer to express the fact by saying that the ordinary encounters of molecules are not of a kind able to excite atomic vibrations, or in any way to disturb the æther. Spectroscopic or luminous vibrations of an atom are excited only by an exceptionally violent kind of collision, which may be spoken of as chemical clash; the ordinary molecular orbital encounters, always going on at the rate of millions a second, are ineffective in that respect, except in the case of phosphorescent or luminescent substances. That common molecular deflections *are* ineffective is certain, else all the energy would be dissipated or transferred from matter into the æther; and the reasonableness of their radiative inefficiency is not far to seek, when we consider the comparatively leisurely character of molecular movements, at speeds comparable with the velocity of sound. Admittedly, how-

[2] For details of my experiment on this subject see Phil. Trans. Roy. Soc. for 1893 and 1897; or a very abbreviated reference to it, and to the other matters above-mentioned, in my small book "The Ether of Space."

[3] See, in the Philosophical Magazine for 1879, my article on a classification of the forms of energy.

ever, the effective rigidity of molecules must be complete, otherwise the sharing of energy must ultimately occur. They do not seem able to be set vibrating by anything less than a certain minimum stimulus; and that is the basis for the theory of *quanta*.

Quantitative applications of Planck's theory, to elucidate the otherwise shaky stability of the astronomically constituted atom, have been made; and the agreement between results so calculated and those observed, including a determination of series of spectrum lines, is very remarkable. One of the latest contributions to this subject is a paper by Dr. Bohr in *The Philosophical Magazine* for July this year.

To show that I am not exaggerating the modern tendency towards discontinuity, I quote, from M. Poincaré's "Dernières Pensées," a proposition which he announces in italics as representing a form of Prof. Planck's view of which he apparently approves:—

"A physical system is susceptible of a finite number only of distinct conditions; it jumps from one of these conditions to another without passing through a continuous series of intermediate conditions."

Also this from Sir Joseph Larmor's preface to Poincaré's "Science and Hypothesis":—

"Still more recently it has been found that the good Bishop Berkeley's logical jibes against the Newtonian ideas of fluxions and limiting ratios cannot be adequately appeased in the rigorous mathematical conscience, until our apparent continuities are resolved mentally into discreet aggregates which we only partially apprehend. The irresistible impulse to atomise everything thus proves to be not merely a disease of the physicist: a deeper origin, in the nature of knowledge itself, is suggested."

One very valid excuse for the prevalent attitude is the astonishing progress that has been made in actually seeing or almost seeing the molecules, and studying their arrangement and distribution.

The laws of gases have been found to apply to emulsions and to fine powders in suspension, of which the Brownian movement has long been known. This movement is caused by the orthodox molecular bombardment, and its average amplitude exactly represents the theoretical mean free path calculated from the "molecular weight" of the relatively gigantic particles. The behaviour of these microscopically visible masses corresponds closely and quantitatively with what could be predicted for them as fearfully heavy atoms, on the kinetic theory of gases; they may indeed be said to constitute a gas with a gram-molecule as high as 200,000 tons; and, what is rather important as well as interesting, they tend visibly to verify the law of equipartition of energy even in so extreme a case, when that law is properly stated and applied.

Still more remarkable—the application of X-rays to display the arrangement of molecules in crystals, and ultimately the arrangement of atoms in molecules, as initiated by Prof. Laue with Drs. Friedrich and Knipping, and continued by Prof. Bragg and his son and by Dr. Tutton, constitute a series of researches of high interest and promise. By this means many of the theoretical anticipations of our countryman, Mr. William Barlow, and—working with him—Prof. Pope, as well as of those distinguished crystallographers von Groth and von Fedorow, have been confirmed in a striking way. These brilliant researches, which seem likely to constitute a branch of physics in themselves, and which are being continued by Messrs. Moseley and C. G. Darwin, and by Mr. Keene and others, may be called an apotheosis of the atomic theory of matter.

One other controversial topic I shall touch upon in the domain of physics, though I shall touch upon it lightly, for it is not a matter for easy reference as yet. If the *Principle of Relativity* in an extreme sense establishes itself, it seems as if even *time* would become discontinuous and be supplied in atoms, as money is doled out in pence or centimes instead of continuously; in which case our customary existence will turn out to be no more really continuous than the events on a kinematograph screen, while that great agent of continuity, the æther of space, will be relegated to the museum of historical curiosities.

In that case differential equations will cease to represent the facts of nature, they will have to be replaced by finite differences, and the most fundamental revolution since Newton will be inaugurated.

Now in all the debateable matters of which I have indicated possibilities I want to urge a conservative attitude. I accept the new experimental results on which some of these theories—such as the principle of relativity—are based, and am profoundly interested in them, but I do not feel that they are so revolutionary as their propounders think. I see a way to retain the old and yet embrace the new, and I urge moderation in the uprooting and removal of landmarks.

And of these the chief is Continuity. I cannot imagine the exertion of mechanical force across empty space, no matter how minute; a continuous medium seems to me essential. I cannot admit discontinuity in either space or time, nor can I imagine any sort of experiment which would justify such a hypothesis. For surely we must realise that we know nothing experimental of either space or time, we cannot modify them in any way. We make experiments on bodies, and only on bodies, using "body" as an exceedingly general term.

We have no reason to postulate anything but continuity for space and time. We cut them up into conventional units for convenience' sake, and those units we can count; but there is really nothing atomic or countable about the things themselves. We can count the rotations of the earth, or the revolutions of an electron, or the vibrations of a pendulum, or the waves of light. All these are concrete and tractable physical entities; but space and time are ultimate data, abstractions based on experience. We know them through motion, and through motion only, and motion is essentially continuous. We ought clearly to discriminate between things themselves and our mode of measuring them. Our measures and perceptions may be affected by all manner of incidental and trivial causes, and we may get confused or hampered by our own movement; but there need be no such complication in things themselves, any more than a landscape is distorted by looking at it through an irregular window-pane or from a travelling coach. It is an ancient and discarded fable that complications introduced by the motion of an observer are real complications belonging to the outer universe.

Very well, then, what about the æther, is that in the same predicament? Is that an abstraction, or a mere convention, or is it a concrete physical entity on which we can experiment?

Now it has to be freely admitted that it is exceedingly difficult to make experiments on the æther. It does not appeal to sense, and we know no means of getting hold of it. The one thing we know metrical about it is the velocity with which it can transmit transverse waves. That is clear and definite, and thereby to my judgment it proves itself a physical agent; not, indeed, tangible or sensible, but yet concretely real.

But it does elude our laboratory grasp. If we rapidly move matter through it, hoping to grip it and move it too, we fail; there is no mechanical connection. And even if we experiment on light, we fail too. So long as transparent matter is moving relatively to us, light can be affected inside that matter; but when matter is relatively stationary to matter nothing observable takes place, however fast things may be moving, so long as they move together.

Hence arises the idea that motion with respect to æther is meaningless; and the fact that only relative motion of pieces of matter with respect to each other has so far been observed is the foundation of the principle of relativity. It sounds simple enough as thus stated, but in its developments it is an ingenious and complicated doctrine embodying surprising consequences which have been worked out by Prof. Einstein and his disciples with consummate ingenuity.

What have I to urge against it? Well, in the first place, it is only in accordance with common sense that no effect of the first order can be observed without relative motion of matter. An æther-stream through our laboratories is optically and electrically undetectable, at least as regards first-order observation; this is clearly explained for general readers in my book, "The Ether of Space," chapter iv. But the principle of relativity says more than that; it says that no effect of any order of magnitude can ever be observed without the relative motion of matter.

The truth underlying this doctrine is that absolute motion without reference to *anything* is unmeaning. But the narrowing down of "anything" to mean any piece of matter is illegitimate. The nearest approach to absolute motion that we can physically imagine is motion through or with respect to the æther of space. It is natural to assume that the æther is on the whole stationary, and to use it as a standard of rest; in that sense motion with reference to it may be called absolute, but in no other sense.

The principle of relativity claims that we can never ascertain such motion: in other words it practically or pragmatically denies the existence of the æther. Every one of our scientifically observed motions, it says, are of the same nature as our popularly observed ones, viz. motion of pieces of matter relatively to each other; and that is all that we can ever know. Everything goes on—says the principle of relativity—as if the æther did not exist.

Now the facts are that no motion with reference to the æther alone has ever yet been observed: there are always curious compensating effects which just cancel out the movement-terms and destroy or effectively mask any phenomenon that might otherwise be expected. When matter moves past matter observation can be made; but, even so, no consequent locomotion of æther, outside the actually moving particles, can be detected.

(It is sometimes urged that rotation is a kind of absolute motion that can be detected, even in isolation. It can so be detected, as Newton pointed out; but in cases of rotation matter on one side the axis is moving in the opposite direction to matter on the other side of the axis; hence rotation involves relative material motion, and therefore can be observed.)

To detect motion through æther we must use an æthereal process. We may use radiation, and try to compare the speeds of light along or across the motion, or we might try to measure the speed, first with the motion and then against it. But how are we to make the comparison? If the time of emission from a distant source is given by a distant clock, that clock must be observed through a telescope, that is by a beam of light; which is plainly a compensating process. Or the light from a neighbouring source can be sent back to us by a distant mirror; when again there will be compensation. Or the starting of light from a distant terrestrial source may be telegraphed to us, either with a wire or without; but it is the æther that conveys the message in either case, so again there will be compensation. Electricity, magnetism, and light, are all effects of the æther.

Use cohesion, then; have a rod stretching from one place to another, and measure that. But cohesion is transmitted by the æther too, if, as believed, it is the universal binding medium. Compensation is likely; compensation can, on the electrical theory of matter, be predicted.

Use some action not dependent on æther, then. Very well, where shall we find it?

To illustrate the difficulty I will quote a sentence from Sir Joseph Larmor's paper before the International Congress of Mathematicians at Cambridge last year:—

"If it is correct to say with Maxwell that all radiation is an electrodynamic phenomenon, it is equally correct to say with him that all electrodynamic relations between material bodies are established by the operation, on the molecules of those bodies, of fields of force which are propagated in free space as radiation and in accordance with the laws of radiation, from one body to the other."

The fact is, we are living in an epoch of some very comprehensive generalisations. The physical discovery of the twentieth century, so far, is the electrical theory of matter. This is the great new theory of our time; it was referred to, in its philosophical aspect, by Mr. Balfour in his presidential address at Cambridge in 1904. We are too near it to be able to contemplate it properly; it has still to establish itself and to develop in detail, but I anticipate that in some form or other it will prove true.[4]

Here is a briefest possible summary of the first chapter (so to speak) of the electrical theory of matter:—

(1) Atoms of matter are composed of electrons—of positive and negative electric charges.

(2) Atoms are bound together into molecules by chemical affinity which is intense electrical attraction at ultra-minute distances.

(3) Molecules are held together by cohesion, which I for one regard as residual or differential chemical affinity over molecular distances.

(4) Magnetism is due to the locomotion of electrons. There is no magnetism without an electric current, atomic or otherwise. There is no electric current without a moving electron.

(5) Radiation is generated by every accelerated electron, in amount proportional to the square of its acceleration; and there is no other kind of radiation, except indeed a corpuscular kind; but this depends on the velocity of electrons and therefore again can only be generated by their acceleration.

The theory is bound to have curious consequences; and already it has contributed to some of the uprooting and uncertainty that I speak of. For, if it be true, every material interaction will be electrical, *i.e.* æthereal; and hence arises our difficulty. Every kind of force is transmitted by the æther, and hence, so long as all our apparatus is travelling together at one and the same pace, we have no chance of detecting the motion. That is the strength of the principle of relativity. The changes are not zero, but they cancel each other out of observation (NATURE, vol. xlvi., p. 165, 1892).

Many forms of statement of the famous Michelson-Morley experiment are misleading. It is said to prove that the time taken by light to go with the æther stream is the same as that taken to go against or across it. It does not show that. What it shows is that the time taken by light to travel to and fro

4 For a general introductory account of the electrical theory of matter my Romanes lecture for 1903 (Clarendon Press) may be referred to.

on a measured interval fixed on a rigid block of matter is independent of the aspect of that block with respect to any motion of the earth through space. A definite and most interesting result: but it may be, and often is, interpreted loosely and too widely.

It is interpreted too widely, as I think, when Prof. Einstein goes on to assume that no non-relative motion of matter can be ever observed even when *light* is brought into consideration. The relation of light to matter is very curious. The wave front of a progressive wave simulates many of the properties of matter. It has energy, it has momentum, it exerts force, it sustains reaction. It has been described as a portion of the mass of a radiating body—which gives it a curiously and unexpectedly corpuscular "feel." But it has a definite velocity. Its velocity in space relative to the æther is an absolute constant independent of the motion of the source. This would not be true for corpuscular light.

Hence I hold that here is something with which our own motion may theoretically be compared; and I predict that our motion through the æther will some day be detected by help of this very fact—by comparing our speed with that of light: though the old astronomical aberration, which seemed to make the comparison easy, failed to do so quite simply, because it is complicated by the necessity of observing the position of a distant source, in relation to which the earth is moving. If the source and observer are moving together there is no possibility of observing aberration. Nevertheless, I maintain that when matter is moving near a beam of light we may be able to detect the motion. For the velocity of light in space is no function of the velocity of the source, nor of matter near it; it is quite unaffected by source or receiver. Once launched it travels in its own way. If we are travelling to meet it, it will be arriving at us more quickly; if we travel away from it, it will reach us with some lag. And observation of the acceleration or retardation is made by aid of Jupiter's satellites. We have there the dial of a clock, to or from which we advance or recede periodically. It gains while we approach it, it loses while we recede from it, it keeps right time when we are stationary or only moving across the line of sight.

But then, of course, it does not matter whether Jupiter is standing still and we are moving, or *vice versâ*: it is a case of relative motion of matter again. So it is if we observe a Doppler effect from the right- and left-hand limbs of the rotating sun. True, and if we are to permit no relative motion of matter we must use a terrestrial source, clamped to the earth as our receiver is. And now we shall observe nothing.

But not because there is nothing to observe. Lag must really occur if we are running away from the light, even though the source is running after us at the same pace; unless we make the assumption—true only for corpuscular light—that the velocity of light is not an absolute thing, but is dependent on the speed of the source. With corpuscular light there is nothing to observe; with wave light there is something, but we cannot observe it.

But if the whole solar system is moving through the æther I see no reason why the relative æther drift should not be observed by a differential residual effect in connection with Jupiter's satellites or the right and left limbs of the sun. The effect must be too small to observe without extreme precision, but theoretically it ought to be there. Inasmuch, however, as relative motion of matter with respect to the observer is involved in these effects, it may be held that the detection of a uniform drift of the solar system in this way is not contrary to the principle of relativity. It is contrary to some statements of that principle; and the cogency of those statements breaks down, I think, whenever they include the velocity of light; because there we really have something absolute (in the only sense in which the term can have a physical meaning) with which we can compare our own motions, when we have learnt how.

But in ordinary astronomical translation—translation as of the earth in its orbit—all our instruments, all our standards, the whole contents of our laboratory, are moving at the same rate in the same direction; under those conditions we cannot expect to observe anything. Clerk Maxwell went so far as to say that if every particle of matter simultaneously received a graduated blow so as to produce a given constant acceleration all in the same direction, we should be unaware of the fact. He did not then know all that we know about radiation. But apart from that, and limiting ourselves to comparatively slow changes of velocity, our standards will inevitably share whatever change occurs. So far as observation goes, everything will be practically as if no change had occurred at all; though that may not be the truth. All that experiment establishes is that there have so far always been compensations; so that the attempt to observe motion through the æther is being given up as hopeless.

Surely, however, the minute and curious compensations cannot be accidental, they must be necessary? Yes, they are necessary; and I want to say why. Suppose the case were one of measuring thermal expansion; and suppose everything had the same temperature and the same expansibility; our standards would contract or expand with everything else, and we could observe nothing; but expansion would occur nevertheless. That is obvious, but the following assertion is not so obvious. If everything in the Universe had the same temperature, no matter what that temperature was, nothing would be visible at all; the external world, so far as vision went, would not appear to exist. Visibility depends on radiation, on differential radiation. We must have differences to appeal to our senses, they are not constructed for uniformity.

It is the extreme omnipresence and uniformity and universal agency of the æther of space that makes it so difficult to observe. To observe anything you must have differences. If all actions at a distance are conducted at the same rate through the æther, the travel of none of them can be observed. Find something not conveyed by the æther, and there is a chance. But then every physical action is transmitted by the æther, and in every case by means of its transverse or radiation-like activity.

Except perhaps Gravitation. That may give us a clue some day, but at present we have not been able to detect its speed of transmission at all. No plan has been devised for measuring it. Nothing short of the creation or destruction of matter seems likely to serve: creation or destruction of the gravitational unit, whether it be an atom or an electron, or whatever it is. Most likely the unit of weight is an electron, just as the unit of mass is.

The so-called non-Newtonian Mechanics, with mass and shape a function of velocity, is an immediate consequence of the electrical theory of matter. The dependence of inertia and shape on speed is a genuine discovery, and, I believe, a physical fact. The Principle of Relativity would reduce it to a conventional fiction. It would seek to replace this real change in matter by imaginary changes in time. But surely we must admit that Space and Time are essentially unchangeable: they are not at the disposal even of mathematicians; though it is true that Pope Gregory, or a Daylight-saving Bill, can play with our units, can turn the 3rd of October in any one year into the

14th, or can make the sun South sometimes at eleven o'clock sometimes at twelve.[5]

But the changes of dimension and mass due to velocity are not conventions but realities; so I urge, on the basis of the electrical theory of matter. The Fitzgerald-Lorentz hypothesis I have an affection for. I was present at its birth. Indeed, I assisted at its birth; for it was in my study at 21 Waverley Road, Liverpool, with Fitzgerald in an armchair, and while I was enlarging on the difficulty of reconciling the then new Michelson experiment with the theory of astronomical aberration and with other known facts, that he made his brilliant surmise:—"Perhaps the stone slab was affected by the motion." I rejoined that it was a 45° shear that was needed. To which he replied, "Well, that's all right—a simple distortion." And very soon he said, "And I believe it occurs, and that the Michelson experiment demonstrates it." A shortening long-ways, or a lengthening cross-ways would do what was wanted.

And is such a hypothesis gratuitous? Not at all: in the light of the electrical theory of matter such an effect ought to occur. The amount required by the experiment, and given by the theory, is equivalent to a shrinkage of the earth's diameter by rather less than three inches, in the line of its orbital motion through the æther of space. An oblate spheroid with the proper eccentricity has all the simple geometrical properties of a stationary sphere; the eccentricity depends in a definite way on speed, and becomes considerable as the velocity of light is approached.

All this Profs. Lorentz and Larmor very soon after, and quite independently, perceived; though this is only one of the minor achievements in the electrical theory of matter which we owe to our distinguished visitor Prof. H. A. Lorentz.

The key of the position, to my mind, is the nature of cohesion. I regard cohesion as residual chemical affinity, a balance of electrical attraction over repulsion between groups of alternately charged molecules. Lateral electrical attraction is diminished by motion; so is lateral electric repulsion. In cohesion both are active, and they nearly balance. At anything but molecular distance they quite balance, but at molecular distance attraction predominates. It is the diminution of the predominant partner that will be felt. Hence while longitudinal cohesion, or cohesion in the direction of motion, remains unchanged, lateral cohesion is less; so there will be distortion, and a unit cube x, y, z moving along x with velocity u becomes a parallelopiped with sides $1/k^2, k, k$; where $1/k^6 = 1 - u^2/v^2$.[6]

The electrical theory of matter is a positive achievement, and has positive results. By its aid we make experiments which throw light upon the relation between matter and the æther of space. The principle of relativity, which seeks to replace it, is a principle of negation, a negative proposition, a statement that observation of certain facts can never be made, a denial of any relation between matter and æther, a virtual denial that the æther exists. Whereas if we admit the real changes that go on by reason of rapid motion, a whole field is open for discovery; it is even possible to investigate the changes in shape of an electron—appallingly minute though it is—as it approaches the speed of light; and properties belonging to the æther of space, evasive though it be, cannot lag far behind.

Speaking as a physicist, I must claim the æther as peculiarly our own domain. The study of molecules we share with the chemist, and matter in its various forms is investigated by all men of science, but a study of the æther of space belongs to physics only. I am not alone in feeling the fascination of this portentous entity. Its curiously elusive and intangible character, combined with its universal and unifying permeance, its apparently infinite extent, its definite and perfect properties, make the æther the most interesting, as it is by far the largest and most fundamental, ingredient in the material cosmos.

As Sir J. J. Thomson said at Winnipeg—

"The æther is not a fantastic creation of the speculative philosopher; it is as essential to us as the air we breathe. . . . The study of this all-pervading substance is perhaps the most fascinating and important duty of the physicist."

Matter it is not, but material it is; it belongs to the material universe, and is to be investigated by ordinary methods. But to say this is by no means to deny that it may have mental and spiritual functions to subserve in some other order of existence, as matter has in this.

The æther of space is at least the great engine of continuity. It may be much more, for without it there could hardly be a material universe at all. Certainly, however, it is essential to continuity; it is the one all-permeating substance that binds the whole of the particles of matter together. It is the uniting and binding medium without which, if matter could exist at all, it could exist only as chaotic and isolated fragments: and it is the universal medium of communication between worlds and particles. And yet it is possible for people to deny its existence, because it is unrelated to any of our senses, except sight—and to that only in an indirect and not easily recognised fashion.

To illustrate the thorough way in which we may be unable to detect what is around us unless it has some link or bond which enables it to make appeal, let me make another quotation from Sir J. J. Thomson's address at Winnipeg in 1909. He is leading up to the fact that even single atoms, provided they are fully electrified with the proper atomic charge, can be detected by certain delicate instruments—their field of force bringing them within our ken—whereas a whole crowd of unelectrified ones would escape observation.

"The smallest quantity of unelectrified matter ever detected is probably that of neon, one of the inert gases of the atmosphere. Prof. Strutt has shown that the amount of neon in 1/20 of a cubic centimetre of the air at ordinary pressures can be detected by the spectroscope; Sir William Ramsay estimates that the neon in the air only amounts to one part of neon in 100,000 parts of air, so that the neon in 1/20 of a cubic centimetre of air would only occupy at atmospheric pressure a volume of half a millionth of a cubic centimetre. When stated in this form the quantity seems exceedingly small, but in this small volume there are about ten million million molecules. Now the population of the earth is estimated at about fifteen hundred millions, so that the smallest number of molecules of neon we can identify is about 7000 times the population of the earth. In other words, if we had no better test for the existence of a man than we have for that of an unelectrified molecule we should come to the conclusion that the earth is uninhabited."

The parable is a striking one, for on these lines it might legitimately be contended that we have no right to say positively that even space is uninhabited. All we can safely say is that we have no means of

[5] In the historical case of governmental interference with the calendar, no wonder the populace rebelled. Surely someone might have explained to the authorities that dropping leap year for the greater part of a century would do all that was wanted, and that the horrible inconvenience of upsetting all engagements and shortening a single year by eleven days could be avoided.

[6] Different modes of estimating the change give slightly different results; some involve a compression as well as a distortion—in fact the strain associated with the name of Thomas Young; the details are rather complicated and this is not the place to discuss them. A pure shear, of magnitude specified in the text, is simplest, it is in accord with all the experimental facts—including some careful measurements by Bucherer—and I rather expect it to survive.

detecting the existence of non-planetary immaterial dwellers, and that unless they have some link or bond with the material they must always be physically beyond our ken. We may therefore for practical purposes legitimately treat them as non-existent until such link is discovered, but we should not dogmatise about them. True agnosticism is legitimate, but not the dogmatic and positive and gnostic variety.

But I hold that science is incompetent to make comprehensive denials, even about the æther, and that it goes wrong when it makes the attempt. Science should not deal in negations: it is strong in affirmations, but nothing based on abstraction ought to presume to deny outside its own region. It often happens that things abstracted from and ignored by one branch of science may be taken into consideration by another:—

Thus, chemists ignore the æther.

Mathematicians may ignore experimental difficulties.

Physicists ignore and exclude live things.

Biologists exclude mind and design.

Psychologists may ignore human origin and human destiny.

Folk-lore students and comparative mythologists need not trouble about what modicum of truth there may be in the legends which they are collecting and systematising.

And microscopists may ignore the stars.

Yet none of these ignored things should be denied.

Denial is no more infallible than assertion. There are cheap and easy kinds of scepticism, just as there are cheap and easy kinds of dogmatism; in fact, scepticism can become viciously dogmatic, and science has to be as much on its guard against personal predilection in the negative as in the positive direction. An attitude of universal denial may be very superficial.

"To doubt everything or to believe everything are two equally convenient solutions; both dispense with the necessity of reflection."

All intellectual processes are based on abstraction. For instance, history must ignore a great multitude of facts in order to treat any intelligently: it selects. So does art; and that is why a drawing is clearer than reality. Science makes a diagram of reality, displaying the works, like a skeleton clock. Anatomists dissect out the nervous system, the blood vessels, and the muscles, and depict them separately—there must be discrimination for intellectual grasp—but in life they are all merged and co-operating together; they do not really work separately, though they may be studied separately. A scalpel discriminates: a dagger or a bullet crashes through everything. That is life—or rather death. The laws of nature are a diagrammatic framework, analysed or abstracted out of the full comprehensiveness of reality.

Hence it is that science has no authority in denials. To deny effectively needs much more comprehensive knowledge than to assert. And abstraction is essentially not comprehensive: one cannot have it both ways. Science employs the methods of abstraction, and thereby makes its discoveries.

The reason why some physiologists insist so strenuously on the validity and self-sufficiency of the laws of physics and chemistry, and resist the temptation to appeal to unknown causes—even though the guiding influence and spontaneity of living things are occasionally conspicuous as well as inexplicable—is that they are keen to do their proper work; and their proper work is to pursue the laws of ordinary physical energy into the intricacies of "colloidal electrolytic structures of great chemical complexity" and to study its behaviour there.

What we have clearly to grasp, on their testimony, is that for all the terrestrial manifestations of life the ordinary physical and chemical processes have to serve. There are not new laws for living matter, and old laws for non-living, the laws are the same; or if ever they differ, the burden of proof rests on him who sustains the difference. The conservation of energy, the laws of chemical combination, the laws of electric currents, of radiation, &c., &c.—all the laws of chemistry and physics—may be applied without hesitation in the organic domain. Whether they are sufficient is open to question, but as far as they go they are necessary; and it is the business of the physiologist to seek out and demonstrate the action of those laws in every vital action.

This is clearly recognised by the leaders, and in the definition of physiology by Burdon Sanderson he definitely limited it to the study of "ascertainable characters of a chemical and physical type." In his address to the Subsection of Anatomy and Physiology at York in 1881 he spoke as follows:—

"It would give you a true idea of the nature of the great advance which took place about the middle of this century if I were to define it as the epoch of the death of 'vitalism.' Before that time, even the greatest biologists—*e.g.* J. Müller—recognised that the knowledge biologists possessed both of vital and physical phenomena was insufficient to refer both to a common measure. The method, therefore, was to study the processes of life in relation to each other only. Since that time it has become fundamental in our science not to regard any vital process as understood at all unless it can be brought into relation with physical standards, and the methods of physiology have been based exclusively on this principle. The most efficient cause [conducing to the change] was the progress which had been made in physics and chemistry, and particularly those investigations which led to the establishment of the doctrine of the conservation of energy. . . .

"Investigators who are now working with such earnestness in all parts of the world for the advance of physiology, have before them a definite and well-understood purpose, that purpose being to acquire an exact knowledge of the chemical and physical processes of animal life and of the self-acting machinery by which they are regulated for the general good of the organism. The more singly and straightforwardly we direct our efforts to these ends, the sooner we shall attain to the still higher purpose—the effectual application of our knowledge for the increase of human happiness."

Prof. Gotch, whose recent loss we have to deplore, puts it more strongly:—

"It is essentially unscientific," he says, "to say that any physiological phenomenon is caused by vital force."

I observe that by some critics I have been called a vitalist, and in a sense I am; but I am not a vitalist if vitalism means an appeal to an undefined "vital force" (an objectionable term I have never thought of using) as against the laws of chemistry and physics. Those laws must be supplemented, but need by no means be superseded. The business of science is to trace out their mode of action everywhere, as far and as fully as possible; and it is a true instinct which resents the mediæval practice of freely introducing spiritual and unknown causes into working science. In science an appeal to occult qualities must be illegitimate, and be a barrier to experiment and research generally; as, when anything is called an act of God—and when no more is said. The occurrence is left unexplained. As an ultimate statement such a phrase may be not only true but universal in its application. But there are always proximate explanations which may be looked for and discovered with patience. So, lightning, earthquakes, and other potents are reduced to natural causes. No ultimate explanation is ever attained by science: proximate explanations only. They are what it exists for; and it is the business of scientific men to seek them.

To attribute the rise of sap to vital force would be absurd, it would be giving up the problem and stating nothing at all. The way in which osmosis acts to produce the remarkable and surprising effect is discoverable and has been discovered.

So it is always in science, and its progress began when unknown causes were eliminated and treated as non-existent. Those causes, so far as they exist, must establish their footing by direct investigation and research; carried on in the first instance apart from the long-recognised branches of science, until the time when they too have become sufficiently definite to be entitled to be called scientific. Outlandish territories may in time be incorporated as states, but they must make their claim good and become civilised first.

It is well for people to understand this definite limitation of scope quite clearly, else they wrest the splendid work of biologists to their own confusion—helped it is true by a few of the more robust or less responsible theorisers, among those who should be better informed and more carefully critical in their philosophising utterances.

But, as is well known, there are more than a few biologists who, when taking a broad survey of their subject, clearly perceive and teach that, before all the actions of live things are fully explained, some hitherto excluded causes must be postulated. Ever since the time of J. R. Mayer it has been becoming more and more certain that, as regards performance of work, a living thing obeys the laws of physics, like everything else; but undoubtedly it initiates processes and produces results that without it could not have occurred—from a bird's nest to a honeycomb, from a deal box to a warship. The behaviour of a ship firing shot and shell is explicable in terms of energy, but the discrimination which it exercises between friend and foe is not so explicable. There is plenty of physics and chemistry and mechanics about every vital action, but for a complete understanding of it something beyond physics and chemistry is needed.

And life introduces an incalculable element. The vagaries of a fire or a cyclone could all be predicted by Laplace's calculator, given the initial positions, velocities, and the law of acceleration of the molecules; but no mathematician could calculate the orbit of a common house-fly. A physicist into whose galvanometer a spider had crept would be liable to get phenomena of a kind quite inexplicable, until he discovered the supernatural, *i.e.*, literally superphysical, cause. I will risk the assertion that life introduces something incalculable and purposeful amid the laws of physics; it thus distinctly supplements those laws, though it leaves them otherwise precisely as they were and obeys them all.

We see only its effect, we do not see life itself. Conversion of inorganic into organic is effected always by living organisms. The conversion under those conditions certainly occurs, and the process may be studied. Life appears necessary to the conversion; which clearly takes place under the guidance of life, though in itself it is a physical and chemical process. Many laboratory conversions take place under the guidance of life, and, but for the experimenter, would not have occurred.

Again, putrefaction, and fermentation, and purification of rivers, and disease, are not purely and solely chemical processes. Chemical processes they are, but they are initiated and conducted by living organisms. Just when medicine is becoming biological, and when the hope of making the tropical belt of the earth healthily habitable by energetic races is attracting the attention of people of power, philosophising biologists should not attempt to give their science away to chemistry and physics. Sections D and H and I and K are not really subservient to A and B. Biology is an independent science, and it is served, not dominated, by chemistry and physics.

Scientific men are hostile to superstition, and rightly so, for a great many popular superstitions are both annoying and contemptible; yet occasionally the term may be wrongly applied to practices of which the theory is unknown. To a superficial observer some of the practices of biologists themselves must appear grossly superstitious. To combat malaria Sir Ronald Ross does not indeed erect an altar; no, he oils a pond—making libation to its presiding genii. What can be more ludicrous than the curious and evidently savage ritual, insisted on by United States officers, at that hygienically splendid achievement, the Panama Canal—the ritual of punching a hole in every discarded tin, with the object of keeping off disease! What more absurd, again—in superficial appearance—than the practice of burning or poisoning a soil to make it extra fertile!

Biologists in their proper field are splendid, and their work arouses keen interest and enthusiasm in all whom they guide into their domain. Most of them do their work by intense concentration, by narrowing down their scope, not by taking a wide survey or a comprehensive grasp. Suggestions of broader views and outlying fields of knowledge seem foreign to the intense worker, and he resents them. For his own purpose he wishes to ignore them, and practically he may be quite right. The folly of negation is not his, but belongs to those who misinterpret or misapply his utterances, and take him as a guide in a region where, for the time at least, he is a stranger. Not by such aid is the universe in its broader aspects to be apprehended. If people in general were better acquainted with science they would not make these mistakes. They would realise both the learning and the limitations, make use of the one and allow for the other, and not take the recipe of a practical worker for a formula wherewith to interpret the universe.

What appears to be quite certain is that there can be no terrestrial manifestation of life without matter. Hence naturally they say, or they approve such sayings as, "I discern in matter the promise and potency of all forms of life." Of all terrestrial manifestations of life, certainly. How else could it manifest itself save through matter? "I detect nothing in the organism but the laws of chemistry and physics," it is said. Very well: naturally enough. That is what they are after; they are studying the physical and chemical aspects or manifestations of life. But life itself—life and mind and consciousness—they are not studying, and they exclude them from their purview. Matter is what appeals to our senses here and now; materialism is appropriate to the material world; not as a philosophy but as a working creed, as a proximate and immediate formula for guiding research. Everything beyond that belongs to another region, and must be reached by other methods. To explain the psychical in terms of physics and chemistry is simply impossible; hence there is a tendency to deny its existence, save as an epiphenomenon. But all such philosophising is unjustified, and is really bad metaphysics.

So if ever in their enthusiasm scientific workers go too far and say that the things they exclude from study have no existence in the universe, we must appeal against them to direct experience. We ourselves are alive, we possess life and mind and consciousness, we have first-hand experience of these things, quite apart from laboratory experiments. They belong to the common knowledge of the race. Births, deaths, and marriages are not affairs of the biologist, but of humanity; they went on before a single one of them was understood, before a vestige of science existed. We ourselves are the laboratory in which men of science, psychologists, and others make experiments. They can formulate our processes of digestion, and the material concomitants of willing, of sensation, of thinking; but the hidden guiding entities they do not touch.

So also if any philosopher tells you that you do not exist, or that the external world does not exist, or that you are an automaton without free will, that all your actions are determined by outside causes, and that you are not responsible—or that a body cannot move out of its place, or that Achilles cannot catch a tortoise; then in all those cases appeal must be made to twelve average men, unsophisticated by special studies. There is always a danger of error in interpreting experience, or in drawing inferences from it; but in a matter of bare fact, based on our own first-hand experience, we are able to give a verdict. We may be mistaken as to the nature of what we see. Stars may look to us like bright specks in a dome, but the fact that we see them admits of no doubt. So also consciousness and will are realities of which we are directly aware, just as directly as we are of motion and force, just as clearly as we apprehend the philosophising utterances of an Agnostic. The process of seeing, the plain man does not understand; he does not recognise that it is a method of æthereal telegraphy; he knows nothing of the æther and its ripples, nor of the retina and its rods and cones, nor of nerve and brain processes; but he sees and he hears and he touches, and he wills and he thinks and is conscious. This is not an appeal to the mob as against the philosopher, it is appeal to the experience of untold ages as against the studies of a generation.

How consciousness became associated with matter, how life exerts guidance over chemical and physical forces, how mechanical motions are translated into sensations—all these things are puzzling and demand long study. But the fact that these things are so admits of no doubt; and difficulty of explanation is no argument against them. The blind man restored to sight had no opinion as to how he was healed, nor could he vouch for the moral character of the Healer, but he plainly knew that whereas he was blind now he saw. About that fact he was the best possible judge. So it is also with "this main miracle that thou art thou, With power on thine own act and on the world."

But although life and mind may be excluded from physiology, they are not excluded from science. Of course not. It is not reasonable to say that things necessarily elude investigation merely because we do not knock against them. Yet the mistake is sometimes made. The æther makes no appeal to sense, therefore some are beginning to say that it does not exist. Mind is occasionally put into the same predicament. Life is not detected in the laboratory, save in its physical and chemical manifestations; but we may have to admit that it guides processes nevertheless. It may be called a catalytic agent.

To understand the action of life itself, the simplest plan is not to think of a microscopic organism, or any unfamiliar animal, but to make use of our own experience as living beings. Any positive instance serves to stem a comprehensive denial; and if the reality of mind and guidance and plan is denied because they make no appeal to sense, then think how the world would appear to an observer to whom the existence of men was unknown and undiscoverable, while yet all the laws and activities of nature went on as they do now.

Suppose, then, that *man* made no appeal to the senses of an observer of this planet. Suppose an outside observer could see all the events occurring in the world, save only that he could not see animals or men. He would describe what he saw much as we have to describe the activities initiated by life.

If he looked at the Firth of Forth, for instance, he would see piers arising in the water, beginning to sprout, reaching across in strange manner till they actually join or are joined by pieces attracted up from below to complete the circuit (a solid circuit round the current). He would see a sort of bridge or filament thus constructed, from one shore to the other, and across this bridge insect-like things crawling and returning for no very obvious reason.

Or let him look at the Nile, and recognise the meritorious character of that river in promoting the growth of vegetation in the desert. Then let him see a kind of untoward crystallisation growing across and beginning to dam the beneficent stream. Blocks fly to their places by some kind of polar forces; "we cannot doubt" that it is by helio- or other tropism. There is no need to go outside the laws of mechanics and physics, there is no difficulty about supply of energy—none whatever—materials in tin cans are consumed which amply account for all the energy; and all the laws of physics are obeyed. The absence of any design, too, is manifest; for the effect of the structure is to flood an area up-stream which might have been useful, and to submerge a structure of some beauty; while down stream its effect is likely to be worse, for it would block the course of the river and waste it on the desert, were it not that fortunately some leaks develop and a sufficient supply still goes down—goes down, in fact, more equably than before: so that the ultimate result is beneficial to vegetation, and simulates intention.

If told concerning either of these structures that an engineer, a designer in London, called Benjamin Baker, had anything to do with it, the idea would be preposterous. One conclusive argument is final against such a superstitious hypothesis—he is not there, and a thing plainly cannot act where it is not. But although we, with our greater advantages, perceive that the right solution for such an observer would be the recognition of some unknown agency or agent, it must be admitted that an explanation in terms of a vague entity called vital force would be useless, and might be so worded as to be misleading; whereas a statement in terms of mechanics and physics could be clear and definite and true as far as it went, though it must necessarily be incomplete.

And note that what we observe, in such understood cases, is an *interaction* of mind and matter; not parallelism nor epiphenomenalism nor anything strained or difficult, but a straightforward utilisation of the properties of matter and energy for purposes conceived in the mind, and executed by muscles guided by acts of will.

But, it will be said, this is unfair, for we *know* that there is design in the Forth Bridge or the Nile Dam, we have seen the plans and understand the agencies at work: we know that it was conceived and guided by life and mind, it is unfair to quote this as though it could simulate an automatic process.

Not at all, say the extreme school of biologists whom I am criticising, or ought to say if they were consistent, there is nothing but chemistry and physics at work anywhere; and the mental activity apparently demonstrated by those structures is only an illusion, an epiphenomenon; the laws of chemistry and physics are supreme, and they are sufficient to account for everything!

Well, they account for things up to a point; they account in part for the colour of a sunset, for the majesty of a mountain peak, for the glory of animate existence. But do they account for everything completely? Do they account for our own feeling of joy and exaltation, for our sense of beauty, for the manifest beauty existing throughout nature? Do not these things suggest something higher and nobler and more joyous, something for the sake of which all the struggle for existence goes on?

Surely there must be a deeper meaning involved in natural objects. Orthodox explanations are only partial, though true as far as they go. When we examine each parti-coloured pinnule in a peacock's tail, or hair in a zebra's hide, and realise that the varying shades on each are so placed as to contribute to the general design and pattern, it becomes exceedingly difficult to explain how this organised co-operation of parts, this harmonious distribution of pigment cells, has come about on merely mechanical principles. It would be as easy to explain the sprouting of the cantilevers of the Forth Bridge from its piers, or the flocking of the stones of the Nile Dam by chemiotaxis. Flowers attract insects for fertilisation; and fruit tempts animals to eat it in order to carry seeds. But these explanations cannot be final. We have still to explain the insects. So much beauty cannot be necessary merely to attract their attention. We have further to explain this competitive striving towards life. Why do things struggle to exist? Surely the effort must have some significance, the development some aim. We thus reach the problem of existence itself, and the meaning of evolution.

The mechanism whereby existence entrenches itself is manifest, or at least has been to a large extent discovered. Natural selection is a *vera causa*, so far as it goes; but if so much beauty is necessary for insects, what about the beauty of a landscape or of clouds? What utilitarian object do those subserve? Beauty in general is not taken into account by science. Very well, that may be all right, but it exists nevertheless. It is not my function to discuss it. No; but it is my function to remind you and myself that that our studies do not exhaust the universe, and that if we dogmatise in a negative direction, and say that we can reduce everything to physics and chemistry, we gibbet ourselves as ludicrously narrow pedants, and are falling far short of the richness and fullness of our human birthright. How far preferable is the reverent attitude of the Eastern poet:—

"The world with eyes bent upon thy feet stands in awe with all its silent stars."

Superficially and physically we are very limited. Our sense organs are adapted to the observation of matter; and nothing else directly appeals to us. Our nerve-muscle-system is adapted to the production of motion in matter, in desired ways; and nothing else in the material world can we accomplish. Our brain and nerve systems connect us with the rest of the physical world. Our senses give us information about the movements and arrangements of matter. Our muscles enable us to produce changes in those distributions. That is our equipment for human life; and human history is a record of what we have done with these parsimonious privileges.

Our brain, which by some means yet to be discovered connects us with the rest of the material world, has been thought partially to disconnect us from the mental and spiritual realm, to which we really belong, but from which for a time and for practical purposes we are isolated. Our common or social association with matter gives us certain opportunities and facilities, combined with obstacles and difficulties which are themselves opportunities for struggle and effort.

Through matter we become aware of each other, and can communicate with those of our fellows who have ideas sufficiently like our own for them to be stimulated into activity by a merely physical process set in action by ourselves. By a time succession of vibratory movements (as in speech and music), or by a static distribution of materials (as in writing, painting, and sculpture), we can carry on intelligent intercourse with our fellows; and we get so used to these ingenious and roundabout methods, that we are apt to think of them and their like as not only the natural but as the only possible modes of communication, and that anything more direct would disarrange the whole fabric of science.

It is clearly true that our bodies constitute the normal means of manifesting ourselves to each other while on the planet; and that if the physiological mechanism whereby we accomplish material acts is injured, the conveyance of our meaning and the display of our personality inevitably and correspondingly suffer.

So conspicuously is this the case that it has been possible to suppose that the communicating mechanism, formed and worked by us, is the whole of our existence: and that we are essentially nothing but the machinery by which we are known. We find the machinery utilising nothing but well-known forms of energy, and subject to all the laws of chemistry and physics—it would be strange if it were not so—and from that fact we try to draw valid deductions as to our nature, and as to the impossibility of our existing apart from and independent of these temporary modes of material activity and manifestation. We so uniformly employ them, in our present circumstances, that we should be on our guard against deception due to this very uniformity. Material bodies are all that we have any control over, are all that we are experimentally aware of; anything that we can do with these is open to us; any conclusions we can draw about them may be legitimate and true. But to step outside their province and to deny the existence of any other region because we have no sense organ for its appreciation, or because (like the æther) it is too uniformly omnipresent for our ken, is to wrest our advantages and privileges from their proper use and apply them to our own misdirection.

But if we have learnt from science that evolution is real, we have learnt a great deal. I must not venture to philosophise, but certainly from the point of view of science evolution is a great reality. Surely evolution is not an illusion; surely the universe progresses in time. Time and space and matter are abstractions, but are none the less real: they are data given by experience; and time is the keystone of evolution. "Thy centuries follow each other, perfecting a small wild flower."

We abstract from living, moving reality a certain static aspect, and we call it matter; we abstract the element of progressiveness, and we call it time. When these two abstractions combine, co-operate, interact, we get reality again. It is like Poynting's theorem.

The only way to refute or confuse the theory of evolution is to introduce the subjectivity of time. That theory involves the reality of time, and it is in this sense that Prof. Bergson uses the great phrase "creative evolution."

I see the whole of material existence as a steady passage from past to future, only the single instant which we call the present being actual. The past is not non-existent, however, it is stored in our memories, there is a record of it in matter, and the present is based upon it; the future is the outcome of the present, and is the product of evolution.

Existence is like the output from a loom. The pattern, the design for the weaving, is in some sort "there" already; but whereas our looms are mere machines, once the guiding cards have been fed into them, the loom of time is complicated by a multitude of free agents who can modify the web, making the product more beautiful or more ugly according as they are in harmony or disharmony with the general scheme. I venture to maintain that manifest imperfections are thus accounted for, and that *freedom* could be given on no other terms, nor at any less cost.

The ability thus to work for weal or woe is no illusion, it is a reality, a responsible power which conscious agents possess; wherefore the resulting fabric is not something preordained and inexorable, though by wide knowledge of character it may be inferred. Nothing is inexorable except the uniform progress of time; the cloth must be woven, but the pattern is not wholly fixed and mechanically calculable.

Where inorganic matter alone is concerned, there everything is determined. Wherever full consciousness has entered, new powers arise, and the faculties and desires of the conscious parts of the scheme have an effect upon the whole. It is not guided from outside, but from within; and the guiding power is immanent at every instant. Of this guiding power we are a small but not wholly insignificant portion.

That evolutionary progress is real is a doctrine of profound significance, and our efforts at social betterment are justified because we are a part of the scheme, a part that has become conscious, a part that realises, however dimly, what it is doing and what it is aiming at. Planning and aiming are therefore not absent from the whole, for we are a part of the whole, and are conscious of them in ourselves.

Either we are immortal beings or we are not. We may not know our destiny, but we must have a destiny of some sort. Those who make denials are just as likely to be wrong as those who make assertions: in fact, denials are assertions thrown into negative form. Scientific men are looked up to as authorities, and should be careful not to mislead. Science may not be able to reveal human destiny, but it certainly should not obscure it. Things are as they are, whether we find them out or not; and if we make rash and false statements, posterity will detect us—if posterity ever troubles its head about us. I am one of those who think that the methods of science are not so limited in their scope as has been thought: that they can be applied much more widely, and that the psychic region can be studied and brought under law too. Allow us anyhow to make the attempt. Give us a fair field. Let those who prefer the materialistic hypothesis by all means develop their thesis as far as they can; but let us try what we can do in the psychical region, and see which wins. Our methods are really the same as theirs—the subject-matter differs. Neither should abuse the other for making the attempt.

Whether such things as intuition and revelation ever occur is an open question. There are some who have reason to say that they do. They are at any rate not to be denied off-hand. In fact, it is always extremely difficult to deny *anything* of a general character, since evidence in its favour may be only hidden and not forthcoming, especially not forthcoming at any particular age of the world's history, or at any particular stage of individual mental development. Mysticism must have its place, though its relation to science has so far not been found. They have appeared disparate and disconnected, but there need be no hostility between them. Every kind of reality must be ascertained and dealt with by proper methods. If the voices of Socrates and of Joan of Arc represent real psychical experiences, they must belong to the intelligible universe.

Although I am speaking *ex cathedra*, as one of the representatives of orthodox science, I will not shrink from a personal note summarising the result on my own mind of thirty years' experience of psychical research, begun without predilection—indeed, with the usual hostile prejudice. This is not the place to enter into details or to discuss facts scorned by orthodox science, but I cannot help remembering that an utterance from this chair is no ephemeral production, for it remains to be criticised by generations yet unborn, whose knowledge must inevitably be fuller and wider than our own. Your President, therefore, should not be completely bound by the shackles of present-day orthodoxy, nor limited to beliefs fashionable at the time. In justice to myself and my co-workers, I must risk annoying my present hearers, not only by leaving on record our conviction that occurrences now regarded as occult can be examined and reduced to order by the methods of science carefully and persistently applied, but by going further and saying, with the utmost brevity, that already the facts so examined have convinced me that memory and affection are not limited to that association with matter by which alone they can manifest themselves here and now, and that personality persists beyond bodily death. The evidence, to my mind, goes to prove that discarnate intelligence, under certain conditions, may interact with us on the material side, thus indirectly coming within our scientific ken; and that gradually we may hope to attain some understanding of the nature of a larger, perhaps ætherial, existence, and of the conditions regulating intercourse across the chasm. A body of responsible investigators has even now landed on the treacherous but promising shores of a new continent.

Yes, and there is more to say than that. The methods of science are not the only way, though they are our way, of being piloted to truth. "*Uno itinere non potest perveniri ad tam grande secretum.*"

Many scientific men still feel in pugnacious mood towards theology, because of the exaggerated dogmatism which our predecessors encountered and overcame in the past. They had to struggle for freedom to find truth in their own way; but the struggle was a miserable necessity, and has left some evil effects. And one of them is this lack of sympathy, this occasional hostility, to other more spiritual forms of truth. We cannot really and seriously suppose that truth began to arrive on this planet a few centuries ago. The pre-scientific insight of genius—of poets and prophets and saints—was of supreme value, and the access of those inspired seers to the heart of the universe was profound. But the camp followers, the scribes and pharisees, by whatever name they may be called, had no such insight, only a vicious or a foolish obstinacy; and the prophets of a new era were stoned.

Now at last we of the new era have been victorious, and the stones are in our hands; but for us to imitate the old ecclesiastical attitude would be folly. Let us not fall into the old mistake of thinking that ours is the only way of exploring the multifarious depths of the universe, and that all others are worthless and mistaken. The universe is a larger thing than we have any conception of, and no one method of search will exhaust its treasures.

Men and brethren, we are trustees of the truth of the physical universe as scientifically explored: let us be faithful to our trust.

Genuine religion has its roots deep down in the heart of humanity and in the reality of things. It is not surprising that by our methods we fail to grasp it: the actions of the Deity make no appeal to any special sense, only a universal appeal; and our methods are, as we know, incompetent to detect complete uniformity. There is a principle of relativity here, and unless we encounter flaw or jar or change, nothing in us responds; we are deaf and blind, therefore, to the Immanent Grandeur unless we have insight enough to recognise in the woven fabric of existence, flowing steadily from the loom in an infinite progress towards perfection, the ever-growing garment of a transcendant God.

SUMMARY OF THE ARGUMENT.

A marked feature of the present scientific era is the discovery of, and interest in, various kinds of atomism; so that continuity seems in danger of being lost sight of.

Another tendency is toward comprehensive negative generalisations from a limited point of view.

Another is to take refuge in rather vague forms of statement, and to shrink from closer examination of the puzzling and the obscure.

Another is to deny the existence of anything which makes no appeal to organs of sense, and no ready response to laboratory experiment.

Against these tendencies the author contends. He urges a belief in ultimate continuity as essential to science; he regards scientific concentration as an inadequate basis for philosophic generalisation; he believes that obscure phenomena may be expressed simply if properly faced; and he points out that the non-appearance of anything perfectly uniform and omnipresent is only what should be expected, and is no argument against its real substantial existence.

NOTES.

IN view of the meeting of the British Association, a "Handbook for Birmingham and the Neighbourhood" has been issued (under the editorshio of Dr. G. A. Auden) at the price of 3*s*. 6*d*. net by Messrs. Cornish Bros., Ltd., Birmingham. The volume is of an encyclopædic character, and should be of great service not only to members of the British Association, but to all who are interested in things pertaining to Birmingham. The work is divided into five main divisions—historical, municipal, educational, industrial, and scientific. In the latter, which of course appeals more especially to our readers, botany is dealt with by Prof. West and Messrs. Grove, Humphreys, Cleminshaw, and Duncan; Midland reafforesting by P. E. Martineau; the ornithology of the district by R. W. Chase; insects by H. W. Ellis; mammalia, amphibia, reptilia, and pisces by H. E. Forrest; microscopic aquatic fauna by H. W. H. Darlaston; meteorology by A. Cresswell; and the geology and physiography of the Birmingham country by Prof C. Lapworth, F.R.S. The last-named contribution is supplemented by very clear geological and topographical maps executed by Messrs. John Bartholomew and Co., of Edinburgh. Besides these maps, there are a number of illustrations in the text. Altogether the volume is an admirable production, and worthy of the occasion for which it has been prepared.

Apropos of the British Association meeting, a recent number of *The Westminster Gazette* contains an article on the Lunar Society, the members of which used to meet monthly in Birmingham in the eighteenth century, as nearly as possible at the time of full moon that they might have the benefit of its light in returning home—hence the name of the society. Each member was permitted to bring a friend, and some very distinguished men from time to time enjoyed the society's hospitality. Thus we find that among such guests were Sir Joseph Banks, Sir William Herschel, John Smeaton, of lighthouse fame, Josiah Wedgwood, Prof. Hugh Blair, Afzelius, the Swedish botanist, Daniel Solander, the naturalist, and Andre de Luc, the geologist. Among the members of the society or club were James Watt, Joseph Priestley, and Erasmus Darwin. The Priestley riots dealt a blow to the little society from which it never recovered, and it is therefore now no more than a memory.

PROF. MILNE bequeathed to the British Association his books, albums, and scientific instruments relating to seismology, and, subject to his wife's interest, the sum of 1000*l*. to the chairman of the seismology committee of the British Association for the furtherance of the study of terrestrial physics and its attendant subjects.

A FURTHER grant of 5000*l*., making 10,000*l*. in all, has been made by the Federal Government of the Commonwealth of Australia towards completing the work of the Mawson Antarctic Expedition and bringing the explorers back.

THE sum of 90,000 francs has been bequeathed to the Pasteur Institute at Paris for the founding of a prize for the best original work in the treatment of meningitis.

WE record, with regret, the death on Saturday last of Dr. Hugh Marshall, F.R.S., professor of chemistry in University College, Dundee.

THE death occurred on September 2, at Abo, Finland, at the age of sixty-three years, of Dr. O. M. Reuter, emeritus professor of zoology in the University of Helsingfors.

A BRONZE statue of the late Dr. Ludwig Mond, erected by Messrs. Brunner, Mond and Co., Ltd., on the lawn opposite Winnington Hall, near Northwich, Dr. Mond's residence, is to be unveiled on Saturday next by Sir John Brunner.

A MEMORIAL of the Russian explorer, Baron E. von Toll, in the form of a bronze portrait tablet, is to be set up on Kotelnyi Island, in the New Siberia group, by the leader of the German Taimyrland Expedition.

PAPERS dealing with various problems of heating and lighting are to be read by Prof. Bone, F.R.S., Prof. Vivian B. Lewes, Mr. L. Gaster, and Mr. T. Thorne Baker at a conference which is to take place on October 29 in connection with the National Gas Congress and Exhibition.

THE plumage prohibition clause in the United States Tariff Bill having been sanctioned by the Senate the importation into the United States of the plumage of wild birds, either raw or manufactured, for purposes other than scientific or educational, is prohibited.

THE first installation of wireless telephony in a coal mine in Great Britain has just been fitted up at Dinnington Main Colliery, South Yorkshire, with, it is said, satisfactory results. The system is the invention of Mr. J. H. Reinecke, of Bochum, Westphalia, and is in use in German collieries. According to *The Times* each instrument is connected by two wires with a piece of metal buried in the ground. The wires can also be attached to ordinary tramway rails, water-pipes, &c. At Dinnington instruments have been placed at two points—one in the transformer house near the pit bottom and the other 1000 yards "in-bye," and conversation has been carried on between these points just as through an ordinary telephone with the use of only about 20 yards of wire. The system also admits of the use of portable instruments weighing about 20 lb. each by means of which it is possible to communicate with the fixed stations from any part of the mine. All that is necessary is for the operator to attach the two wires of the instrument to any metallic substance at hand. Thus in the event of a disaster in a pit miners entombed by falls would be able to open up communication with other parts of the colliery. In ordinary working the portable instruments should be very useful in the case of a breakdown of the signalling apparatus, and coal turning could be carried on while the repairs were being done. The portable instrument can also be used in the cage while ascending or descending the shaft.

THE Italian archæological mission to Crete, under the leadership of Prof. Halbherr, announces the discovery at Cortina of a temple dedicated to Egyptian deities, bearing a dedication by Flavia Philyra, the foundress. In the inner cella were found images of Jupiter, Serapis, Isis, and Mercury, with fragments of a colossal statue, supposed to be that of the foundress. A little flight of steps leads down to a subterranean chamber in which ceremonies of purification were performed.

THE excavation of the numerous prehistoric sites in the island of Malta is being actively prosecuted under the direction of Prof. T. Zammit. The most important discovery is that of a series of well tombs of the Punic type at the Kallilia plateau, north-west of Rabat. A large number of skeletons, with pottery, lamps, spindle-whorls, and a circular bronze mirror, has been unearthed. A partial exploration of the Ghar Dalam cave, conducted by Prof. Tagliaferro and Mr. C. Rizzo, produced bones of a hippopotamus and a deer, above which lay a quantity of prehistoric sherds. The museum, by the bequest of the late Mr. Parnis, has received a large collection of books about Malta and numerous antique objects. The *Malta Herald*, in recording the progress of excavation, very reasonably urges that means should be taken to protect the sites partially examined from spoliation by the villagers.

LESS than 300 miles to the north of Rio de Janeiro, on the coast range of Minas Geraes, live the Uti-krag, a tribe of Botocudos still retaining some of their old customs, but rapidly succumbing to the fostering care of the recently established Board of Protection of the Native Indians. Mr. W. Knocke paid them a very short visit in the month of October, 1912, and he describes his observations in a pamphlet entitled "Algunas Indicaciones sobre los Uti-krag del Rio Doce," issued separately from the *Revista de Historia y Geografia* (vol. v., 1913). The name of Botocudos, given them by the Portuguese, refers to the plugs with which the men distend their ear lobes, the women also the lower lip; this is now becoming unfashionable. When in their wilds the women are stark naked. They are the ugly and less intelligent sex, with a considerably darker colour than the decidedly intelligent men. Their household goods seem to be restricted to bows and arrows, plaited bags, and bamboo water-vessels; consequently they cannot cook, but only roast their food. They are clay-eaters. The nasal flute is disappearing. They are able to count up to five, have three kinds of dances, and bury their dead. There is the following curious parallelism between these Uti-krag, which in their idiom means Tortoise-Sierra, and the Mimba of New Guinea (*cf.* Pilhofer, *Petermann's Mittheil.*, September, 1912):—They construct stockades by putting numbers of sharpened sticks, 4 to 5 in. in length, into the ground, covered with leaves. As the enemy, when treading on these spikes, is sure to stumble, he falls upon a second line of larger sharpened sticks, also concealed. The author thinks that this little tribe is not so much a sample of the vigorous primitive savage as rather ethically impoverished through life in the forest. There are eight photographs of the people, their arms, and the stockade spikes.

THE excellence of the work being done by French physical anthropologists is exemplified by the elaborate descriptive memoir by Prof. M. R. Anthony on the fossil skull of La Quina, contributed to *Bulletins et Mémoires de la Société d'Anthropologie* (No. 2, for 1913). The writer identifies it with the Neanderthal group, including the Spy, La Chapelle, and Gibraltar skulls. This comprehensive, well-illustrated memoir is an important contribution to our knowledge of palæolithic man.

THE seventh annual report on the results of the chemical and bacteriological examination of London waters for the twelve months ending March 31, 1913, by Dr. Houston, has been issued by the Metropolitan Water Board. After a summary of the condition of the raw water and the effects of storage and filtration, Dr. Houston's final conclusion is that the "quality policy" of the Metropolitan Water Board should be directed towards securing an "epidemiologically sterile" water (*i.e.*, a water containing none of the microbes associated with water-borne disease) *antecedent* to filtration, by means of storage (sedimentation, devitalisation, and equalisation), aided, if need be, by the occasional employment of supplementary processes of water purification.

THE final report of the Luangwa Sleeping Sickness Commission, by Dr. Kinghorn, Dr. Yorke, and Mr. Lloyd, published in a recent number of the Annals of Tropical Medicine and Parasitology (vol. vii., No. 2) with many illustrations, is a very important contribution to the study of trypanosomiasis in man and animals. Especially valuable are the observations on the human trypanosome, *T. rhodesiense*, its wide distribution in south Central Africa, its occurrence in wild game and domestic stock, and its transmission by *Glossina morsitans*. The authors affirm emphatically that the fly does not become infective until the trypanosome has invaded its salivary glands, an event which is the second and final act of a developmental cycle that begins in the gut of the fly. It was found that the first portion of this cycle could proceed at lower temperatures (60°–70° F.), but that for its completion higher temperatures (75°–85° F.) are essential. The parasites can, however, persist in the fly at an incomplete stage of their development for at least sixty days under unfavourable climatic conditions. Several species of trypanosomes, some old, some new, are described from wild game or domestic stock; remarkable among the new species is a large form of the ingens-type, to which the name *T. tragelaphi* is given, found in the blood of the sitatunga, *Limnotragus spekei*.

THE problems connected with tsetse-flies and the parasites of man and animals which they unwittingly transmit are perhaps the most important questions with which European administrators of African territories have to deal at the present time, and these troublesome insects continue to receive an amount of attention which their purely scientific interest would never have aroused. In the Annals of Tropical Medicine and Parasitology (vol. vii., Part 2), Prof. Newstead describes a new species of tsetse-fly from the Congo Free State under the name *Glossina severini*; and in the same number Mr. Llewellyn Lloyd publishes records and photographs of the breeding-places of *G. morsitans* at Ngoa, on the Congo-Zambesi watershed. The pupæ of *G. morsitans* were always found either in association with trees or in holes in the ground; in the former case the trees were always abnormal or injured. The pupæ were never found at the base of normal trees or under bushes, and they are always deposited in such positions that they are not likely to be scratched up by game-birds. In the Bulletin of Entomological Research (vol. iv., Part 1), Dr. Scott Macfie discusses, with the aid of many photographs, the distribution of tsetse-flies in the Ilorin province of northern Nigeria, and describes a new variety of *G. palpalis*, with an excellent coloured illustration. In the same journal Dr. J. O. Shircore describes two new varieties of *G. morsitans* from Nyasaland.

THE proceedings of the Orchid Conference held by the Royal Horticultural Society in November last are reported at length in the Society's *Journal* (vol. xxxviii., Part 3). They include four papers read at the Conference, in the first of which Prof. F. Keeble discussed the physiology of fertilisation, with special reference to recent investigations by Lutz, Fitting, and others, and pointed out that pollination may bring about three types of events: (1) fertilisation, (2) changes due to contact of pollen with the stigmatic surface, and (3) results which may be described as intoxications or responses to chemical stimulation. In a paper on the application of genetics to orchid breeding, Major C. C. Hurst recapitulated the first principles of genetics, and pointed out that as regards any one heritable character represented by a factor, there are three distinct kinds of individual plants—homozygous or pure, heterozygous or impure, and zerozygous or wanting. He also dealt with the identification of individual "stud" plants, colour and albinism, self-sterility in orchids, &c.

IT requires an altogether special equipment, not only of exact zoological and historical knowledge but also of sympathetic insight into the conditions which prevailed in the past, to compose such a delightful lecture as that which Prof. F. J. Cole, of Reading, has published in the Transactions of the Liverpool Biological Society (February 14, 1913). In his crisp and epigrammatic treatment of a series of well-chosen incidents he has admirably brought before us "the early days of comparative anatomy," and the feeling of most readers, and especially those who from their personal experience realise how difficult such knowledge is to acquire, will be to emulate Oliver Twist's example and ask for more. It is quite impossible to summarise a report so crowded with curious information, witty comment, and historical insight, illuminating the whole development of the science of comparative anatomy. From the knowledge acquired as a collector of old "anatomies," Dr. Cole has been able to explain the loose methods of publication in the seventeenth and eighteenth centuries, which opened the way for those glaring instances of unscrupulous plagiarism that have ever been a source of amazement to us who live in such vastly different circumstances. But no part of the discourse excels in piquancy and common sense the opening "apology" for the study of the history of biology.

A RECENT number of the *Centralblatt für Bakteriologie, Parasitenkunde*, &c. (Zweite Abt., Band 38) contains a detailed account by O. Schneider-Orelli of investigations on the life-history and habits of *Xyleborus dispar*, one of the bark-beetles (Scolytidæ). This species, notorious for the injuries it inflicts on fruit-trees, is remarkable for its symbiosis with a fungus, *Monilia candida*, Hartig. The female beetles, fertilised in the autumn, hibernate in their burrows through the winter and swarm out in the following April and May. Each female then becomes the foundress of a new colony; she bores into a tree and makes a system of burrows, the walls of which become lined with a growth of the fungus, forming a dense white mass, the so-called "ambrosia." The mother-beetle lays her eggs in the burrows and the larvæ feed on the ambrosia-fungus, not on the wood of the tree. Living cells or spores of the fungus are not to be found in the digestive tract of the larva, pupa, or newly hatched adult beetle, but the female beetles appear to take up the fungus from the walls of the burrow in which they have been bred, and the stomachs of the mother-beetles always contain a store of the fungus, capable of germinating. The culture is started in the new burrows by regurgitation of the fungus from the stomach, and is continued by the beetle plucking off clumps of the young culture and planting them further along in the burrow. If disturbed in her agricultural operations, the mother-beetle hastily swallows as much as she can of the fungus.

In a paper on the psychology of insects, read before the General Malarial Committee at Madras in November, 1912, Prof. Howlett, after giving an account of experiments carried out by him on the response of insects to stimuli, comes to the conclusion that insects are to be regarded "not as intelligent beings consciously shaping a path through life, but as being in a sort of active hypnotic trance." It is claimed that this view of insect-psychology opens up great possibilities in the study of insect carriers of disease, since "it is no intelligent foe we have to fight, but a mere battalion of somnambulists." If we discover the stimuli or particular conditions which determine the actions of an insect, we can apply them to its undoing. It was found, for example, that the females of the fruit-fly, a serious pest in some parts of India, emitted an odour resembling ordinary citronella, and that the males could be caught in very large numbers by baiting traps with citronella, since they came to the traps and remained there apparently under a blind impulse to follow the scent of the female. In this way they had succeeded in checking largely the incidence of the fruit-fly pest.

In reference to a recent paragraph in our notes columns on a large dinosaurian limb-bone from Bushman's River, S. Africa, we have received a letter from Dr. R. Broom pointing out that Owen was incorrect in stating that Anthodon came from that locality, and that (as mentioned in *Brit. Mus. Cat. Foss. Reptilia*) its real place of origin was Stylkrantz. It is added that Anthodon is not a dinosaur, but a pariasaurian, and is thus rightly classified in the work just quoted. Dr. Broom appears to forget that in 1895 (*Rec. Albany Mus.*, vol. i., p. 277) he himself stated in reference to Anthodon that there "seems a strong probability that the three original specimens were got by Bain at Bushman's River." Later on he observed that "by Owen Anthodon was believed to be a dinosaur; by Lydekker and others it has been believed to be allied to Pareiasaurus. . . . The teeth are unlike those of Pareiasaurus, and strikingly like those of dinosaurs, and it seems possible that Owen may ultimately prove to be right." Basing our remarks on these statements, our one error was the assertion that Anthodon is *known* to be a dinosaur. As the Stylkrantz beds are Permian, and those of Bushman's River Cretaceous, there can, of course, be no community between their faunas.

The September number of *The Selborne Magazine* contains a list of lectures delivered before the Selborne Society during the past few years, and the names of the lecturers. Any of these discourses, which cover a great range of subjects, and are profusely illustrated with lantern-slides, the respective lecturers are prepared to repeat, either singly or in series, to local natural history societies or schools in return for their expenses, or moderate fees.

To the August number of *The Irish Naturalist* Dr. R. F. Scharff contributes a note on the Belmullet whaling station, based on a paper by Mr. Burfield in the British Association report for 1912. The number of whales taken by the Blacksod Whaling Company in 1911 was sixty-three, against fifty-five the previous year. The catch of the other company is not given.

An interesting article by Mr. C. H. Eshleman on the "Climatic Effect of the Great Lakes as Typified at Grand Haven, Mich.," on the east of the lake, is published in the meteorological chart for September issued by the U.S. Weather Bureau. Few stations are more favourably placed for this purpose; it has a broad expanse of eighty-five miles of water to the westward, and the shore is comparatively regular and almost straight to the north and south. Its temperature is compared with that of Milwaukee on the west shore, and with several inland stations lying to the westward in the same latitude. The tables show, *inter alia*, that the annual means are practically the same; the monthly maxima along the lake are strikingly modified in spring and summer, but only slightly in the other seasons; the minima are greatly modified in autumn and winter. The lake acts as a barrier against the extreme cold from the far north-west; the temperature at Grand Haven is often 20° higher than at Milwaukee, but with easterly winds it is almost as cold at Grand Haven as away from the lake. All the other climatic features are modified, but the effect on yearly or monthly precipitation is not striking. We notice with regret that the publication of these valuable meteorological charts, including those of the great oceans, has now ceased.

The after-shocks of the Messina earthquake of December 28, 1908, have been referred to in several of our Notes. On the last occasion (vol. xci., p. 93) a summary was given of observations made at Messina during the year 1909. From these it appeared that the distribution in time of the after-shocks did not follow Omori's law, $y=h/(k+x)$, where h and k are constants and y the number of after-shocks during a given interval at time x from the earthquake. These observations, however, referred to all the shocks felt at Messina, and not only to the true after-shocks of the great earthquake. The latter are distinguished in the valuable notices of earthquakes observed in Italy during 1909, of which we have received the last three numbers for the year. From these it is seen that the decline in frequency of the true after-shocks, though exhibiting the usual fluctuations, does not depart widely from Omori's well-known law.

Part 14 of the *Verhandlungen* of the German Physical Society contains further details of the method used and the results obtained by Drs. A. Eucken and F. Schwers, of the University of Berlin, in their measurements of specific heats of substances at very low temperatures. A cylindrical block of the material to be investigated had a constantan heating wire of 2 mm. diameter and 200 ohms resistance wound round it, electrical insulation and adequate thermal contact being secured by varnish. The temperature attained was determined from the resistance of a lead wire wound round the cylinder in the same way. The electrical heating was carried out in a vacuum vessel at temperatures between 16° and 92° on the absolute scale. Over this range the specific heats of fluorspar and iron pyrites crystals vary as the third power of the absolute temperature in agreement with the theory put forward by Debye in the first instance for monatomic substances.

"THE Coal Resources of the World," to which allusion was made in NATURE of September 4, is being brought out in this country by the American Book Supply Co., Ltd., 149 Strand.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A telegram from the Centralstelle at Kiel, dated September 3, announced the discovery of a comet of magnitude 10·0 by Dr. Metcalf, of Winchester, Massachusetts, on September 1, at 8h. 42·0m. M.T. Winchester. Its position was given as RA 6h. 50m., and declination 57° 0′ N., and was stated to have a slow motion to the north. It was suggested that it possibly might be Westphal's comet. A second telegram, dated September 4, stated that Prof. Antoniazzi had seen the same object on September 3 at 15h. 39·4m. M.T. Padua. The position he gave was RA 6h. 48m. 12s., and declination 57° 25′ 34″ N., the daily motion in RA being −1m. 16s., and in declination +34′. According to a writer in *The Times* (September 6), Prof. Antoniazzi's observation indicates that the comet cannot be that of Westphal, as the daily motion is diminishing instead of increasing.

The new comet is in the constellation of the Lynx, and therefore to be observed any time during the night, but best visible after midnight.

The following elements and ephemeris of comet *b* (Metcalf) have been communicated from Kiel, based on the observations of September 2, 3, and 4:—

$$T = 1913 \text{ July } 20.1129 \text{ Berlin.}$$

$$\left.\begin{aligned} \omega &= 51^\circ\ 31{\cdot}47' \\ \Omega &= 136^\circ\ 9{\cdot}99' \\ i &= 142^\circ\ 49{\cdot}23' \end{aligned}\right\} 1913{\cdot}0.$$

$$\log q = 0{\cdot}20954$$

12h. M.T. Berlin.

		R.A. (h. m. s)		Dec.
Sept. 11	...	6 32 54	...	+62 21·6
13	...	27 1	...	63 44·7
15	...	6 19 53		65 10 5

The magnitude is given as 10·5 on September 5 and 10·3 on September 15.

ANOTHER COMET.—Another telegram from Kiel, dated September 7, states that Dr. K. Graff discovered on September 6, at 15h. 9·1m. M.T. Bergedorf, a comet of the 11th magnitude. Its position is given as R.A. 23h. 48m. 1·8s., and declination 0° 27′ 44″ S. It is thus situated in the constellation of Pisces, and should be best seen about midnight.

THE PROTECTION OF SILVERED MIRRORS FROM TARNISHING.—Everyone who uses mirrors for astronomical purposes would welcome a satisfactory method of coating them with some material for preventing tarnishing. M. Perot some years ago published an account of a process he employed successfully for treating mirrors at the Meudon Observatory. It consisted of a thin coating of collodion being applied to the surface of the mirror, the film being obtained by pouring over the mirror a solution of collodion in amyl acetate. The mirrors used at the Helwan Observatory are subject to becoming spotted a few weeks after silvering, and attempts have been made to protect them. Mr. S. H. Trimen, of the Survey Department Laboratories, made the various trials (Khedivial Observatory, Helwan, Bulletin No. 10), but after repeated attempts with solutions of varying percentages he had at length to abandon the process. Blurred images of the stars and curious flares on the photographs of the bright stars were always the result of the application of the film. It is suggested that the problem may possibly be solved by using a solution possessing a lower viscosity, and it is to be hoped that such an attempt will be made.

RESEARCHES ON THE SUN.—The last two numbers of the *Astrophysical Journal* (June and July) have contained several important researches relating to solar physics. Prof. George E. Hale, in the July number, publishes his most valuable paper on the "Preliminary Results of an Attempt to Detect the General Magnetic Field of the Sun," a summary of which, based on an advanced proof, having been given in a previous number of this journal (June 17, p. 505). In connection with this research, Mr. Frederick H. Seares gives in the same number a paper entitled, "The Displacement-curve of the Sun's General Magnetic Field." The spectrum lines observed with the 75-ft. spectrographs and the polarising apparatus of the 150-ft. tower telescope showed displacements that apparently could not be attributed to any other cause than a general magnetic field of the sun, and the object of his research was to provide a more rigorous control of the results and their interpretation. Thus in the paper he compares the observed displacements with the theoretical displacement-curve derived on the assumption that the sun is a magnetised sphere, and further he provides formulæ for determining the position of the magnetic axis relative to the axis of rotation.

In the June number Mr. Charles E. St. John deals with the remarkable discovery by Mr. Evershed of the displacement of the Fraunhofer lines in the penumbræ of sunspots. The paper is entitled, "The Distribution of Velocities in the Solar Vortex," and the observations recorded in this research are in entire accord with Mr. Evershed's hypothesis that the displacements considered are due to a movement of the solar vapours tangential to the solar surface and radial to the axis of the spot vortex. Previous reference has already been made of Prof. Slocum's second paper on the circulation in the solar atmosphere as indicated by prominences.

THE INSTITUTE OF METALS.

THE autumn meeting of the Institute of Metals took place at Ghent on August 28 and 29 last. This was the first occasion on which this institute has held a meeting abroad, and the gathering may be described as a complete success. The attendance of members (about seventy-five) was particularly satisfactory on account of the representative character of those present, the foreign members of the institute, including members from Russia, Germany, Belgium, and America, being particularly well represented. The mornings of August 28 and 29 were devoted to the discussion of a long and interesting list of papers, while the afternoons were utilised for visits to works, the inspection of the exhibition, and the antiquities of the city. The social functions included a reception by the Burgomestre of Ghent in the ancient and beautiful Hotel de Ville.

The foremost place in the work of the meeting was taken by the reading and discussion of the second report to the Corrosion Committee, presented by Dr. G. Bengough and R. M. Jones. This report deals with the examination of a considerable number of examples of corroded tubes from service, of the investigation of the mechanism of corrosion in sea-water, both at the ordinary temperature and at higher temperatures by means of small laboratory experiments, and the systematic study of corrosion in condenser tubes of various composition under conditions as nearly like those of practical service as possible in an experimental condenser plant set up by the committee at Liverpool University. The results as stated in the report are remarkable, and diverge widely from the views generally accepted hitherto. The examination of material from service did not lead to any conclusive results, but the data furnished by the experimental plant—so far as they yet go—confirm the results of the small laboratory experiments. The report deals entirely with the process of corrosion by dezincification, which the authors have found to be the most common form of corrosion, although it appeared in the discussion that they admitted that pitting does occur in the absence of dezincification. They find, however, that none of the alloys tested by them undergo selective corrosion or dezincification when exposed to sea-water at the ordinary temperature, but they are all subject to it at higher temperatures, the process becoming vigorous towards 40° C. The action of dezincification is connected by the authors with the formation of a basic zinc chloride, or of zinc hydroxide, which is found attached to the surface of the tube, and under these patches the metal is dezincified. The action of this basic salt is described as regenerative and dependent upon the presence of dissolved oxygen in the water. The experiments of the authors dealt with four alloys, viz. brass, containing copper 70 per cent., zinc 30 per cent.; Muntz metal, containing copper 61 per cent., zinc 39 per cent.; "Admiralty" brass, containing copper 70 per cent., zinc 29 per cent., and tin 1 per cent.; and a special alloy, containing copper 70 per cent., zinc 28 per cent., and lead 2 per cent. As regards resistance to dezincification at 40° and 50° C. the last-named proved superior to the others, the Muntz metal and 70/30 brass being the least resistant. Another interesting and surprising result obtained by the authors is that dezincification does not appear to be due to electrolytic action; they find—contrary to what has been generally believed—that the presence of particles of carbon, or similar materials, even including a plug of pure copper screwed into the tube, does not give rise to local action of this kind. The report contains a detailed account of the experiments upon which these conclusions are based, and thus constitutes a record of work which must be of fundamental importance in the future study of the whole question of corrosion in copper alloys.

Of considerable general interest also was the paper on the intercrystalline cohesion of metals by Dr. W. Rosenhain, F.R.S., and Mr. D. Ewen, of the National Physical Laboratory. The authors of this paper elaborate their theory that the crystals of a metal, forming a crystalline aggregate, are held together by a thin layer of the same metal in the amorphous or undercooled liquid condition. The experimental evidence offered in their first paper they now supplement by evidence obtained from an entirely different direction. In the present paper the relative mechanical properties of the crystals and of the amorphous cement are discussed, and the authors indicate that while at ordinary temperatures the cement would be much harder and stronger than the crystals, at temperatures near the melting point this relation must be reversed, since the undercooled liquid cement must pass into the ordinary fluid condition in a gradual and continuous manner while the crystals will soften suddenly on melting. Just below the melting point, therefore, the theory indicates that the crystals could be pulled apart from one another without undergoing any distortion, thus giving a perfectly brittle fracture—the brittleness being entirely intercrystalline. The authors show such brittle intercrystalline fractures in the case of the purest lead, tin, aluminium, and bismuth, the lead fractures being particularly striking in appearance. At the meeting these data were supplemented by a similar brittle fracture obtained in a bar of the purest gold which had been prepared for the authors by Dr. T. K. Rose, of the Royal Mint. The discussion showed that the theory of an amorphous cement is still received with some reserve, but it was admitted that the accumulation of experimental evidence has considerably strengthened the position of the theory.

The list of papers dealt with at the meeting included nine others, among which those of Dr. T. K. Rose on the annealing of gold, of Dr. W. M. Guertler on the specific volume and constitution of alloys, of Prof. S. L. Hoyt on the constitution of the copper-rich kalchoids, or alloys of copper, zinc, and tin, of Mr. J. H. Chamberlain on volume changes in alloys, and of H. Garland on the metallographic study of some Egyptian antiquities, were of considerable interest. The discussions were in all cases vigorous and full of interest, and the meeting marks a decided advance in the development of the Institute of Metals.

THE PAST SUMMER.

BROADLY speaking, the past summer was essentially dry, generally cool, and particularly sunless considering the small amount of rain.

The reports issued by the Meteorological Office show that for the whole period of thirteen weeks which comprise the summer the mean temperature was below the average in all parts of the United Kingdom except in the north of Scotland, the deficiency being greatest over the east and south-east of England. The mean temperature was higher than in 1912 over the entire kingdom with the exception of the east of England, but it was everywhere much cooler than in the abnormally hot summer of 1911, the difference being greatest in the midland, southern, and eastern districts of England.

The sunshine was deficient over the eastern portion of the kingdom, but generally in excess in the western districts. The hours of bright sunshine were everywhere more numerous than in 1912, but far fewer than in 1911. Taking the British Isles as a whole the total hours of sunshine were 492 in 1913, 373 in 1912, and 679 in 1911.

The average rainfall for the whole of the British Isles for the three summer months—June, July, and August—was 4·47 in. this year, 12·92 in. last year, and 6·27 in. in 1911; the average number of rainy days are thirty-five this summer, sixty-one last year, and thirty-seven in 1911. The rainfall this summer was less in all districts of the United Kingdom than in the dry summer of 1911. In the south-west of England the aggregate summer rainfall was only 39 per cent. of the average, in the north-east of England 44 per cent., and in the midland counties and the south-east of England 45 per cent. The wettest districts were the north of Ireland, 68 per cent. of the normal, north-west of England, 67 per cent., and north of Scotland, 66 per cent.

At Greenwich, which fairly represents England, the weather at the end of May was persistently hotter than at any time during the summer. On six consecutive days the sheltered thermometer rose to 80° or above. Throughout the summer, from June to August, there were only four days with 80° or above, the average number of such warm days for the summer is fourteen, and in 1911 there were thirty-seven days as warm.

The following are the chief meteorological results at Greenwich:—

1913	Temperature							Rainfall			Sunshine	
	Mean highest day	Diff. from average	Mean lowest night	Diff. from average	Mean	Diff. from average	Days above average	Rainy days	Total	Diff. from average	Hours	Diff. from average
	°	°	°	°	°	°			In.	In.		
June ...	71	0	50	0	61	0	12	8	0·61	−1·33	204	+22
July ...	68	−6	52	−1	60	−4	1	12	2·01	+0·12	95	−91
August ...	71	−2	52	−1	62	−1	9	11	2·07	−0·27	143	−34
Summer...	70	−3	51	−1	61	−2	22	31	4·60	−1·45	442	−103

It is seen that June was very dry, but in other respects fairly normal. July had a fairly normal rainfall, but only about one-half of the average sunshine, whilst the temperature was exceptionally low. August was very dry until quite the close of the month, when exceptionally heavy rains fell over the south-eastern portion of England; at Greenwich the total for the last three days of the month was 1·22 in.; both sunshine and temperature were deficient.

CHAS. HARDING.

A MEMOIR ON THE ARTHROPOD EYE.[1]

CONSIDERABLE progress has been made of late towards the elucidation of the structure of the arthropod eye. Prof. G. H. Parker, of Harvard, was the first seriously to attack the more intricate problems of its structure, and his insight was such that most of his work stands unchanged even after the more recent elaborate researches of Hesse, Schneider, and others. In the present paper Dr. Trojan has, in addition to his own researches, verified or corrected the observations of these later investigators, whose work had summarised and illuminated the results of earlier writers.

It will be of profit to mention briefly the interesting points that Dr. Trojan has been able to add to our knowledge. The corneal cells are not "tile-shaped," but they are broader distally than proximally, so that they appear triangular in transverse section. The author is unable to support Schneider's observation that they are four in number, but agrees with Parker and Hesse that there are only two. The structure of the crystalline cells (cone cells) differs in one respect from that described by other writers; the upper part, the "Zapfen," is abruptly cone-shaped distally, and passes between the corneal cells to the facet. The general structure of the retinular cells and rhabdome is as Parker and later writers have described, but Dr. Trojan supports Hesse's opinion (and differs from Parker and Schneider) that there is no "zwischensubstanz" (matrix) between the "stiftchen" (fine rods) composing each half-plate of the rhabdome. The innervation of the rhabdome is effected as Hesse described, the nerve fibrillæ passing up the outer side of the retinular cell, round the nucleus, and terminating on "knöpfchen" as the base of the "stiftchen" composing the lamellæ of the rhabdome. Three optic ganglia are described.

The most important part of the paper is devoted to a study of the pigment of the eye in darkness and light; this, however, is best consulted in the original. There are only two pigment-bearing cells which form a continuous tubular sheath enclosing the whole ommatidium from the crystalline cones to the bundles of nerve fibrillæ under the basement membrane. The author's observations on the movements of the pigments of these cells, and also of the non-pigmented tapetum cells are of considerable interest.

In the course of the paper Dr. Trojan deals successively, under separate headings, with the different elements of the eye, giving an exhaustive anatomical and historical account of each, an arrangement which is lucid and very easy to follow. The plates illustrating the paper are very fine—we wish we could believe they could have been as exquisitely reproduced in this country—though we should have preferred to have had more of the author's own drawings in place of the photographs, beautiful as they are.

Dr. Trojan's paper is an important contribution to the literature of the arthropod eye, not only for the original matter it contains, but also as a critical review of the work of previous observers.

H. G. J.

BIOLOGY OF AQUATIC PLANTS.

DR. W. H. BROWN has contributed an important paper on the biology of aquatic flowering plants to *The Philippine Journal of Science* (vol. viii., pp. 1–20), under the title, "The Relation of the Substratum to the Growth of Elodea." He confirms the statements of previous observers that in this and in other submerged plants there is a "transpiration current" of water up the vessels of the stem, but his experiments lead to the conclusions that this current is simply a necessary consequence of the physical construction of the plant, and that the passage of water through a submerged plant does not show that the movement is of advantage to the plant by causing condensation of nutrient salts or that the roots are of advantage as absorbing organs.

Dr. Brown gives tables showing the relative growth of Elodea with and without addition of carbon dioxide to the water, in tap water, and in Knop's solution, with and without soil, rooted in and simply anchored over soil or sand, &c., and summarises the results as follows. Sufficient carbon dioxide to keep Elodea growing or even alive does not diffuse from the air into the water during winter and spring; the substratum probably serves as an important source of this gas. Elodea is not dependent on its roots for absorption of mineral salts, the chief function of the roots being to anchor the plant to the soil, which is advantageous when the soil contains organic matter and gives off carbon dioxide; plants rooted in good soil grow better than those anchored over the same soil. When carbon dioxide was supplied by a generator instead of by the soil, rooted and anchored plants grew about equally well; with similar soils, and no external supply of carbon dioxide, floating plants grew better than rooted ones, the air being in this case the source of carbon dioxide.

The author's work is of great interest with reference to the relation between the growth and abundance of plankton organisms (which form a large proportion of the food of fishes) and of larger water plants, and has obvious economic bearings; for instance, his experiments would seem to show that the larger submerged plants compete with the plankton algæ for both carbon dioxide and mineral salts, and must therefore be detrimental to their growth.

F. C.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—A course of twelve post-graduate lectures on "Conductors for the Electrical Transmission of Energy" will be delivered at University College by Prof. J. A. Fleming, F.R.S., beginning on October 20. The course, which is intended for post-graduate students and for telegraphic and electrical engineers, engaged in practical work, will be divided into two parts, which may be attended separately. Part i. will be devoted to "Telegraph and Telephone Conductors," and part ii. to "Electric Light and Power Conductors."

The Maharaja of Jaipur has made a contribution of three lakhs towards the establishment of a Women's Medical College at Delhi.

Among recent appointments at American universities we notice the following:—Dr. A. H. Ryan to the chair of physiology in the medical department of the University of Alabama; Dr. J. A. Bullitt to the chair of pathology in the University of North Carolina.

Mr. D. C. Matheson, at present on the veterinary staff of the Board of Agriculture and Fisheries, and formerly connected with the veterinary school of the University of Liverpool, has been appointed to the chair of pathology and bacteriology in the Royal (Dick) Veterinary College, Edinburgh.

It is stated in *The Lancet* that of the scholarships to be founded at Aberdeen University by the bequest of Mr. W. Robbie (briefly referred to in our issue of August 21) one is to be for chemistry. The principal of the sum left to the University by Mr. Robbie is to be kept intact, and the interest used in providing perpetual scholarships.

An alarming outbreak of fire took place on Friday morning last at Dulwich College, damage being done to the extent of about 300*l*. The fire appears to have been the work of Suffragettes. The scene of the outrage was one of the chemical laboratories on the first floor of a block of buildings devoted partly to the engineering section of the college and partly to chemistry. Before the fire could be extinguished a lecture platform was destroyed, the floor of the room badly damaged, and the windows broken by the heat.

The recently published reports for 1911–12 from those universities and university colleges in Great Britain which are in receipt of grants from the Board of Education show that, in the twenty-five institutions of higher education concerned, there were 22,895 students, excluding 238 who were preparing for matriculation. In English colleges there were 7827 full-time students, 3370 part-time day students, and 7295 part-time evening students. Of this number it appears that 1596 were engaged upon post-graduate work. In Wales there were 1377 full-time students and 343 part-time students, none of them attending in the evening. Of the total number of full-time students admitted during the session 1911–12 to English colleges, 4·6 per cent. were under seventeen years of age, 11·9 per cent. between seventeen and eighteen years of age, 27·6 between eighteen and nineteen years of age, and 55·9 per cent. more than nineteen years old. In Wales, 33·7 per cent. of the students were between eighteen and nineteen, and 54·1 per cent. more than nineteen years of age.

A copy of the calendar of the day and evening classes to be held at the Battersea Polytechnic during the session which begins on September 16 has been received. Courses have been arranged both during the day and in the evening in preparation for degrees in science, engineering, and music at the University of London. In the day technical college, full-time courses are arranged in mechanical, civil, electrical, and motor engineering, architecture, and building, and chemical engineering, each covering a period of three years, at the end of which time students passing the necessary examinations are awarded the polytechnic diploma. There are also courses in mathematics, physics, chemistry, and botany. The training department of domestic science offers two, three, or four year courses in preparation for the teachers' diplomas in domestic subjects. In the evening, classes have been arranged to meet the needs of every class of student. Science, technology, commerce, art, and literature are all to be taught in a thoroughly practical manner, and the social and physical education of the students is not neglected.

The new session of the Sir John Cass Technical Institute, Aldgate, E.C., will commence on September 22. The syllabus of classes, which has reached us, shows that the educational needs of the district are being cared for admirably. In connection with the higher technological work, several new departures are being made for the coming session. The curriculum in connection with the fermentation industries has been much developed, and now includes courses of instruction on brewing and malting, bottling and cellar management, brewery plant, and on the microbiology of the fermentation industries. A connected series of lectures dealing with the supply and control of power has also been arranged to meet the requirements of those engaged in works connected with chemical, electrical, and the fermentation industries. These will comprise a course of lectures on the supply and control of liquid, gaseous, and solid fuel, a course on electrical supply and control, and a course on the transmission of power. The courses in the metallurgical and other departments will be of the same character as in previous years, and the object will be to meet the needs of the industries in the districts served by the institute.

The ninth annual report of the Education Committee of the County Council of the West Riding of Yorkshire is an excellent account of a good year's educational work. From the section dealing with higher technical education we learn that in consideration of the grants received from the County Council the Universities of Leeds and Sheffield have been engaged in the organisation and supervision of classes in coal mining, the Leeds University in the area of the West Yorkshire Coalfield, the Sheffield University in the area of the South Yorkshire Coalfield; and each University has made provision for the training in mine gas testing, of persons selected by the Education Committee as prospective teachers of this subject. The Joint Agricultural Council of the three Ridings of Yorkshire have continued the work connected with education and instruction in agricultural subjects, acting through the agricultural department of Leeds University, on the same lines as before. The two outstanding features of the year's work in the technical and evening schools which call for special mention have been, first, a successful summer meeting of teachers in evening schools, and secondly, a considerable development in regard to the provision of evening classes for adults in non-vocational subjects.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 25.—M. A. Chauveau in the chair.—Kr. **Birkeland**: Remarks on the attempts made by Hale to determine the general magnetism of the sun. The results recently published by Hale are at variance with the author's views, if the general magnetism of the sun is similar to that of the earth. The objection made by Hale to the theory of local vortices is discussed. According to the author's researches, the magnetic moment of the sun is of the order of 10^{25} C.G.S. units, and the magnetisation is directed in a sense contrary to that of the earth.—

THE STRUCTURE OF THE ATMOSPHERE IN CLEAR WEATHER.

The Structure of the Atmosphere in Clear Weather: a Study of Soundings with Pilot Balloons. By C. J. P. Cave, M.A. Pp. xii + 144. (Cambridge: The University Press, 1912.) Price 10s. 6d. net.

MR. CAVE'S book is a welcome addition to the valuable contributions of amateurs to the common stock of scientific knowledge, and is the more welcome as the first book on this special subject. The investigation of the upper air is of such interest and the incidental problems which it presents are so numerous, so attractive, and, in these days of flying, so practical, that it is a matter of some surprise that there are not found more men of leisure to follow the notable examples of Prof. Lawrence Rotch and M. Teisserenc de Bort in the investigation of the free atmosphere. Mr. Cave in his introduction refers to the circumstances in which he began the study of the subject. As a matter of history, they can be traced to a letter by the present writer in *The Times* asking for the cooperation of yachtsmen in the exploration of the air over the sea by means of kites. Since that letter appeared we have had to chronicle the division of the atmosphere into two distinct layers, an upper layer, the *stratosphere,* in which there is little or no variation of temperature in the vertical, but sensible variation from day to day, or along the horizontal, and a lower layer, the *troposphere,* in which the variation of temperature is greatest in the vertical and relatively small along the horizontal. At the boundary between the two layers which is found at different heights in different regions, and on different occasions according to the barometric pressure, there is generally a slight inversion in the fall of temperature with height. Ten kilometres may be taken as a rough and ready estimate of the average thickness of the troposphere with the understanding that there is a latitude of three or more kilometres to be allowed in either direction according to circumstances.

With the progress of the general investigation of the upper air attention has been directed especially to the observation of air-currents at different levels by means of pilot balloons watched through theodolite-telescopes of special construction, introduced by M. de Quervain. Mr. Cave's book gives a comprehensive account of the methods and results of work of this character based upon his own experience at Ditcham Park and elsewhere. The apparatus is simple and less expensive than that required for the determination of temperatures:—a balloon which need not be large enough to carry recording instruments, some hydrogen, and accessories, two theodolites to be used simultaneously from two ends of a base for the observation of the altitude and azimuth of the rising balloon at the end of each minute or half minute from the start. One of the theodolites may be dispensed with if the observer knows with reasonable accuracy the rate of ascent of the balloon, and, as appears from one of Mr. Cave's chapters, this condition may be assumed without fear of losing the characteristic features of the ascent. In fact, observations of pilot balloons with one theodolite have been asked for as part of an international enterprise. The reduction of the observations is laborious, as each sounding entails the solution of many triangles, but with the judicious use of a slide rule and tables as described on p. 12, the labour is apparently not intolerable. The results of two hundred soundings in 1907, 1908, and 1909, with one in 1910 involving the solution of 8000 triangles, are given in the book. They are classified according to certain types of structure. For each sounding the velocity and direction of the horizontal motion of the air at each half kilometre are given in tables on pp. 84–107, and they are illustrated by a number of diagrams showing the variation of direction and velocity with height, accompanied by the weather maps which represent the distribution of surface pressure on the occasions of the ascents. A word of praise must here be given for the excellence of the arrangement and printing of the tables and of the diagrams and maps.

The order of the book also deserves remark. Mr. Cave has departed from the usual course in not taking the mean values of all the fish that have come into his net. He has sorted out his catch before submitting it to digestion. In fact, there are, if we recollect rightly, no mean values anywhere in the book. In the present state of our knowledge this decision is a wise one, for until the variations are reduced to those of observation alone, a mean value often conceals more truth than it reveals, and is sometimes actually misleading.

The first step in the discussion is to form a selection of types of structure. These are excellently illustrated by photographs of cardboard models.

The use of pilot balloons is subject to some obvious limitations. There is no little difficulty in pursuing a balloon with a theodolite for great distances. On one favourable occasion Mr. Cave kept a balloon in view until it was forty miles away, but ordinarily a sounding comes to an end by losing sight of the small speck in the field of view of the theodolite either by a trick of eyesight or by the accident of clouds, long before any such distance has been reached. Consequently, the investigation is limited to clear weather, and for the most part to the lower layers of the atmosphere. The lower half of the troposphere, say, up to five kilometres from the surface, is the region specially under observation, but when the sky happens to be clear the investigation can be extended to much greater heights. Mr. Cave gives twelve examples of series of observations beyond 11 kilometres, and one up to 18 kilometres. He is therefore able to devote a chapter to the winds of the upper layer, the stratosphere, and he supports the general conclusion that the wind falls off rapidly as the boundary of the stratosphere is approached and passed, though we must wait to learn whether this result is characteristic of the stratosphere or merely characteristic of the weather when the stratosphere comes under observation.[1]

Useful chapters will be found devoted to methods of observing and their accuracy, and to the rate of ascent of balloons, with an examination of the effect thereupon of the orographical features of the neighbourhood. The author then takes up the meteorological applications of his results. This section takes the form, for the most part, of a study of the relation of the strength and direction of currents aloft to the distribution of pressure and temperature at the surface, and leads up to an important diagram on p. 75 showing the upper winds in relation to a hypothetical distribution of high and low pressure at the surface. The diagram represents increased velocity aloft in the westerly currents of a "low," and in the south-westerly and north-westerly currents of a "high," but a diminished velocity in the easterly wind of a "high." To judge by the text, an unchanging current might have been represented in the more central area where there is little pressure gradient, and certainly a reversal of the north-easterly current on the south-eastern side of a high-pressure area. But the most striking feature of the diagram is a strong north-westerly upper current increasing with height (across the surface isobars and the south-westerly surface winds) from the central region of a "low" to the eastern region of the neighbouring "high." This noteworthy current which must be closely associated with the dynamical structure of the atmosphere is rightly selected as one of the types of structure to which attention is specially called. It is in line with observations of cirrus cloud in front of a low-pressure area.

[1] The falling off of wind with height in the stratosphere can be shown to be a logical consequence of the higher temperature of the region of lower pressure.

The relations to the sequence of weather on many occasions are set out in detail, but the results are not easily generalised except in the special case of the reversal of the current over a north-easterly wind, which is shown in many instances to be the precursor of rain and thunderstorms.

Some attention is given to the relation of the direction and strength of the wind in the upper air to the pressure gradient at the surface, assuming that the gradient wind is tangential to the isobars. As regards direction, there are useful diagrams showing the relation of the gradient directions to the surface winds for the three types of structure, viz.: (1) "solid current," (2) increase of velocity aloft, and (3) decrease of velocity aloft; the last shows the decreasing winds to be limited to cases of surface wind between north and south-east. As regards strength, gradient velocities are calculated from the usual formula:

$$V = \gamma/(2\omega\rho \sin\lambda),$$

and the increase of velocity with height for some situations is attributed to an increase of gradient deduced from the distribution of temperatures in the lowest layers indicated in the published weather-charts.

The increase of gradient is calculated from the surface temperature by a rough and ready formula which, considering the local influences upon temperature and other circumstances, is sufficiently accurate for Mr. Cave's immediate purpose; but it may be useful to give here a more accurate formula, to which that used by Mr. Cave approximates. Neglecting the effect of humidity, which is certainly small and usually unknown, the *increase* of pressure difference in millibars for h metres of height measured from any level is given by the formula:

$$\Delta p_h - \Delta p = 0{\cdot}0342 h \frac{p}{\theta}\left(\frac{\Delta\theta}{\theta} - \frac{\Delta p}{p}\right),$$

where p is the pressure at one place, $p + \Delta p$ that at another on the same level, θ and $\Delta\theta$ are the temperature and temperature difference, and Δp_h is the pressure difference at h metres above the given level.

Near the surface p/θ is approximately equal to 3, so that for the first k kilometres from the surface the formula would become approximately:

$$\Delta p_k - \Delta p_0 = 100k\left(\frac{\Delta\theta}{\theta} - \frac{\Delta p}{p}\right).$$

The approximate formula used by Mr. Cave is practically identical with this, except that the term $\Delta p/p$ is omitted. The omitted term may be sufficiently small to be neglected for the surface layers when Δp is not large, because p is numerically of the order of 1000 in that region, but $\Delta p/p$ cannot be neglected in calculations requiring greater accuracy, or in the upper reaches of the atmosphere, where p has a much smaller value because θ does not fall proportionally to the fractional fall of p.

In considering any physical explanation of the structure of the atmosphere, the difference $\Delta p/p - \Delta\theta/\theta$ is an important quantity. In fact, as a rule, it appears that, somewhere or other in a vertical section of the troposphere (where $\Delta\theta$ and Δp are of the same sign), in consequence of the variations in the magnitudes involved, the quantity $\Delta p/p - \Delta\theta/\theta$ *becomes zero and changes sign*. To that curious circumstance is due the dominance of the influence of the stratosphere upon the dynamics of the surface layers, although it only represents about a quarter of the whole mass of the atmosphere. In the stratosphere Δp and $\Delta\theta$ are of opposite signs, and their influences in the production of pressure difference reinforce each other. Hence in the stratosphere, pressure differences are rapidly built up, while in the troposphere changes are capricious and contradictory.

But fortunately these considerations are, so far as can be judged, of little importance in the cases to which Mr. Cave has applied his rough and ready formula, and do not affect the general accuracy of his conclusions.

For the practical study of the dynamics of the atmosphere we are largely dependent upon observations with pilot balloons. They may be taken as supplementing observations of clouds, and, in due time, both must be brought into relation with the observations of pressure and temperature obtained from registering balloons. It is in many ways unfortunate that the track of a registering balloon cannot always be followed by a theodolite or otherwise determined. As it is, we often get our kinematical conditions from one occasion, and our baric and thermic conditions from a different one.

Something may be done to bring the two together by means of observations of cloud-sequence, which can be observed on either occasion. At present these have hardly come within the range of meteorological work. Few observers are effectively conscious of the rapidity of the changes which are indicated by clouds, and which must be the results of the distribution of pressure, temperature, and wind.

In the book before us little is said of the association of cloud-forms and cloud-changes with the variations of the structure of the atmosphere disclosed by pilot balloons, but that part of the subject has great possibilities, and this leads us to express the hope that in a subsequent edition of this interesting work Mr. Cave may be able to give us the benefit of his experience in that direction also.

W. N. SHAW.

SOCIOLOGY AND MEDICINE.

(1) *The Task of Social Hygiene.* By Havelock Ellis. Pp. xv+414. (London: Constable and Co., Ltd. 1912.) Price 8*s*. 6*d*. net.

(2) *The People's Medical Guide: Points for the Patient, Notes for the Nurse, Matter for the Medical Adviser, Succour for the Sufferer, Precepts for the Public.* By Dr. John Grimshaw. Pp. xx+839. (London: J. & A. Churchill. 1912.) Price 8*s*. 6*d*. net.

(1) THE title of this book somewhat masks the nature of its contents, for by "social hygiene" the author means to convey the study of those things which concern the welfare of human beings living in societies. The various chapters, or essays as they practically are, include such varied subjects as the changing status of woman and the woman's movement, eugenics and love, religion and the child, the falling birth-rate, sexual hygiene, war against war, international language, and others. The author generally presents the two points of view, supporting them by quotations and summaries from many sources. The essays are interesting reading, but at the end leave us somewhat in doubt as to what would be for the best, or what the writer considers would be best.

(2) This book covers almost the whole range of subjects comprised within the scope of the practice of medicine and surgery, including the specialities such as diseases of the throat and eye. The information given seems generally to be accurate, is imparted in simple language, and important points are frequently driven home by some terse sentence, *e.g.* "a tooth in the head is worth two on the plate" (p. 57). Some capital sections are given on the management of children, diets and cooking, and physical exercises. The matter does not always seem to come quite in the right place, and simple domestic remedies and treatment may be omitted; for example, that common complaint of children, "child crowing," or "spasmodic croup," is scarcely noticed under children's ailments, but is relegated to the chapter on diseases of the throat, and it is certainly by no means "invariably" associated with rickets.

We think that the compass of the work is somewhat beyond that necessary or desirable for the general public, but the volume would serve as an excellent book of reference for the district nurse, health visitor, missionary, ship's captain, and the like.

R. T. H.

OUR BOOKSHELF.

British Rainfall, 1912. On the Distribution of Rain in Space and Time over the British Isles during the Year 1912, as recorded by more than 5000 Observers in Great Britain and Ireland, and discussed with Articles upon various Branches of Rainfall Work. By Dr. H. R. Mill, assisted by C. Salter. Fifty-second annual volume. Pp. 96+372. (London: E. Stanford, Ltd., 1913.) Price 10*s*.

THE plan of this valuable annual volume remains almost exactly as before; it is well known to many of our readers, and is welcomed by meteorologists and others for its comprehensiveness and the scrupulous care exercised in dealing with matters of detail. Part i. is devoted mainly (1) to the unprecedented rainstorm of August 25–26 in East Anglia, the area being now extended to the whole of England and Wales. The rainfall exceeded 7·5 in. over about sixty-seven square miles, with a small patch where more than 8 in. fell, between Norwich and Brundall. The weight of precipitation over England and Wales is estimated at 4473 million tons. (2) the wettest summer in England and Wales. The rainfall was not exceeded during the last fifty years; in August the amount in south England was more than three times the average over large areas. The general rainfall for June-August was 78 per cent. above the normal. Part ii. deals with the rainfall for the year, and includes the observers' remarks on the weather, with heavy falls and monthly and seasonal rainfall, illustrated by maps. The year was a wet one; expressed in percentages the totals were: England, 123; Wales, 119; Scotland, 111; Ireland, 108; British Isles, 115. Part iii. contains the general tables of total rainfall at 5272 stations; maps of the river-divisions are now given, with the tables for each of the twenty-three large divisions of the country. We notice with regret that this useful and unique organisation is not yet self-supporting, and that the deficit has to be met by the director; further, that owing to the continual strain of the work, Dr. Mill has to take a complete temporary rest, during which time Mr. Mossman, of the Argentine Meteorological Office, will undertake the editorship of the publications.

(1) *Die Süsswasser-Flora Deutschlands, Osterreichs und der Schweiz.* Herausgegeben von Prof. A. Pascher. Hefts. 2, 3, 9, and 10. Price 5, 1.80, 1.50, 4 marks.
(2) *Die Süsswasserfauna Deutschlands eine Exkursions-fauna.* Herausgegeben von Prof. Dr. Brauer. Heft. 14. (Jena: Gustav Fischer, 1912–13.) Price 7 marks.

THESE little monographs on the fresh-water flora and fauna of Germany, Austria, and Switzerland are issued under the general editorship of Prof. Pascher and Prof. Brauer respectively. The series on the fauna is issued in nineteen parts, extending from the Mammalia to the Hydrozoa; that on the flora in sixteen parts, of which the first twelve and part of the thirteenth deal mostly with microscopic forms, the remainder with fungi, mosses, lichens, &c.; a volume on the Protozoa does not seem to be included. The volumes range in price from 1.50 marks to 7 marks, are purchasable separately, and are written by well-known authorities on the subjects of which they treat. Each volume commences with a general description of the particular group dealt with, methods of investigating and preserving the organisms, and a brief list of the principal works and papers on the subject, after which follows a systematic description of species, diagnoses of genera, &c.

(1) These volumes deal with several groups of flagellated micro-organisms (Heft. 2 and 3), including *Euglena*, diatoms (Heft. 10), and the Zygnemales (Heft. 9), *i.e.*, chlorophyl-green, cylindrical-celled algæ, such as *Spirogyra*. All the volumes seem very complete, and that on the diatoms should serve as a very useful handbook on this interesting group of micro-organisms.

(2) This volume deals with the Rotatoria and Gastrotricha. A good account is given of rotifer structure, and the diagnostic tables and descriptions of species are excellent.

All the volumes are profusely illustrated, *e.g.*, no fewer than 379 illustrations are allotted to the diatoms and 474 to the rotifers, many comprising two or more figures.

We believe that these series will be of the greatest service to the field-naturalist and others.

R. T. H.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Nature and Treatment of Cancer and Malaria.

MAY I ask your courtesy for a brief reference to the article by Dr. C. W. Saleeby on the International Medical Congress (NATURE, August 14, pp. 608–9)? Dr. Saleeby notes, that recent research is tending in the direction of the views advanced by me some few years ago. How long will yet elapse before these views as to the germinal origin, trophoblastic (asexual) nature, and enzyme or pancreatic treatment of cancer are "generally accepted" cannot be said. But whenever that time does arrive, mankind in general and medical mankind in particular will have no other refuge against the ravages of cancer than its treatment with genuine strong injections of trypsin and amylopsin. Scientifically, what evidences are there of this? In the first place, among others, three successful cases treated by Major Lamballe were described in my book on cancer, published two years ago. It is quite four years since the patients were treated. Two of them are certainly alive and well, and I believe that this is also so with the third. More recently, I have pointed out, in a paper on the occurrence of dextro-rotatory albumins in organic nature, noticed not long ago in your columns, that the asexual generations, such as the malaria parasite, &c., which induce disease, are the same in nature as cancer-cells, and have foretold their total destruction by the ferments, trypsin and amylopsin. In a memoir, which is about to be published, Major F. W. Lamballe, R.A.M.C., has demonstrated the scientific truth of this. He has shown in a way which must carry complete conviction, that cases of benign and malignant tertian malaria, even very grave cases with cerebral symptoms, in all of which, as his results show, quinine had proved quite useless to stem the disease and to prevent relapses, from *one to three* injections of pancreatic enzymes sufficed not merely to kill all the parasites, but to cure the patient. Relapses in the patients—which had been the rule in very nearly all the cases—did not occur after this brief treatment, and the men (British soldiers) were able to return to duty *at once*, even in some instances on the day of the second or third injection. That is to say—and it is a matter for great scientific satisfaction—the original work, which I began in 1888, has now resulted in the easy and complete conquest of malaria. What this means can be understood from the facts concerning the treatment of malignant malaria, which at present is the rule in the Army. This entails a course of treatment by quinine lasting at least *four months*, and very often, if not always, even then the patient is not cured. But I understand that during this time the soldier is regarded as unfit for active service, and sometimes 25 per cent. of a regiment stationed in the tropics may be in this condition. In contrast to this the pancreatic treatment of malignant malaria in the hands of Major Lamballe entails not more than *three injections*, costing at the outside three shillings, it need not last *two weeks*, and the patient can return to duty at once, and so far as we know is then free from all danger of relapse, but *not* immune to a new infection. The facts here outlined indicate that, properly applied, that which cures malignant malaria *must* cure cancer.

J. BEARD.

8 Barnton Terrace, Edinburgh, August 30.

[I AM delighted that my brief reference to Dr. Beard's work should have elicited this interesting letter. He might also have referred to the astonishingly successful treatment of surgical tuberculosis by the pancreatic ferments, which was reported upon by Baetzner in the special tuberculosis number of *The Practitioner* recently. (Being abroad, I cannot give the reference.) When Dr. Beard refers to the malaria parasite as an asexual generation, he must, of course, be thinking of only one-half of its complete reproductive cycle. It would be interesting to make clinical observations as to the action of trypsin and amylopsin upon the sexual and asexual stages of these parasites respectively. As for cancer, I shall never be able to believe that the good results I saw under Dr. Beard's method of treatment six years ago were not causally connected with it. And if it be true, as is now asserted, that the leucocytes, our defenders against morbid cells, normally produce trypsin, perhaps the last has not been heard, after all, of this daring and original theory of Dr. Beard.—C. W. SALEEBY.]

Note on the Dicynodont Vomer.

IN a paper on Dicynodon now being printed by the Royal Society we have already described the bone which Dr. Broom now regards as the "typically mammalian median vomer." It is the bone which he has described previously as the anterior continuation of the basisphenoid, but without recognising the groove on the dorsal surface. No trace of a suture exists between it and the basisphenoid. To us it seemed, as stated in our paper, that the form of this bone, so far from confirming Dr. Broom's views, rendered his interpretation of the grooved bone in Diademodon even more doubtful than before.

That the bone generally recognised as the vomer in Dicynodon had a paired origin we readily admit, and we had already set forth reasons for this view in a paper now in MSS. on the structure of the skull in a small unnamed Dicynodont genus; as we have pointed out in our paper on Dicynodon, the vomer is paired in the guinea-pig, and had probably a paired origin in mammals.

Oxford, September 6.

An Aural Illusion.

I AM not aware that the following curious particular has been noticed.

If a sounding body has a velocity greater than that of sound in air, it will outstrip its previous sounds as it goes, and leave them to follow in its wake. Let it be supposed that such a body ceases sounding directly it passes an observer. In this case the sound waves of the greatest intensity will be the first to act, and those of the least intensity, the last. Hence the modulation of the sound will be reversed, and will have the character of a *diminuendo*, which we associate with sound that comes from a receding body. In such circumstances, therefore, it would seem to the observer that the source of sound had been travelling away from, instead of towards, him; an illusion touching the swell of the sound, and so the apparent direction of the sounder, quite distinct from those pitch effects which are duly taken cognisance of by Doppler's principle.

NORMAN ALLISTON.

THE NINTH INTERNATIONAL PHYSIOLOGICAL CONGRESS.

THE triennial International Physiological Congress, which was held at Groningen on September 2 to 6, was unanimously voted by those who attended it to be one of the most successful scientific congresses held during the present year. The number of workers engaged in physiological investigation being not very large, the congress, although larger than might have been anticipated, was of manageable size, and since physiologists on the whole are not a fluctuating body, everyone felt at ease and *en famille*.

It would be impossible to speak too highly of the admirable manner in which the president, Prof. Hamburger, with his characteristic precision, provided for the welfare and convenience of all those who attended the congress and who gave demonstrations in the laboratories; these latter are beautifully equipped, and leave nothing to be desired.

To English physiologists this particular physiological congress is of especial interest, since it is now twenty-five years since the congress was founded at the suggestion of the Physiological Society; the late Sir Michael Foster, its first president, was one of those who was most directly connected with its foundation, and it was as a fitting tribute to his labours that his portrait was chosen as the frontispiece for the special Festschrift, edited by Prof. Hamburger and Dr. Laquer. In this volume an excellent *résumé*, arranged according to subject, is given of the work of the congress during the past twenty-five years; this is preceded by the opening address of the president, Prof. Hamburger, at the present congress.

The congress numbered about 400 members, of whom about sixty were British, and the social events were numerous. On September 1 the visitors received in De Harmonie a warm welcome from the Dutch physiologists and the Medical Association of Groningen. The following evening there was a reception in the large hall of the University buildings by the Queen's representative and the Dutch Government. On Wednesday, at the "Sterrebosch" Park, the guests enjoyed the hospitality of the municipality of the town, and on the next day, at the Paterswolder Lake, that of the Ex-Senator M. J. E. Scholten. On Thursday evening there was also an excellent entertainment at the theatre and in De Harmonie. On the last evening a banquet terminated the congress. But the hospitality was not confined to the above-mentioned events; many members enjoyed private hospitality during their stay, and, as stated by Prof. Starling, all the people in the town were so cordial that "we felt that we were not merely the guests of the physiologists, but of every bargee and every tram conductor in the town." There was a special ladies' committee, and several excursions were arranged for the ladies who attended the congress.

To commemorate the occasion of the congress, the Dutch medical journal, *Nederlandsch Tijdschrift voor Geneeskunde,* issued a special number, largely devoted to physiological communications, and to the history of the development of physiology in Holland. The same journal also had a special medal struck, and duplicates were presented to all members of the congress. The medal bore the portrait of the famous Dutch physiologist, Donders, executed by the well-known sculptor Pier Pander; on the back were the words, "Aan de leden van het IXe Intern. Physiologen Congres. te Groningen, aangeboden door het Nederlandsche Tijdschrift voor Geneeskunde September MCMXIII."

("Offered to the members of the IXth International Physiological Congress in Groningen, by the Nederlandsch Tijdschrift voor Geneeskunde September 1913.")

The demonstrations and communications were very numerous, and it was not possible for one person to see and hear much more than one-third of the whole programme, which occupied most of the mornings and afternoons. The English physiologists contributed largely to the demonstrations, which, as in the meetings of our Physiological Society, had precedence over merely oral communications. The demonstrations of Profs. Starling (heart-lung preparation) and Sherrington (rhythmic reflex produced by antagonising reflex excitation by reflex inhibition) are familiar to English physiologists. A demonstration which attracted much interest was that of Prof. Abel and Dr. Rowntree, of Baltimore; this consisted in an apparatus for what may be termed "vividiffusion," and must be accounted one of the most distinct improvements in physiological technique which have been seen in recent years. The apparatus is called the "artificial glomerulus," and consists of a series of collodion tubes arranged in parallel, and surrounded by warm Ringer's solution; there may be from sixteen to forty-eight tubes in the apparatus, and through this system blood from a chloralosed and hirudinised animal is led. The blood flows out from an artery or vein (*e.g.* from the carotid artery, or from one of the tributaries of the portal vein) through the apparatus, and returns again to the circulation of the animal by a vein (*e.g.* the external jugular vein or the femoral vein). Such a circulation can be carried out under sterile conditions, and may be continued for sixteen hours with ease, and in favourable circumstances for much longer. At intervals the fluid surrounding the collodion "glomerulus" is run off and replaced by fresh Ringer's solution. The solution thus run off will contain all the diffusible substances of the blood other than the saline constituents of Ringer's solution, and on evaporation these may be recovered. In this manner it is possible to detect the presence of substances which are only present in minute traces in the circulating blood; thus, at the end of sixteen hours considerable amounts of amino-acids and of urea can be recovered from the dialysate; sugars and a polypeptide substance are also present. It is worthy of note that, as regards efficiency, the artificial kidney thus made compares very favourably with the animals' own kidneys; thus, when salicylates are given, the artificial glomerulus may excrete as much or more than the kidneys in a given time. It is hoped that a surgical application of this principle will prove of value. The applications of the method to the study of intermediary metabolism are obvious, and interesting results have already been obtained in this direction.

Another interesting demonstration was that of Prof. Benjamin Moore and Dr. Webster, who showed that when carbon dioxide was passed through solutions of such inorganic colloids as uranic oxide or ferric oxide in high dilution, in presence of sunlight or of light from the mercury arc, formaldehyde is formed, and may be detected by Schryver's test. They discussed the relation of this phenomenon to the question of the first appearance of organic matter on the globe.

Dr. Carlson, of Chicago, showed that it is easy to demonstrate on man the presence of rhythmic and of so-called "tetanic" contractions of the walls of the stomach during fasting. For this purpose two long indiarubber tubes are swallowed until their lower ends reach the stomach. One of the tubes serves for the introduction of substances into the stomach, and the other ends in a thin rubber sound which is inflated, and which, when connected with a water manometer, serves to record the contractions of the stomach. Dr. Carlson maintains that these contractions give rise to the sensation of hunger by stimulation of the afferent nerves of the stomach wall, that they are initiated by local automatic mechanisms, and that they are inhibited by various substances which stimulate the nerve endings in the gastric mucosa (gastric juice, acids, alcohol, &c.). Prof. Asher, of Berne, claimed to have demonstrated the presence in the vagus of secretory fibres to the kidneys, and Prof. Noyons, of Liège, showed curves which he believed indicated that there is an antagonism between the internal secretion of the pancreas and adrenalin. The demonstration by Prof. Magnus, of Utrecht, on the influence of the position of the head on the posture in decerebrate rigidity and in normal rabbits was very interesting. The effects are in part due to reflexes from the neck and partly to labyrinthine reflexes.

A novelty of great interest to those interested in painting was the demonstration by Mr. A. H. Munsell, of Boston. This was a quantitative classification of pigment colours based upon measurements by a daylight photometer, Maxwell discs, and the trained discrimination of the painter. The photometer uses the daylight adapted eye, and reads in terms of the Weber-Fechner law.

A somewhat surprising communication came from Prof. Hürthle, of Breslau, who has made a careful study of the variations in pressure and velocity in various arteries during the pulse wave in living animals, and in dead animals perfused by means of an "artificial heart." From these experiments the conclusion is drawn that the arteries are rhythmically contractile, and that their contraction aids the circulation of the blood. It would be interesting to see these experiments repeated with a dead animal perfused from a living heart prepared according to Starling's method.

Many interesting apparatus were shown; among these may be mentioned the now well-known apparatus of Prof. Krogh, of Copenhagen, for the investigation of various respiratory problems; that of Dr. Franz Müller, of Berlin, for the determination of the minute-volume output of the heart in man by a simple application of the nitrous oxide method; the "Kurvenkino" devised by Prof. Straub, of Freiburg, by means of which tracings made on smoked glass in the laboratory may be projected on a screen with realistic effect (apparatus made by Jaquet, of Basel); and the apparatus of Dr. Rohde, of Heidelberg, for the measurement of the oxygen usage of the frog's heart under various conditions of contraction. Dr. Laqueur also showed a projection method for exhibiting the movements of the intestines to a large audience.

The great event of the congress so far as communications are concerned was the closing lecture, which was given by Prof. Pawlow, of St. Petersburg, on "Die Erforschung der höheren Nerventätigkeit," in which he dealt with the subject of conditional reflexes, to which he has devoted the latter third of his active scientific career. Prof. Pawlow is of the opinion that psychology in its present condition can be of little service to the physiologist. The physiologist must remain a physiologist, and must investigate his problems by the recognised methods which have been so fruitful in other fields—he must study the brain as an integrated working organ, and must build up his knowledge independently of the psychologist. The study of reflex action as a purely physiological topic has already yielded valuable results on treatment by the methods of experimental physiology. It is rendered clear by the work of the Pawlow school that we must extend our ideas of reflex action and recognise that besides the elementary function of carrying out ready-formed reflexes, the nervous system has another equally important and fundamental function—that of the formation of new reflexes. It is a generally recognised property of living organisms to adapt themselves to their surroundings, or, in other words, to respond in suitable manner to what were previously indifferent agencies. So far, the reflexes which have been most studied by Pawlow have been those concerned with the secretion of saliva in dogs. Various stimuli can be given so as to affect different sense-organs in different cases, and at the same time the animal is fed, or acid introduced into its mouth; after a short period of such treatment a new reflex has been introduced, for now on application of the accompanying ("conditional") stimulus alone, without the introduction of the food or acid ("unconditional stimulus"), a reflex secretion of saliva occurs. Such reactions have all the characters of the true reflexes, and are equally simple in character, and not, as might seem at first sight, complicated processes grafted on to an unconditional reflex. The intricacy of the conditional reflex is due not to the complex nature of the neural processes involved in the reflex, but to the ease with which it can be inhibited; innumerable conditions in the nervous system itself and in the outer world modify it in this way, and thus investigation of the phenomena is not easy. In close relation to the formation of a conditional reflex is the function of the analysis of the sensations which reach the organism from the outer world, and from which some components are selected by the process of analysis; it is only these selected components which are really utilised in the construction of the new reflex. It seems, then, that by careful study of these reflexes we have the means for acquiring an accurate knowledge of the functional activity of the analysing mechanism. The chief problems which have been investigated are those concerned, firstly, with the origin of the conditional reflexes, and secondly with the mechanism of analysis of sensations. These reflexes can be formed in relation to strong as well as to indifferent stimuli; thus powerful electric stimuli applied to the skin, when the reflex has been trained, do not lead to movements of defence or aggression as is at first the case, but merely to the feeding reflexes of which the flow of saliva is the easiest to follow. This is to be explained as due to the formation of new nerve paths, determined by different excitability of the various nerve centres. Thus the stimulation of bone cannot be made to yield the conditional reflex, since the centres connected with painful stimulation of bone are more powerful than those connected with alimentation.

An important condition for the upbuilding of a conditional reflex is that the particular conditional stimulus used must precede, or accompany, not follow, the unconditional stimulus (food or acid). If it follows the unconditional stimulus, inhibitions are set up, and this inhibition has also been studied. It is also of great importance that the stimulus employed be strictly isolated from incidental ones; in some of the earlier investigations it appeared that the real conditional stimulus was given by the operator himself, by some peculiarity of odour or movements, and not at all by the stimulus which he believed he was employing. For this reason the animals are now always isolated in special rooms, which no person enters during the course of an experiment, all the conditions and observations being controlled from without by means of electrical or pneumatic arrangements.

With regard to the inhibitory processes to which the reflexes are so subject, there may be distinguished three kinds of inhibition. Firstly, we have the inhibition during sleep. Secondly, the inhibition by means of the arrival of other stimuli which have an inhibitory effect (external inhibition). Thirdly, there is a variety which is called "internal inhibition." This is developed as a result of special relations between the conditional and unconditional stimuli by means of which the particular reflex has been prepared. When, for instance, the conditional stimulus is not followed by the customary unconditional one for some time, it becomes converted into an inhibition. When in the developed reflex the conditional stimulus is not followed (or "confirmed") by the unconditional one, the type of inhibition is called "extinction"; when in working out the reflex the unconditional stimulus only follows some minutes after the conditional, the inhibition which intervenes is called "retardation." "Conditional inhibition" is seen when the conditional stimulus, when accompanied by an indifferent stimulus, is not followed by the unconditional stimulus; lastly, "differential inhibition" is seen in the fact that stimuli approaching closely to the conditional stimulus, and which at the commencement are effective, become eventually inactive. That all these phenomena are really due to inhibition can be shown by the fact that under appropriate conditions the inhibition may be removed, and the effect manifested ("Loshemmung").

The powers of discrimination of the analysors are greatly increased during the development of the reflex, and the conditional stimulus becomes more and more limited and specialised until finally it corresponds to a very small part of the analysing mechanism. Experiments in which definite parts of the cerebral hemispheres have been removed have taught that the cerebrum is the organ which is responsible for the upbuilding of these new reflexes. Want of space renders it impossible to give an account of these experiments on the results of partial extirpation of the cerebrum, since these were given in such brief outline in the lecture that further abstraction is not possible. It is to be hoped, however, that Prof. Pawlow will soon give to the world a book on the subject similar to his famous work on the "Work of the Digestive Glands," since practically all the abundant literature on this new subject is only to be obtained in the Russian language at the present time.

The next International Physiological Congress will be held in Paris in 1916, with Prof. Tigerstedt, of Helsingfors, as President.

C. Lovatt Evans.

THE DUAB OF TURKESTAN.[1]

In its opening sentence this book raises an important question, of the propriety of appropriating a word belonging to a language foreign to us and using it, in a sense equally foreign to

Fig. 1.—Mudspate-track opposite Veshab in the Zarafshan Valley. From "The Duab of Turkestan."

its native country, in order to express a concept at variance with its original sense. The word *doab*, signifying originally the confluence of two streams, and secondarily the tongue of land between them, has been introduced by Prof. W. M. Davis for a portion of a coastal plain lying between two rivers which never unite, but flow independently to the sea; in the form "duab" it is used by Mr. Rickmers for the country lying between two rivers, the Oxus and Jaxartes, which flow independently into the Sea of Aral, and includes not only the area of plain, which would come under Prof. Davis's use of the word *doab*, but the whole of the mountain region bounded on either side by the main streams of the two rivers.

[1] "The Duab of Turkestan: A Physiographic Sketch and Account of some Travels." By W. Rickmer Rickmers. Pp. xv+564+plates+maps. (Cambridge: University Press, 1913.) Price 30s. net.

For the purpose of a title there is comparatively little objection to this use of the word, but when Mr. Rickmers goes on to coin the adjective "duabic" for the type of scenery developed in this region, a protest must be entered against the needless introduction of a term that conveys no impression of the thing which it represents. The region dealt with presents the results of conditions which are widely spread, and repeated wherever mountains rise high enough, out of what would otherwise be a desert plain, to catch and condense rain from the upper layers of the atmosphere. In such a region the effects of erosion and deposition caused by running water are much more conspicuous than in a moister climate, for the simple reason that they are uncomplicated by the action of other agencies of denudation, with the exception of wind and rapid changes of temperature.

Something, also, must be said in protest against the extremes to which Mr. Rickmers carries the use of metaphor and illustration, too commonly adopted by geographical writers. The use of an illustration by analogy is often illuminating, and may serve to render the result of a complicated series of observations and deductions intelligible to those who have neither need nor leisure to follow the whole course of the research, but quite as often it may merely produce a misleading appearance of understanding where no true explanation is forthcoming, and it is especially dangerous when used, as Mr. Rickmers appears to use it, as a method of research. The description of a range of hills as a "squashed and warty reptile" may recall its appearance to the writer, but does not help the reader; and to talk of the "solid octopus of the Mustagh Pamirs sending out its long, spare tentacles towards the east, gripping the expanses of Tibet, Lop, and Mongolia," is likely to mislead the uninitiated.

Having said this, we must acknowledge the interest of the work as a description of a type of scenery, race, and civilisation absolutely different from anything which the dweller in western Europe or North America will meet with, and would especially commend the description of what the author terms the pamirian type of scenery, which characterises the mountains of central Asia, and his study of the features which distinguish it from the alpine type, met with in the mountains of Europe and western Asia. Something, too, must be said in praise not merely of the number and excellence of the illustrations, but, what is unfortunately more rare, of the judgment with which they have been selected to serve as real illustrations and elucidations of the text.

BRITISH ASSOCIATION BIRMINGHAM MEETING.

As anticipated, this year's meeting of the British Association has been the largest since 1904. In that year, Cambridge mustered 2789 members, and the Birmingham figure of 2635 does not fall far short of that.

Besides the amplitude of Birmingham's resources in the matter of public institutions, hotel accommodation, and private hospitality, the glorious weather which illumined the proceedings must be given its due share of credit for the success of the gathering. The somewhat unusual combination of the Presidency of the Association and the Principalship of the local University in one person seems, on this occasion, to have been attended with the happiest results. It certainly had a great effect in stimulating local interest, besides attracting a number of the foremost foreign exponents of the exact sciences. The ovation accorded to Madame Curie, more especially by her own sex, was as remarkable as the extraordinary popularity achieved by Prof. Lorentz, who succeeded in making even so formidable a subject as entropy attractive and entertaining to the generality of members.

The fact that the old Mason College, the Midland Institute, and the Technical College are within a stone's throw of each other accounts for the ease with which members could pass from one section to the other. The Geography Section, it is true, was inconvenienced by the noise of the traffic outside the Midland Institute, which is greatest in the morning, but the other sections were admirably housed. Section A had, on the whole, the best lecture theatre, although the applause in the Zoology Section overhead occasionally disconcerted (pleasantly, perhaps) the lecturing physicist below, who sometimes failed to locate the sound.

The arrangements in the reception room met with high commendation on all sides. The spacious Town Hall was an ideal place for the purpose. The ground floor was fitted with luxurious carpets and easy chairs, and a specially built staircase ascended to the gallery, which was laid out in some forty writing compartments. Even at times of the greatest activity, it was reasonably easy to find one's way about, and the local secretaries deserve much credit for the completeness and adequacy of the accommodation afforded.

A still greater triumph of organisation was the Lord Mayor's reception at the Council House, where 3500 visitors had to be marshalled and entertained. Large as was the assemblage, it was quickly distributed over a large space, the new Art Gallery and the Natural History Museum being thrown open for the occasion, so that the sense of crowding conveyed by the hour's procession into the reception chamber was quickly dispelled. The visitors had an agreeable choice between band music; exhibits of British birds, nests, and eggs; dancing; and Dr. Collisson's musical and humorous entertainment in the Council Chamber.

Friday's afternoon reception at Messrs. Cadbury's factory at Bournville gave visitors an interesting though short glimpse of the well-known model village and its various institutions. The spacious recreation ground was the scene of a pretty masque and some maypole dances by the village children which were set off very attractively by the brilliant sunshine, though provision had been made for the event of rain by the erection of three spacious marquees capable of accommodating the whole of the visitors, numbering, as they did, several thousand. The guests were taken back to Birmingham by special trains running by two routes, so that both platforms could be utilised—a fortunate detail which avoided much inconvenience.

Saturday's excursions were a welcome change, both to the visitors who had conscientiously spent their time every morning at the sections, and the secretarial officials, who gained some time to make up arrears of work. It was notable that the foreign visitors preferred the roads that led to Stratford-on-Avon, though Malvern, Kenilworth, Worcester, Coventry, Lichfield, and the Forest of Arden put forth their strongest magnetism, aided by the hospitable efforts of their resident aristocracy. The geological excursions to Nuneaton and Hartshill, the Lickey and Clent Hills, the Wrekin, and the Lutley Valley, the botanical excursion to Sutton, and the excursion to the Burbage experimental farm were of absorbing interest to those specially concerned.

The ecclesiastical services on Sunday were well attended, and the various preachers took pains to emphasise the points in which they agreed with the declarations of prominent speakers from Association chairs. They seemed to find these points unusually numerous. The afternoon saw a large social gathering of physicists and mathematicians at "Mariemont," Sir Oliver Lodge's residence, at which Friday's radiation discussion was informally continued, though not by any means concluded.

The entertainments provided by the local committee for the Monday evening gave members a choice of three. There was St. John Hankin's "Return of the Prodigal" at the Repertory Theatre, Glück's "Orpheus" at the Prince of Wales's Theatre, and a special series of animated pictures dealing with scientific and historical subjects at the Picture House, New Street. The opera was patronised by a brilliant gathering which filled the theatre to overflowing, and Herr Denhof's company gave a new life to the eighteenth century work by symbolic dances and movements which brought out all the tenderness and pathos of the music and the otherwise rather formal acting.

Of the scientific proceedings of the meeting it is difficult to speak with discrimination until a few days have elapsed after its conclusion. The twelve main sections each had their devoted band of special followers, and each had some special occasion on which its proceedings commanded a larger general interest. Thus it was with the radiation discussion in Section A, the fuel and radioactivity discussions in Section B, the joint discussions of Sections D, I, and K on the synthesis of organic matter by inorganic colloids in the presence of sunlight (in which, by the way, Prof. Moore did not by any means succeed in carrying the majority of his colleagues with him, though his exposition was of masterly clearness); the waterways debate in Section F (a matter of vital interest to Birmingham); the anæsthetics report in Section I; and the modern university discussion in Section L.

The great popularity of these discussions has again emphasised the fact that the average member does not come to hear isolated papers of miscellaneous interest. It more than ever throws upon the recorder of each section the responsibility of grouping its papers according to their natural affinities. This seems to be the only chance which the isolated paper has of surviving at the British Association meetings. The numerous facilities now available for publication render it less and less necessary to look to the British Association for a platform from which to announce discoveries, and the practice, so common in the earlier days, is now largely in abeyance. But for bringing like-minded people together to discuss matters of scientific interest, for gauging the trend of opinion on matters of controversy, and for focussing public opinion on matters of importance to the commonweal, the British Association is pre-eminently useful, and the Birmingham gathering has shown that it is not likely to abandon that function for many years to come.

E. E. F.

At an Honorary Degree Congregation of the University of Birmingham, on Thursday, September 11, some distinguished foreigners received honorary degrees, and the following speeches were made by the Principal in presenting them to the Vice-Chancellor:—

Dr. Arrhenius.

Director of the Nobel Institute for Physics and Chemistry, at Stockholm, fellow of the Swedish Academy of Sciences, and foreign member of our own Royal Society. The courageous way in which Dr. Arrhenius applied the theory of electrolytic dissociation to a quantitative study of chemical reactions has profoundly modified the trend of chemical science during the past thirty years, enlarging the scope of chemical investigation, harmonising previously disconnected facts, and bringing an ever-increasing number of chemical phenomena within the range of quantitative and mathematical treatment. He is thus one of the most prominent of the founders of modern physical chemistry, the principles of which he has even applied, with singular success, to some of the most subtle phenomena of organic life. Recently his writings on cosmogony have aroused wide interest; terrestrial electricity and the aurora have yielded to him some of their secrets; and his speculations on worlds in the making are more than interesting and suggestive. A man of genius, and one of the founders of physical chemistry, I present for the honorary degree of doctor of laws, Svante August Arrhenius.

Madame Curie.

The discoverer of radium, director of the Physical Laboratory at the Sorbonne, and member of the Imperial Academy of Sciences at Cracow. All the world knows how Madame Curie (coming from Warsaw as Marie Sklodowska to work in Paris), inspired by the spontaneous radio-activity newly discovered by Becquerel, began in 1896 a metrical examination of the radio-activity of minerals of all kinds; and how, when a uranium residue showed a value larger than could have been expected from its uranium content, she, with exemplary skill and perseverance, worked down some tons of this material (given her by the Austrian Government on the instigation of Prof. Suess), chemically dividing it and retaining always the more radioactive portion, until she obtained evidence first of a new element which she christened polonium, in memory of her own country, and then after months of labour succeeded in isolating a few grains of the other and more permanent substance now so famous—a substance which not only exhibits physical energy in a new form, but is likely to be of service to suffering humanity. Of the metallic base of this substance she determined the atomic weight, finding a place for it in Mendeléeff's series; and with the aid of her husband, whose lamentable death was so great a blow to science, she proceeded to discover many of its singular properties, some of them so extraordinary as to rivet the attention of the world. Subsequent workers engaged in the determination of numbers belonging to either of her special elements, radium and polonium, have sought her advice, and it has proved of the utmost value. I have now the honour of presenting for our honorary degree the greatest woman of science of all time, Marie Sklodowska Curie.

Prof. Dr. Keibel.

The professor of anatomy in the University of Freiburg is the leading authority on the development of man and the embryology of vertebrates. He originated the international standards used in estimating embryological data, and through his classical work on comparative development he has reformed anatomical teaching by the infusion of developmental ideas. His important contributions to anatomical knowledge and method are widely known and highly esteemed, but nowhere more heartily and cordially than in the anatomical department of this University. Held in affectionate esteem by his colleagues, and directing one of the largest schools of anatomy in Germany, this eminent embryologist has been invited to receive our honorary degree, and I present to you Franz Karl Julius Keibel.

Prof. H. A. Lorentz.

To the great school of mathematical physicists of the last and present centuries we in England have proudly contributed even more than our share; but we recognise in the professor of physics in the University of Leyden a contemporary worker worthy to rank with our greatest. Prof. Lorentz has extended the work of Clerk Maxwell into the recently explored region of electrons, and has developed in the molecular direction the Maxwellian theory of electrodynamics. He is a chief authority on the behaviour of material bodies moving through the æther of space, and he has adopted and reduced to order many of the progeny resulting from the fertile marriage of electricity and light. A specially interesting magneto-optic phenomenon, experimentally discovered by his countryman, Zeeman, of Amsterdam, received at his hands its brilliant and satisfying interpretation; an interpretation clinched by predictions of what, on the electric theory of radiation, ought additionally to be observed—predictions which were speedily verified. The Zeeman phenomenon thus interpreted not only gives information as to the intimate structure of various elemental atoms, but, in the hands of the great American astronomers, has shown that sun-spots are electric cyclones of high magnetic power, and is likely further to contribute to our knowledge of solar and stellar constitution. As a great authority on electron theory, and one whose name will for ever be associated with the now nascent electrical theory of matter, I present to you the distinguished mathematical physicist, Hendrik Antoon Lorentz.

Prof. R. W. Wood.

The professor of experimental physics in the Johns Hopkins University of Baltimore is a prolific experimentalist, and one to whose researches in physical optics modern science is greatly indebted. By ingenious use of little-known properties of light, he has explored the structure of molecules, applying the principle of resonance to determine their natural electronic period of vibration. He has, in fact, discovered a new type of spectra in the fluorescent resonance of metallic vapours. What more he has done, in connection with the anomalous absorption of sodium vapour, with specially designed diffraction gratings, and with the application of monochromatic photography to the geology of the moon, it were long to tell; among other things, he anticipated and realised the attainment of regular reflection from a sufficiently dense absorbing vapour; while to the public in America he is known as the inventor of a practical method of thawing frozen pipes by an electric current. The idea of a gigantic telescope in the form of a sunk well, with a revolving pool of mercury at its base to constitute a truly parabolic mirror, may not be a new one, but Prof. Wood has taken it out of the region of the chimerical and shown that it is possible, even if not practically useful. We in this country have reason to envy the splendid resources which the munificence of citizens in America, and of Governments elsewhere, places at the disposal of scientific explorers, and we honour and admire the use which is being made of those resources in every branch of science. As one of the most brilliant experimental physicists of the world, I present for our honorary degree Robert Williams Wood.

Synopsis of grants of money appropriated for scientific purposes by the general committee at the Birmingham meeting September, 1913:—

Section A—Mathematical and Physical Science.

Prof. H. H. Turner, seismological observations ...	£60 0 0	
Dr. W. N. Shaw, upper atmosphere	25 0 0	
Sir W. Ramsay, constants and numerical data	40 0 0	
Prof. M. J. M. Hill, calculation of mathematical tables	20 0 0	
Lieut.-Col. A. Cunningham, copies of the "Binary Canon" for presentation ...	5 0 0	
		£150 0 0

Section B—Chemistry.

Dr. W. H. Perkin, study of hydro-aromatic substances	15 0 0	
Prof. H. E. Armstrong, dynamic isomerism ...	25 0 0	
Prof. F. S. Kipping, transformation of aromatic nitroamines	15 0 0	
A. D. Hall, plant enzymes ...	25 0 0	
Prof. W. J. Pope, correlation of crystalline form with molecular structure ...	25 0 0	
Prof. H. E. Armstrong, solubility phenomena	15 0 0	
		£120 0 0

Section C—Geology.

R. H. Tiddeman, erratic blocks	5 0 0	
Prof. P. F. Kendall, list of characteristic fossils ...	5 0 0	
Dr. A. Strahan, Ramsay Island, Pembroke	10 0 0	
Prof. Grenville Cole, Old Red Sandstone of Kiltorcan	10 0 0	
G. Barrow, trias of western midlands	10 0 0	
Prof. W. W. Watts, sections in Lower Palæozoic rocks	15 0 0	
		£55 0 0

Section D—Zoology.

Dr. A. E. Shipley, Belmullet Whaling Station	20 0 0	
Dr. Chalmers Mitchell, nomenclator animalium ...	50 0 0	
S. F. Harmer, Antarctic whaling industry	90 0 0	
		£160 0 0

Section E—Geography.

Prof. J. L. Myres, maps for school and university use...	40 0 0	
Prof. H. N. Dickson, tidal currents in Moray and adjacent firths	40 0 0	
		£80 0 0

Section G—Engineering.

Sir W. H. Preece, gaseous explosions	50 0 0	
Prof. J. Perry, stress distributions	50 0 0

SECTION A.

MATHEMATICS AND PHYSICS.

Opening Address by H. F. Baker, Sc.D., F.R.S., President of the Section.

The Place of Pure Mathematics.

It is not a very usual thing for the opening address of this section to be entrusted to one whose main energies have been devoted to what is called pure mathematics; but I value the opportunity in order to try to explain what, as I conceive it, the justification of the pure mathematician is. You will understand that in saying this I am putting myself in a position which belongs to me as little by vocation as by achievement, since it was my duty through many years to give instruction in all the subjects usually regarded as mathematical physics, and it is still my duty to be concerned with students in these subjects. But my experience is that the pure mathematician is apt to be regarded by his friends as a trifler and a visionary, and the consciousness of this becomes in time a paralysing dead-weight. I think that view is founded on want of knowledge.

Of course, it must be admitted that the mathematician, as such, has no part in those public endeavours that arise from the position of our Empire in the world, nor in the efforts that must constantly be made for social adjustment at home. I wish to make this obvious remark. For surely the scientific man must give his time and his work in the faith of at least an intellectual harmony in things; and he must wish to know what to think of all that seems out of gear in the working of human relations. His own cup of contemplation is often golden; he marks that around him there is fierce fighting for cups that are earthen, and largely broken; and many there are that go thirsting. And, again, the mathematician is as sensitive as others to the marvel of each recurring springtime, when, year by year, our common mother seems to call us so loudly to consider how wonderful she is, and how dependent we are, and he is as curious as to the mysteries of the development of living things. He can draw inspiration for his own work, as he views the spectacle of a starry night, and sees

> How the floor of heaven
> Is thick inlaid with patines of bright gold.
> Each orb, the smallest, in his motion, sings,

but the song, once so full of dread, how much it owes to the highest refinements of his craft, from at least the time of the Greek devotion to the theory of conic sections; how much, that is, to the harmony that is in the human soul. Yet the mathematician bears to the natural observer something of the relation which the laboratory botanist has come to bear to the field naturalist. Moreover, he is shut off from inquiries which stir the public imagination; when he looks back the ages over the history of his own subject, the confidence of his friends who study heredity and teach eugenics arouses odd feelings in his mind; if he feels the fascination which comes of the importance of such inquiries, he is also prepared to hear that the subtlety of Nature grows with our knowledge of her. Doubtless, too, he wishes he had some participation in the discovery of the laws of wireless telegraphy, or had something to say in regard to the improvement of internal-combustion engines or the stability of aëroplanes; it is little compensation to remember, though the mathematical physicist is his most tormenting critic, what those of his friends who have the physical instinct used to say on the probable development of these things, however well he may recall it.

But it is not logical to believe that they who are called visionary because of their devotion to creatures of the imagination can be unmoved by these things. Nor is it at all just to assume that they are less conscious than others of the practical importance of them, or less anxious that they should be vigorously prosecuted.

Why is it, then, that their systematic study is given to other things, and not of necessity, and in the first instance, to the theory of any of these concrete phenomena? This is the question I try to answer. I can only give my own impression, and doubtless the validity of an answer varies as the accumulation of data, made by experimenters and observers, which remains unutilised at any time.

The reason, then, is very much the same as that which may lead a man to abstain from piecemeal indiscriminate charity in order to devote his attention and money to some well-thought-out scheme of reform which seems to have promise of real amelioration. One turns away from details and examples, because one thinks that there is promise of fundamental improvement of methods and principles. This is the *argumentum ad hominem.* But there is more than that. The improvement of general principles is arduous, and if undertaken only with a view to results may be ill-timed and disappointing. But as soon as we consciously give ourselves to the study of universal methods for their own sake another phenomenon appears. The mind responds, the whole outlook is enlarged, infinite possibilities of intellectual comprehension, of mastery of the relations of things, hitherto unsuspected, begin to appear on the mental horizon. I am well enough aware of the retort to which such a statement is open. But, I say, interpret the fact as you will, our intellectual pleasure in life cometh not by might nor by power—arises, that is, most commonly, not of set purpose—but lies at the mercy of the response which the mind may make to the opportunities of its experience. When the response proves to be of permanent interest—and for how many centuries have mathematical questions been a fascination?—we do well to regard it. Let us compare another case which is, I think, essentially the same. It may be that early forms of what now is specifically called art arose with a view to applications; I do not know. But no one will deny that art, when once it has been conceived by us, is a worthy object of pursuit; we know by a long trial that we do wisely to yield ourselves to a love of beautiful things, and to the joy of making them. Well, pure mathematics, as such, *is* an art, a creative art. If its past triumphs of achievement fill us with wonder, its future scope for invention is exhaustless and open to all. It is also a science. For the mind of man is one; to scale the peaks it spreads before the explorer is to open ever new prospects of possibility for the formulation of laws of nature. It resources have been tested by the experience of generations; to-day it lives and thrives and expands and wins the life-service of more workers than ever before.

This, at least, is what I wanted to say, and I have said it with the greatest brevity I could command. But may I dare attempt to carry you further? If this seems fanciful, what will you say to the setting in which I would wish to place this point of view? And yet I feel bound to try to indicate something more, which may be of wider appeal. I said a word at starting as to the relations of science to those many to whom the message of our advanced civilisation is the necessity, above all things, of getting bread. Leaving this aside, I would make another reference. In our time old outlooks have very greatly changed; old hopes, disregarded perhaps because undoubted, have very largely lost their sanction, and given place to earnest questionings. Can anyone who watches doubt that the courage to live is in some danger of being swallowed up in the anxiety to acquire? May it not be, then, that it is good for us to realise, and to confess, that the pursuit of things that are beautiful, and the achievement of intellectual things that bring the joy of overcoming, is at least as demonstrably justifiable as the many other things that fill the lives of men? May it not be that a wider recognition of this would be of some general advantage at present? Is it not even possible that to bear witness to this is one of the uses of the scientific spirit? Moreover, though the pursuit of truth be a noble aim, is it so new a profession; are we so sure that the ardour to set down all the facts without extenuation is, unassisted, so continuing a purpose? May science itself not be wise to confess to what is its own sustaining force?

Such, ladies and gentlemen, in crude, imperfect phrase, is the *apologia*. If it does not differ much from that which workers in other ways would make, it does, at least, try to represent truly one point of view, and it seems to me specially applicable to the case of pure mathematics. But you may ask: What, then, is this subject? What can it be about if it is not primarily directed to the discussion of the laws of natural phenomena? What kind of things are they that can occupy alone the thoughts of a lifetime? I propose now to attempt to answer this, most inadequately, by a bare recital of some of the broader issues of present interest—though this has difficulties, because the nineteenth century was of unexampled fertility in results and suggestions, and I must be as little technical as possible.

Precision of Definitions.

First, in regard to two matters which illustrate how we are forced by physical problems into abstract inquiries. It is a constantly recurring need of science to reconsider the exact implication of the terms employed; and as numbers and functions are inevitable in all measurement, the precise meaning of number, of continuity, of infinity, of limit, and so on, are fundamental questions; those who will receive the evidence can easily convince themselves that these notions have many pitfalls. Such an imperishable monument as Euclid's theory of ratio is a familiar sign that this has always been felt. The last century has witnessed a vigorous inquiry into these matters, and many of the results brought forward appear to be new; nor is the interest of the matter by any means exhausted. I may cite, as intelligible to all, such a fact as the construction of a function which is continuous at all points of a range, yet possesses no definite differential coefficient at any point. Are we sure that human nature is the only continuous variable in the concrete world, assuming it be continuous, which can possess such a vacillating character? Or I may refer to the more elementary fact that all the rational fractions, infinite in number, which lie in any given range, can be enclosed in intervals the aggregate length of which is arbitrarily small. Thus we could take out of our life all the moments at which we can say that our age is a certain number of years, and days, and fractions of a day, and still have appreciably as long to live; this would be true, however often, to whatever exactness, we named our age, provided we were quick enough in naming it. Though the recurrence of these inquiries is part of a wider consideration of functions of complex variables, it has been associated also with the theory of those series which Fourier used so boldly, and so wickedly, for the conduction of heat. Like all discoverers, he took much for granted. Precisely how much is the problem. This problem has led to the precision of what is meant by a function of real variables, to the question of the uniform convergence of an infinite series, as you may see in early papers of Stokes, to new formulation of the conditions of integration and of the properties of multiple integrals, and so on. And it remains still incompletely solved.

Calculus of Variations.

Another case in which the suggestions of physics have caused grave disquiet to the mathematicians is the problem of the variation of a definite integral. No one is likely to underrate the grandeur of the aim of those who would deduce the whole physical history of the world from the single principle of least action. Everyone must be interested in the theorem that a potential function, with a given value at the boundary of a volume, is such as to render a certain integral, representing, say, the energy, a minimum. But in that proportion one desires to be sure that the logical processes employed are free from objection. And, alas! to deal only with one of the earliest problems of the subject, though the finally sufficient conditions for a minimum of a simple integral seemed settled long ago, and could be applied, for example, to Newton's celebrated problem of the solid of least resistance, it has since been shown to be a general fact that such a problem cannot have any definite solution at all. And, although the principle of Thomson and Dirichlet, which relates to the potential problem referred to, was expounded by Gauss, and accepted by Riemann, and remains to-day in our standard treatise on natural philosophy, there can be no doubt that, in the form in which it was originally stated, it proves just nothing. Thus a new investigation has been necessary into the foundations of the principle. There is another problem, closely connected with this subject, to which I would allude: the stability of the solar system. For those who can make pronouncements in regard to this I have a feeling of envy; for their methods, as yet, I have a quite other feeling. The interest of this problem alone is sufficient to justify the craving of the pure mathematician for powerful methods and unexceptionable rigour.

Non-Euclidean Geometry.

But I turn to another matter. It is an old view, I suppose, that geometry deals with facts about which there can be no two opinions. You are familiar with the axiom that, given a straight line and a point, one and only one straight line can be drawn through the point parallel to the given straight line. According to the old view the natural man would say that this is either true or false. And, indeed, many and long were the attempts made to justify it. At length there came a step which to many probably will still seem unintelligible. A system of geometry was built up in which it is assumed that, given a straight line and a point, an infinite number of straight lines can be drawn through the point, in the plane of the given line, *no one* of which meets the given line. Can there, then, one asks at first, be two systems of geometry, both of which are true, though they differ in such an important particular? Almost as soon believe that there can be two systems of laws of nature, essentially differing in character, both reducing the phenomena we observe to order and system —a monstrous heresy, of course! I will only say that, after a century of discussion we are quite sure that many systems of geometry are possible, and true; though not all may be expedient. And if you reply that a geometry is useful for life only in proportion as it fits the properties of concrete things, I will answer, first, are the heavens not then concrete? And have we as yet any geometry that enables us to form a consistent logical idea of furthermost space? And, secondly, that the justification of such speculations is the interest they evoke, and that the investigations already undertaken have yielded results of the most surprising interest.

The Theory of Groups.

To-day we characterise a geometry by the help of another general notion, also, for the most part, elaborated in the last hundred years, by means of its group. A group is a set of operations which is closed, in the sense that the performance of any two of these operations in succession is equivalent to another operation of the set, just as the result of two successive movements of a rigid body can be achieved by a single movement. One of the earliest conscious applications of the notion was in the problem ot solving algebraic equations by means of equations of lower order. An equation of the fourth order can be solved by means of a cubic equation, because there exists a rational function of the four roots which takes only three values when the roots are exchanged in all possible ways. Following out this suggestion for an equation of any order, we are led to consider, taking any particular rational function of its roots, what is the group of interchanges among them which leaves this function unaltered in value. This group characterises the function, all other rational functions unaltered by the same group of interchanges being expressible rationally in terms of this function. On these lines a complete theory of equations which are soluble algebraically can be given. Anyone who wishes to form some idea of the richness of the landscape offered by pure mathematics might do worse than make himself acquainted with this comparatively small district of it. But the theory of groups has other applications. It may be interesting to refer to the circumstance that the group of interchanges among four quantities which leave unaltered the product of their six differences is exactly similar to the group of rotations of a regular tetrahedron the centre of which is fixed, when its corners are interchanged among themselves. Then I mention the historical fact that the problem of ascertaining when that well-known linear differential equation called the hypergeometric equation has all its solutions expressible in finite terms as algebraic functions, was first solved in connection with a group of similar kind. For any linear differential equation it is of primary importance to consider the group of interchanges of its solutions when the independent variable, starting from an arbitrary point, makes all possible excursions, returning to its initial value. And it is in connection with this consideration that one justification arises for the view that the equation can be solved by expressing both the independent and dependent variables as single-valued functions of another variable. There is, however, a theory of groups different from those so far referred to, in which the variables can change continuously; this alone is most extensive, as may be judged from one of its lesser applications, the familiar theory of the invariants of quantics. Moreover, perhaps the most masterly of the analytical discussions of the theory of geometry has been carried through as a particular application of the theory of such groups.

The Theory of Algebraic Functions.

If the theory of groups illustrates how a unifying plan works in mathematics beneath bewildering detail, the next matter I refer to well shows what a wealth, what a grandeur, of thought may spring from what seem slight beginnings. Our ordinary integral calculus is well-nigh powerless when the result of integration is not expressible by algebraic or logarithmic functions. The attempt to extend the possibilities of integration to the case when the function to be integrated involves the square root of a polynomial of the fourth order, led first, after many efforts, among which Legendre's devotion of forty years was part, to the theory of doubly-periodic functions. To-day this is much simpler than ordinary trigonometry, and, even apart from its applications, it is quite incredible that it should ever again pass from being among the treasures of civilised man. Then, at first in uncouth form, but now clothed with delicate beauty, came the theory of general algebraical integrals, of which the influence is spread far and wide; and with it all that is systematic in the theory of plane curves, and all that is associated with the conception of a Riemann surface. After this came the theory of multiple-periodic functions of any number of variables, which, though still very far indeed from being complete, has, I have always felt, a majesty of conception which is unique. Quite recently the ideas evolved in the previous history have prompted a vast general theory of the classification of algebraical surfaces according to their essential properties, which is opening endless new vistas of thought.

Theory of Functions of Complex Variables: Differential Equations.

But the theory has also been prolific in general principles for functions of complex variables. Of greater theories, the problem of automorphic functions alone is a vast continent still largely undeveloped, and there is the incidental problem of the possibilities of geometry of position in any number of dimensions, so important in so many ways. But, in fact, a large proportion of the more familiar general principles, taught to-day as theory of functions, have been elaborated under the stimulus of the foregoing theory. Besides this, however, all that precision of logical statement of which I spoke at the beginning is of paramount necessity here. What exactly is meant by a curve of integration, what character can the limiting points of a region of existence of a function possess, how even best to define a function of a complex variable, these are but some obvious cases of difficulties which are very real and pressing to-day. And then there are the problems of the theory of differential equations. About these I am at a loss what to say. We give a name to the subject, as if it were one subject, and I deal with it in the fewest words. But our whole physical outlook is based on the belief that the problems of nature are expressible by differential equations; and our knowledge of even the possibilities of the solutions of differential equations consists largely, save for some special types, of that kind of ignorance which, in the nature of the case, can form no idea of its own extent. There are subjects the whole content of which is an excuse for a desired solution of a differential equation; there are infinitely laborious methods of arithmetical computation held in high repute of which the same must be said. And yet I stand here to-day to plead with you for tolerance of those who feel that the prosecution of the theoretic studies, which alone can alter this, is a justifiable aim in life! Our hope and belief is that over this vast domain of differential equations the theory of functions shall one day rule, as already it largely does, for example, over linear differential equations.

Theory of Numbers.

In concluding this table of contents, I would also refer, with becoming brevity, to the modern developments of theory of numbers. Wonderful is the fascination and the difficulty of these familiar objects of thought—ordinary numbers. We know how the great Gauss, whose lynx eye was laboriously turned upon all the physical science of his time, has left it on record that in order to settle the law of a plus or minus sign in one of the formulæ of his theory of numbers he took up the pen every week for four years. In these islands perhaps our imperial necessities forbid the hope of much development of such a theoretical subject. But in the land of Kummer and Gauss and Dirichlet the subject to-day claims the allegiance of many eager minds. And we can reflect that one of the latest triumphs has been with a problem known by the name of our English senior wrangler, Waring—the problem of the representation of a number by sums of powers.

Ladies and gentlemen, I have touched only a few of the matters with which pure mathematics is concerned. Each of those I have named is large enough for one man's thought; but they are interwoven and interlaced in indissoluble fashion and form one mighty whole, so that to be ignorant of one is to be weaker in all. I am not concerned to depreciate other pursuits, which seem at first sight more practical; I wish only, indeed, as we all do, it were possible for one man to cover the whole field of scientific research; and I vigorously resent the suggestion that those who follow these studies are less careful than others of the urgent needs of our national life. But pure mathematics is not the rival, even less is it the handmaid, of other branches of science. Properly pursued, it is the essence and soul of them all. It is not for them; they are for it; and its results are for all time. No man who has felt its fascination can be content to be ignorant of any manifestation of regularity and law, or can fail to be stirred by all the need of adjustment of our actual world.

And if life is short, if the greatest magician, joining with the practical man, reminds us that, like this vision,

> The cloud-capp'd towers, the gorgeous palaces,
> The solemn temples, the great globe itself,
> Yea, all which it inherit, shall dissolve
> And . . . leave not a rack behind,

we must still believe that it is best for us to try to reach the brightest light. And all here must believe it; for else—no fact is more firmly established—we shall not study science to any purpose.

But that is not all I want to say, or at least to indicate. I have dealt so far only with proximate motives; to me it seems demonstrable that a physical science that is conscientious requires the cultivation of pure mathematics; and the most mundane of reasons seem to me to prompt the recognition of the æsthetic outlook as a practical necessity, not merely a luxury, in a successful society. Nor do I want to take a transcendental ground. Every schoolboy, I suppose, knows the story of the child born, so small, if I remember aright, that he could be put into a quart pot, in a farmhouse on the borders of Lincolnshire—it was the merest everyday chance. By the most incalculable of luck his brain-stuff was so arranged, his parts so proportionately tempered, that he became Newton, and taught us the laws of the planets. It was the blindest concurrence of physical circumstances; and so is all our life. Matter in certain relations to itself, working by laws we can examine in the chemical laboratory, produces all these effects, produces even that state of brain which accompanies the desire to speak of the wonder of it all. And the same laws will inevitably hurl all into confusion and darkness again; and where will all our joys and fears, and all our scientific satisfaction, be then?

As students of science, we have no right to shrink from this point of view; we are pledged to set aside prepossession and dogma, and examine what seems possible, wherever it may lead. Even life itself may be mechanical, even the greatest of all things, even personality, may some day be resoluble into the properties of dead matter, whatever that is. We can all see that its coherence rises and falls with illness and health, with age and physical conditions. Nor, as it seems to me, can anything but confusion of thought arise from attempts to people our material world with those who have ceased to be material.

An argument could perhaps be based on the divergence, as the mathematician would say, of our comprehension of the properties of matter. For though we seem able to summarise our past experiences with ever-increasing approximation by means of fixed laws, our consciousness of ignorance of the future is only increased thereby. Do we feel more, or *less*, competent to grasp the future possibilities of things, when we can send a wireless message 4000 miles, from Hanover to New Jersey?

Our life is begirt with wonder, and with terror. Reduce it by all means to ruthless mechanism, *if you can;* it will be a great achievement. But it can make no sort of difference to the fact that the things for which we live are spiritual. The rose is no less sweet because its growth is conditioned by the food we supply to its roots. It is an obvious fact, and I ought to apologise for remarking it, were it not that so much of our popular science is understood by the hasty to imply an opposite conclusion. If a chemical analysis of the constituents of sea-water could take away from the glory of a mighty wave breaking in the sunlight, it would still be true that it was the mind of the chemist which delighted in finding the analysis. Whatever be its history, whatever its physical correlations, it is an undeniable fact that the mind of man has been evolved; I believe that is the scientific word. You may speak of a continuous upholding of our material framework from without; you may ascribe fixed qualities to something you call matter; or you may refuse to be drawn into any statement. But anyway, the fact remains that the precious things of life are those we call the treasures of the mind. Dogmas and philosophies, it would seem, rise and fall. But gradually accumulating throughout the ages, from the earliest dawn of history, there is a body of doctrine, a reasoned insight into the relations of exact ideas, painfully won and often tested. And this remains the main heritage of man; his little beacon of light amidst the solitudes and darknesses of infinite space; or, if you prefer, like the shout of children at play together in the cultivated valleys, which continues from generation to generation.

Yes, and continues for ever! A universe which has the potentiality of becoming thus conscious of itself is not without something of which that which we call memory is but an image. Somewhere, somehow, in ways we dream not of, when you and I have merged again into the illimitable whole, when all that is material has ceased, the faculty in which we now have some share, shall surely endure; the conceptions we now dimly struggle to grasp, the joy we have in the effort, these are but part of a greater whole. Some may fear, and some may hope, that they and theirs shall not endure for ever. But he must have studied nature in vain who does not see that our spiritual activities are inherent in the mighty process of which we are part; who can doubt of their persistence.

And, on the intellectual side, of all that is best ascertained, and surest, and most definite, of these; of all that is oldest and most universal; of all that is most fundamental and far-reaching, of these activities, pure mathematics is the symbol and the sum.

SECTION B.

CHEMISTRY.

Opening Address by Prof. W. P. Wynne, D.Sc., F.R.S., President of the Section.

When the present position of education in Birmingham is considered, the transformation effected since the 'seventies is little short of marvellous. Five-and-thirty years ago, when I became an evening student, classes conducted by the Midland Institute met the demand for arts and science subjects; now a University—venerable in comparison with all civic universities save the Victoria University of Manchester—exists to provide instruction in every branch of learning. The spacious building in which we meet—already too small for the demands made on it—is the lineal descendant of that part of the Midland Institute which formerly was used for evening class instruction in science, organised in connection with the science and art department, and financed largely by the system of payment on results; this large lecture theatre replaces the small and inconvenient class-room in which the teaching of chemistry and physics under Mr. Woodward was carried on. Payment on results is obsolete, and the "May" examinations on which it was based have almost disappeared, assessment by inspection now replacing both; nevertheless, it is more than doubtful whether any other system—in the circumstances of the time—could have spread so widely a knowledge of science among the people, or prepared the way for the Technical Instruction Act, and that appreciation of the value of scientific training for industrial pursuits, which is exemplified by the provision through municipal agencies of technical schools in the industrial centres of this country. I sometimes think the Science and Art Department, and those great men, Sir John Donnelly and Prof. Huxley, who did much to shape its attitude towards science instruction in evening classes and in the science schools at South Kensington,[1] have received something less than their share of credit for pioneering work which finds its fruition in well-equipped institutions like this, and in the enhanced position which science holds to-day in the estimation of our countrymen. In those far-off times, before the foundation-stone of Mason College was laid, such evening classes in Birmingham provided the only means by which instruction in science, or scholarships to South Kensington, could be obtained. It is not unfitting, therefore, that I—a product of the system—should acknowledge here the obligation under which I stand both to the Midland Institute and to the Science and Art Department for providing the ladder by which I have risen, however undeservedly, to the honourable position of president of this section.

The historian of our times will not fail to note some of the consequences which have followed the application of science to industry, possibly also some of the educational results which have followed the development of science teaching in schools of all grades. Except from one point of view these need not concern us now as they fall, the one in so far as chemistry is concerned, into the province of the Society of Chemical Industry, the other mainly within the purview of Section L. This bringing of chemistry to the people has aroused a widespread interest in some aspects of the subject, of which the Press has not been slow to take note. Not even the heuristic method can hide from the schoolboy the fact that certain fundamental conceptions are accepted which do not admit of proof, such as the indivisible atom, the non-decomposable element, the indestructibility of matter. When, therefore, as one of the first-fruits of his discovery that positive rays furnish the most delicate method of chemical analysis, Sir J. J. Thomson has obtained from the most diverse solids a new gas, X_3; and by a different procedure, Prof. Collie with Mr. Patterson have discovered that hydrogen, under the influence of electric discharges at low pressure, becomes replaced by neon, helium, and a third gas which is possibly identical with X_3,[2] it is not surprising that we should hear much about it in the newspapers, just as was the case when the disintegration of radium was in process of being established. Further investigation may fail to substantiate some of the views which have been expressed about this unexplained disappearance of hydrogen; the origin of the neon and helium which make their appearance in the tube as the experiments proceed; the source of the gas X_3. Fortunately, X_3, unlike neon and helium, has some chemical properties—it disappears, for example, when violently exploded with a mixture of oxygen and hydrogen[3]—but we do not yet know whether it is a new element with an atomic weight of about 3, or a compound of hydrogen with an element yet to be discovered. This much at least seems certain: it is not the gas which, according to Mendeleef, should precede fluorine in the halogen series, but whether its discovery, like that of argon, will necessitate a revision of the periodic table of the elements we cannot know until the mystery which at present surrounds it has been dispelled.

It was in 1886, at the last meeting of this association in Birmingham, that Sir William Crookes—whose continued activities are a source of pride and gratification to his brother chemists—gave that famous address in which, clothing his ideas in language which has something of the magic of word-painting, he traced the evolution of the elements, as we know them, from the hypothetical protyle or Urstoff. The common origin of all elementary substances is now an accepted theory, although the question whether the idea underlying the term "transmutation" is verifiable under available conditions is answered differently according to the view we take of the disintegration of radium and kindred phenomena. But no one could have imagined that before another Birmingham meeting, the periodic table to which Sir William Crooks devoted much attention would have been enriched not only by a series of

[1] These schools in 1881 became the Normal School of Science, and in 1900 the Royal College of Science, now incorporated in the Imperial College of Science and Technology.

elements devoid of chemical properties, but by a second series, known only in minute quantities, and displaying those extraordinary properties of radioactivity which have revolutionised our ideas in more than one direction.

It is not necessary for me to chronicle even the more striking achievements in chemistry since 1886; a few examples will show how great the progress has been. It is on record that Arrhenius was present at that meeting, but his advocacy of that theory of solutions with which his name will always be associated came a little later; phenylhydrazine, which was to play so important a part in Emil Fischer's investigation of the sugars, had been discovered by him only two years previously; the Grignard reagent, which in other directions has played a no less important part in synthetical organic chemistry, did not become available until some fourteen years later. Theories then emerging, such as that of geometrical isomerism, have either been discarded or modified by the discovery of new facts, and who shall say that the ionic theory of dissociation stands where it did, now that ions in solution have incurred the suspicion of associating with the solvent, and to that extent have come into line with molecules, for the orthodox behaviour of which Prof. Armstrong himself would no doubt be prepared to vouch.

Residual Valency.

Among the many doctrines which have suffered under the stress of long-sustained investigation, that of valency is a prominent example. Valency is that property by which an atom attracts to itself other atoms or radicals, and its numerical value is deduced from the structural formulæ of compounds in which that atom occurs. Claus seems to have been the first to recognise that this attraction between two atoms is not a constant, but depends on the nature of the other atoms or radicals in the molecule,[4] and it is of interest to note in connection with what follows that he used methane and its chloro-derivatives to illustrate his point of view. Valency may vary, therefore, from compound to compound; it is known to alter under the influence of change in temperature, as, for example, when carbon dioxide or phosphorus pentachloride undergoes thermal dissociation. But Claus's view did not meet with ready acceptance; hence at the Birmingham meeting few chemists, if any, would have questioned the quadrivalency of carbon, despite the difficulty caused by the existence of carbon monoxide. Now, carbon is believed to be bivalent in the carbamines, fulminic acid and other compounds, as well as in carbon monoxide, and its tervalency is coming to be accepted in the light of the latest investigations on triphenylmethyl and its congeners. What is true of carbon is equally true of all other elements, except argon and its companions. Hence the doctrine of constant valency for which Kekulé contended, or that of variable valency in which the uncombined units varied by even numbers has necessarily given place to one of less rigid type, although the final form has yet to be determined.

For the purpose of this address it will be sufficient to refer only to one of these later theories: that in which Werner, as the outcome of his exhaustive study of inorganic molecular compounds, and especially of the ammines, supposes that an atom may have both principal and auxiliary or residual valency.[5] There are difficulties in its application to certain problems of organic chemistry—for example, the structure of the benzene molecule—but the conspicuous success which has attended Werner's investigation of the complicated isomerism of the cobalt and chromium ammines is evidence of its value as a guide in stimulating research in the most unpromising directions.[6] Werner's view that valency is an attractive force acting from the centre of the atom, being of equal value at all points on the surface and independent of units of affinity, has the merit of meeting the objection long urged to the idea that affinity has fixed direction in space, but otherwise leaves untouched Van't Hoff's brilliant conception of asymmetry which plays so great a part in the chemistry of to-day.

What light does this conception of residual valency, dating back to 1885, if not earlier,[7] and now embodied in many theories besides Werner's, throw on some of the problems with which the organic chemist is faced? Much every way. The question of the distribution of valency in the molecules of carbon compounds is discussed probably more than any other; it arises in connection with the structure of unsaturated compounds, the properties of fluorescence or colour which many of them exhibit, and the relation between chemical constitution and physical properties, to the elucidation of which an increasing amount of research is being directed. The double linkings in our formulæ no longer represent two units of valency in terms of hydrogen, nor are they now used to indicate polarity of the central atom or distribution of the valency in space; Werner's conception of valency accounts, as the phrase goes, for the concentration of re-activity at that part of the molecule where unsaturation exists, and it is of service when different degrees of unsaturatedness are displayed by compounds which, on the older view, would be expected to show similarity in chemical behaviour.[8] With your permission I propose briefly to review our knowledge of that type of chemical change known as substitution from the point of view of residual valency.

Substitution in the Paraffin Series.

So far back as 1839 the fact was discovered that replacement of hydrogen by chlorine in the acetic acid molecule does not lead to any essential modification in the properties of the acid. It is not a little remarkable, therefore, that although much of the progress in organic chemistry has been achieved by substitutions of the most diverse types, we are still unable to say that agreement has been reached with regard to the nature of the processes by which this replacement of one radical by another in a molecule is brought about. Never has attention been concentrated more closely than now on the study of what, for want of a better phrase, is termed the "mechanism of chemical reactions"—the processes which are covered and hidden by the sign of equality used, inaptly, in chemical equations—but the integrating mind, to the need for which Professor Frankland alluded on a recent occasion,[9] has not yet been evolved to reconcile the uncertain or contradictory answers vouchsafed to much patient experimenting. Organic

4 A. Claus, *Ber.*, 1881, xiv, 435. It may be noted that Claus concludes his paper with the statement, ". . . die Annahme von Valenzen, als in den mehrwerthigen Atomen präexistirender ihrer Wirkungsgrösse nach bestimmter Anziehungseinheiten eine ebenso unbegründete, wie unnatürliche Hypothese ist."

5 A. Werner, "Neuere Anschauungen auf dem Gebiete der anorganischen Chemie" (Friedr. Vieweg u. Sohn, Braunschweig, 1908): English edition. "New Ideas on Inorganic Chemistry." E. P. Hedley. (Longmans, 1911.)

6 A. Werner, *Ber.*, 1911, xliv, 2445, 3231.

7 S. U. Pickering, Proc. Chem. Soc., 1885, i, 122; H. E. Armstrong, Proc. Roy. Soc., 1886, xl, 285.

8 As an example of the unsatisfactory character of the doubly-linked formula to which the older meaning was attached, the following may be quoted: *unsym.*-Diphenyldichloroethylene, like ethylene, combines molecularly with bromine, but tetraphenylethylene does not:

$$\begin{array}{c} CH_2 \\ \| \\ CH_2 \end{array} \qquad \begin{array}{c} C(C_6H_5)_2 \\ \| \\ C\,Cl_2 \end{array} \qquad \begin{array}{c} C(C_6H_5)_2 \\ \| \\ C(C_6H_5)_2 \end{array}$$

yet a similar structure has been assigned to each (Biltz, *Annalen*, 1897 ccxcvi, 219).

9 P. F. Frankland, Proc. Chem. Soc., 1913, xxix, 101.

chemistry is not singular in this respect: as much might be said about controversies not yet settled which concern themselves with such every-day phenomena as the chemistry of the candle-flame or of the rusting of iron.

It is a commonplace that Kekulé, to whom theoretical chemistry owes so many fruitful suggestions, was of the opinion that substitution is not a process in which what may be called a direct exchange of radicals occurs, but is preceded by the temporary union of the molecules of carbon compound and addendum, followed by disruption into two new molecules, the substituted carbon compound being one of them. It is clear, then, from the point of view of Kekulé's hypothesis, that some degree of unsaturation is to be looked for in all carbon compounds and in all addenda. Hence, the paraffin hydrocarbons which furnish derivatives only by substitution, and, under the older, more rigid view of valency propounded by Kekulé himself, are typically saturated compounds, supply the exceptions to prove the general validity of the hypothesis that addition precedes substitution.

Before examining the case of these hydrocarbons, however, some advantage may be gained if the behaviour of other groups of compounds be examined in the light of the idea underlying Kekulé's view. By reference to the literature, it is evident that since the beginning of this century attention has been concentrated on the phenomena of substitution in the important group of carbonyl compounds, particularly the ketones and acids, which in many cases yield halogen substitution derivatives of one type. Thus methyl ethyl ketone when brominated in sunlight yields two bromoketobutanes of the constitution shown in the following formulæ, and propionic acid with bromine and red phosphorus under Volhard's conditions [10] gives α-bromopropionic acid,

$$CH_2Br.CO.CH_2.CH_3 \text{ and } CH_3.CO.CHBr.CH_3\ ^{11}$$
$$CH_3.CHBr.CO.OH$$

the halogen occupying what is termed the α-position with reference to the carbonyl radical. Why is substitution easier in the methyl group when it is present in the ketone or acid than when it occurs in methane, is one question that may be asked. A second will inquire whether the carbonyl group has a directing influence, and, if so, by what means is it exercised.

It has been supposed by Werner that the distribution of valency is disturbed by the introduction of the oxygen atom of the carbonyl group into the molecule of the hydrocarbon; that this oxygen atom absorbs much of the valency of the carbon atom of the carbonyl group, leaving less to bind its neighbour or neighbours, which results in their having free valency, and thereby attaching substituents to themselves. This explanation, if accepted for the bromination of ketones and acids, also for the chlorination of ketones, does not account for the results recorded by Michael and by Montemartini in the case of carboxylic acids. Michael has found that the β-chloro-, not the α-chloro-acid is the chief product (60–65 per cent.) when homologues of acetic acid are chlorinated [12]; and Montemartini states that if the radical CH occur in any part of the carbon chain the exchange of hydrogen for chlorine takes place in that position, however distant it may be from the carbonyl group of the acid.[13]

(Michael)

$$\left.\begin{matrix}CH_3\\CH_3\end{matrix}\right\rangle CCl.CH_2.CH_2.CO.OH$$
(Montemartini)

At present there seems to be no clue to the reason why chlorine and bromine in these reactions behave alike towards ketones and not towards acids.

An alternative explanation of this reaction, which has come to be widely accepted, is based on the remarkable property called desmotropy or dynamic isomerism, which certain of these carbonyl compounds exhibit. A desmotropic compound may exist in two or more forms, and its peculiar isomerism is known to depend on the mobility of a hydrogen atom in the complex $.CH_2.CO.$ whereby an equilibrium is set up of the type:

$$\underset{\text{Ketonic form}}{.CH_2.CO.} \rightleftharpoons \underset{\text{Enolic form}}{.CH{:}C(OH).}$$

Of these two forms, the enolic is the more unsaturated, and presumably the more reactive.[14] Lapworth, making use of this desmotropic relationship, supposes that when the ketone reacts with halogen in dilute aqueous solution three changes occur which, for the case of acetone, may be represented by the following expressions:—

$$\begin{aligned}&CH_3.CO.CH_3 &&\rightarrow CH_3.C(OH){:}CH_2\\&CH_3.C(OH){:}CH_2+Br_2 &&\rightarrow CH_3.C(OH)Br.CH_2Br\\&CH_3.C(OH)Br.CH_2Br &&\rightarrow CH_3.CO.CH_2Br+HBr\end{aligned}$$

the first being one of slow enolisation, accelerated catalytically by halogen acid, leading to the production of an unsaturated compound, which then by rapid addition of bromine and subsequent elimination of hydrogen bromide conforms with Kekulé's hypothesis. The intermediate compounds, it is true, have not been isolated, but a study of the dynamics of the reaction by Lapworth, and later by Dawson with his collaborators (using iodine instead of bromine), shows that this explanation is in harmony with the data obtained.[15] When the reaction is applied to carboxylic acids under similar conditions, the view that it takes a similar course finds support from an investigation of the dynamics of the bromination of malonic acid in aqueous solution.[16]

Whether evidence drawn from reactions found to take place in aqueous solution is relevant when bromination is effected by heating a carboxylic acid with bromine and red phosphorus may be doubted. Certainly it seems to afford no assistance in accounting for the course of chlorination in the acids examined by Michael and by Montemartini. Nevertheless, Aschan employs the keto-enolic hypothesis [17] to elucidate the results of a recent inquiry into the "mechanism" of the Volhard reaction [18]; and it may be added that racemisation has been found to occur when *laevo*-valeric acid is brominated by Volhard's method [19]—a result which must follow if enolisation

[14] It may be of interest to note that the long controversy respecting the composition of ordinary ethyl acetoacetate $CH_3.CO.CH_2.CO.OEt$, the first of these desmotropic compounds to be discovered, has been brought to an end by the isolation of each desmotropic form at temperatures sufficiently low to inhibit the desmotropic change. From refractometric observations with mixtures of the pure isomerides, Knorr concludes that this ester at the ordinary temperature contains about two per cent. of the enolic form, whereas from bromination experiments with the ester itself, which may possibly be accompanied by a disturbance of the equilibrium, K. H. Meyer infers that the amount may be as much as seven per cent. (L. Knorr, O. Rothe, and H. Averbeck, *Ber.*, 1911, xliv, 1138; K. H. Meyer, *Annalen*, 1911, ccclxxx, 222; K. H. Meyer and P. Kappelmeier *Ber.*, 1911, xliv, 2718.]

take place, although susceptible of another explanation.

So far as I can form a judgment, no case has been made out for the view that substitution of halogen for hydrogen under Volhard's conditions differs in its "mechanism" from substitution in the paraffins. This opinion finds support in the discovery just announced by Leuchs[20] that, while the chief product of the bromination of *dextro*-β-carboxybenzyl-α-hydrindone

$$C_6H_4\begin{array}{l}\diagup CH_2 \diagdown \\ \diagdown CO \diagup\end{array} CH.CH_2.C_6H_4.CO_2H \rightarrow$$

$$C_6H_4\begin{array}{l}\diagup CH_2 \diagdown \\ \diagdown CO \diagup\end{array} CBr.CH_2.C_6H_4.CO_2H$$

is the racemic compound, no less than 10 per cent. is the *dextro*-bromo-derivative; therefore, the inference is clear that in the formation of the latter compound, if not of both, substitution was effected by a process in which migration of the hydrogen atom did not occur.

Attention may now be directed to the question of "direct substitution," which, in its simplest form, is encountered in the paraffin series. As will be gathered from the following selection from among the various theories propounded to account for the mechanism of substitution, alternative explanations of the intermediate reactions leading up to substitution in these cases involve either elimination of the hydrogen atom before introduction of the halogen, or addition of the halogen in virtue of the supposed residual valency of both molecules, followed by disruption of the complex thus formed into the known products of the change.

Dealing with these alternatives in the order given, Arrhenius adopts a view of the process of substitution which, including as it does his explanation of optical inversion and racemisation, should perhaps be given in his own words:—

"Every valency linking can be broken; this is true in all cases, since it is a necessary condition for every chemical reaction. An atom or an atomic complex is thereby removed from the molecule, and its place taken by another atom or atomic complex. One must therefore assume, as was first pointed out by Williamson, that the atoms or complexes separate themselves from the molecule from time to time, even when they do not react with other molecules. Consider now a molecule in which four different atoms, A, B, C, and D, are bound to one carbon atom. The atoms A and B, which may possess equal charges, *e.g.* positive, are therefore separated at times from the molecule, and it may happen that they are both separated at one and the same time. It is therefore possible for them to change places on combining with the carbon atom again. This is synonymous with a transformation of the original molecules into its optical isomer."[21]

Nef, making use of "the conception of dissociation in its broadest sense," is of opinion that the decomposition of ethane into hydrogen and ethylene at 800° "proves that an extremely small per cent. of [its] molecules must exist at ordinary temperature in an active or dissociated condition,

$$CH_3.CH_3 \rightarrow CH_3.CH_2 + H-\text{''}^{22}$$

consequently, when "chlorine reacts with ethane to give the monochloro-substitution product, we have this reagent in the *active molecular* condition simply uniting by addition with the dissociated ethane particles,

$$\begin{array}{c}Cl=Cl\\ |\end{array} + H-C_2H_5 \rightarrow \begin{array}{cc}\multicolumn{2}{c}{Cl=Cl}\\ | & |\\ H & C_2H_5\end{array} \quad [\rightarrow \; HCl+C_2H_5Cl.]\text{''}$$

Finally, he draws the conclusion that "excluding reactions called ionic, a chemical reaction between two substances always first takes place by their union to form an additive compound."

Michael,[23] in many published papers, has emphasised the view that in the substitution of halogen for hydrogen in a saturated hydrocarbon or saturated acid the principal factors to be taken into account are the mutual chemical attraction of the two elements, on one hand, and that of the halogen and carbon, on the other. By applying his "positive-negative" hypothesis to the directing influence of "relatively-positive" methyl, and "relatively-negative" carboxyl, he draws conclusions about the degree of firmness or looseness with which particular hydrogen atoms are bound to carbon in the molecule, and is thereby able to forecast with some success the position or positions in which replacement of hydrogen by halogen will occur. Flürscheim, in the discussion of the relation between the strength of acids and bases, and the quantitative distribution of affinity in the molecule, also makes use of the idea that the relative degree of firmness or looseness with which a hydrogen atom is held depends on the nature of the other atoms or radicals associated with the same carbon atom.[24] The hydrogen atoms therefore are not to be regarded as retained in the molecule with the same degree of firmness; in other words, valency is not a constant to be measured in units.

It will be gathered therefore that Arrhenius and Nef, from different points of view, support the idea that separation of hydrogen from the hydrocarbon precedes entry of the substituent into the molecule; Michael and Flürscheim are concerned chiefly with the distribution of valency in the molecule, which determines whether a particular hydrogen atom shall be displaced by hydrogen or not; Kekulé's hypothesis requires addition to precede substitution. Is there any experimental evidence to indicate where the balance of probability lies? I think it can be argued that the phenomena of substitution observed with optically active substances do not lend support to the views of Arrhenius or of Nef, which imply actual or virtual dissociation, but that they point to the intermediate formation of an additive product, which undergoes scission as Kekulé supposed. Such an additive product can be formed only if residual valencies be present in both carbon compound and addendum.

The argument runs thus: Unless valency has fixed direction in space, a conception now abandoned if modern theories of valency be accepted, the conclusion seems to be inevitable that dissociation of the optically active compound:—

$$CWXYZ \text{ into } CWXY+Z,$$

must lead to racemisation, the radicals W, X, Y, distributing themselves in two-dimensional space, thus destroying the asymmetry; whence it follows that introduction of the substituent, V, into the molecule in place of Z can give rise only to an optically inactive product. Now, it is a well-established fact that a radical attached directly to the asymmetric carbon atom may be replaced by another without racemisation following.[25] Therefore, preliminary dissociation being excluded, Kekulé's additive hypothesis remains. But the prolonged study of that remarkable reaction known as the "Walden inversion" by Emil Fischer, McKenzie, and other investigators, has led to results

[20] H. Leuchs, *Ber.*, 1913, xlvi, 2435.
[21] S. Arrhenius, "Theories of Chemistry," edited by T. Slater Price (Longmans, 1907), p. 76.

[23] A. Michael, *Ber.*, 1901, xxxiv, 4028, covering reference to earlier papers.
[24] B. Flürscheim, Trans. Chem. Soc., 1909, xcv, 721.
[25] P. Walden, *Ber.*, 1895, xxviii, 1297; W. Tilden and B. M. C. Marshall, Trans. Chem. Soc., 1895, lxvii, 494.

which, if the views formed independently by Fischer,[26] Werner,[27] and Pfeiffer [28] may be accepted, are inexplicable unless a preliminary addition, effected as it is supposed by means of residual valencies, precedes this replacement of the eliminated radical by the substituent.

The Walden inversion may be illustrated by a brief statement of some of the facts discovered in connection with the conversion of optically active chlorosuccinic acid into malic acid

$$R.CH(OH).CO_2H \longrightarrow R.CHCl.CO_2H \longrightarrow R.CH(OH).CO_2H.$$

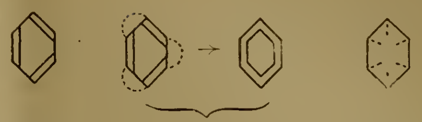
Walden found that *laevo*-chlorosuccinic acid, obtained from *dextro*-malic acid, furnished either *dextro*- or *laevo*-malic acid, according to the reagent used to effect of the replacement of the Cl by the OH radical.

$$l\text{-chlorosuccinic acid} \begin{cases} (+\,Ag_2O) \rightarrow l\text{-malic acid} \\ (+\,KOH) \rightarrow d\text{-malic acid.} \end{cases}$$

And as the corresponding inversion was found to occur with *dextro*-chlorosuccinic acid under similar conditions, a complete cycle of changes can be brought about.[29] That preservation of optical activity, and not racemisation, should accompany the replacement of a radical, attached to the asymmetric carbon atom, by another is a fact of much theoretical interest, as has already been indicated; that a change in the sign of rotation should occur when an exchange of the same radicals is achieved by one reagent and not by another is a mystery, that deepens rather than diminishes with each addition to the list of inversions, already long, in which it has been observed.[30] In all probability the discovery of the Walden inversion, as Prof. Frankland has said, "may mark an epoch in our views with regard to the mechanism of the process of substitution in general." [31]

The Structure of the Benzene Molecule.

The abandonment of the theory of the fixed valency unit in favour of the view that the carbon atom has both principal and residual valencies has raised afresh that perennial topic of controversy—the structure of the benezene molecule. Probably few will contest the statement that for practical purposes only three formulæ have emerged from the long discussion of the problem, viz. Kekulé's oscillation formula with fixed valency units, for which much physical evidence has been pleaded: Thiele's formula, in which his theory of "conjugated double linkings" is applied to the Kekulé formula, with the consequence that the three double linkings disappear owing to self- neutralisation of the partial valencies, the benzene molecule thus containing six inactive double linkings; [32] and Armstrong's "centric" formula, in which by its residual valency "each individual carbon atom exercises an influence upon each and every other carbon atom." [33] The dotted lines indicate the residual valencies.



Kekulé. Thiele. Armstrong.

The discovery of *cyclo*octatetraene has brought a new interest into the discussion,[34] for the structural formula assigned to this hydrocarbon shows alternate single and double linkings as in Kekulé's symbol, and the optical behaviour (refractivity) corresponds with that of benzene.

CH=CH
CH CH
| ||
CH CH
CH=CH

But its chemical properties are entirely different from those of benzene; it forms compounds not by substitution but by addition, and it has the reactivities of a highly unsaturated compound. If these experimental results be accepted, then—as Willstätter shows—the peculiar properties of benzene are not to be explained by Kekulé's or Thiele's formula, and the verdict is given in favour of the "centric" symbol—that earliest embodiment of the conception of residual valency, which Armstrong later turned to such good account in the quinonoid theory of colour identified with his name.

The reference to the optical behaviour of *cyclo*-octatetraene may perhaps suggest the inquiry: Do not the physical properties of the carbon compounds throw light on the questions that have been raised? A little consideration will show that, on the contrary, the answer must be: It is only by chemical evidence that physical data can be interpreted or corroborated, and in the absence of such evidence the "additive" results which accrue from physical observations have no bearing on questions involving the determination of structure or the structural transformations which accompany a chemical change. For example, the anomalous results obtained by Brühl and by Sir William Perkin [35] in the investigation of the refractivity and the magnetic rotation of certain unsaturated compounds, remained without explanation until Thiele in 1899, by his hypothesis of partial valency, accounted for the comparative inactivity of the central pair of carbon atoms in compounds of this type—compounds which are characterised by containing alternate single and double linkings in their formulæ:—

. CH : CH . CH : CH . → . CHBr . CH : CH . CHBr .

This conception of Thiele's has both focussed attention on the distribution of valency within the molecule, contributing largely to the wide acceptance of theories of valency such as Werner's, and given to the study of physical properties—especially those "constitutive" properties of refraction, dispersion, and magentic rotation—an impetus which has by no means spent its force. Further, the occurrence of this anomaly, "exaltation" as it is called, is now relied on as evidence of the presence of this particular distribution of valency, with results which in Auwers's

30 Without the aid of a model it is not possible to show that the production of the *dextro*- or *lævo* acid may be accounted for by the hypothesis that an intermediate additive compound is formed, which undergoes scission in one or other of two ways. Diagrams of models will be found in Fischer's paper (*loc. cit.* cf. "Annual Reports on the Progress of Chemistry" (Gurney and Jackson, 1911, viii, 67), and to illustrate Werner's hypothesis, which is more exolicit than Fischer's, in a paper by W. F. Garner (Proc. Chem. Soc., 1913, xxix. 200)

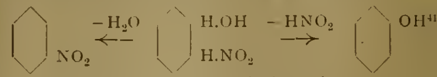
hands have furnished important clues to the structural formulæ of terpenes and other compounds.

As additive properties become constitutive, so the value of a knowledge of the physical properties of a substance will tend to increase, but there is little ground for hope that the problem of the constitution of benzene will be solved from the physical side. The controversy which has arisen between Hantzsch and Auwers regarding the physical properties of *cyclo*-tatetraene in relation to its chemical structure is a case in point;[36] the absence of optical exaltation in this hydrocarbon is wholly unexpected, but, on the other hand, the type of compound is entirely new. With benzene also the distribution of valency within the molecule differs from that in any known compound; our knowledge of it, admittedly far from complete, has been gained from the chemical side, and is summarised in the various structural formulæ; but the limitations of the physical method of attack can be traced from Thomsen's endeavour to determine its structure from thermochemical data[37] to the more recent invention of isorropesis. And, despite the evidence obtained from refractivities, we may not unreasonably demur to the suggestion that derivatives of benzene, which by their behaviour towards substituting agents show themselves to be wide apart in chemical properties, such as nitrobenzene and aniline on one hand or chlorobenzene and phenol on the other, should respectively be classified together.[38]. Undoubtedly, most useful information is obtained from a comparison of the physical properties of two related substances, the exact constitution of one of which is uncertain, but that of the other known. Therefore, bearing in mind the great development that has taken place recently in the correlation of physical properties with chemical constitution by methods based on refraction and absorption, every chemist will welcome the entry of Dr. Lowry into that field of research on the relation between magnetic rotation and structure, which for all time will be associated with Sir William Perkin's name.

Substitution in the Benzene Series.

Turning now to a discussion of the problem of substitution in cyclic compounds, one important factor must not be overlooked; the even distribution of the residual affinity of the benzene molecule is disturbed by the introduction of a substituent. The study of substitution in benzene derivatives indicates that, as a consequence of this disturbance, a directing influence comes into play which, when the substituent is changed, may vary in the effect it exercises on the course of substitution.

Arising probably from this even distribution of valency, it is characteristic of benzene to furnish additive compounds in which six atoms of hydrogen or a halogen, but not two or four, become attached symmetrically to the molecule; substitution, however, occurs when a catalyser is present, such as the aluminium-mercury couple for halogenation, or sulphuric acid for nitration or sulphonation, leading initially to the production of mono-substituted derivatives. Whether the catalyser by association with the benzene molecule[39] limits this additive capacity, or whether its function is to promote the elimination of the halogen acid or water respectively,[40] is still a subject of discussion, but in the absence of a reaction of additive type it is not easy to account for facts such as the production of a certain amount of trinitrophenol when benzene is nitrated in the absence of sulphuric acid.



(in presence of sulphuric acid) (in absence of sulphuric acid)

The much-debated questions still remain: Why and by what mechanism, when a second or third substituent is introduced into the molecule, is the orientation of the isomeric products determined by the radical or radicals already present? For disubstitution, the *ortho-para*- and the *meta*-laws have been deduced, and the radicals which respectively promote mainly *ortho-para*-substitution on one hand, and *meta*-substitution on the other, have been catalogued.[41] But these laws take account only of the orientation of the chief product or products, whereas all three derivatives, *ortho*, *meta*, and *para*, have been detected in most of the reactions studied, and their relative proportion in many cases is known to depend on the conditions, being affected by such influences as variation in temperature or in the medium employed.[42] Nitration of acetanilide, for example, furnishes a mixture of *ortho*- and *para*-nitracetanilide, but of aniline in the presence of much sulphuric acid yields chiefly *meta*-nitraniline.[43] And, to illustrate the inadequacy of the *meta*-law, the fact that sulphonation of benzene-sulphonic acid with concentrated sulphuric acid at 230°–240° furnishes an equilibrium mixture of the *meta*- and *para*-disulphonic acids in the proportion of 2 : 1 may be quoted.[44]

In the exploration of this field many workers have participated, but the results, recorded almost as often in patent specifications as in journals, are seldom quantitative, so great is the difficulty at times in isolating the minor product or products of the change. Recently, however, by a most ingenious use of melting-point curves and density determinations, Holleman and his collaborators have carried out an exhaustive series of substitutions with small quantities of material and under known conditions;[45] yet after a survey of the whole field the conclusions reached are:—

(1) That uncertainty cannot be removed until some basis exists for different reactions to be carried out under comparable conditions.[46]

(2) That even if the relative amounts of the isomerides formed when a radical C is introduced into each of the mono-substitution derivatives $C_6H_5.A$ and $C_6H_5.B$ be known, it is not possible to calculate the proportion in which the isomerides $C_6H_3.ABC$ will be produced when the radical C is substituted in the compound $C_6H_4.AB$.

Although the validity of the *ortho-para* and of the *meta*-laws may be impeached, they serve as a first approximation, and many theories have been propounded to account for them. Armstrong has suggested that in *ortho-para*-substitution the additive compound is formed by association of the addendum with the carbon atom carrying the radical already substi-

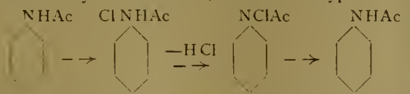
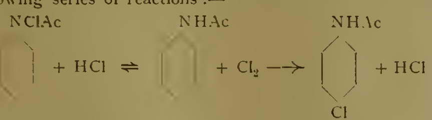
46 For example, nitration is effected chiefly at low temperatures, but sulphonation of mono- substituted benzenes at temperatures higher than the ordinary, which if employed in nitration would lead to mixed products.

tuted in the molecule,[47] whereas in *meta*-substitution it arises by union of the addendum with this radical,[48] transformation to the respective disubstitution derivatives being effected possibly in step-by-step progression, as conjectured by Lapworth.[49] Holleman, who also adopts the additive hypothesis, is of the opinion that the radical already present in the molecule may promote or retard the association of the addendum with the pair of carbon atoms, to one of which it is itself attached. By the operation of the first of the alternatives an *ortho*- and by conjugation a para-derivative will arise; from the second a *meta*-derivative will result, when scission of the additive compound ensues. Holleman's is the only hypothesis which has been submitted to the test of quantitative investigation, and although, as already mentioned, the results do not suggest that finality has been reached, it marks an advance in the study of this obscure problem.[50]

No discussion of substitution in the benzene series would be adequate without reference to the remarkable behaviour of amines and phenols. Unlike other mono-substitution derivatives, which do not differ markedly from benzene in reactivity, these furnish mono-, di-, and tri-derivatives very readily. With aniline or acetanilide, substitution occurs first of all in the side chain, being followed under appropriate conditions by removal of the substituent from the amino-group and entry into positions relatively *ortho*-, *para*-, or both *ortho*- and *para*- to it. The earliest of these changes to be studied was the transformation of methylaniline into *para*-toluidine; many of them have been discovered by Chattaway and his collaborators, and until a critical study of the chlorination of acetanilide was undertaken by Orton and Jones,[51] it was held that the changes, which occur only in the presence of hydrochloric acid, were of the type :—

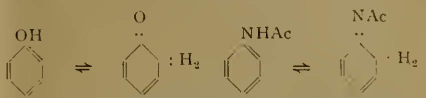


From the dynamics of the reaction, it is now known that intra-molecular transformation from the side chain to the ring does not occur, the agent promoting the substitution being chlorine arising from the following series of reactions :—



As bromination has been shown to follow the same course, it is evident that no secure foundation now exists for the view, formerly widely held, that the reactivity of amines is intimately connected with the variable valency of nitrogen leading to initial substitution in the side chain.

Even were this view, now discredited, still applicable to the amines, it could not be extended with the same certainty to the phenols. Hence, in explanation of the rigid adherence to the *ortho-para*-law observed among the mono-substitution derivatives of these two groups of compounds, it is noteworthy that Thiele,[52] for the phenols, suggests that the reactivity may be due to these substances being stable enolic forms of ketodihydrobenzenes, and that Orton,[53] for the amines, conjectures that it may arise from the formation of dynamic isomerides of quinonoid structure :—



How far these suggestions may open up a new field of inquiry into the "mechanism" of substitution remains to be seen; it is at least interesting that their extension to the naphthalene series shows that not only does the reactivity of the naphthols and of α-naphthylamine recall that of phenol and aniline, but the orientation of their mono-substitution derivatives[54] in almost every case is the same as that of one or other of the six naphthaquinones, the existence of which has been predicted by Willstätter.[55]

Symmetric and Asymmetric Syntheses.

It must not be supposed that the "mechanism" of substitution can be explained by reference only to the examples of this type of reaction which have been mentioned, or that the summary attempted in the restricted field of the replacement of hydrogen by halogen is a complete picture of all the different views advanced to account for this chemical change. Rather, the effort has been made to indicate in broad outline the difficulties that beset any exploration of that debatable region which lies between the two sides of a chemical equation. But, as the wonderful story of carbon chemistry shows, the failure to comprehend the processes operative in substitution does not impede rapid progress in other directions. The study of the mobility of radicals, desmotropy being only one of many examples of this phenomenon, continues to present fresh problems, of which that raised by Thorpe[56] in connection with the mobile hydrogen atom of glutaconic and aconitic acids may be mentioned, as it revives a question of old standing: Do free units of valency exist in carbon compounds? The syntheses of caffeine and certain alkaloids, of sugars and peptone-like polypeptides, of natural terpenes and camphor, of indigo and rubber, are well-known achievements, while natural processes, in which enzyme action plays a part, are yielding their closely guarded secrets to the persistent inquiry of Armstrong and his collaborators, who are probing the relationship between enzyme and substrate which Emil Fischer pictured as that of lock and key. Further, there is that large field of work which includes not only the Walden inversion but new problems of asymmetry, with which the names of Frankland, Pope, Werner, and others are associated; while Barlow and Pope's conception of the relation of valency to atomic volume, by correlating crystalline structure with the composition, constitution, and configuration of carbon compounds, has given a new interest to the study of crystallography.

Nor is progress less rapid in that other important branch of chemistry—the unravelling of the structure

[47] Kinetic studies of the chlorination and bromination of toluene, $C_6H_5{\cdot}CH_3$, however, gave no indication of the production of an intermediate additive compound of the hydrocarbon and addendum (*cf.* Holleman, Polak, van der Laan, and Euwes, *Rec. trav. chim.*, 1908, xxvii, 435; Bruner and Dluska, Bull. Acad. Sci., Cracow, 1907, 693; Bancroft, J. Physical Chem., 1908, xii, 417; Cohen, Dawson, Blockey, and Woodmansey, Trans. Chem. Soc., 1910, xcvii, 1623.

[49] A. Lapworth, Trans. Chem. Soc., 1898, lxxiii, 454; 1901, lxxix, 1265.

[50] It should be mentioned that other views, based on the loosening or strengthening of the affinity of the hydrogen atoms situated in *ortho-para-* or in *meta-* positions, brought about by the disturbing influence of the radical already present in the molecule on the valency of the carbon atom to which it is attached, and therefore on that of the other five carbon atoms, have been advanced by Flürscheim (J. prakt. Chem., 1902 [ii], lxvi, 321), Tschitschibabin (*ibid.*, 1912 [ii], lxxxvi, 397), and others.

of natural products. The constitution of rubber is approximately known; most of the alkaloids have been explored with a greater or less degree of completeness; and now the study of starch,[57] chlorophyll, and hæmatin (the non-proteid constituent of hæmoglobin)[58] has been taken up afresh during the last three years, with results which, in the case of the two latter, eclipse in importance and interest all that was previously known. In whatever direction we may look, there is the same evidence that we can take to pieces the most complicated structure which nature has devised, and by the aid of valency conceptions can fit the pieces into a formula which is an epitome of the chemical activities of the molecule. Again, in many cases the resources of our laboratories enable us to build up the structure thus displayed, and to establish the identity of nature's product and our own. Nevertheless, the fact remains that all these syntheses leave untouched and unexplained the profound difference between the conditions we find necessary to achieve our purpose and those by which the plant or animal carries on its work in presence of water and at a temperature differing only slightly from the normal. It is, of course, a well-known fact that an enzyme under the appropriate conditions can bring about the same chemical transformation of a substrate as is effected by the living cell from which it can be separated; but our knowledge of these complex, ill-defined, nitrogenous organic compounds is relatively very meagre; they are difficult to purify, and their composition—apart from any question of structure—is largely unknown. Yet because Wöhler chanced to discover that urea can be produced synthetically from an inorganic source the conclusion is not infrequently drawn that all chemical changes in living substance are brought about by ordinary chemical forces.[59] Probably everyone present will concur in that view, but the assent, if given, can scarcely arise from a consideration of the facts, of which there is no great store. Where so little is known accurately, chemistry is not on very safe ground if she infer the rest. What common basis of comparison exists between Wöhler's process and the metabolic changes by which urea is produced in the living body? What evidence have we that because an enzyme and an inorganic agent under different conditions give rise to the same end product, the driving force is the same, although the lines along which it is exercised are very different? I think it is not the least of the many services which Prof. Meldola has rendered to chemistry, that he has given us this warning: "If we have gone so far beyond nature as to make it appear unimportant whether an organic compound is producible by vital chemistry or not, we are running the risk of blockading whole regions of undiscovered modes of chemical action by falling into the belief that known laboratory methods are the equivalents of unknown vital methods."[60]

I turn now to a no less interesting question than that involved in enzyme reactions, namely the wide distribution in plants and animals of single asymmetric substances which if synthesised in the laboratory would be produced as inactive mixtures of both asymmetric forms. It has been argued that the occurrence of racemic compounds in nature, although infrequent, is a proof that in the organism, as *in vitro*, they are in all cases the initial products from which, when separated into antipodes, one of the asymmetric compounds is utilised in the life processes and the other left. But whether this be the case, or whether only the one asymmetric form result from the synthesis, Pasteur firmly held the view that the production of single asymmetric compounds or their isolation from the inactive mixture of the two forms is the prerogative of life. Three methods were devised by Pasteur to effect this isolation, and in only one of them are living organisms—yeasts or moulds—employed; but Prof. Japp, in his address to this Section at Bristol in 1898, emphasised the fact, hitherto overlooked, that in the two others, nevertheless, "a guiding power [is exercised by the operator] which is akin in its results to that of the living organism, and is entirely beyond the reach of the symmetric forces of inorganic nature." Hence, to quote again from his address, "Only the living organism with its asymmetric tissues, or the asymmetric products of the living organism, or the living intelligence—with its conception of asymmetry, can [bring about the isolation of the single asymmetric compound.] Only asymmetry can beget asymmetry." After an exhaustive review of the subject, Japp came to the conclusion that the failure to synthesise single asymmetric compounds without the intervention, either direct or indirect, of life is due to a permanent disability, and although—as was to be expected—this conclusion was challenged,[61] the only "asymmetric syntheses" effected since that time have been operations controlled by the chemical association of an optically active substance with the compound undergoing the synthetical change.[62]

Recently the problem has assumed a more hopeful character. Ostromisslensky[63] in 1908 made the remarkable discovery that inactive asparagine, which is not racemic but a mixture of the *dextro-* and *laevo-*forms in molecular proportion, gave a separation of one or other isomeride when its saturated solution was inoculated by a crystal of glycine—a substance devoid of asymmetry. Now Erlenmeyer claims to have achieved a true asymmetric synthesis by boiling an aqueous solution of inactive asparagine for sixteen hours, when by crystallisation part of the *dextro-*form separated in an almost pure state.[64] The theoretical conclusions which led to this investigation are of much interest because they raise afresh the question whether without displacement of the individual radicals, and apart from antipodes, more than one compound can exist, in the molecule of which two carbon atoms are united by a single linking.[65] As an illustration, reference may be made to the malic-acid series, in which three optically active compounds are known, the *dextro-*acid, the *laevo-*acid, and Aberson's acid.[66] In the *laevo-*series the three isomerides obtainable by rotation of one of the carbon atoms with its attached radicals relatively to the other would be

[59] "Quite similar changes can be produced outside the body (*in vitro*) by the employment of methods of a purely physical and chemical nature. It is true that we are not yet familiar with all the intermediate stages of transformation of the materials which are taken in by the living body into the materials which are given out from it. But since the initial processes and the final results are the same as they would be on the assumption that the changes are brought about in conformity with the known laws of chemistry and physics, we may fairly conclude that all changes in living substance are brought about by ordinary chemical and physical forces."—Sir Edward Schäfer, President's Address at the Dundee Meeting, British Association Report, 1912, p. 9.

With the inactive asparagine it is supposed by Erlenmeyer that prolonged heating in aqueous solution produces a rotation of this type, possibly to an unequal extent or in opposite directions in the *dextro-* and *laevo*-forms, whereby the products being no longer antipodes become separable by ordinary laboratory methods. It is too early yet to say whether, by exclusion of all asymmetric influences, the riddle has been solved, but it is easy to understand with what interest confirmation of Erlenmeyer's results is awaited.

Honours Students and Post-Graduate Scholarships.

In bringing this address to a conclusion, it will not be an innovation if I refer—it shall be only briefly—to the training of those who will carry on and amplify the work which we in this generation have attempted to do. This section stands for the advancement of chemistry which includes, so closely are pure and applied chemistry intertwined, the advancement of chemistry as applied to industry. Once again the cry has been raised in the Press[67] that chemists trained in our universities are of little value in industrial pursuits; they are too academic; they are not worth their wage—little as that often is, whether judged by a labourer's hire or the cost of a university training. It may be so. On the other hand, it is possible the employer obtains all that he pays for, and by paying more would receive in return much more by the inducement offered to more highly trained men to enter the field. Three years' training for the ordinary degree cannot carry a student very far in chemistry, and this preliminary training—for it is little more—is insufficient to equip the young graduate for more than routine work. With the honours student it is otherwise. He must either enter on his three years' residence at a university with a knowledge which does not fall below the requirements of the intermediate examination, and devote the greater part of his time to his honours subject, or he must be prepared to spend a fourth year to reach the necessary standard. More highly equipped in the academic sense than a man who has worked only for the ordinary degree, he undoubtedly is, yet there is seldom time to begin his training in research methods or in methods of commercial analysis where rapidity rather than extreme accuracy is the object in view.

Two reforms, I venture to think, are needed: the first would avoid early specialisation, which is apt to be disastrous, the second would encourage post-graduate training in directions where the student's inclinations or aptitude may be stimulated and developed. If the civic universities, established in virtue of charters drafted mainly on similar lines and inspired by similar aims, could come to some agreement requiring three years' residence, subsequent to the intermediate, for an honours degree in chemistry, the first reform would be effected—it is a measure for which a strong case can be made out. If, further, they could see their way to standardise their ordinances and regulations for the M.Sc. degree, cease to confer it on honours graduates of one or more years' seniority in return for payment of a fee, and confine it to graduates—not necessarily honours graduates—who have carried out an approved piece of research during not less than one academic year, selection committees, boards of directors, or individual employers would have some clue to the type of man before them. I would go further and suggest that the interchange of honours graduates between the civic universities, or between them and other universities or colleges, if it could be arranged, would be of much benefit to the student himself. No university in this country is wealthy enough to attract to its service teachers who are pre-eminent in each branch of chemistry. How great, then, would be the gain to an honours graduate working for the M.Sc. degree, if, instead of being associated with the same teacher during the whole of his academic career, he could migrate from the place which had trained him to spend part, or the whole, of his time in the laboratory of an Armstrong, a Donnan, a Perkin, or a Ramsay, during that most critical period when he is sorting out his own ideas and learning how to use his fingers and his wits. But whether enforcement of the longer training for the honours degree be possible; whether a research degree as a step to the doctorate be desirable or practicable, there can be no doubt that the urgent need of the present time is the provision of scholarships and exhibitions, sufficient in value to secure at least a bare livelihood, for post-graduate work. He who is able to convert education committees and private donors to the view that a far better return for the money could be assured if part of the large expenditure on scholarships for matriculated or non-matriculated students were diverted to post-graduate purposes, will have done a service to science and the State the value of which, in my opinion, cannot be overestimated.

[67] Cf. *The Times*, Engineering Suppl., 1913, May 7, 21, 28, June 4, 11, 18.

NOTES.

WE announce, with deep regret, the death, on Thursday last, of Sir Walter Noel Hartley, F.R.S., formerly professor of chemistry at the Royal College of Science, Dublin. He was in the sixty-eighth year of his age.

PROF. ARMINIUS VAMBÉRY, the Oriental scholar, died at Budapest on September 14, in his eighty-second year. The obituary article on him in *The Times* states that in 1851 the sum of 1000 florins was voted to him by the Hungarian Academy of Sciences on condition that he went into the interior of Asia to investigate the affinities of the Magyar tongue. In the following year he left for Persia, joining a caravan of Tartar pilgrims returning from Mecca. In no way intimidated by predictions of privations and dangers or by the melancholy fate of Conolly, Stoddart, Moorcroft, and others, he decided to maintain throughout the journey a strict disguise as a dervish. Leaving Teheran on March 28, 1863, Vambéry reached Khiva at the end of May, after intense sufferings from thirst in the trackless desert. In 1864 he visited London, gave an account of his travels at a meeting of the Royal Geographical Society, and did his best to convince public men in England of the necessity for the creation of a neutral zone or a geographical buffer State in Central Asia.

THE death is announced at Chatham, Ontario, of Dr. Alex. MacFarlane, in his sixty-third year. A native of Blairgowrie, he graduated at Edinburgh in

1875, after a brilliant University career. The thesis by which he obtained the doctorate in 1878 was a remarkable experimental research into the conditions governing the electric spark. This brought him under the notice of Clerk Maxwell. In the same year he was elected F.R.S. Edinb. In 1885 Dr. MacFarlane was appointed to the chair of physics in the University of Texas. About fifteen years ago he took up his residence in Canada, where he continued to be actively engaged in physical and mathematical research. The latest of his many publications was a "Bibliography of Quaternions," issued in 1904.

ONE of the passengers killed in the disastrous New Haven Railway collision, which occurred on the same day as that at Aisgill, was Dr. Joseph Benson Marvin, professor of medicine and neurology at the University of Louisville. Dr. Marvin was born in Florida in 1852. At the age of eighteen he was appointed assistant professor of chemistry and physics at the Virginia Medical Institute. He then took a medical course, and afterwards held professorial posts at the Louisville Hospital College of Medicine, the Kentucky School of Medicine, and Kentucky University successively. Dr. Marvin's wife and daughter, who had been with him on a holiday in Maine, were also victims of the disaster.

CHANGES in the staff of the Central Research Institute at Kasauli are announced. Major W. F. Harvey, I.M.S., is taking the place of Sir David Semple as head of the institute, and Capt. J. W. McCoy, I.M.S., is to join the bacteriological department.

A BOARD for the study of tropical diseases has been established at Ponce, Porto Rico, by the Medical Department of the United States Army. The first president of the board is to be Major B. K. Ashford.

ACCORDING to *The Times*, arrangements are being made for an expedition to King Edward the Seventh's Land, in the south polar region, to start in August next. The leader is to be Mr. J. Foster Stackhouse, who was associated with Capt. Scott in organising the voyage of the *Terra Nova*. The present arrangements are that the members of the expedition shall sail from the Thames about the middle of August in the steam yacht *Polaris*, a ship especially built for ice navigation in accordance with designs approved by an international committee of explorers, including Charcot, de Gerlache, and Nansen. It is contemplated that the expedition will be absent for twenty months or more.

PARTICULARS of the plans of the Italian expedition to the Himalayas, which is to be led by Dr. Filippi are given in *The Pioneer Mail*. According to our contemporary the explorers will work in Karakoram throughout the summer of 1914, spend the autumn in Chinese Turkestan, and leave for Europe by about Christmas. It is the object of the leader to carry out observations across Chinese Turkestan into Russian Turkistan, to winter in Scardo in Baltistan, and early in the spring of 1914 to travel by the inner Indus valley to Leh. From the latter place the expedition will leave for the Karakoram district to survey and map the unknown portion of the Karakoram range which lies between the Karakoram pass and the Siachen glacier. The Government of India, which has subscribed 1000*l*. towards the funds, has appointed Major Woods, of the Trigonometrical Survey, to accompany the expedition.

AMONG the communications to be made at the forthcoming meeting of German Naturalists and Medical Practitioners, at Vienna (September 21–28), we notice the following:—An address by Prof. von Behring on the prophylaxis of diphtheria, and papers on the development of the light and colour senses in the animal kingdom, vision, and the problem of race crossing in man by, respectively, Profs. von Hess, O. Lummer, and E. Fischer.

THE seventeenth annual fungus foray of the British Mycological Society, lasting a week, is to begin at Haslemere on September 22. The meeting place of the party will be the Hutchinson Museum. On September 24 the presidential address will be delivered by Mr. A. D. Cotton, who will take as his subject, "Some Suggestions as to the Study and Critical Revision of Certain Genera of Agaricaceæ." On the following day a paper, entitled "Recent Work on Resupinate Theleshoreæ," will be read by Miss E. M. Wakefield, and on September 26 Mr. J. Ramsbottom will read a paper entitled "Some Notes on the History of the Classification of the Discomycetes."

THE twenty-fourth annual general meeting of the Institution of Mining Engineers is to take place at Manchester on September 24–26, when the following papers will be read, or taken as read:—"A Method of Measuring Goaf Temperatures," T. F. Winmill; "The Absorption of Oxygen by Coal," T. F. Winmill; "Dust Problems in Mines and their Solution," Hermann Belger and A. Owen Jones; "Further Researches in the Microscopical Examination of Coal, especially in Relation to Spontaneous Combustion," James Lomax. In addition to the foregoing, the following papers, which have already appeared in the Transactions, will be open for discussion:—"Recent Methods of the Application of Stone-dust in Mines," Dr. W. E. Garforth; "The Reopening of Norton Colliery with Self-contained Breathing-apparatus after an Explosion," J. R. L. Allott; "The Slow Oxidation of Coal-dust and its Thermal Value," F. E. E. Lamplough and A. Muriel Hill; "Insulated and Bare Copper and Aluminium Cables for the Transmission of Electrical Energy, with Special Reference to Mining Work," B. Welbourn. In connection with the meeting a lecture on explosion experiments at Eskmeals will be given on September 25 by Prof. H. B. Dixon, F.R.S.

WE understand that the title of Prof. W. Ostwald's journal, *Annalen der Naturphilosophie*, has been changed to the more comprehensive one of *Annalen der Natur- und Kulturphilosophie*; also that Prof. R. Goldscheid is now associated with Prof. Ostwald in editing the periodical.

THE correspondent of *The Times* at Rome reports an interesting discovery made by Mr. Adolfo Cozza in excavating at Pompeii with the object of tracing the site of the port where, in his opinion, three-fourths of the population sought escape from the eruption of Mount Vesuvius, hoping that the Roman fleet would be able to remove them into safety. After various try-pits had been sunk he discovered plaster and concrete, and finally a road leading to the sea showing signs of the passage of wheels. The masonry-work of a harbour was then unearthed with the marks left by the waves. The port which has just been discovered is at a distance of about 1300 yards from the existing seashore and about 700 yards from the ruined city. It is covered with a layer about 23 ft. deep, consisting of earth, lava, ashes, and *lapilli*. Further excavations will, it is thought, bring to light the skeletons of the majority of the population of Pompeii as well as treasures of gold and works of art.

A LARGE Etruscan necropolis, containing several skeletons, as well as vases and terra-cottas, dating from the seventh century B.C., has been discovered near Civita Vecchia in Italy, on the coast of Latium.

A CURIOUS story comes from Ireland that Mr. E. S. Dodgson, of Jesus College, Oxford, has discovered at Killult, Falcurragh, Donegal, a stone said to contain an Ogham inscription giving a clue to a great treasure concealed in the neighbourhood by an ancient Irish chieftain. The stone is being examined by Mr. R. Macalister. We wish the discoverer success in unearthing the treasure, but until he succeeds, or some other interpretation of the supposed inscription is suggested, it may be well to reserve opinion on the matter.

A RECENT message from San Francisco stated that the Falcon and Hope Islands of the Tonga group had disappeared. The information was brought by Capt. Trask of the steamship *Sonoma*, from Sydney, who is reported to have said :—"One of the regular trading steamships between Sydney and the Tonga group reported the sinking of the islands. The vessel steamed to where Falcon Island should have been, but it was nowhere in sight. Just before this the instruments at Sydney naval station showed that several violent earthquake shocks had taken place about 2000 miles north-east of Sydney." With reference to the foregoing message, Mr. Basil A. Thomson (who acted for a time as Prime Minister of Tonga), wrote to *The Times* on September 14 that the news should be received with reserve for the reasons, "first, that Falcon had already ceased to exist as an island fourteen years ago; and, second, that Hope Island, better known by its native name of Niuafo'ou ('New Niua'), is reported to have disappeared whenever a serious volcanic disturbance shakes the nerves of the white residents of Tongatabu."

THE Museum Journal of the University of Pennsylvania announces in its March issue the despatch of an expedition, under charge of Dr. Farabee, to explore the primitive tribes of the Amazon forests. The Brazilian Government promises active assistance to Dr. Farabee and his staff. From Para they will proceed to Manaos, and from thence ascend the Rio Negro, the largest tributary of the Amazon from the north-west. The examination of this region will occupy the attention of the expedition for six months or perhaps a year. The collections to be made will consist of weapons, utensils, and all objects relating to the arts of life procurable among the various tribes to be visited. They are destined to supply material for future research, and especially to enable the museum to reproduce the actual life of some of the most interesting native tribes, soon destined to disappear.

IN No. 2, vol. xxiv., of *Folk-lore* we have the final, but unhappily fragmentary, dissertation by the late Mr. Andrew Lang, in which he develops his theory of the origin of exogamy and totemism. Following Darwin, he assigns the beginnings of exogamy to the expulsion by the sires of the group of the younger males. He assumes that the establishment of totemic groups and practices cannot have been sudden; men cannot have, all in a moment, conceived that each group possessed a protective and sacred animal or other object. But if each group woke to the consciousness that it bore the name of a plant or animal, and did not know how it came to bear that name, no more was needed to establish a belief in the essential and valuable connection of the group with certain animals, birds, or other objects. These names, he thinks, originated in sobriquets given by one group to another. In this exposition he is in general agreement with the views of Dr. A. C. Haddon in his address delivered before the British Association at the Belfast meeting in 1902.

IN *Man* for September Mr. W. J. Lewis Abbott describes a collection of pygmy flint implements made by Mr. J. M. Bain from the base of the sand-dunes at Fishook, Cape Colony. They closely resemble the series presented by Miss Nina Layard to the Ipswich Museum. Mr. Abbott believes that this is the result of culture-transmission. "It is obvious," he believes, "that the prototypes of these shapes could not have arisen in a country where the native material did not lend itself to their manufacture; but in one where a homogeneous silica, such as flint, was the common indigenous material; and in following up the search for these interesting little objects, we shall be getting together the material to show the migrations of this old race over the face of the earth, and perhaps be able to trace it to its cradle."

IN the Philadelphia Museum Journal for June Dr. Arno Poebel, of Johns Hopkins University, announces an important discovery among the collection of clay tablets obtained at Nippur during the years 1888–1900, which are now being arranged for exhibition. One tablet, unfortunately imperfect, gives a version of the Creation story, in which the origin of the first human beings is attributed to the gods Enlil and Enki, and the goddess Ninharsagga—a question which has led to much speculation among Assyrian and biblical scholars. In the present version, when Enlil, the creator of heaven and earth, wished to people the world with human beings, the god Enki, the deity of wisdom and knowledge, devised the image of man after the image of the gods, and the goddess Ninharsagga moulded it in clay, while the blood of Enlil gave it life and intellect. Whether the idea that Enlil cut off his head will be corroborated from other cuneiform sources we cannot tell at present. Meanwhile the present discovery is obviously of the highest importance.

In the May number of *The Irish Naturalist* (vol. xxii., No. 5), Mr. N. Colgan gives an interesting account of the renascence flora of certain areas on Killiney Hill, Co. Dublin, formerly covered with old gorse but burnt out in July, 1911. Three months after the fire the burnt areas showed thirteen species of flowering plants, partly survivals from old root-stocks, partly immigrants from adjacent unburnt areas, and partly perhaps the product of seeds that had retained their vitality throughout the fire. Later observations showed that eighteen months after the fire a renascence flora of sixty-four species, including nine cryptogams, had taken possession of the areas burnt clear of all vegetation. Of these species, forty-five had certainly or very probably entered from adjacent unburnt areas, thirteen were survivals, and the remaining six could not with certainty be placed among either immigrants or survivals, and are classed as of doubtful origin. The cryptogams covered much more ground than the flowering plants, the most abundant species, dominating above all other plants in the burnt ground flora, were the mosses *Funaria hygrometrica* and *Barbula fallax*; other common bryophytes were three species of Polytrichum and the liverwort *Marchantia polymorpha*; while two species of the lichen genus Parmelia were also frequently found. Among the phanerogamic immigrants the grasses were strongly predominant, and the immigrant flora as a whole consisted largely of plants provided with special adaptations for seed dispersal, one of the most prominent of these plants being *Senecio sylvaticus*. The most interesting fact arising from this new flora is the conflict between its higher and lower members, the phanerogams and the cryptogams, the latter having so far kept in check the much more varied phanerogamic flora. The probable successive changes in the vegetation are outlined by the author.

We have received a reprint of an interesting paper by Dr. C. B. Crampton, "The Use of Geology to the Forester" (*Trans. Argyll Foresters and Gardeners*, 1912), pointing out some of the geological facts that have a bearing upon the nature and origin of the various types of surface occupied by plants, and emphasising the importance to foresters in particular of a knowledge of the nature of the ground under his charge in so far as it reacts with the vegetation, and the reasons for differences in the surface and in these reactions. The author indicates the geographical and geological factors upon which depends the nature of a habitat for trees or other plants, with special reference to the action of gravity in screes and landslips, the erosive action of wind and streams, coastal erosion, glacial erosion and deposition, and the characters of soils and subsoils.

In a recent number of *The Herts Advertiser* it is stated that, in consequence of Dr. Sambon's remarks on pellagra at a recent meeting of the British Medical Association, Dr. Blandy, of the Lunatic Asylum at Napsbury, near St. Albans, undertook an examination of the patients in that institution, with the result that no fewer than eleven were found to be suffering from that disease. As the majority of these come from the moist, low-lying district of the Colne Valley, support is afforded to the opinion that the disease is propagated by insects.

As a result of the examination of the large series of specimens of mammals and birds collected in East Africa by the Roosevelt and other American expeditions, very considerable additions have been made recently to the list of species and races from that area, the descriptions having been published for the most part in various issues of the Smithsonian Miscellaneous Collections. The latest of these papers include one by Mr. E. Heller (vol. lxi., No. 7), on new races of antelopes, and another, by Mr. E. A. Mearns (*ibid.*, No. 9) on new weaver-birds. As regards the antelopes, it must suffice to mention that some of the new races are founded on very slight differences from previously known forms, and it is thus rendered difficult to see where the modern fashion for excessive splitting is to stop.

In connection with the preceding paragraph, it may be mentioned that in the current issue of the Zoological Society's Proceedings three additions are made by Messrs. Barrett-Hamilton and Hinton to the British mammal-fauna, all three being from the Inner Hebrides. The most interesting of these is a shrew-mouse (*Sorex granti*), distinguishable at a glance from the common English *S. araneus* by the contrast presented by the light-coloured flanks to the dusky upper parts. As it also exhibits certain dental peculiarities, its right to specific rank seems undoubted. The other are field-mice; one (*Evotomys alstoni*) a species from Mull, and the other (*Microtus agrestis macgillivraii*) a race from Islay.

The September number of *The Museums Journal* contains an illustrated account of Mr. J. A. C. Dean's method of "showing" objects in museums and art galleries to blind persons, as explained at the Hull meeting of the Museums Association. The method appears to have attained considerable success, and to have awakened a new interest in the class for which it is intended. It may be remarked—as indeed was hinted by the president at the close of the discussion—that if this mode of demonstration is adopted in up-to-date zoological museums it will be necessary for each to have a separate series of stuffed specimens for this purpose.

In the *Verhandlungen der Naturforschenden Gesellschaft in Basel* (Bd. xxiv.) will be found a paper by the late Fr. Burckhardt, entitled "Die Stellung des Osterfestes im christlichen Kalender." It is a contribution to the historical side of the question, and contains several original documents of some interest. An extract from the writings of Luther is given, in which he advocates a fixed date for Easter, not merely without regard to the moon's phases, but also, like Christmas, without regard to the days of the week. Other documents refer to the adoption of the reformed calendar by the Protestants in Switzerland. Practical convenience forced them to follow the Gregorian calendar in the main, though not until the end of the seventeenth century, and even then one difference was maintained. This arose from basing the calculation of the Easter full moon on the Rudolfine Tables instead of the Gregorian Epact. The first discrepancy occurred in the year 1724, when the Gregorian full moon fell on Sunday, April 9, while the Tables gave the day preceding. The question was referred for decision to the Protestant Conference at Ratisbon early in 1723, and the Basel authorities sought the advice of John Bernoulli. The replies are reproduced in full. In the result Easter was celebrated by Catholics and Protestants on successive Sundays in 1724 and again in 1744. Agreement was finally brought about by an order of Frederic the Great in 1776 on the basis of the Gregorian calendar. The desirability of a fixed Easter has been commonly felt from the time of the Gregorian reform, and it was the last act of Father Denza, late director of the Vatican Observatory, to prepare a memorandum on the subject for Pope Leo XIII. His proposal was to adopt the third Sunday following the vernal equinox, which would limit Easter between April 4 and 11.

THE Director-General of Observatories (India) has issued a memorandum dated August 9 on the monsoon conditions prevailing during June and July, with anticipations for August and September. From the recent data regarding the conditions most likely to be of influence, and which are stated in detail, the unfavourable factors appear to predominate slightly. But the inferences drawn are (*a*) that the total rainfall of the months in question will probably be normal or in slight defect, (*b*) that in north-west India the monsoon is not likely to be affected prejudicially by snowfall. (The fall of temperature and dry north-westerly winds that usually follow widespread and heavy snowfall have not been experienced.) The above forecast agrees practically with that issued on June 8 (NATURE, August 7).

DR. NILS EKHOLM has contributed an important article on the weather in the North Sea during the first half of June, 1911, illustrated by synoptic charts, to No. 64 of the Occasional Publications issued under the authority of the International Council for the Study of the Sea. The period is chosen because the council had then six hydrographical expeditions stationed in that sea. The author prefaces his inquiry by a careful historical summary of the development of meteorology and its methods from the invention of the barometer to the present time, and with a description of barometric changes and their relation to wind and weather, in which we were pleased to see that the valuable pioneer work of Admiral FitzRoy, the first chief of the Meteorological Office, is duly recognised. The author explains that the difficulties with which modern conceptions of cyclones and anticyclones have to contend led him to supplement the usual isobaric charts by plotting the ± differences of barometric readings since the last observation, and thus constructing "isallobars," or lines of equal differences. He remarks, *inter alia*, that a close study of the movements of the isallobars shows that pressure changes are the primary, and cyclonic and anticyclonic whirls the secondary phenomena. The charts for the North Sea for the above period and two other cases are discussed upon those principles.

DR. H. GEIGER, of the Reichsanstalt, who four years ago, in conjunction with Prof. Rutherford, devised a method of counting the number of α particles emitted by a radio-active body, has now, according to a communication from the Reichsanstalt, succeeded in perfecting a very simple method which allows both the α and β particles to be counted. The α or β rays are allowed to enter a short metal cylinder 2 cm. diameter, by a small hole in the base. Through an ebonite block which closes the other end of the cylinder a sharp pointed rod projects into the cylinder to within 0·8 cm. of the base. The cylinder is raised to about 1200 volts, and the pointed rod is connected to a string electrometer provided with a high-resistance leak. The entry of either an α or a β particle into the cylinder causes a spark to pass between point and cylinder, and the electrometer of 10 cm. capacity acquires a charge corresponding to 10–20 volts. The throws of the electrometer are recorded photographically, and the results obtained are in agreement with those calculated from ionisation observations in the case of the polonium preparation used in the observations.

Engineering for September 5 contains an illustrated account of the Sulzer-Diesel locomotive built by Messrs. Sulzer Brothers at Winterthur, in the early part of this year, and supplied to the Prusso-Hessian State Railway, Berlin. This is the first locomotive fitted with Diesel engines, and is designed for fast traffic. The length over-all is 54·5 ft., and the weight in working order is 95 tons. The main engines are of the reversible two-cycle type, single-acting, having two pairs of cylinders inclined at 90° to each other. The pistons are 15 in. diameter by 21·7 in. stroke. Running at 304 revolutions per minute, a speed of sixty-two miles per hour is obtained. The auxiliary machinery required is of a somewhat complicated character. Trials have been made, and show that the engine is adaptable to a wide range of work. It is reported that the change from air to oil-fuel is accomplished without trouble at a speed of about six miles per hour, and that the reversing arrangements were equally successful.

Engineering of the same date has an article dealing with problems of the internal-combustion locomotive, in which further reference is made to the Sulzer-Diesel locomotive. Our contemporary considers that any locomotive engineer reading the full description of this engine would be somewhat appalled at the extraordinary amount of machinery the type involves. The main engine requires another engine, of one-quarter or one-fifth of its power, to make it start at all. The second engine, also of Diesel type, requires similar provision in the way of air and circulating-water supply, &c., to the main engines, involving pumps for the supply of starting air, scavenging air, injection air, fuel to each cylinder, jacket water, circulating water for pistons, and for lubrication of bearings, &c. A comparison of this collection of machinery with that in a modern steam locomotive is greatly in favour of the latter. Neither does the Diesel locomotive appear to show up any too well as a power plant; one horse-power is developed for about 190 lb. weight. A modern steam locomotive develops one horse-power for about 100 lb. of engine weight, or for every 140 to 150 lb. of combined engine and tender weight. Rapid perfecting of this type of engine is not to be expected, but it is to be hoped that the efforts instituted on the Continent will be persisted in. The greater the initial handicap, the more glorious the ultimate victory.

Attention may be directed to a slight error in the date assigned to Messrs. Cartailhac and Breuil's monograph on "La Caverne d'Altamira"; the frontispiece bears the date 1906, but this work was not published until 1908.

OUR ASTRONOMICAL COLUMN.

The Rotating Ellipsoid RU Camelopardalis.—The elaborate investigations recently carried out by Prof. H. N. Russell upon the treatment of photometric observations of variable stars have been the means of bringing to light a new class of these bodies. By taking into account the hypothetical, but, of course, quite possible ellipticity of the components of a binary system, a method was developed which may be applied equally well to the case of an isolated rotating ellipsoid—an early stage in the development of a binary system. At Princeton during the last two years the light changes of three stars—S Antliæ, SZ Tauri, and RU Camelopardalis—have been explained in the most satisfactory way on the hypothesis that they are rotating ellipsoids. In Bulletin No. 21 of the Laws Observatory Mr. Harlow Shapley discusses 292 photometric measures of the third of these stars, and comes to the conclusion that "the light variations . . . can be satisfactorily accounted for on the hypothesis of a single, uniformly luminous, ellipsoidal body rotating in a period of 44·344 days." With regard to the spectrum of this star the author quotes a letter from Prof. E. C. Pickering to the effect that it is peculiar and apparently variable, and that Miss Cannon thinks it may belong to class N.

The publication of the curves and results for S Antliæ and SZ Tauri is promised for the near future. As both these stars have spectra of classes much less prone to variability of a physical character the realisation of this promise will be awaited with great interest.

The Diminution of the Solar Radiation in 1912.—Further evidence regarding the existence of a widespread atmospheric opacity during 1912 appears in a note by M. Ladislas Gorczynski in the *Comptes rendus* (vol. clvii., No. 1). The pyrheliometer record made at Varsovie shows that during the latter half of the year there was a marked falling off in the intensity of the solar radiation. The detailed measures, we are informed, show that the depression lasted from about the middle of June, 1912, to the middle of January, 1913, and was most severe in September. Similar results were obtained at the Meteorological Observatory of Olczedajów, and it is pointed out that analogous records were obtained at Mount Weather.

Comet 1913*b* (Metcalf).—A supplement to *Astronomische Nachrichten*, No. 4679, contains a continuation of the ephemeris of this comet which was given last week, after the first approximate elements computed by Prof. Kobold. The comet is slowly increasing in brightness, according to the ephemeris, but on September 3 it was observed as of magnitude 9·5, and on September 4 as of magnitude 10·0.

12h. M.T. Berlin.

22	5 40 26	70 24·3	—
23	5 32 2	71 8·8	10·3
24	5 22 42	71 52·9	—

Comet 1913*c* (Neujmin).—This comet when first observed (September 3) was thought to be a minor planet, but later observation has suggested its cometary nature. Herr M. Ebell has computed the elements from the observations of September 6, 7, and 8, and these, with an ephemeris, have been communicated in a Kiel circular. They are as follows:—

$$T = 1913 \text{ July } 22.5755 \text{ M. T. Berlin.}$$

$$\left.\begin{aligned}\omega &= 320^\circ\ 56{\cdot}70'\\ \Omega &= 347^\circ\ 19{\cdot}42'\\ i &= 12^\circ\ 22{\cdot}97'\end{aligned}\right\}1913{\cdot}0.$$

$$\log q = 0{\cdot}11296$$

Ephemeris for 12h. M.T. Berlin.

	R.A. h. m. s.	Dec. ° ′	Mag.
Sept. 18	22 43 10	+4 9·3	—
19	22 42 40	4 27·7	—
20	22 42 10	4 45·5	11·2

According to Dr. Graff, at Bergedorf, the comet showed a short tail on September 6, but on September 8, from observations made at Pulkova, the object was recorded as stellar.

New Laboratory Spectroscopic Results.—The physical laboratory of the Imperial College of Science and Technology is responsible for four different spectroscopic researches recently communicated to the Proceedings of the Royal Society (Ser. A., vol. lxxxix., pp. 125–149). Mr. L. C. Martin, a research student, writes on a band spectrum attributed to carbon monosulphide, and has found a new spectrum consisting of a number of bands degraded to the less refrangible side, the wave-lengths of which he gives in his paper. Prof. Fowler records new series of lines in the spark spectrum of magnesium incidentally tying up the well-known spark line at λ4481 in one of the series. In conjunction with Mr. W. H. Reynolds, research student, Prof. Fowler has another paper on additional triplets and other series lines in the spectrum of magnesium. Eight additional triplets have been measured in the spectrum of magnesium arc *in vacuo*, six belonging to the diffuse and two to the sharp series. Four additional members of the Rydberg series of single lines have been photographed, and four strong solar lines of unknown origin have been identified with lines of the Rydberg series. Two known lines, 5711·31 and 4730·21, have been coupled up in a series with 4354·53, a previously unrecorded line. Mr. W. E. Curtis, the demonstrator of astrophysics, has a paper on a new band spectrum associated with helium, but the question of its origin is still doubtful, as hydrogen was present in all the tubes examined. A list is given of the wave-lengths determined. A search in celestial spectra was made, owing to its association with helium, but the result was negative.

The Perth Observatory Section of the Astrographic Chart.—Vols. ii. and iii. of the Perth Observatory (Western Australia) section of the astrographic chart have just come to hand. These volumes are two out of the thirty-six volumes which will be published. The region of the sky assigned to this observatory lies between 31° and 41° S. declination, and the photographs have been taken and measured under the direction of Mr. W. Ernest Caske, the Government Astronomer for Western Australia. Vol. ii. contains the measures of rectangular co-ordinates and magnitudes of 20,211 star images, R.A. 6h. to 12h., on plates with centres in declination −32°, and vol. iii. those of 20,988 images, R.A. 12h. to 18h., on plates with centres also in declination −32°.

The completed work will be a valuable contribution to the great international scheme, initiated so many years ago. Incidentally a number of double stars were met with during the measurement of the zone plates, and these, 242 in number, have been collected and published in a separate catalogue, forming Bulletin No. 1. The reduction of the measures was undertaken by Mr. Nossiter, acting first assistant.

The Extension of the Zone Time System.—Brazil has now officially fallen into line by adopting standard time. The country has been divided into four zones, and the legal time for each respectively will be two, three, four, and five hours slow on Greenwich. The islands of Trinidad and Fernando Noronha fall in the first zone. The western side of the second zone is a line from Mount Pecuary Grevaux, on the French Guiana boundary, by the rivers Pecuary and Javary to the Amazon, and by Xinsu to the Matto-Grasso boundary. The fourth zone includes the western part of Amazonas, the Acre territory, and other territory recently ceded by Bolivia.

Hind's Nebula.—M. Borrelly has communicated to the Academie des Sciences (*Comptes rendus*, vol. clvii., No. 7) a brief note stating that the nebula discovered by Hind in the year 1845 (No. 6760 in Dreyer's N.G.C.) and suspected of variability of brightness seven years later by d'Arrest, now appears to be in a period of maximum. For the first time since 1867 it is easily seen with a comet-seeker of 6½ in. aperture.

The Royal Observatory, Cape of Good Hope.—The annual report of his Majesty's Astronomer at the Cape of Good Hope for the year 1912 has been received. In connection with the reduction of the circumpolar observations made in the previous year some interesting determinations of personality have been made. It appears that, while with the older methods of observing, transits of equatorial stars are mostly recorded *late*, transits of slow-moving circumpolars are *anticipated* by 0·3s. The astrophysical work has been actively advanced, both in the observatory and laboratory. Provisional spectroscopic determinations of solar parallax and the constant of aberration, based as the measures of 800 plates, yielded 8·802″±0·004″ as the value of the former, and 20·47″±0·01″ for the latter. In the laboratory it has been found more convenient to employ the spark spectrum obtained from the cores of lead pencils as a comparison spectrum in preference to the spectra of iron or titanium.

A CURIOUS METEORIC DISPLAY.

The universal disappointment experienced by keen meteor observers on the expected return of the November Leonid meteor swarm in 1899, the swarm which created such a stir of excitement at its appearance in the year 1866, is no doubt responsible for the apparent lack of interest taken in the announcements of probable meteoric displays to-day. Many of us thought that this celebrated display, due possibly to planetary perturbations, might be accelerated, and so were careful to keep a good look-out in the appointed month in 1897 and 1898, and their non-appearance in 1899 suggested that possibly, for a similar reason, the swarm might have been belated, and so watched at the correct season for the overdue display. The expected event did not take place, and faith was lost in the predicted times of these space wanderers.

Our interest is, however, again wakened by what is described as "an extraordinary meteoric display" which was seen over a very extensive area in the United States of America and Canada on the evening of February 9 this year. The magnitude of the display was such that a very great number of people distributed in the path of observation had their attention drawn to it, and its peculiar nature was so marked that nearly every observer remarked similarly of the extraordinary feature of the event.

Fortunately Prof. C. A. Chant, of Toronto, although not an eye-witness of the phenomenon, undertook to collect all the available information of this very exceptional, if not unique, occurrence. In the May–June number of the *Journal* of the Royal Astronomical Society of Canada he presents a very judicious summary of the observations made, and accompanies this with extracts from letters received from observers.

The sum total of the discussion of the data is to show that the apparition took the following form:—

As seen from western Ontario there suddenly appeared in the north-western sky a fiery red or golden-yellow body, which quickly grew larger as it approached, and had attached to it a long tail; observers vary in their descriptions as to whether the body was single or composed of three or four parts with a tail to each part.

This body or group of bodies moved forward on an apparently perfectly horizontal path "with peculiar, majestic, dignified deliberation; and continuing its course without the least apparent sinking towards the earth, it moved on to the south-east, where it simply disappeared in the distance." After this group of bodies had vanished, another group emerged from precisely the same region. "Onward they moved, at the same deliberate pace, in twos or threes or fours, with tails streaming behind them, though not so long or bright as in the first case." This group disappeared in the same direction. A third group followed with less luminosity and shorter tails.

In reading some of the communications from the numerous observers, the extraordinary feature of the phenomenon seems to have been the regular order and movement of the groups. Thus some compared them to a fleet of airships with lights on either side and fore and aft; others to a number of battleships attended by cruisers and destroyers; others again to a brilliantly lighted passenger train travelling in sections and seen from a distance of several miles.

Such descriptions indicate that the display was of a very unusual kind, very different from the usual quick-moving and scattered bodies. It may be of interest to reprint here in full one of the accounts. Mr. J. G. MacArthur writes:—

"There were probably thirty or thirty-two bodies, and the peculiar thing about them was their moving in fours, threes, and twos, abreast of one another, and so perfect was the lining-up you would have thought it was an aerial fleet manœuvring after rigid drilling. About half of them had passed when an unusually large one hove in sight, fully ten times as large as the others. Five or six would appear in two detachments, probably five seconds apart; then another wait of five or ten seconds, and another detachment would come into view. We could see each detachment for probably twenty or twenty-five seconds. The display lasted about three minutes. As the last detachment vanished, the booming as of thunder was heard—about five or six very pronounced reports. It sounded in the valley as if some of the balls of fire had dashed into Humber Bay. The bodies vanished in the south-east, but the booming appeared to come from the west or north-west, and the time it was heard was close to 9.12 p.m."

It is fortunate that Prof. Chant lost no time in gathering together all the available material concerning this unusual stream of meteors, and his communication is a valuable record for future reference, containing numerous charts and sketches and one coloured drawing.

THE BRUSSELS MEETING OF THE IRON AND STEEL INSTITUTE.

THE autumn meeting of the Iron and Steel Institute was held in Brussels from September 1 to 4, after an interval of nineteen years. It will probably rank as one of the most successful of the foreign visits ever paid by the institute, and the thanks of members and their wives are due to their Belgian hosts, whose forethought had provided for every contingency, and whose charming hospitality could not have been surpassed. The chairman of the reception committee was Mons. Adolphe Greiner, the managing director of the famous Société "John Cockerill," Seraing, a works founded by an Englishman of that name in 1817, and the international character of the Iron and Steel Institute is well illustrated by the council's selection of Mons. Greiner as the president-elect. It is customary at such foreign meetings for stress to be laid on papers dealing with the particular iron and steel industries of the district, and the discussions chiefly ranged round the contributions of the Belgian members. In an interesting historical survey of the metallurgy of iron in Belgium, Baron de Laveleye shows that Liége, Charleroi, and the central district are the principal centres of production, the first-named being "the true cradle of the industry." He gave it as his opinion that at the present day the workers in the Charleroi district are inferior to none in their aptitude and endurance. At the present time Belgium retains only 20 per cent. of her iron and steel products for home consumption, and exports 80 per cent., a larger proportion than that of any other country. This being so, she is compelled to accept as an average selling price that which rules in the international export market. The cost of production has certainly been brought down to a very low figure, and the author claims that it is "only by never allowing an improvement to be made without either adopting or trying it, by relying upon the energetic and hardworking labour classes to whom free trade supplies cheaply the necessaries of life, and by constantly increasing the productive capacity of their works that the ironmasters have succeeded in maintaining the struggle on an equal footing."

It was in Belgium that the first coke ovens were constructed which were heated at the side and underneath by the gas evolved from the coal during coking, and a paper by Baron Coppée, the son of Evence Coppée, the inventor of the oven bearing this name, dealing with modern processes of coke manufacture, was therefore of unusual interest. In Belgium the beehive oven has disappeared, and 97 per cent. of the coke is made in by-product ovens. On the other hand, in England the by-product oven has made less headway, partly because the first ovens erected were by no means as perfect as they are now, and produced a coke which was undoubtedly inferior to beehive coke, and partly on account of difficulties in connection with refractory materials which resulted in defective working of the ovens. In spite of the fact that most of the English bricks resist high temperatures as well as the continental varieties, according to the author they have the disadvantage of contracting at high temperatures, thereby causing cracks and dislocations in the structure of the ovens. The result is that all the leading constructors now use Belgian or German firebricks for those parts of their ovens which are in contact with the hot gases. By means of an apparatus which was on view during the meeting the author has tested numerous varieties of firebricks from the point of view of their expansion during heating, and has found that they vary considerably in this respect. Some of them appear to undergo no expansion above 700–800° C., and above this range to remain constant. This is the best result thus far obtained. In the discussion, however, one of the speakers claimed that the life of a good English brick is from seven to eight years. The modern trend in Belgium and Germany is to produce concurrently metallurgical coke and lighting gas, and at the present day the latter country has no less than forty-five towns or communes which are wholly or partially supplied with lighting gas derived from coke ovens.

Somewhat closely connected with the foregoing was a paper by Houbaer on the utilisation of blast-furnace and coke-oven gases in metallurgy. The application of the former to the development of motive power is a problem which has been solved for some time past. It is, however, only within the last few years that the utilisation of its calorific power for heating industrial furnaces has been taken into serious consideration, and the author passes in review its employment in heating metal mixers, open-hearth furnaces, and reheating furnaces. An arrangement has been adopted at the Deutscher Kaiser Steelworks for heating the three 1200-ton metal mixers with a single burner capable of taking either blast-furnace gas, coke-oven gas, or a mixture of both with air from the Cowper stoves.

Again, at the Bethlehem steelworks coke-oven gas is being applied as the heating fuel to a battery of six 75-ton open-hearth furnaces specially built with this object, and to an existing series of thirteen 60-ton furnaces. For many years calculations have been made as to the saving in fuel and advantages in working that may be expected to accrue from an artificial enrichment with oxygen of the air blown into a blast furnace. But in spite of the claims thus put forward, blast-furnace managers have hitherto refused to make the experiment, and with some reason, for the breakdown of such a furnace would be a very expensive matter, and the tendency has been to wait for someone else to make the test. A paper by Trasenster, presented at the meeting, indicates that the step has just been taken at the Ougrée-Marihaye works in Belgium. The oxygen plant is composed of three similar liquid-air units, each yielding 200 cubic metres of oxygen per hour. No results of working are given in the paper, but during the discussion the author stated that a month's trial had been run, in which the oxygen in the blast was raised to about 23 per cent. by volume. Moreover, a small blast furnace has been built in which the working will be carried out with very high percentages of oxygen, and even with pure oxygen. There is no doubt that these tests will be watched with the deepest interest, and in particular blast-furnace managers will desire to be informed as to how the difficulties which may be expected to result from increased temperature at the tuyeres are overcome. This is the main reason why they have been so much disinclined to make the experiments with their own plants.

Mr. Talbot, the inventor of the Talbot tilting furnace, presented a paper on modern open-hearth steel furnaces, in which he discussed the reasons which have militated against their adoption on anything like an extensive scale. The two main criticisms brought against them are the initial capital outlay and the increased cost of upkeep, and these the author sought to combat and to point out some of the principal advantages which in his opinion accrued from the use of tilting furnaces as compared with those of the fixed type. With a view to settling this question in a practical fashion, one of the largest continental steel-making firms is running in the same shop furnaces of both types under exactly similar conditions of shop practice, and it was clear from the discussion that until the results of this test are known most manufacturers prefer to adhere to the fixed furnaces the particular advantages of which are well known by this time.

It is characteristic of the rapid development of electric steel processes that scarcely a meeting of the institute is held without one or more papers on this subject. The paper by Otto Frick on the electric refining of steel in an induction furnace of special type marks a distinct development in the applicability of this type of furnace the use of which has hitherto been confined to the melting of high-class steels in which no refining took place. The results are based on the data obtained in the Frick furnaces at Krupp's works in Essen, which have been in operation for the last five years. With regard to the lining, the induction furnace offers certain intrinsic difficulties owing to the ring-shaped form of the crucible. On one hand greater difficulties arise in making the lining stand high temperatures without cracking, and on the other the ring-shaped form makes it impossible to give the furnace walls sufficient slope to enable repairs to be made in the same manner as in the open-hearth furnace. The difficulties with regard to cracking are due to the fact that the outer wall is ring-shaped, and has its highest temperature on the inside, whereas the equally ring-shaped inner wall is hottest outside. The only way of overcoming these difficulties is to use a material which neither contracts nor expands appreciably at very high temperatures. The lining used is made of very pure magnesite without any binding agent, and treated in a particular way. It possesses remarkable compactness, mechanical strength, and resistance to the action of slags. But even the best linings will not stand more than a few weeks if they are not further protected against the cutting action of ordinary slags. This difficulty the author claims to have solved by adding crushed magnesite in such a way that the slag can become saturated before it is able to attack the lining, an action which is much facilitated by the inclination and rotation of the bath. In this way it has even proved possible to make the inner wall grow by adding too much magnesia, and the lining of the furnace now has a life of from two to three months, a result which represents a considerable advance on industrial practice hitherto. The foregoing account does not do more than bring out the chief points of importance discussed at the meeting. In all nineteen papers were presented, several of them of distinct scientific value and interest, but time did not permit of their discussion.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Dr. M. Bartuzzi, president of the Italian Society for the Critical History of the Medical and Natural Sciences, has been appointed to the newly established chair of medical history in the University of Siena.

Dr. Clifton F. Hodge, professor of biology at Clark University, Massachusetts, since 1902, has resigned that post, having accepted the offer of a chair in the same subject at the University of Oregon. In his new sphere Prof. Hodge will have special responsibilities in connection with a scheme of university extension lectures.

Sir Rickman J. Godlee, Bart., president of the Royal College of Surgeons, London, has accepted an invitation to confer the fellowships of the American College of Surgeons at the first Convocation of that institution, which is to be held at Chicago on November 13 next. About 1400 prominent surgeons of the United States and Canada are to be created fellows.

Dr. W. F. G. Swann has resigned his position as assistant-lecturer and demonstrator of physics at the University of Sheffield in order to take up, on October 1, the post of physicist in charge of experimental work in the new laboratory at Washington of the department of terrestrial magnetism of the Carnegie Institution of Washington.

A course of three lectures dealing with the early history of medicine has been arranged for delivery by the historical section of the Royal Society of Medicine. The first lecture will be given on October 10, by Prof. Jastrow, of the University of Pennsylvania, and will treat of Babylonian Medicine; the subsequent discourses will be delivered by Prof. Elliot Smith, F.R.S., on Egyptian medicine, and by Prof. R. Caton, on Greek medicine.

The widow of Principal Caird has bequeathed to the University of Glasgow, in memory of her late husband's long connection with the University, the sum of 4000*l.* for the founding of two scholarships, to be known as "The Principal Caird Scholarships," to be awarded annually by examination to the student in the University who is most distinguished in either classics or mental philosophy, or both. The sum of 1000*l.* is also left to the Western Infirmary, Glasgow, and 500*l.* to the professor of moral philosophy of Glasgow University for books or prizes.

We learn from *Science* that Dr. H. G. Leach, secretary of the American-Scandinavian Foundation (endowed by the late Mr. Niels Poulson with a gift of 600,000 dollars to maintain an interchange of students, teachers, and lecturers, and to promote in other ways intellectual relations between the United States and Scandinavia), has returned from an official tour in Sweden, Norway, and Denmark. Fellowships have been awarded to two representatives from each of the three countries referred to, and those selected will enter American universities in the autumn. Plans also have been discussed for an exchange of professors between the University of Copenhagen, the University of Christiania, the University of Upsala, and several American institutions.

The Northampton Polytechnic Institute, Clerkenwell, London, E.C., has now issued its "Announcements" for the session 1913–14. The educational aim of the polytechnic is to provide classes in technological and trade subjects, special attention being directed to the immediate requirements of Clerkenwell. There are day and evening courses in mechanical and electrical engineering, in technical optics, and in horology. The engineering courses include sub-sections in automobile work, aëronautics, and radio-telegraphy. In addition, there are evening courses in electrochemistry, metallurgy, and domestic economy. We notice that during the past year the equipment has been extended. Amongst the more important items may be mentioned in the mechanical engineering department a Linde refrigerating plant, available for carbonic acid or for ammonia, and an outfit for the microphotographic examination of engineering materials. In the electrical engineering department the laboratory equipment for radio-telegraphy has been increased, and additions have been made to the equipment of generators, measuring instruments, and photometers. In the metallurgical department the equipment of electric and gas furnaces and pyrometers has been augmented. A new departure is being made in the section of telegraphy and telephony in the arrangement of special classes for workmen on the maintenance and constructional staff of the Post Office, and also for boy messengers. The latter classes are intended to meet the difficulty of the blind-alley occupation into which the Post Office plunges these boys, and the experiment, which is of public interest, will be watched sympathetically.

THE prospectus of university courses in the Municipal School of Technology, Manchester, for the session 1913–14, is now available. It will be remembered that university work in Manchester was co-ordinated in 1905 by the establishment of a faculty of technology in the University of Manchester, with the principal of the Municipal School as dean of the faculty and with the heads of the mechanical and electrical engineering, of the applied chemistry, and of the architecture departments of the school as professors of the University. The University courses provided by the School of Technology lead to the degrees of bachelor and master of technical science (B.Sc.Tech. and M.Sc.Tech.). These degrees may be taken in the following divisions of technology:—Mechanical engineering, electrical engineering, sanitary engineering, applied chemistry, mining, architecture, and textile industries. In addition, the school provides courses of post-graduate and specialised study and research, in numerous branches of technical science, for a fourth year, to students who have completed the three years' course for a degree or certificate successfully, or are otherwise deemed competent to enter upon them. The School of Technology has also published departmental prospectuses of the part-time evening courses, and the apprentices' day courses to be held at the school during the coming session. The number of evening students has reached the limit of the accommodation provided by the present building, but the demand for advanced courses continues to increase, and it has been found necessary to abandon the more elementary classes, and to raise the fees in other cases. A special feature is the large proportion which the advanced work bears to the whole. This evening work in the case of a number of courses is of the same standard as that given to third year students reading for an honours degree in a British University.

ELECTRICAL STANDARDS.

Reports of the Committee on Electrical Standards appointed by the British Association. Pp. xxiv+783+10 plates. (Cambridge: University Press, 1913.) Price 12*s.* 6*d.* net.

THE reissue by the Cambridge University Press of the annual Reports of the Committee on Electrical Standards, with Mr. F. E. Smith as editor, has placed in our hands in a convenient form an extremely interesting chapter of the history of scientific research in this country. The committee was first appointed in 1861, as the outcome of a paper on the subject by the late Sir Charles Bright and Mr. Latimer Clark. At that time no generally recognised system of electrical units existed, and its initial object was to decide on the most convenient unit of resistance and embody it in a material standard. Its first members were Profs. W. Thomson, Williamson, Wheatstone, and Miller, Dr. Mattiessen, and Mr. Jenkin. Seven other members, including Profs. Maxwell, Stewart, and Dr. Joule, were added in 1863, and four others, including Prof. C. Foster and Mr. Hoskin, in 1867.

During the first eight years of its existence the committee displayed great activity, its first six annual reports covering 290 pages of the book, the contributions of the members named being especially prominent. As a result a unit equal to 10^9 cm. per second had been adopted, and named at first the Ohmad and subsequently the Ohm. This had been embodied in wires of several materials, and in a column of mercury of a square millimetre section and 104·85 cm. long. In its seventh report in 1870 the committee complained of the difficulty of getting its many members together, and of the remissness of its subcommittees, and suggested that the further problems of selecting units of capacity, difference of potential and current, and the construction of standards, be dealt with by new committees. Neither the old committee nor the suggested new committees were appointed, however, until 1880, when other measurements had cast doubt on the accuracy of the committee's ohm, and four of its original members, and nine others, were constituted the re-appointed committee charged with the construction of standards of resistance, capacity, and electromotive force.

For the next twenty years the activities of the committee centred round the Cavendish Laboratory at Cambridge, where under Lord Rayleigh the value of the old ohm was shown to be more than 1 per cent. too low, and under Dr. Glazebrook a systematic comparison of the various copies of the ohm was kept up for many years as a test of their relative permanency. Standard capacities were also constructed, but the middle years of this period were chiefly occupied with the Clark cell as the standard of electromotive force. The end of the period brought the question of the measurement of current by the "current balance" to the fore, and for the next decade the work of the committee was centred in the National Physical Laboratory, and fell largely on the shoulders of Mr. F. E. Smith. Under the new conditions the order of accuracy of the results obtained was rapidly increased, and at the present time measurements of electrical resistance, current, and electromotive force can be made in terms of the international units with an accuracy of about five parts in 100,000.

The work of constructing practical electrical standards for which the committee was appointed fifty years ago has therefore been achieved, and each of the twenty-two members who formed the committee last year when it dissolved, may look back with satisfaction to his share in an advance of national and international importance.

The book is well printed, the type used is larger than that of the British Association Reports, and the spacing between the lines is somewhat greater. The index covers ten pages, and much facilitates the use of the work. A list of the whole of the members of the committee, with their years of service, is given in the introduction, but the familiar headings to the reports with the names of the members, and the specification of the chairman and secretary, have been omitted, much to the present writer's regret.

C. H. L.

TRADE WASTE WATERS.

A Text-book on Trade Waste Waters: their Nature and Disposal. By Dr. H. Maclean Wilson and Dr. H. T. Calvert. Pp. xii+340. (London: C. Griffin and Co., Ltd., 1913.) Price 18*s.* net.

MANUFACTURING prosperity implies the increasing production of trade waste waters, and the increased pollution of our rivers unless the greatest care is taken to utilise or minimise such waste, or processes of purification more efficient than many of those in general use are adopted.

In north and central England the problems attendant upon the utilisation or purification of waste liquors are numerous and of special importance, but there are few districts in this country where difficulties do not occasionally arise. The authors of this work, as chief officials of the West Riding of Yorkshire Rivers Board, have had ample opportunity of gaining experience, and they have turned this to good account, having placed the results of their labours and observation at the disposal of all who are interested in the subject. The trades dealt with are so numerous and so varied in character that it has been apparently impossible to describe any process of purification of wide applicability, hence the trades are dealt with separately, and in most cases exhaustively.

The detailed illustrations of different kinds of purification plants are numerous, and greatly enhance the utility of the work. Wherever it has been found possible to utilise a waste liquor, and such cases will become more and more numerous as greater care is taken to improve the condition of our rivers, the results actually obtained are given. Upon occasions it is found that one waste liquor may be used for purifying another, in itself a process of utilisation, and upon others that by modifying a process or improving a plant the amount of waste could be markedly decreased. The authors' experience, moreover, is not limited to this country, since they have visited Germany and France to see processes actually at work, and they have availed themselves of the evidence given before Royal and other Commissions.

The book is therefore thoroughly up to date, but excellent as it is it does not solve, nor does it pretend to solve, all the difficulties with which local authorities have to deal. For example, the writer is now attempting to deal with the waste liquor from a "producer" gas plant, in which gas is made from sawdust and wood-shavings. He naturally hoped to obtain assistance by consulting this work, but the information available is too meagre. An excellent feature of the book is that it describes the origin and nature of the polluting waste liquors dealt with, and then sets out the means which have in actual practice been found most successful in dealing therewith. At the end of each section is a bibliography, which is particularly useful.

The authors are to be congratulated upon having produced a work which was urgently required, and will be as useful to the manufacturers as to sanitary authorities and their officials. It becomes increasingly obvious as our knowledge of trade processes is broadened that a great deal of the river pollution which now takes place is easily preventible, and it is to be hoped that one of the results of making this special knowledge more accessible will be to encourage both manufacturers and local authorities in their endeavours to take such steps as will tend to restore our rivers and streams to something like their pristine condition of purity.

ENGINEERING MANUALS AND TEXT-BOOKS.

(1) *A Course of Elementary Workshop Drawing.* By H. A. Darling. Pp. 172. (London: Blackie and Son, Ltd., 1913.) Price 1*s.* 6*d.*

(2) *A Text-book on Field Fortification.* By Colonel G. J. Fiebeger. Third edition. Pp. ix+155+xxvii plates. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 8*s.* 6*d.* net.

(3) *Machine Construction and Drawing.* By A. E. Ingham. Pp. xii+143. (London: George Routledge and Sons, Ltd., 1913.) Price 1*s.* 6*d.* net.

(4) *Earthwork Haul and Overhaul, including Economic Distribution.* By Prof. J. C. L. Fish. Pp. xiv+165. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 6*s.* 6*d.* net.

(5) *Continuous Beams in Reinforced Concrete.* By Burnard Geen. Pp. iv+210. (London: Chapman and Hall, Ltd., 1913.) Price 9*s.* net.

(1) THIS work on elementary drawing is well arranged and concisely written. It takes the student up to (but not including) intersection of solids, and leaves him there with a crop of good ideas regarding the use of familiar drawing instruments, and the elements of orthographic projection and isometric drawing. The catechisms in the form of elementary exercises throughout the book are a useful addition. Works on this subject are seldom charged with a sufficient supply of such examples. The chapter on "full-size drawing" is a commendable innovation, for much work is laid out on a floor full size in a workshop, and a knowledge of how to lay out designs in this manner forms a part of the work in a structural iron works or boiler shop, while for a moulding loft it is especially necessary. It would have been preferable if more space had been devoted to orthographic projection, and less to isometric projection. Moreover, the student finds it easier to proceed to the latter from the former, and too much time cannot be spent in assisting the learner to think in three dimensions. This little book should commend itself to teachers in elementary mechanical drawing.

(2) This edition is entirely re-written to bring it up to date, the more necessary as the science of field fortification expands with the experience derived from modern wars. The precision and penetrating power of the firearm to-day have raised the duty of the sapper to an importance now fully recognised, and instruction in the rapid construction of shelters for an army is one of the principal features of military science and engineering. The

author, who is professor of civil and military engineering at the Westpoint Military Academy, draws extensively upon the experience gained in recent wars, as far back as the American Civil War, and up to the Russo-Japanese war. In this period much has taken place to modify field works and entrenchments, and the art of concealment due to the use of smokeless powder becomes one of the characteristic features of military field work. It would be impossible to follow the author through the various types of entrenchments, breastworks, embankments, stockades, palisades, revetments, blockhouses, and buildings, that he describes and illustrates. It is all clearly set forth in short, if somewhat disjointed, sentences. The chapters on passage of rivers and military demolitions contain little that is new, but there is quite enough new material in the book without expecting something fresh on every page. The work should prove to be valuable to the student of military science.

(3) In the preface the author states his intention of providing a course of training in machine construction and drawing, not only to conform to the requirements of actual workshop practice, but to provide approximately a year's work in the evening technical school. This he has done by rendering numerous examples of parts of machines, reserving for each general type a separate chapter, the first four chapters being devoted to such elementary matters as nuts, bolts, screws, and riveted joints. The student is supposed to have a fair acquaintance with mechanical drawing before entering on the subjects in this book. The machine details and examples are of the usual pattern.

(4) Perhaps a more descriptive title for this book would be one which conveyed the impression of economical operations in excavations and fillings for railways, for such is the matter of which it treats. The term "overhaul" is employed to describe a distance of hauling excavated materials in excess of a specified distance on the basis of which the contract is let. Overhaul is the product of the number of cubic yards hauled by the average overhaul distance. The unit of haul used throughout the work is the station-yard, the station being a distance of 100 ft., and the volume the cubic yard. By taking cross-sections of cuts and fills mass curves are drawn, due allowance being made for the "swell ratio," or the increase in bulk resulting from moving the material from its initial position to a fill. The engineer and contractor would derive much condensed information from the examples that are worked out, showing for different cross-sections the most economical way of handling the material. Such problems are, however, capable of indefinite variations, but the author has covered the ground by illustrative types which point the way to solutions in special cases.

(5) In the form of diagrams information is set forth for the rapid calculation of the maximum possible bending moments, vertical and horizontal shearing forces, and stirrups or binding for any number of equal continuous spans with any possible arrangement of loading of complete spans for all types of loading generally met with in practice. The work contains sixty-nine diagrams besides tables, and the bending moments and shear for continuous girders up to five spans are shown. It would have added considerably to the value of the work if scales had been put to all the diagrams; as it is, some of them are bare, without any scales or reference marks. They are very instructive as showing the variation of bending moment and shear in continuous beams, and are capable of wide application.

DIET AND HEALTH.

(1) *Health Through Diet: A Practical Guide to the Uric-Acid-Free Diet.* By Kenneth G. Haig. With the Advice and Assistance of Dr. Alexander Haig. Pp. x+227. (London: Methuen and Co., Ltd., n.d.) Price 3*s*. 6*d*. net.

(2) *The Elements of Heating and Ventilation.* A Text-book for Students, Engineers, and Architects. By Prof. A. M. Greene, jun. Pp. vi+324. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 10*s*. 6*d*. net.

(3) *Chloride of Lime in Sanitation.* By A. H. Hooker. Pp. v+231. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.)

(1) THIS little volume is most practical in its treatment of problems of diet. The author approaches the subject with such whole-hearted enthusiasm that he equals, if not excels, that of his father, whose work he continues and extends. The rules emphasised as to selection of food are to secure ample proteid, and a preferential position for this in making up a dietary, so that digestion shall not be previously weakened by any less valuable constituent.

Four classes of food are given, the above coming first, then the cereals, then a mixed group of fruits and vegetables with the vegetable and animal fats. Lastly foods containing no nourishment (proteid)—tapioca, arrowroot, and commercial cornflour. Two meals a day are recommended, the optima being 11.30 a.m. and 7.30 p.m., though the author admits practical difficulty in the former.

An interesting claim made is that the use of hard water causes visceral retention of uric acid. The rheumatism of peasants using but little meat in certain districts of Ireland, Wales, and Scotland he attributes to the abuse of tea, and in a lesser degree to exposure to cold. In referring to the "frugivorous teeth" of man it is suggested that the proneness to decay may be in the nature of a penalty for attempting to use these as "carnivorous" organs. No mention is made here of the dentists' opinion that the essentially decay-producing foods are those "claggy" with local acid fermentation to follow, *e.g.* the bun and glass of milk at night.

(2) This work will appeal especially to the engineer, as the author has endeavoured throughout to give the data and laws required in designing to any specification. Following American practice, very low outer temperatures are reckoned with, such as 0° F. as lasting some days.

The temperatures set forth as optima for various kinds of room are higher than those in use in this country. Thus a hospital ward is taken at 72° F., and rooms, offices, and laboratories at 70° F. Chimneys—other than furnace-flues—appear to be unknown, implicit reliance being placed on a combination of air warming with induction or exhaustion methods.

The section dealing with the flow of air in ducts is well considered, and the anemometer is recommended for velocities not exceeding 1500 ft. per minute. After reviewing the Pitot, Venturi, and orifice devices the author mentions a novel and ingenious method depending on the increased temperature found after using a known amount of electrical energy, and so from this arriving at the mass of the air so warmed.

The criterion adopted for purity of the air is the old chemical standard of carbonic acid, where, taking 4 per 10,000 as low, 11 as causing oppression, 7 is taken for those ill, and 15 permissible in a group of healthy persons. An estimation apparatus in portable form, adapted for accurate work with small amounts of air, is illustrated and described, and appears likely to give good results as the pressure correction is simple and delicate.

Humidity has to be considered where air is artificially warmed, and various forms of apparatus are shown, though the hot-air system outlined at the commencement appears to have none. Prof. Greene points out the objectionable features of both extremes, but does not realise how, to English ways of thinking, the dryness is usually overdone. He points out a weak point in Mason's hygrometer, namely, its inaccuracy in still air, but the sling instrument shown does not impress one as practicable for average observers.

The discussion of the wet-bulb temperature and its cause for exceeding the dew-point is lucid and interesting. Carrier's work showing the mode of warming the wet bulb by heat rendered sensible is quoted briefly. After alluding to the disturbance of the mucous membranes by exposure to air itself too dry, no reference is made to the well-known feelings of malaise and depression brought about by life in a system of manipulated air monotonous in character. No matter what may be the carbonic-acid content, the normal cutaneous stimulus is lost.

(3) The author of this monograph is the technical director of a large American electrochemical company. The work falls into two portions: (1) The text—in which is a general description of the substance and its mode of action. This is continued by accounts of six main applications to public health work, thus: Water purification, sewage disinfection, street flushing, medical and surgical uses, agricultural, house-fly campaign (68 pp.). (2) A series of summarised references and reports dealing very fully with American practice, but which also includes many quotations from English publications (154 pp.).

The mode of its action being essentially that of oxidation is well stated, and the confusion with chlorine preparations pointed out.

The relative unsuitability of copper sulphate additions to polluted water destined for animal consumption is well brought out in the account of the Chicago stockyard and the sewage-contaminated waters of Babbly Creek. The animals were found to thrive less than when allowed to drink city water. The change was made to hypochlorite treatment, with the result that a purer water organically was obtained than from the city mains by some thirty-seven times less *B. coli* frequency.

Limits to the powers of hypochlorite are given on pp. 22 and 23. But though small in quantity, it should be clearly shown that some increase in hardness is inevitable in the water treated by it.

The volume concludes with an admirable index arranged separately under subjects and names.

OUR BOOKSHELF.

The Under Dog: a Series of Papers by Various Authors on the Wrongs Suffered by Animals at the Hand of Man. Edited by S. Trist. Pp. xv + 203 + v. (London: *Animals' Guardian* Office, 1913.) Cloth, 3*s*. 6*d*.; paper, 1*s*.

APART from the main title, which is much more suitable for a novel, and utterly fails to convey the faintest inkling as to the nature of its subject, the editor and authors of this volume are to be congratulated on the fair and temperate manner in which they have brought their case before the court of public opinion. Pain and suffering are unfortunately inseparable from the lot of many kinds of domesticated animals, as well as of those wild species which are hunted for sport or for their spoils; but it is the bounden and paramount duty of all civilised nations to see that these are reduced to the smallest possible minimum. Those who read this book—and it is, for the most part, at any rate, very painful reading—will, however, be convinced that even in our own country matters too often are by no means as they should be in this respect. In fact the authors have, unhappily, in many instances, a very strong, and in almost every instance a very sad, case; and it is sincerely to be hoped that their book may be the means of bringing to pass a better state of affairs in regard to our treatment of the lower animals in such cases as amendment and amelioration are most urgent and at the same time practicable. Apart from the ruthless slaughter of birds for their plumage—accompanied too frequently by the lingering starvation of their helpless young—one of the worst and most pitiable cases in the whole sad story is the treatment meted out to worn-out horses; and it must indeed be a hardened heart which is not rent by the illustrations depicting these wretched animals on their last journeys. Fortunately, several European Governments are already awake to the need of stringent measures to remedy this crying evil, and we trust the present volume may give a further stimulus to their efforts. R. L.

Les Moteurs Thermiques dans leurs Rapports avec la Thermodynamique. Moteurs à explosion et à Combustion. Machines Alternatives à Vapeur. Turbines à Vapeur. By F. Moritz. Pp. vi+297. (Paris: Gauthier-Villars, 1913.) Price 13 francs.

In writing this book on heat engines the author has divided very unequally the space given to engines operating with external combustion and those in which combustion takes place inside the cylinder. By far the larger part is given up to the steam engine, and particularly the steam turbine. As is usual in French books, mathematical analysis is the natural line of approach to any difficult problem, however obscure the relationship of theory and practice. The book is divided into six chapters, of which the first two relate to the laws of thermodynamics—and a very careful and complete statement of them is given—to gaseous cycles and to a concise explanation of what is meant by entropy.

The twenty-five pages of chapter iii. are made to suffice for the application of preceding theory to the gas engine, and as a natural consequence of such compression the conclusions reached are incomplete. The gaseous mixture used in the gas engine is throughout assumed to have a specific heat quite independent of all temperature changes—an assumption which naturally removes almost all practical value from any conclusions which may be arrived at on theoretical grounds. The chapter concludes with the following quaint suggestion:—"On peut en tirer des conclusions practiques intéressantes, par example, sur l'influence de la circulation d'eau autour des cylindres. Nous laissons au lecteur le soin de faire cette comparison pour tous les cas qui peuvent se présenter à lui."

Chapters iv., v., and vi. (some two hundred pages) are given up to piston steam engines and steam turbines. The author shows much skill in his analysis of the theory of jets and of turbine flow; he treats very fully also of turbine leakage, and uses freely the entropy diagram to illustrate his meaning. Students of the steam turbine will find M. Moritz' book both interesting and stimulating.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Spectra of Helium and Hydrogen.

With regard to Mr. Evans's communication to Nature, September 4, p. 5, I should like to remark that while I have for some time recognised that the experimental evidence, on the whole, seems to be in favour of helium as the origin of the new lines 4686, &c., it should not be too hastily concluded that they are not due to hydrogen. Mr. Evans appears to have succeeded in eliminating the ordinary spectroscopic indications of hydrogen from his helium tubes, but is it not possible that, under the special conditions of the strongly disruptive discharge, with helium also present, residual hydrogen may be represented only by the new lines? This would not be the only known case in which the presence of helium aids the development of the spectrum of another gas with which it is mixed. I have observed this effect in the case of the series of bands of carbonic oxide which are characteristic of the tails of comets; these bands are of very feeble intensity at the low pressures necessary for their approximate isolation in the spectrum of the pure gas, but I have seen them greatly intensified when carbonic oxide was present as an impurity in helium. Also, the Ritz series of infra-red hydrogen lines was found by Paschen to be brighter in a mixture of hydrogen and helium than in hydrogen alone. Apart from this, I find it difficult to believe that the close agreement of one set of lines with the principal series calculated for hydrogen by Rydberg is merely accidental.

Dr. Bohr's theory (*Phil. Mag.*, July, 1913) does not at present seem to me to give much evidence for helium, in preference to hydrogen, as the origin of the lines in question. The formula derived from the theory gives no better agreement with the observations than that of Rydberg, so far as the two are comparable, and apparently requires that the seven observed lines, beginning with 4686, should be capable of arrangement in a single series. I think, however, that the lines cannot be so united within the limits of error of observation, though very nearly so, and I believe that my separation into two series converging to the same limit is correct. The necessity for two series is rather more clearly indicated in the case of the analogous series of magnesium spark lines which I have lately described (Proc. Roy. Soc., vol. lxxxix., p. 133). Moreover, the merging of two such series into one formula is open to the objection that it involves multiplication by 4 of the series constant, which would otherwise be universal. It may be possible, however, to test this point by observations of the Zeeman effects on the lines, and I shall make this experiment at the first opportunity.

I may add that experiments made by Prof. Strutt and myself are in harmony with those of Mr. Evans in showing that the lines under consideration do not occur in mixtures of hydrogen with neon or argon.

The Elephant Trench at Dewlish Was it Dug?

The Rev. Osmond Fisher makes the interesting suggestion that the curious trough at Dewlish, in which numerous remains of *Elephas meridionalis* were found, was an artificial trench, dug as a sort of pitfall to intercept and disable wild animals driven across it. Perhaps, as having seen the excavations made by Mr. Mansel-Pleydell, I may say a word on this point.

Open trenches in the soft chalk are unknown elsewhere, though they are common enough in the hard mountain limestone. I therefore examined this trench most carefully, in order to find out how it had originated, and whether man had had anything to do with it. I am still much puzzled as to its exact mode of excavation; but certain peculiarities convinced me that it was due to natural agencies, and that it was probably cut by the swirl of the fine dust-like quartz-sand which, mixed with polished flints, now fills its lower part. I could find no implements, and could nowhere see traces of pick marks. The sides of the trench, where not damaged by the workmen who had just cleared it, were curiously smooth; but the flint-nodules projected into the cavity from either side, as though the softer chalk had been scoured away. The abrupt rounded end of the trench was most peculiar, and as I cleaned this out myself, dusting away the sand from the smoothed face of the chalk, I am sure that there were here neither tool-marks nor rubbings such as might be made by a man working in the trench, or by wild beasts. In short, the smooth, rounded contours suggested the eddying of wind, and the absence of any crack or joint showed that here at any rate the rounding was not likely to be due to percolating water.

Beneath the elephant bones, which occurred in a layer a few feet down, the infilling of the trench seems to be a fine dust-like, unfossiliferous sand, which was not bottomed, as Mr. Mansel-Pleydell's excavations were made primarily to obtain elephant remains, and these were in such a soft condition as to make removal almost impossible. If this sand-filled fissure is found to continue downward, but is too narrow for a man to work in, it will show that the trench is not artificial. I could only just squeeze past in one or two places; but the upper part of the trench was passable; I think, however, that it tended to narrow downward, but at the time of my visit the bones had not been removed, and I could not excavate below them.

Perhaps someone acquainted with plateaus of soft limestone under desert conditions can say whether there is any tendency for the wind to cut trenches with rounded blind ends, such as the Dewlish trench has. In this connection, it is worth noting that our newer Pliocene land-faunas show distinct indications of drier and more sunny conditions than we have at present. A gazelle, an antelope, and several land and fresh-water mollusca point in that direction. Under dry conditions, and before the loose flints were swept away during the glacial period, our chalk-downs would probably be stony deserts, quite unlike the green hills we now see.

Red-water Phenomenon due to Euglena.

The red-water phenomenon due to a Euglena described by Prof. Dendy in Nature of August 7 has been observed by me in Pretoria. In this case, however, the Euglena swims freely about in the water, and also forms a red gelatinous scum on the surface of the damp mud on the side of the pond. In swimming they seldom show euglenoid movement. A flagellum longer than the body can be easily seen under the microscope at the anterior end of the body, but it always trails along the body with lashing movements. If they become stranded on the mud at the edge of the pond, they soon become spherical and encysted in a mucilaginous covering much wider than the body and showing a layered formation. I have not observed any bubbles of gas given off, although I have kept large quantities of them under observation for long periods. They appear to prefer the encysted form, as they always swim to the edge of the vessel towards the light and form a deep red line along the edge, which gradually becomes dry. If more water is added and the vessel turned round, they will leave their cysts and again swim towards the light side. They are of a fairly large size, and have a cylindrical body tapering to a sharp point at the posterior end, where the last portion is free from pigment Chlorophyll is present, and is easily seen amongst the red in those that have just come out of the encysted stage, but later on it entirely disappears.

Distance of the Visible Horizon.

Mr. W. Moss's account in Nature for August 7, p. 583, as to how to get the area of a sphere theoretically visible at any altitude is interesting; but can he, or any of your readers, say what the formula is for obtaining the distance actually visible with an average amount of refraction? So far as I can discover, all ordinary books of tables ignore this, although such a table would be very useful.

A table is given in Chamber's Mathematical Tables, p. 436, for the distance of the visible horizon, but the explanation, p. xl., states that this is theoretical, and that a correction for refraction should be made, although nowhere is any table or formula given for such correction.

T. W. Backhouse.

West Hendon House, Sunderland September 6, 1913.

Atmospheric refraction is such a varying quantity that no rule respecting it can be laid down applicable in all circumstances; as in cases of mirage, for instance, where vessels below the horizon are seen standing above it, and turned upside down. The refraction of the sea horizon is the great difficulty in obtaining correctly the position of vessels at sea. This can be eliminated in most cases by taking observations of the heavenly bodies to opposite sides of the horizon; for latitude in a north as well as in a south direction; for longitude in an east as well as in a west direction. When only one heavenly object is available this is not always practicable, but it can be done when the altitude is 60° or upwards.

In the appendix to Captain Parry's "Arctic Voyage, 1821–3," p. 187, some observations of the sea horizon by Mr. Fisher are given. He found a variation of 18° in the Arctic region, the ice horizon being elevated in summer and depressed in winter. The variation of the place of the apparent horizon, as a question of unequal temperature, was discussed generally by M. Biot in 1809. But no detailed observations on the subject have, so far as I am aware, been yet made.

The correction for refraction in obtaining the heights of mountains by angles of depression to the waterline of points or lighthouses, or by angles of elevation from points the height of which has been ascertained, is taken empirically, in nautical surveying, as $\frac{1}{12}$th the distance of the object observed. The results thus obtained are fairly accurate. For instance, when surveying the Gulf of Suez in 1871, the observations from the summit of Jebel Hooswah gave the results shown in the accompanying table.

T. H. Tizard.

Place of observation	Object observed	Angle of elevation	Angle of depression	Refraction + or − $\frac{1}{12}$ dist.	Corrected angle	Dist.	Diff. of level	Height of Object observed	Height of Theod.	Dip.	Corrected height Place of observer	Corrected height Object observed
Summit of Jebel Hooswah	Water line of Tur point...	—	1° 27′ 30″	+1′ 21″	1° 28′ 51″	16′·38	2573	0	5 ft.	237	2331	0

Mean height 6706 ft. Max. 6803. Min. 6583. Extreme range 220 ft.

The Undagraph.

Last week the Dominion Astronomical Observatory installed at Chebucto, near Halifax, Nova Scotia, a wave-counter, which I have called an "undagraph." The site, a granite cliff 110 ft. high, on which is a lighthouse, faces the broad waters of the Atlantic. The coast hereabouts is bold and rocky.

Modern seismographs record tremors of the earth—microseisms—not attributable to earthquakes, and investigators have traced them to the action of the sea during storms. These microseisms manifest themselves particularly markedly in Ottawa and in Europe from autumn to spring, *i.e.* during the winter or stormy season. Their period ranges, say, from four to seven seconds, and the greater the storm or steeper the gradient of the "low" on the water along the coast, the greater is the amplitude of the microseisms.

In order to correlate the period of the waves of the ocean which pound upon the coast with the period of the microsiesms, the above instrument has been installed. It may be mentioned that a trial instrument was made for the International Seismological Association by the Cambridge Instrument Company, and installed on the pier at Newcastle-on-Tyne. It did its work, but the position is not suitable for the purposes of correlation. The west coast of Ireland or of Norway would have been better. However, practical difficulties stood in the way for utilising either for the trial instrument. The present instrument, made by the same company, has been improved on the former, but has as yet no contrivance for registering the height or magnitude of the waves, which is so very desirable.

The principle of the instrument is very simple. It is based on Boyle's law, PV = constant. An iron pipe—in our case 625 ft. long—is led from the instrument, the diaphragm part, to and into the ocean to a depth beneath the trough of the assumed highest waves at low tide, say 15 ft. The sea-end of the pipe is open. The wave passing over it causes the water to rise in the pipe and compress the air beyond, whereby the leather diaphragm is raised, and electric contact is made. By means of the armature of an electromagnet a toothed wheel is pushed forward, one tooth for every wave, and with one revolution, or 120 waves, the recording pen returns to its zero. The record presents a series of finely serrated oblique lines, each representing 120 waves. Clockwork with pen traces at the edge of the paper a time scale, making a break every hour, the linear measure of which is 6 cm. A fresh roll of paper is put on once a week. A small leak is provided in the diaphragm chamber, to cut out the effect of the slowly rising and ebbing tide, which, however, does not affect the rapid action by the waves.

The sea-end of the pipe gives the most anxiety, as it has to resist the immense force of the waves during storms. The greater part of the 625 ft. is of half-inch galvanised iron pipe, while the ocean end, about 100 ft., is of four-inch pipe, with reducing pipes between the preceding two. The bedding of the submerged part will be in about four tons of concrete with iron girders surrounding the pipe. The whole subject is so new that we have to feel our way in this investigation. Here in Ottawa, three hundred miles from the nearest sea-coast, we have in a general way correlated microseisms recorded by the seismograph with the storms along the Atlantic coast from Cape Hatteras to St. John's, Newfoundland, a distance of 1500 miles, so that for an exhaustive study there should be quite a number of undagraphs installed. However, a beginning has been made at Chebucto, distant in an air-line about 620 miles from Ottawa, and the results will be published as soon as available.

Geographical Distribution of Phreatoicus.

THE occurrence of the isopod Phreatoicus in a fresh-water stream near Cape Town, in South Africa, as recorded in your issue of June 12 by Mr. Keppel H. Barnard, is of very considerable interest from the point of view of the geographical distribution of the group. Since I described the first species of the genus in 1884 our knowledge of this group has grown very rapidly, and there are now known three species of Phreatoicus in New Zealand, two subterranean and one from surface waters, and several species grouped under allied genera from Australia and Tasmania. The genus is shown both by its generalised character and by its distribution to be an ancient one. I have long considered that it is probably a fresh-water form that has developed in subantarctic lands, and its discovery in South Africa seems to confirm this. In New Zealand it appears to be confined to the more southerly portion, but it was not found in the subantarctic islands to the south of New Zealand when these were visited in 1907. It should, however, be looked for in other subantarctic islands, particularly St. Paul and Amsterdam Islands in the Indian Ocean, and the Falkland Islands and adjoining parts of South America.

The Characters of Hybrid Larvæ obtained by Crossing Different Species of the Genus Echinus.

I HAVE carried out this summer hybridisation experiments on certain species of echinoids, and, in view of the interesting condition in which this inquiry was left last year by other workers, I venture to think that my results may be worth recording.

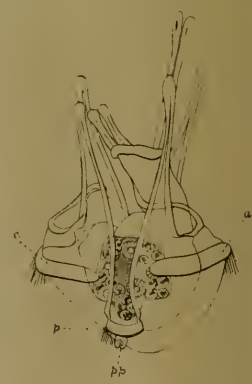
In 1911, Shearer, De Morgan, and Fuchs, as the result of three seasons' crossing experiments at Plymouth, stated (Journal M.B.A., ix., 2) that the hybrids between *Echinus miliaris*, on the one hand, and *E. esculentus* or *E. acutus*, on the other, showed, in respect of certain larval characters, a purely maternal inheritance. In 1912 the same workers, in a letter to NATURE, and later in *The Quarterly Journal of Microscopical Science*, published the result of their latest experiments, which was, briefly, that when *E. miliaris* was mother the inheritance was *paternal*. They found one culture which was exceptional. Debaisieux, working at the same time, and independently, first in London upon Plymouth material, and afterwards at Millport, obtained substantially identical results. These results he expressed in terms of dominant and recessive characters in the larvæ.

This disparity between the results of 1912 and those of former years raised a number of interesting questions, and made urgent a repetition of the experiments —a work that at the suggestion of Prof. E. W. MacBride (whose encouragement and advice I gratefully acknowledge) I undertook to perform.

The species used by me were those mentioned above, and the symbols, **M** and **m**, **E** and **e**, **A** and **a**, may be used to represent the ♀ and ♂ gametes respectively of each of them, the zygotes being then written **Mm**, **me**, **Em**, **Ee**, &c. The larval characters, the inheritance of which was studied, were the green pigment masses of **Mm** plutei, on one hand, and, on the other, the posterior pair of ciliated epaulettes and the posterior pedicellaria of **Ee** and **Aa** plutei. Debaisieux found the first of these "recessive," the other two "dominant."

In London I succeeded in raising cultures of **Mm**, **Em**, and **Am** plutei only, the reciprocal crosses failing for want of ripe males. Plymouth sea-urchins were used, and sea-water from Lowestoft. The hybrids, without exception, showed maternal characters. But in these crosses the dominant characters of Debaisieux were also maternal characters. I accordingly made further experiments at the Millport Marine Biological Station during July and August, using *E. miliaris* and *E. esculentus* only for my crosses.

After many failures, four healthy cultures of the **Me** cross were reared, one culture to a stage at which the anterior epaulettes were formed, the other three to the stage of metamorphosis. In the first culture green pigment was absent from all the larvæ examined; in the other three cultures all the individuals (132) had posterior epaulettes, eighty-one had the posterior pedicellaria, none had green pigment.



The reciprocal cross agreed in its characters with the one made in London.

There was a very notable difficulty in making the **Me** cross —a difficulty which would seem to be intrinsic, and unconnected with any defect in the egg, because it has occurred again and again in experiments in which the **Mm** and **Ee** controls have both yielded good cultures of plutei. The *E. miliaris* used as parents were small, and the ovaries contained a large proportion of unripe eggs; but a majority of the apparently ripe eggs developed, when fertilised with sperm of their own species, while only a small proportion developed when *E. esculentus* sperm was used.

The mortality in the **Me** cultures finally examined was unusually low after the blastula stage, and could be assessed with considerable accuracy on account of the small number of individuals in a culture. Differential mortality would seem then to be improbable as accounting for the final character of a culture.

The sketch shows a hybrid pluteus (**Em**) as seen from the left side: *a*, anterior epaulettes; *p* posterior epaulette; *pp*, posterior pedicellaria.

THE "GESELLSCHAFT URANIA" OF BERLIN.

An illustrated article on the "Gesellschaft Urania" of Berlin, by Dr. P. Schwahn, appeared in the June issue of *Himmel und Erde*.

On April 29 the society celebrated its twenty-fifth anniversary, when a distinguished audience gathered in the large theatre of the Urania building in the Tauben-strasse. Among those present were representatives from the various state departments of Germany and from the municipality of Berlin; members of the professorial staff of the University and the Charlottenburg Technical Institute; representatives of the various learned societies of Germany and many members of the leading technical and manufacturing firms of Germany. During the course of the evening a congratulatory telegram was read from the Kaiser. The proceedings were opened by Prof. Foerster, who gave a brief historical survey of the origin and work of the society during the last twenty-five years, and a lecture was delivered by Prof. Donath, the director of the physics department of the institution, in the course of which some of the most recent results and applications which have arisen from the classical discoveries of Hertz and of Röntgen were demonstrated.

The "Urania" Observatory, in the Ausstellungs Park.

The society was formed in 1888, at a time when the applications of electrical science were beginning to excite the interest of the general public. Its object was the foundation of an educational institution which should foster and stimulate the interest of the people in scientific knowledge and acquaint them with the more important advances and applications of science. Among the originators of the scheme were Werner von Siemens and Prof. Wilhelm Foerster, the director of the Royal Observatory of Berlin. The Minister of Education expressed his sympathy with the scheme and through his kindly interest a suitable building site was obtained in the Ausstellungs Park, near the Lehrte Bahnhof. By the aid of public subscriptions the building "Urania" was erected and equipped. The building contained a lecture theatre, galleries for the exhibition of scientific apparatus, and an astronomical platform.

The first director of the institution was Dr. Wilhelm Meyer, and the popular lectures on astronomical and geological subjects which he organised proved a great source of attraction. Urania became a popular scientific theatre and was visited by the residents of Berlin with as much eagerness as the opera house or the theatre. The institution, however, did not limit its activities to the provision of popular lectures; systematic evening courses in physics, electrotechnics, chemistry, biology, and astronomy were arranged, and from time to time eminent men of science both of Germany and other countries were invited to lecture on special subjects.

The need of more extended premises was soon felt, and as the Ausstellungs Park was somewhat difficult of access, it was thought desirable to obtain a site in the centre of the town. Consequently, in 1896, the operations of the society were transferred to a much larger edifice in the Tauben-strasse and designated "Urania." The old building in the Ausstellungs Park, now known as the "Urania Sternwarte," passed into the hands of the Government, and with the removal of the Royal Observatory from the Encke Platz in Berlin to Neubabelsberg is now being utilised with its equipment as an astronomical institute in connection with the Berlin University. Lectures on astronomy are still given at the Observatory by the society during the winter months, but only a portion of the building is open on special days in the week to visitors. The large refracting telescope, which has a focal length of five metres and an aperture of 314 millimetres, and other smaller telescopes and instruments may still be inspected by the public, and on the appearance of comets and occurrence of eclipses the Observatory is visited by large numbers of the general public.

The "Urania" building, Tauben-strasse, Berlin.

The new institute in the Tauben-strasse, which is under the direction of Dr. Schwahn and Franz Goerke, contains a large lecture theatre with seating accommodation for 700 people and a smaller lecture room to hold 200. It is also provided with library and reading-room, workshop and preparation rooms. The scientific exhibits are placed in six galleries, two being allotted to physics, two to natural science, one to chemical technology, and one to machinery. The apparatus exhibited in the physics section has been arranged to illustrate an ordinary college course in experimental physics. It is possible for the visitor to perform for himself many of the experiments he would see demonstrated in a lecture or carry out in a laboratory. Thus, he may verify the ordinary laws of optics, measure a resistance with a metre bridge, excite the kathode rays and deflect them with a magnet, and so on. This idea was due to Prof. Goldstein, who had the arrangement of the physics apparatus in the smaller building in the Ausstellungs-Park. A similar plan, wherever possible, has been followed in the other departments, and no doubt has proved extremely beneficial to many earnest students who prosecute their studies in their spare time or lack the opportunity of a college training.

During the last sixteen years the average annual number of visitors to Urania has been 200,000, and the society has arranged on an average 700 lectures yearly. Urania has welcomed the members of the various scientific congresses which have held their conferences in Berlin during the past few years, and the institution numbers among its visitors many of the world's leading men of science. From many of these the society has received gifts of various objects of scientific interest.

The popular scientific lectures have been given in many of the larger German towns, and in 1903 the society was invited by the Russian Government to conduct a series in St. Petersburg. Urania took part in the organisation of the German educational section at the Brussels Exhibition of 1909, and was granted a premier award by the Commissioners of the exhibition. With the advent of the kinematograph the popularity of the institution is still further ensured, and at the present time great interest is being displayed in the exhibitions in the domain of hygiene and the laws of health. Urania is undoubtedly fulfilling the wishes of its founders and has become an established factor in the educational life of Germany.

Magnetism and electricity gallery of the Urania Society, Berlin.

THE FAUNA OF THE SANDWICH ISLANDS.[1]

IN 1890 a Joint Committee of the Royal Society and of the British Association was formed "to report on the present state of our knowledge of the Sandwich Islands," and it at once entered into relationship with the Trustees of the Bernice P. Bishop Museum at Honolulu. It wisely decided to restrict its investigations to the land fauna, and it recently issued the last part of its "Fauna Hawaiiensis." Its chairmen have been Sir W. H. Flower, Prof. Alfred Newton, and Dr. F. D. Godman, while Dr. D. Sharp and Prof. S. J. Hickson have respectively been secretary and treasurer during the twenty-three years of its existence. A number of the greatest authorities collaborate in the production of the "Fauna," which throughout has the high standard usually associated with the name of Dr. Sharp. Dr. R. C. L. Perkins was the collector and naturalist, and in both lines he is pre-eminent.

Hawaiia has about the area of Yorkshire, and consists of eight main islands, of which the fauna of six has been collected. California is their nearest continental land, being 2100 miles distant, while Samoa and Fiji are 30°–40° S. and Tahiti is still further away, intervening islands being mostly of coral-reef origin. These groups are not sufficiently well-known to make a comparison with their fauna of much value, but Fiji is usually regarded as continental. The islands of Hawaiia are of volcanic origin and vary up to 14,000 feet in height. They present great diversities of climate, some coastal parts subtropical, the mountain summits snow-capped in winter, some parts relatively dry, even parched up, and others with more than 200 inches of rain. Probably all was at one time covered with forest, relatively tropical by the coasts, dense rain-forest above, more open on the much drier higher slopes. Most of the lower forest has long been cleared away, but parts of the rain-forest persist as well as great stretches of the higher woods.

The fauna may be said to be a function of the flora, and this flora has only 860 known species, of which 653 are endemic with 40 endemic genera, the rest being introduced weeds or common littoral forms. Geographically this flora must take precedence, for the first animals must not only be able to land, but to find suitable vegetation on which to feed. These animals must flourish or carnivorous beasts will never become regular components of the fauna. Again, most immigrants to oceanic islands must be supposed to be best adapted to the conditions of the low country, where later man's ravages by axe and fire will be most felt. In any case most of those that survive the passage will be unproductive, since, even if they do find suitable climate and food, few indeed will find mates.

For a small insect to become widespread round the coast of one of these islands would take many generations. A still longer time would be required to take each step up the mountains, because either each step would mean the adaptation of the needs of the animal to fresh environments, resulting later in the production of new forms, or each step would be taken as the result of some variant of its physical organisation resulting in a new need. Each beast in each step must take a mate with him, and the time required for

[1] "Fauna Hawaiiensis; or, the Zoology of the Sandwich (Hawaiian) Isles.' Being Results of the Explorations instituted by the Joint Committee appointed by the Royal Society of London for Promoting Natural Knowledge and the British Association for the Advancement of Science, and carried on with the assistance of those Bodies and of the Trustees of the Bernice Pauahi Bishop Museum at Honolulu. In three volumes. Edited by David Sharp, F.R.S. (Cambridge University Press.)

the production of new forms by either physiological or morphological variation becomes still more considerable.

Dr. Perkins, and apparently all the contributors to the "Fauna" agree that Hawaiia is oceanic. Dr. Perkins summarises the evidence in his "Review of the Land-Fauna," the last published part. He further points out that nineteen-twentieths of the endemic species are found in the forest belt. This is in accordance with theory, for the isolation as varieties leave the coast land is to be expected to be helpful to species formation, though the largeness of the proportion is doubtless helped by the destruction of the lowland vegetation. The inconspicuousness of the fauna and flowers is noted, but the paucity of individuals—some parts are barren to the collector owing to the devastation of carnivorous ants—is doubted, as is interbreeding as producing diminished fertility. 3325 species of insects are known, and practically all the endemic species are of small size and special habits; many are flightless. Their large amount of variability is interesting as well as a distinct tendency to specialisation in variation in different localities.

Dr. Perkins clearly considers that the fauna arose from a very few immigrants, which have varied to form the present large genera and groups of allied genera. Some genera are confined to one of the six forest-clad islands, and in large genera few species from different islands are identical. Isolation even without selection is supposed to have brought about change, and the extreme difficulty that the systematist has in limiting his species is ascribed to the absence of agencies by which natural selection works. On every theoretical point Dr. Perkins has some fertile suggestion, but the writer hesitates to quote more because such might be misconceived by the reader, who had not the altogether unique facts before him.

J. STANLEY GARDINER.

SIR W. N. HARTLEY, F.R.S.

By the death of Sir Walter Noel Hartley, the scientific world has lost a man who undoubtedly has enriched it in very many ways. Although perhaps his name is more intimately connected with work upon absorption spectra and their relation to the constitution of organic compounds, yet Hartley also carried out most important investigations in many other branches of spectroscopy.

Sir Walter Hartley was born on February 2, 1846, and was appointed professor of chemistry in the Royal College of Science, Dublin, in 1879, a position he held until his retirement under Civil Service regulations in 1911. One of the founders of the Institute of Chemistry, he was a vice-president from 1900 to 1903. He was elected a Fellow of the Royal Society in 1884, and was awarded the Longstaff medal by the Chemical Society in 1906. He received his knighthood on the occasion of the opening of the new buildings of the Royal College of Science, Dublin, by the King and Queen in 1911. His death, which occurred on September 11, at Braemar, was due to heart failure following on bronchitis.

Hartley's investigations were almost entirely connected with spectroscopy, and his published papers deal with three of its principal branches, namely, flame spectra, spark spectra, and absorption spectra. Perhaps the most striking thing in connection with all his work is the singular interest which he instilled into it. To many, spectroscopy may appear as a somewhat dry statistical study of the wave-lengths of emission lines and absorption bands, but no one on reading Hartley's numerous and varied contributions to the literature of the subject could lay such an accusation against his work. There is to be found there no mere dull compilation of accurate measurements, but copious evidence of wonderful insight and keenness. In all his work, Hartley showed himself a pioneer in the application of spectroscopic methods to the study of the nature and properties of the chemical atom and molecule, and it is from this that the great interest of his work arises.

In 1872 Hartley became the possessor of Dr. W. A. Miller's spectroscope, and he not only showed that it was possible to obtain the whole spectrum in focus upon a flat plate with the use of quartz prisms and unachromatised quartz lenses, but he was the first to use dry plates in the photography of spectra. The original apparatus was modified considerably, and amongst other improvements it was so devised that a number of photographs could be taken on the same plate This in itself marked a great advance in technique. Hartley in the early days almost entirely restricted himself to the use and study of spark spectra. In 1883 he published a series of photographs of spark spectra, and in 1884 he put forward, in conjunction with Dr. W. E. Adeney the wave-lengths of the lines in these spectra. This later paper also contained the wave-lengths of the lines due to air which are of such importance in all spark spectra observations. The publication of these wave-lengths marked a very important advance in spectroscopy.

Later, Hartley turned his attention to the spark spectra of solutions of metallic salts, and it is to him that we owe almost the whole of our knowledge of the nature and character of the lines in these spectra. From a study of the effect of concentration it was soon noted that all the lines do not disappear at the same dilution. Hartley found that there exists a constant relation between the dilution and the appearance or disappearance of certain lines of each metal, and based on this he was able to found a system of quantitative analysis. The value of this method he proved by applying it with perfect success to the analysis of an Egyptian coin. Similarly, from his knowledge of the relative persistence of spectrum lines, he was the first to prove the presence of gallium in the sun and many of the stars. In the same way he showed the remarkably extensive distribution of the rare earth metals, and also the great prevalence of lithium in very small quantities. He pointed out that the latter fact is of considerable interest with reference to recent work on radioactivity.

Again, Hartley was the first to discover the relation between the wave-lengths of lines in the spectra of analogous elements. He explained the fact by saying that analogous elements do not consist of different kinds of matter, but of different quantities of the same kind of matter. This relation possesses a fundamental significance in connection with modern views on the electronic nature of the atom; and, moreover, the deduction Hartley himself made affords support to the theories recently put forward as to the evolution of the elements.

In his work on flame spectra, Hartley showed the value of the oxy-hydrogen flame. In conjunction with Dr. H. Ramage, he discovered the existence of the bands in the flame spectra of many metals, and from a study of these he was able to draw important conclusions about the relation between the band and line spectra of the same element. Further, both alone and with Ramage, he made an exhaustive study of the spectroscopy of the Bessemer process, and was able to contribute largely to the knowledge of the thermochemistry of that process.

With Hartley's work on absorption spectra it is not possible adequately to deal in a brief epitome. In this direction he has undoubtedly founded a field of research which is of great importance and promise, as Prof. von Baeyer has recognised. Hartley was the first to establish a scientific method of observation and recording of absorption spectra, and was the first to show that they may be applied to the problems of chemical constitution. In a series of nearly fifty papers he dealt with the absorption exerted by both inorganic and organic compounds. In the first-named, he showed how the spectroscopic evidence was antagonistic to the ionic hypothesis in its earlier development. In the second, he showed, among many other fundamentally important facts, that the colour of all dyestuffs and similar compounds is to be traced to the absorptive power of the hydrocarbons from which they are derived. In fact, he gave the scientific explanation of the chromophore theory. Also may be mentioned his investigation of the absorption exerted by the alkaloids, and his record of facts that are of great importance to the synthetic chemist, and also from the medico-legal point of view. The application of the method to the elucidation of the constitution of carbostyril, *o*-oxycarbanil, isatin, and other compounds is perhaps too well known to need emphasis. It is impossible to specify the many lines of work Hartley successfully carried on in absorption spectra. He has left accurate records of the absorption curves of a vast number of substances, and he discovered a series of fundamental laws governing the relation between absorption and chemical constitution with which his name always will be associated.

In conclusion, it may well be said of Hartley that whatever research he undertook, his results were always most valuable, and he conferred distinction upon everything to which he put his hand.

E. C. C. B.

DR. ALEXANDER MACFARLANE.

DR. ALEXANDER MACFARLANE, whose name is well known to workers in vector algebras, died at his home in Chatham, Ontario, on August 28. He was born in Blairgowrie on April 21, 1851, and was trained as a pupil teacher. As a student in Edinburgh University he soon impressed his contemporaries with his mental capacity. He gained high distinctions in the class of logic and philosophy as well as in mathematics and natural philosophy. After graduating with first class mathematical honours, he proceeded to study for the science degree, gaining his doctorate in 1878 with a thesis on the conditions governing the sparking of electricity between electrodes in air and in paraffin. The experimental work was carried out in Prof. Tait's laboratory, but the idea of the research was entirely Dr. Macfarlane's own. Some of these early results are referred to by Clerk Maxwell in his "Electricity and Magnetism."

Dr. Macfarlane did not, however, pursue experimental research, but turned his mind to the application of mathematical symbols in somewhat unusual directions. His "Algebra of Logic" was published in the late 'seventies, and he read before the Royal Society of Edinburgh a series of papers on the algebra of the relationships of consanguinity and affinity. In 1885 he was appointed professor of physics in Texas University, and was of great service in developing that institution as a centre of scientific teaching. About this time he published a book on physical arithmetic, which was the first sustained systematic treatment of methods of calculation useful in physical reductions. He was also the compiler of a compact and well-arranged book of mathematical tables.

He retired from active teaching in 1894, and some years later settled in Canada on a large farm which had been bequeathed to him by an uncle. Here and subsequently in the neighbouring town of Chatham, he turned his attention to the study of vector algebras. Already he had taken part in the controversy which appeared in NATURE (1893–4) as to the rival merits of quaternionic and non-quaternionic vector analysis. Prof. Tait, Prof. Willard Gibbs, and Dr. Heaviside were among the disputants. Dr. Macfarlane agreed with none of these, but took a line of his own, which he has worked out with ingenuity in many later papers. Last year, for example, he read a short paper on the subject before the Mathematical Congress at Cambridge. It was, however, as the devoted secretary of the Association for the Study of Quaternions and Allied Systems of Mathematics that he found his chief opportunity. This association, which was started by Dr. Kimura, of Japan, is now a fairly strong body of mathematicians representing all countries of the civilised world. Much of the success attending its labours must be attributed to the zeal and energy of the secretary, whose last letter to me, written just a fortnight before his death, anticipated a new departure which would increase the efficiency of the association.

Throughout his life Dr. Macfarlane was keenly interested in educational methods, and at the time of his death was Chairman of the Board of Education in Chatham, Ontario. C. G. KNOTT.

DR. JULIUS LEWKOWITSCH.

WE regret to announce that Dr. Julius Lewkowitsch, the well-known authority on fats and oils, died at Chamonix on September 16, after a short illness. He was born at Ostrovo, in Prussian Silesia in 1857, and had a brilliant university career at Breslau. After graduating as doctor of philosophy at Breslau, Lewkowitsch devoted himself to an academic career; he carried out a considerable quantity of original investigation under Prof. Victor von Richter at Breslau, and subsequently took a position under Prof. Hans Landolt in the chemical laboratory of the Berlin Agricultural High School. At a later date he became assistant to Prof. Victor von Meyer in the University of Heidelberg.

Lewkowitch's first published work consisted in the study of the action of nitric acid on fatty acids, but he soon applied himself to experimental work on stereochemistry, which was at that time a new and undeveloped subject, and was far from assuming the commanding position which it now holds. He was the first to develop the method given by Pasteur for the resolution of externally compensated substances by the action of living organisms, and in 1882 and 1883 prepared the optically active modifications of tartaric, lactic, glyceric, and mandelic acids from the corresponding racemic substances by the action of penicillium glaucum, aspergillus mucor, yeasts, and a schizomycetes. At a later date he attacked the problem presented by the optical inactivity of benzene derivatives, and made many experimental attempts to obtain such substances in optically active modifications.

The brilliance of Lewkowitsch's early experimental work indicates that, had he continued to devote himself to pure science, he would rapidly have achieved a foremost place as a teacher and investigator. About twenty-five years ago, however, he came to this country, became naturalised, and, abandoning his aspirations towards a purely scientific career, entered upon what proved to be his life-work, the development of the industrial technology of fats and oils. At the time of his death he was the first living authority on the vegetable and animal fats and oils; a large number of processes which are widely employed in the utilisation and valuation of these important raw materials were devised by him. His treatise on the "Chemical Technology and Analysis of Oils and Fats" is now in its fifth English edition, and has been published also in French and German; his "Laboratory Companion to Fats and Oils Industries" has a wide sphere of usefulness in English and in its German translation. Lewkowitsch wrote the article on oils and fats in the "Encyclopædia Britannica" and the articles on oils in the last and the current editions of Thorpe's "Dictionary of Applied Chemistry"; his writings on his own subject have set a standard of precise treatment which has been accepted and adopted in later works by others upon this great branch of chemical industry.

Dr. Lewkowitsch served in many capacities upon the Councils of the Chemical Society, the Society of Chemical Industry, the Institute of Chemistry, and the Society of Public Analysts; at the time of his death he was the honorary foreign secretary of the Society of Chemical Industry, and had held the chairmanship of the London Section of the society. In 1909 he received the Lavoisier medal as conférencier of the Société chimique de France; as a Cantor lecturer of the Royal Society of Arts he delivered a course of lectures on fats and oils which, in their published form, are of considerable value, and exhibit the great mastery which he had acquired over our language.

Lewkowitsch was a keen mountaineer; few men possessed so intimate and complete a knowledge as he had gained of the French and Swiss Alps, in sight of which he passed away. He married in 1902, and his widow, with a son and daughter, survives him. W. J. P.

NOTES.

DR. ROUX, director of the Paris Pasteur Institute, has been made a grand officer of the Legion of Honour.

THE death occurred on September 15, at the age of fifty-nine, of Dr. Louis Merck, senior partner of the firm of E. Merck, Darmstadt.

IT is stated in *The Lancet* that Mr. W. F. Fiske has been asked by the Tropical Diseases Committee of the Royal Society to investigate the life-history of the tsetse flies in Uganda.

THE *Chemist and Druggist* for September 20 contains the reproduction of a photograph of the bronze statue of Dr. Ludwig Mond, which was unveiled by Sir John Brunner, Bart., on September 13, and was alluded to in our issue of September 11 (p. 48).

THE death is reported, in his sixty-eighth year, of Prof. Lucien A. Wait. On graduating at Harvard in 1870 he was appointed assistant professor of mathematics at Cornell University. In 1877 he became associate professor, and in 1890 full professor. From 1895 to 1910 he was head of the department of mathematics.

ACCORDING to *Science*, a national museum is to be established in the city of Santo Domingo for the purpose of retaining and preserving in the country objects and relics of historical character connected with the discovery and development of the country.

The museum is to occupy the old palace known as the house of Don Diego Colon. The sum of 20,000 dollars has been appropriated by the National Congress for repairing the building.

THERE is no doubt as to the efficiency of the radium emanations in the cure of certain forms of superficial cancer, ulcers, &c. It is now stated that the emanations of mesothorium, derived from the waste in the manufacture of incandescent gas mantles, possess similar properties, but in an enhanced degree, and efforts are being made to prepare a sufficient supply of the material so that a thorough trial of it may be made.

WE notice with regret the death, on September 18, at eighty-five years of age, of Mr. Samuel Roberts, F.R.S., president of the London Mathematical Society from 1880 to 1882, and De Morgan medallist in 1896. Another well-known mathematician whose death, on September 19, is announced is Mr. John Greaves, bursar and senior mathematical lecturer at Christ's College, Cambridge, and author of "A Treatise on Elementary Statics."

THE death is announced, at the age of sixty-seven, of the eminent French surgeon, Prof. Antonin Poncet, who in 1882 was appointed to the chair of operative medicine at Lyons, and in 1895 was elected to the Academy of Medicine. He was the author of many medical works dealing with diseases of the bones, and was well known for his investigations into the cause of death of Napoleon, Richelieu, Rousseau, and many other famous men.

IT was briefly announced in our issue for September 11, that the importation into the United States of the plumage of wild birds, raw or manufactured, save for scientific or educational purposes, is by the new Tariff Bill prohibited. We now learn from Mr. W. T. Hornaday, of the New York Zoological Park, that the prohibition movement was inaugurated and carried through by the New York Zoological Society and the National Association of Audubon Societies. It would be well if their example were copied in this and other countries.

WE learn from *The Pioneer Mail* that Sir Aurel Stein, K.C.I.E., has been deputed by the Government of India, with the sanction of the Secretary of State, to resume his archæological and geographical explorations in Central Asia and westernmost China. For his journey to the border of Chinese Turkestan on the Pamirs Sir Aurel Stein is taking on this occasion a route which offers special interest to the student of the geography and history of the Hindu Kush regions. It leads through the Darel and Tangir territories which have not been previously visited by a European, and which only recent political developments have brought under British influence. The Survey of India Department has deputed with Sir Aurel Stein his old travel companion Rai Bahadur Lal Singh, and a second surveyor to assist him by topographical work.

As was announced in NATURE of September 11, the eminent entomologist, Dr. Odo Morannal Reuter, of Abo, Finland, Emeritus professor of zoology at Helsingfors University, died on September 2 in his sixty-fourth year. As an entomologist Prof. Reuter's name was known throughout the world as a leading authority on the Hemiptera-Heteroptera, whilst he was also a worker in the more obscure groups, the Collembola (spring-tails), Psocidæ and Thysanoptera (thrips). About five years ago it was learned from Prof. Sahlberg that his colleague, O. M. Reuter, had been sadly stricken with blindness, yet, despite this great affliction, he plodded on with the aid of a secretary, and shortly before his death a work—so written—on the habits and instincts of solitary insects saw light at Stockholm. His work was characteristically thorough, and though his contribution to zoological literature numbered about 480 publications, large and small, and included a number of works on animal psychology and practical entomology, he was also a writer on literary subjects and a poet of high attainments and merit. In this country he will be missed by many, and it is pleasing to know that the highest honour British entomologists can bestow—the honorary fellowship of the Entomological Society of London—was conferred upon him in 1906.

IN vol. iii. of the publications of the Babylonian section of the University Museum of Pennsylvania Mr. J. A. Montgomery contributes an elaborate memoir on a collection of Aramaic incantation texts from Nippur. These bowls were found above the stratum of the Parthian temple, which was destroyed and became covered with sand, and was occupied by small ascetic communities of Jews and Mandæans, probably attracted to this deserted place by motives of religious community life. They appear to date from approximately 600 A.D. The importance of the present discovery lies in the fact that this bowl magic is in part the lineal descendant of ancient Babylonian sorcery, while at the same time the unexpected result is arrived at that it takes its place in the great field of Hellenistic magic which pervaded the whole of the western world at the beginning of the Christian era. The monograph is a scholarly piece of work, and will be indispensable to all students of Oriental magic.

THE *Reading University College Review* for August, an attractive volume, includes an article on bovine tuberculosis in man, by Dr. Stenhouse Williams, which gives a good summary of the subject. He concludes that the bovine type of tubercle bacillus is the cause of one-third of the cases of tuberculous disease other than the pulmonary at ages 0–16 years, which corresponds to about 4000 deaths per annum in this country.

To the July-August issue of *Naturen* Mr. P. A. Øyen contributes an illustrated article on remains of the mammoth and the musk-ox in Norway, with a discussion as to the horizons in which they respectively occur.

WE have received a copy of a fifth edition of the late Mr. T. Southwell's admirable guide to the Norwich Castle Museum, brought up to date by Mr. F. Leney, the curator. Among the illustrations are figures of the stuffed skin and egg of the great auk, which form two of the chief treasures of the museum. To Prof. McIntosh we are indebted for a copy of a reprint of his sketch of the Natural History Museum of the University of St. Andrew's, originally published in the Museum's Journal.

ACCORDING to the report of the Madras Museum for the past year (issued by the Educational Department), a large collection of marine organisms has been obtained from the coral reef at Kilaharai, in the Ramnad district, the examination and classification of which are expected to occupy a considerable period. The superintendent also records the third or fourth specimen (it is not quite clear which) of the great snipe (*Gallinago major*) killed in India; all these appear to have been obtained since the publication, in 1898, of the fourth volume on birds in the "Fauna of British India," as the species is not mentioned in that work.

IN an article on the ancestry of Edentate mammals published in a recent issue of the American Museum Journal (vol. xii., pp. 300–303), Dr. Matthew, after mentioning that armadillos are probably the most primitive existing members of the group, and that "armadillos without armour" occur in the early N. American Tertiary, observes that although the latter and the tæniodonts of the N. American Eocene cannot be regarded as direct ancestors of the typical S. American edentates, yet they suggest the possibility that the group originally came from N. America, and penetrated to S. America about the beginning of the Tertiary, where it developed into a host of new forms.

GREAT interest attaches to the description by Dr. W. D. Matthew in vol. xxxii., art. 17 (pp. 307–314), of the Bulletin of the American Museum of Natural History, the imperfect skull of a new genus and species (*Palaeoryctes puercensis*) of the so-called zalamdodont insectivorous mammals from the Puerco, or Basal, Eocene of New Mexico. At the present day that group is represented by the Solenodontidæ of Haiti and Cuba, the Potamogalidæ of Equatorial (Dr. Matthew, judging from his map, seems to be unaware that the "otter-shrew" occurs in the eastern as well as in the western part of the forest-zone) and the Chrysochloridæ, or golden moles, of southern, eastern, and central Africa, and the Centetidæ, or tenrecs, of Madagascar. In 1891 the extinct genus Necrolestes, more or less nearly related to the Chrysochloridæ, was described from the Patagonian Miocene. At that time fossil forms were unknown from the northern hemisphere, which led to the suggestion that the group was essentially southern; but between 1903 and 1907 five extinct genera were recorded from the N. American Tertiary. The new genus now described serves to show the great antiquity of the tritubercular type of molar characteristic of the zalamdodonts; and also, if rightly associated with that family, indicates that the Centitidæ are the oldest existing group of placental mammals.

AMONGST the familiar sporozoan parasites known as gregarines, one genus, Porospora, has always stood apart from all others by reason of the possession of peculiar and anomalous characteristics. The genus comprises species parasitic in Crustacea, and *P. gigantea*, parasite of the lobster, is the largest gregarine known. Recent researches have shown that the peculiar "gymnospores," so-called, of these gregarines are not true spores at all, but clusters of merozoites, and that the apparent sporogony of these parasites in their crustacean hosts is really a process of non-sexual schizogony, different from that of all other gregarines. The question then arose: Where and under what circumstances does the true sporogony take place? The answer has now been given by the distinguished French investigators, Messrs. Léger and Duboscq, who have discovered that the sexual cycle and sporogony of Porospora takes place in bivalve molluscs, and is no other than that of the curious parasite described many years ago by Aimé Schneider under the generic name Nematopsis, a genus of which the systematic position has been hitherto quite uncertain. Thus *Porospora portunidarum*, parasitic in crabs, has its Nematopsis-phase in *Cardium edule*, the common cockle, in which host the parasite produces a single spore, containing a single vermiform sporozoite, in the gills of the mollusc. A preliminary account of the development of this species, illustrated by nineteen text-figures, is published in the *Comptes rendus des séances de la Société de Biologie* (vol. lxxv., p. 95).

WE have received the concluding numbers of the sixteenth volume (for 1912) of the *Bollettino* of the Italian Seismological Society. The complete volume contains eleven papers, the more important of which deal with the recent eruption of Etna, the luminous phenomena associated with the Valparaiso earthquake of 1906 (NATURE, vol. xc., p. 550), and the sea-waves of the Calabrian earthquake of 1907 (vol. xci., p. 327). The greater part of the volume, however, consists of the notices of earthquakes observed in Italy during the year 1909, compiled by Dr. G. Martinelli. These notices occupy more than six hundred pages, and their value has been increased by several improvements recently made. The constants of the seismographs used in twenty-nine Italian observatories are given in an appendix; the notices relating to different earthquakes are separated by a space (it would be still more useful if they were numbered); the earthquakes, with the exception of those recorded by a single instrument or from one place only, are named according to the districts chiefly affected by them, and of these an alphabetical index is added.

A RECENTLY issued Bulletin (No. 54) of the Bureau of American Ethnology, by Messrs. Hewett, Henderson, and Robbins, deals with the Rio Grande valley, an arid region in New Mexico. The bulletin contains three papers; the first two, on the physiography and general geology respectively, are more or less introductory to the third, which deals with the climate and climatic changes. The evidence for the latter is (1) archæological, (2) botanical, and (3) geological. (1) There are great numbers of ruins in the country, many of them far from present known sources of water, and even as late as the coming of the Spaniards the population seems to have been denser than now. (2) Study of the trees shows that the rock pine and the piñon pine are the most widespread, the latter occupying the drier situations. The boundary between these two species is shifting towards the moister regions, indicating that the area which is too dry for the rock pine to inhabit is increasing. (3) Geologically, the authors have to take a wider field. Of chief importance is the evidence that the whole of the south-west States have suffered a great diminution of their mountain glaciers and enclosed lakes, commencing several thousand years ago, and probably still in progress, as shown by measurements in the last few decades. No single line of evidence is conclusive, but the convergence of so many, coupled with the experience of observers in other lands, renders dessication in this region in human times very probable. In connection with the authors' suggestion for the careful measurement of the fluctuations of land-locked lakes, it may be noted that such records are now being kept in the British colonies in tropical Africa. The work is illustrated with a number of very clear photographs, but the omission of the names of the months and the scales of units in the diagrams of monthly rainfall and temperature is unfortunate.

We have received the "Pilot Chart" of the North Atlantic Ocean for September, published by the United States Hydrographic Office, containing similar useful information relating to winds, currents, &c., to that included in the "Meteorological Charts" formerly published by the Weather Bureau, but now discontinued (Nature, September 11). An interesting account is given of observations on ocean temperatures in the vicinity of icebergs and in other parts of the ocean by officers of the U.S. Bureau of Standards, with illustrations of the temperature equipment and of samples of the records obtained. Practically continuous temperature readings were obtained from June 4 to July 10, 1912, and these show that the variations in parts of the ocean far removed from ice are often as great and sudden as in the vicinity of icebergs. The authors consider that the question is still in doubt whether these influence to any considerable extent the temperature of sea-water at a mile or so distant.

An interesting article on evaporation in the great plains and intermountain districts as influenced by the haze of 1912, by Messrs. L. J. Briggs and J. O. Belz, of the Bureau of Plant Industry, appeared in the Journal of the Washington Academy of Sciences of August 19. The haze was presumably due to the eruption of Mount Katmai (Aleutian Islands) on June 6–7 of that year, during which volcanic ashes fell at Sitka, 700 miles distant, and the sun was obscured for a time. It gave rise to a marked diminution in the intensity of solar radiation, which was particularly noticed in subsequent months at the Mount Wilson, Mount Weather, and Madison observatories in the United States. The authors, who had been engaged in evaporation measurements during the last five years, deemed it desirable to determine to what extent this reduction of solar intensity affected the evaporation (not forgetting that this is also greatly influenced by other factors). Tables of monthly normal evaporation for fifteen stations show that during four months following the eruption the average reduction was about 10 per cent. This reduction in the mean evaporation, although somewhat less than the observed reduction in solar intensity, appears to afford an approximate measure of the reduction of the latter at the earth's surface.

The *Scientific American* (vol. cix., No. 5) contains two illustrated articles on the modern developments of the electric furnace. In the first (p. 84) an account is given of recent patents covering improvements in the electric arc as used in the purification of steel and iron and in the production of compounds of nitrogen from the air; whilst in the second a special account is given of the electrical production of steel, from the early experiments of Siemens to the thirty-ton furnace of to-day. Illustrations are given of the Stassano arc furnace in use at Turin, of the Kjellin and the Röchling-Rodenhausen induction furnaces, and of the Heroult 15-ton arc furnace in use at the works of the U.S. Steel Corporation.

Aëronautical science in America receives fresh recognition in the decision of the Smithsonian Institution to reopen the Langley Aërodynamical Laboratory. The first serious contribution from the scientific side of aëronautics is to be found in the work of Langley, the necessary funds being provided by a Governmental grant; had the light petrol motor come into existence twenty years ago, it is probable that the Langley Laboratory would never have been closed, and would now be the leading aëronautical laboratory in the world. The Smithsonian Institution is a private concern, although closely connected with the U.S. Government departments. For the present it will be dependent on private donations for its income for aëronautical research, though in time it is hoped to receive a Governmental grant in aid. Apparatus useful in aëronautics already exists in the U.S. Bureau of Standards, and the U.S. Weather Bureau, with which the Langley Laboratory will be closely connected, and financial support is primarily needed for the construction of two wind tunnels and the necessary model-making apparatus. In addition to experiments on models an aircraft field laboratory is proposed, for measurements of stress, moments of inertia, &c., and for the adjustment and repair of several full-scale land and water aëroplanes.

In the July number of *The Biochemical Journal* (vol. vii., No. 4) Mr. Egerton C. Grey demonstrates the production of acetaldehyde during the anaerobic fermentation of glucose by *Bacillus coli communis*, and states that, by artificial selection by means of growth on sodium chloracetate, strains of the original organism can be obtained which produce either a greatly diminished amount of the aldehyde or none at all. As this diminution is accompanied by a falling-off of the production of alcohol and carbon dioxide, it is probable that the aldehyde is a primary, not a secondary, product of fermentation, and that the process of alcohol formation by *B. coli communis* is analogous to the alcoholic fermentation set up by the zymase of yeast.

In the current number of the *Berichte* (No. 11, p. 2401), Prof. Willstätter and L. Zechmeister publish an important communication on the quantitative conversion of cellulose into dextrose by means of cold, fuming hydrochloric acid of sp. gr. 1·204° to 1·212°, containing from 40 to 41·4 per cent. of hydrogen chloride. A problem has thus been solved which for more than one hundred years has been vainly attempted by the use of hot mineral acids and other means. Although ordinary concentrated hydrochloric acid containing 37·6 per cent. of hydrogen chloride does not dissolve cellulose but merely disintegrates the fibre and causes gelatinisation, the more concentrated acid containing 40 per cent. rapidly dissolves it, and after twenty-four to forty-eight hours 95 to 96 per cent. of the theoretical quantity of dextrose is present in the solution. The course of the hydrolysis has been followed by observing the specific rotatory power and copper-reducing value of the solution in successive intervals of time. In this way it was found that the cellulose at first dissolves in an optically inactive form, thus differing entirely from starch, which gives a highly dextro-rotatory modification from the start. Only after one hour is a slight dextro-rotation to be observed, which progressively increases; in the early stages the product, which can be precipitated from solution by water or alcohol, is of a dextrin-like character, but without either reducing power or specific rotation. The solution gradually develops reducing properties as the specific rotation increases, but during the first six hours the amount of "dextrose" calculated from the reducing power is much less than that calculated from the change of rotation. It is thus probable that a complex, optically active, but non-reducing sugar is formed first, and that this is later further resolved into dextrose. One of the most striking observations recorded in the paper is the very high specific rotation shown by dextrose when dissolved in concentrated hydrochloric acid. In 41·4 per cent. hydrochloric acid $[\alpha]_D^{16°}$ was found to be 106°, which approximates to that of the so-called α-form of dextrose (110°), the ordinary value observed in aqueous solution for the equilibrium mixture of α- and β-forms being 52·5°. In 44·5 per cent. hydrochloric acid, however, the extraordinarily high value of 164·6° was observed for $[\alpha]_D$ at 5° C.

No. 29 of *Scientia* contains a number of articles of general scientific interest. Dr. E. E. Fournier d'Albe writes on interstellar space, Dr. A. Findlay gives a short account of the phase rule and its applications, and Mr. Léon Fredericq contributes an interesting summary of the methods by which animals utilise chemical and physical forces as means of defence. Mr. E. Rignano discusses the problem of the evolution of reason, and G. Cardinali traces the influence of Hellenic culture on the development of Roman civilisation.

OUR ASTRONOMICAL COLUMN.

VARIABLE NEBULÆ.—M. Borrelly's recent announcement in the *Comptes rendus* that Hind's nebula appeared to be passing through a period of maximum is now followed (No. 9, *Comptes rendus*) by a note from M. G. Bigourdan incorporating a list of the dates of published measures together with the names of the observers dating from Schönfield's observations, July 26, 1861. Attention is directed to the importance of confirming M. Borrelly's observation.

COMET (1913*b*) METCALF.—The following is the ephemeris of Metcalf's comet as taken from the *Astronomische Nachrichten*, No. 4682:—

12h. M.T. Berlin.

	R.A. h. m. s.	Dec. ° ′	Mag.
Sept. 25	3 41 54	+76 44·2	—
26	3 6 0	77 17·7	—
27	2 25 33	77 31·4	8·4
28	1 42 38	77 16·6	—
29	1 0 15	76 40·9	—
30	0 21 36	75 33·3	—
Oct. 1	23 47 1	74 1·0	8·2
2	23 18 26	72 6·0	—

The above ephemeris has been calculated by Prof. Kobold from the observations on September 2, 6, and 10, which gives quite a new set of parabolic elements and makes the places of the comet very different from those calculated from his previous elements.

The present elements are as follows:—

T = 1913 Sept. 13·9168 M.T. Berlin.

$$\left.\begin{aligned}\omega &= 117^\circ\ 7'\ 51''\\ \Omega &= 157^\circ\ 9'\ 59''\\ i &= 143^\circ\ 24'\ 25''\end{aligned}\right\}1913{\cdot}0.$$

$\log q = 0{\cdot}133805$

As this comet is getting brighter and higher up in the sky, it should be observable with telescopes of small aperture.

COMET 1913*c* (NEUJMIN).—This comet, discovered by Neujmin, is becoming fainter, being now nearly of the 12th magnitude. For the sake of those who wish to follow it further with larger telescopes, the following ephemeris by Herr M. Ebell, taken from a supplement to the *Astronomische Nachrichten*, No. 4680, is given:—

12h. M.T. Berlin.

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.

,, 29	23 38 36	6 57·9	
,, 30	23 38 19	7 10·0	
Oct. 1	23 38 3	7 21·6	
,, 2	23 37 49	7 32·7	12·1

ANNALS OF THE BUREAU OF LONGITUDES.—Containing accounts of the inception, organisation, programmes, and transactions of two international conferences which have led to results of the highest practical importance in applied astronomy, the ninth volume of the Annals of the Bureau of Longitudes attains the distinction of being not only a valuable document in the history of that science, but also of marking a stage in the growth of international cooperation in scientific work. Of the successful issue of the Congrès des Ephémérides, let us recall only the sixth of the seven general resolutions adopted, namely, that the names of stars should be accompanied by designations of their spectral type after the notations of Pickering. The work last autumn of the Conférence Internationale de l'Heure, of course, chiefly centred around the employment of wireless telegraphy not only in the distribution of time, but also in the service of meteorology. The value of these applications is attested both by the rapidly increasing numbers using the time-signals, especially on land, and by the fact that it has recently been found necessary to add more than a dozen stations to the original six for which the meteorological elements were distributed on the resolution of the conference.

In addition to the reports just mentioned, the volume also contains a detailed account of the determination by wireless telegraphy of the difference in longitude between Paris and Bizerta.

SPECTRUM OF WOLF-RAYET STAR D.M. $+30°$ 3639.—Mr. Paul W. Merrill records in the Lick Bulletin, No. 230, the result of the examination of the red end of the spectrum of the Wolf-Rayet star D.M. $+30°$ 3639, the photographic magnitude of which is 10·0, and position for 1900·0 R.A. 19h. 30m. 8s., Dec. $+30°$ 18′. The following previously observed bright lines appear:—λ4652 broad; $H\beta$ monochromatic, strong; λ5694 broad; λ581 broad, trace; D_3 doubtful; $H\alpha$ monochromatic, strong. In addition to the above, the following two bright lines appear:—λ6548·5 monochromatic, 0·4 as strong as $H\alpha$; λ6583·4 monochromatic, slightly stronger than $H\alpha$. The chief nebular lines are not seen in the star's spectrum. It is pointed out that these two nebular lines were observed by Wright in the nebula N.G.C. 7027, but are otherwise unidentified. While the two lines appear together it does not necessarily follow that their origins are identical.

THE BERLIN MEETING OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION.

THE meeting of the International Electrotechnical Commission was held in Berlin at the Kunstlerhaus from September 1 to September 6. It was well attended, twenty-four nations being represented by seventy delegates. In addition to the voting delegates sent by the local committees of the countries represented, some of the Governments also nominated their official representatives, those representing England being Dr. Glazebrook, who was unfortunately not able to attend, Dr. Gisbert Kapp, Dr. Silvanus P. Thompson, and Mr. Duddell, the president of the Institution of Electrical Engineers. The German Government was represented by Dr. Jaegar, Geheimrat Dr. Strecker, and several others. Unfortunately, Dr. E. Budde, the president of the International Electrotechnical Commission, was absent through illness, but his place was very efficiently filled by Dr. Warburg, the president of the Reichsanstalt.

The commission was welcomed on behalf of the German Government by Dr. Lewald, Director of the Ministry of the Interior. Prof. Paul Janet, of the Laboratoire Centrale, Paris, replied on behalf of the commission.

The proceedings were opened by the reading of the report of the honorary secretary, Col. Crompton, on the work which had been accomplished up to date and confirmed by the last plenary meetings held two years previously at Brussels; he also briefly described the new work which had been prepared during the two years' interval by the various national committees, and by the four special committees which had been appointed to bring forward the four main subjects requiring international treatment; and which required confirmation at this the second plenary meeting, to ensure final acceptance by all the national committees.

The first two days were occupied by the final meetings of the special committees. The first, and certainly the most difficult, question to be decided internationally, was that of providing a means of international rating of electrical machinery. This matter, touching closely as it does on industrial questions, was naturally very warmly debated, both in the meetings of the special committee, which was presided over by Huber Stockar, the well-known Swiss engineer, and at the full meeting, but although much valuable evidence was brought forward on the test methods to be adopted for international rating, the only figures that were unanimously agreed to were the final temperatures permissible in the hottest parts of working generators, motors, and transformers, but the remaining very necessary factors, namely agreement as to temperature-rise and as to the standard temperature of the ambient air from which the temperature-rise must be calculated, were not considered to be sufficiently settled to allow of unanimity.

On the latter point the English and American engineers insisted on taking the ambient air temperature at a figure of 40° C., which is very frequently obtained at certain times of the year in all tropical and in many temperate climates, especially in engine-rooms, stokeholds, and similar places. It will be noted that the choice of this high temperature is greatly to the advantage of a purchaser, as it ensures that a machine ordered on standard international rating will be a somewhat large machine capable of a larger overload in cool weather than was hitherto considered necessary by manufacturers. The majority of the meeting was apparently in favour of adopting this high figure so favourable to the consumer; but the German and Swedish engineers thought that the matter was too important to be decided off-hand, so the filling in of these two figures is left for further consideration by the national committees. It is hoped that an agreement may be arrived at in the course of this year, or at any rate before the next plenary meeting, which is to be held at San Francisco two years hence.

The reports and the recommendations of the three other special committees, first that on nomenclature, second on the international standardisation of symbols in use for formulæ, and third on the definitions and terminology for prime-movers used for electrical generating plant, were all unanimously adopted. It is needless to point out that the unification of symbols is of immense benefit to the engineering student, and the unanimity arrived at by a number of delegates who, in the majority of cases, are largely interested in other branches, and particularly mechanical engineering, makes it probable that this unification of symbols will extend to all branches of engineering science, and perhaps eventually to all branches of physical investigation.

As regards nomenclature, although the work done is undoubtedly good and useful, at first sight it seems small in amount, as a list of only eighty terms with the expressions defining them was adopted. It has been found necessary to modify the original arrangements by which there should be two official languages, English and French, to which others should be referred, but the inconvenience of having two languages of reference was so marked that the English agreed to forego their claim that English should continue to be one of the official languages, French now remains as the one language of reference from which all words and expressions must be translated, but it was decided that the vocabulary which has now been prepared should contain the official corresponding words now agreed to, in four languages—French, English, German, and Spanish. The delegates from five countries using the Spanish language informed the meeting that this unification of terms in the Spanish language would be of great service to them, for already misunderstandings had arisen, as some of the South American countries using the Spanish language had shown a tendency to adopt different Spanish words for one and the same expression.

Another matter satisfactorily settled was the copper standard, which had long been discussed between the four National Physical Laboratories of England, France, Germany, and America, and the ultimate figures were agreed to, so that the tables of copper conductors based on this standard will be common to all the countries.

Mr. Maurice Leblanc, of Paris, was unanimously elected to succeed Dr. Budde, as president of the I.E.C., for a term of two years, and he will therefore preside at San Francisco.

Colonel Crompton was re-elected honorary secretary for the third time.

The Spanish delegates invited the special committees to hold their next meetings in April next in Madrid, and the Russian delegate, Prof. de Chatelain, on behalf of the Russian Committee, invited the I.E.C. to hold the plenary meeting of 1917 in St. Petersburg.

BUDGETS OF CERTAIN UNIVERSITIES AND UNIVERSITY COLLEGES IN ENGLAND AND WALES.

THE reports for the year 1911–12 from those universities and university colleges in Great Britain which are in receipt of grant from the Board of Education have been issued in two bulky volumes (Cd. 7008 and Cd. 7009). The first volume contains reports from the provincial universities and university colleges in England, and the second reports from the London college, including the medical schools, the Welsh colleges, and Dundee University College.

The tabular matter which precedes the separate reports from the various universities contains detailed information as to the income and expenditure of the places of higher education concerned. The following summaries have been compiled from the tables, and show at a glance the amount available for education and research in the universities and colleges receiving Treasury grants and how the income is expended.

UNIVERSITIES AND UNIVERSITY COLLEGES.

(1) ENGLAND.

(*a*) *Income.*

	Amount £	Percentage of total
Fees	180,371	29·0
Endowments	85,435	13·7
Donations and Subscriptions	22,437	3·6
Annual Grants from Local Authorities	95,875	15·4
Parliamentary Grants	215,003	34·5
Contributions from Hospitals, &c., for services rendered	659	0·1
Other Income	22,694	3·7
Total	622,474	100·0

(*b*) *Expenditure.*

	Amount £	Percentage of total
Administration	64,528	10·7
Provision and Alteration of Buildings	6,785	1·1
Maintenance	63,714	10·6
Educational Expenses	400,001	66·4
Superannuation	13,575	2·3
Scholarships, &c., from sources other than Trust Funds	9,187	1·5
Other Expenses	44,228	7·4
Total	602,028	100·0

(2) WALES.

(*a*) *Income.*

	Amount £	Percentage of total
Fees	18,117	28·2
Endowments	4,191	6·5
Donations and Subscriptions	1,911	3·0
Annual Grants from Local Authorities	5,283	8·2
Parliamentary Grants	33,805	52·7
Other Income	890	1·4
Total	64,197	100·0

(*b*) *Expenditure.*

	Amount £	Percentage of total
Administration	8,104	12·7
Maintenance	4,659	7·3
Educational Expenses	46,399	72·6
Superannuation	1,640	2·6
Scholarships, &c., from other than Trust Funds	395	0·6
Other Expenses	2,670	4·2
Total	63,867	100·0

The total income from endowments in England has increased by about 4500*l.*, due chiefly to new endowments for Reading University College, which bring in about 4000*l.* a year, and the increased income of about 1600*l.* a year available for East London College. On the other hand, the income from Welsh endowments has fallen by nearly 300*l.* The total income from donations and subscriptions shows some falling-off, both in England and Wales, owing in part at least to the exclusion of donations specially earmarked for scholarship purposes. The net annual grants from local education authorities show an increase of about 10,000*l.* in England and about 800*l.* in Wales. The income received from Parliamentary grants increased during the year by about 58,000*l.*

The expenditure during 1911–12 out of income upon the provision and alteration of buildings in England was more than 4000*l.* greater than in the previous year, owing in the main to heavy expenses at Leeds largely due to the provision of a hostel for women and to alterations and equipment at University College, London.

THE PILTDOWN SKULL.

IN his evening lecture to the British Association at Birmingham on September 16, Dr. Smith Woodward took the opportunity of replying to Prof. Arthur Keith's recent criticisms on his reconstruction of the Piltdown skull. It will be remembered that Dr. Woodward regarded the mandible as essentially that of an ape, and restored it with ape-like front teeth, while he determined the brain-capacity of the skull to approach closely the lowest human limit. Prof. Keith, on the other hand, modified the curves of the mandible to accommodate typically human teeth, and reconstructed the skull with a brain-capacity exceeding that of the average civilised European.

Fortunately, Mr. Charles Dawson has continued his diggings at Piltdown this summer with some success, and on August 30, Father P. Teilhard, who was working with him, picked up the canine tooth which obviously belongs to the half of the mandible originally discovered. This tooth corresponds exactly in shape with the lower canine of an ape, and its worn face shows that it worked upon the upper canine in the true ape fashion. It only differs from the canine of Dr. Woodward's published restoration in being slightly smaller, more pointed, and a little more upright in the mouth. Hence, there seems now to be definite proof that the front teeth of Eoanthropus resembled those of an ape, and its recognition as a genus distinct from Homo is apparently justified.

The association of such a mandible with a skull of large brain-capacity is considered by Dr. Woodward most improbable, and he has made further studies of the brain-case with the help of Mr. W. P. Pycraft, who has attempted a careful reconstruction of the missing base. Dr. Woodward now concludes that the only alteration necessary in his original model is a very slight widening of the back of the parietal region to remedy a defect which was pointed out to him by Prof. Elliot Smith when he first studied the brain-cast. The capacity of the brain-case thus remains much the same as he originally stated, and he maintains that Prof. Keith has arrived at a different result by failing to recognise the mark of the superior longitudinal sinus on the frontal region and by unduly widening that on the parietal region.

It is understood that Mr. Dawson and Dr. Woodward will offer an account of the season's work to the Geological Society at an early meeting, and Prof. Elliot Smith will include a detailed study of the brain-cast of Eoanthropus in a memoir on primitive human brains which he is preparing for the Royal Society.

THE BRITISH ASSOCIATION AT BIRMINGHAM.

SECTION C.

GEOLOGY.

Opening Address by Prof. E. J. Garwood, President of the Section.

On the last occasion when members of the British Association met in Birmingham, in 1886, this section was under the able presidency of my friend Prof. T. G. Bonney, who at that time occupied the chair of geology at University College, London. Fifteen years later I succeeded him on his retirement from that post, and to-day I succeed him as president of this section, at the second meeting of the Association at Birmingham; and again I feel the same diffidence in following him as I did on the former occasion.

In his address in 1886 Prof. Bonney discussed the "Application of Microscopic Analysis to Discovering the Physical Geography of Bygone Ages."

Strangely enough, this title might apply almost equally well to the subject of my address to-day; but whereas Prof. Bonney employed for his purpose the evidence obtained from observations on mechanical sediments, I propose to deal with certain organically formed deposits with the same object

More than twenty years ago, whilst engaged in the study of the lower carboniferous rocks of Westmorland, I noticed the occurrence of certain small concretionary nodules of very compact texture, in the dolomites near the base of the succession in the neighbourhood of Shap.

Shortly afterwards, when examining the Bernician rocks of Northumberland, I again met with similar compact nodular structures. It was obvious, however, even at that time, that the Northumberland specimens occurred here at a much higher horizon than those which I had observed in Westmorland.

More recently, whilst studying the lithological characters of the lower carboniferous rocks of the North of England and the Border country, I have been still further impressed by the abundance of these nodular structures at several horizons, and the large tracts of country over which they extend. An examination of these nodules in thin sections showed their obvious organic character, and I was at first inclined to refer them to the Stromatoporoids. Dr. G. J. Hinde, who was kind enough to examine my specimens from the Shap district, reported, however, that they were probably not Stromatoporoids, but calcareous algæ, and referred me to the descriptions of Solenopora published by the late Prof. Nicholson and Dr. Brown.

Since then I have examined a large number of nodules collected from different horizons in the lower carboniferous rocks of Britain and Belgium; and the examination has convinced me that the remains of calcareous algæ play a very much more important part in the formation of these rocks than has hitherto been generally realised.

The majority of geologists in this country have been slow to recognise the importance of these interesting organisms, and, with the notable exception of Sir Archibald Geikie's text-book, we find but scant allusion in English geological works of reference to the important part played by calcareous algæ in the formation of limestone deposits.[1]

From the more strictly botanical standpoint, however, we are indebted to Prof. Seward for an admirable account of the forms recognised as belonging to this group, up to the date of the publication of his text-book on fossil plants in 1898; while in an article in *Science Progress,* in 1894, he has also dealt with their importance from a geological point of view.

Since these publications, not only have several new and important genera been discovered in this country and abroad, but the forms previously known have also been found to have a very much wider geological and geographical range than was formerly suspected. For these reasons I venture to hope that a summary of our knowledge of the part they play as rock builders, more especially in British deposits, will serve to stimulate an interest among geological workers in this country in these somewhat neglected organisms.

Previous to 1894, in which year Dr. Brown first referred Solenopora to the Nullipores, with the exception of the Jurassic and Tertiary Characeæ, we meet with little, if any, reference to the occurrence of fossil calcareous algæ in British deposits.

Indeed, in this country the subject has attracted but few workers, and they can almost be counted on the fingers of one hand. When we have mentioned the late Prof. H. A. Nicholson and Mr. Etheridge, jun., Mr. E. Wethered, Dr. Brown, Dr. Hinde, and Prof. Seward, we have practically exhausted the list of those who have contributed to our knowledge of the subject. To these we may add the name of Mrs. Robert Gray, whose magnificent collection of fossils from the Ordovician rocks of the Girvan district has always been freely placed at the disposal of geological workers, and has furnished numerous examples of these organisms to Prof. Nicholson and the officers of the Geological Survey.

It was Nicholson and Wethered who first recognised the important part played in the formation of limestones by certain organisms, which, though referred at the time to the animal kingdom, are now generally considered to represent the remains of calcareous algæ.

The presence of these organisms in a fossil state, especially in the older geological formations, has only been recognised in comparatively recent years; though it was suggested as long ago as 1844 by Forchhammer[2] that fucoids, by abstracting lime from sea-water, probably contributed to the formation of Palæozoic deposits. When we remember that it was

[1] Geikie. "Text-book of Geology." 4th ed., vol. i, pp. 605 and 611. 1903.

[2] British Association, 1844, p. 155.

not until the researches of Phillipi were published in 1837 that certain calcareous deposits were discovered to be directly due to the growth of living forms of lime-secreting algæ, it is not surprising that, only in comparatively recent years, has the importance of the fossil forms as rock-builders in past geological formations been recognised.

The original genera established by Phillipi—namely, Lithothamnion and Lithophyllum—are known now to have a wide distribution in the present seas, and it is therefore natural that it was members of these groups which were the first to be recognised in a fossil state in Tertiary and, subsequently, in upper cretaceous rocks.

Thus in 1858, Prof. Unger of Vienna showed the important part played by Lithothamnion in the constitution of the Leithakalk of the Vienna Basin, while seven years later Rosanoff contributed further to our knowledge of tertiary forms. In 1871 Gümbel published his monograph on the "so-called Nullipores found in limestone rocks," with special reference to the Lithothamnion deposits of the Danian or Maestricht beds. Since then Lithothamnion has also been reported from Jurassic rocks, and even from beds of Triassic age, though in the latter case, at all events, the reference to this genus appears to require confirmation. In this country the recognition of fossil calcareous algæ dates from a considerably later period. It will be best first to review the chief genera which appear to be referable to the calcareous algæ, and afterwards to show the part they play as rock-builders in the different geological formations.

Two important genera are usually recognised at the present day as occurring in the British Palæozoic and Mesozoic rocks—namely, Solenopora and Girvanella—and to these I propose to add Wethered's genus, Mitcheldeania, together with certain new forms from the Carboniferous rocks of the North of England, which appear also to be referable to this group.

Solenopora.

This genus was first created by Dybowski in 1877 for the reception of an obscure organism, from the Ordovician rocks of Esthonia, which he described under the name *Solenopora spongioides,* and regarded as referable to the Monticuliporoids.

Nicholson and Etheridge in 1885 (*Geol. Mag.*, p. 529) showed that the form described by Billings in 1861 as *Stromatopora compacta,* from the Black River limestones of North America, was in reality Dybowski's genus Solenopora, and in all probability was specifically identical with the form from Esthonia. Moreover, they considered that the organism they themselves had described under the name of *Tetradium Peachii* in 1877, from the Ordovician rocks of Girvan, was also referable to Billing's species, though perhaps a varietal form. Thus *Solenopora compacta* was shown to have a very wide distribution in Ordovician times.

Nicholson in 1888 defined the genus as including "Calcareous organisms which present themselves in masses of varying form and irregular shape, composed wholly of radiating capillary tubes arranged in concentric strata. The tubes are in direct contact, and no coenenchyma or interstitial tissue is present. The tubes are thin-walled, irregular in form, often with undulated or wrinkled walls, without mural pores, and furnished with more or fewer transverse partitions or tabulæ." [3]

At that time Nicholson still considered Solenopora as representing a curious extinct hydrozoon, though already, in 1885, Nicholson and Etheridge had discussed its possible relationship to the calcareous algæ. They did not, however, consider that there was sufficient evidence for concluding that the true structure of Solenopora was cellular, but added: "If evidence can be obtained proving decisively the existence of a cellular structure in Solenopora, then the reference of the genus to calcareous algæ would follow as a matter of course." [4]

In 1894 Dr. A. Brown investigated more fully the material which had been placed in his hands by Prof. Nicholson, and gave an account of all the forms referable to Solenopora known at that date.

To those already recorded, he added descriptions of four new species from the Ordovician rocks—namely, *S. lithothamnioides, S. fusiformis, S. nigra,* and *S. dendriformis,* the two latter being from the Ordovician rocks of Esthonia.

In the same paper also he published for the first time a description of a new species of Solenopora from the Jurassic rocks of Britain, to which Nicholson, in manuscript, had already assigned the name of *S. jurassica,* though, as will be pointed out later, it is probable that two distinct forms were included by Brown under this name.

This record of Solenopora from the lower Oolites of Britain extended the known range of this genus, for the first time, well into the Jurassic period. In this paper Brown first brought forward good evidence for removing Solenopora from the animal kingdom, and placing it among the coralline algæ, and Prof. Seward, in Vol. i. of his work on fossil plants, considers that there are good reasons for accepting this conclusion.

At the time of the publication of Dr. Brown's paper, and for some years afterwards, the only formations in which Solenopora was known to occur were the upper Ordovician and the lower Oolites. The diversity of forms, however, met with in the Ordovician rocks, and their widespread distribution, pointed to the probability of the existence of an ancestral form in the older rocks, while it also appeared incredible that no specimens of intervening forms should have been preserved in the rocks representing the great time-gap between the Ordovician and Jurassic formations.

In this connection Prof. Seward remarks [5]: "It is reasonable to prophesy that further researches into the structure of ancient limestones will considerably extend our knowledge of the geological and botanical history of the Corallinaceæ." This prophecy has been amply fulfilled, especially as regards this particular genus, and recent discoveries go far towards filling the previously existing gaps in our knowledge of the vertical distribution of this interesting genus.

Thus the recent detection in the lowest Cambrian rocks of the Antarctic continent of a form which appears to be referable to this genus enables us to trace the ancestry of Solenopora back almost to the earliest rocks in which fossils have yet been discovered, while the gap in the succession which previously existed between the Ordovician and Jurassic forms was decreased by the description in 1908 by Prof. Rothpletz of a new species *Solenopora Gothlandica,* from the Silurian rocks of the Faröe Islands in Gotland.[6] A large number of deposits, however, still remained, between the Gotlandian and lower Jurassic beds, from which no example of Solenopora had so far been recorded.

The identification, therefore, a few years ago, by Dr. G. J. Hinde, of examples of this genus from among the nodules I had collected from the Shap dolomites, is of considerable interest, as the presence of Solenopora in the lower Carboniferous rocks of this

country materially decreases the gap in our knowledge of the succession of forms belonging to this genus, which had previously existed.

Girvanella.

This organism, which is now known to be widely distributed in the Palæozoic and Mesozoic rocks of this country, was originally described in 1878 by Nicholson and Etheridge, jun., from the Ordovician rocks of the Girvan district. The genus was established to include certain small nodular structures composed of a felted mass of interlacing tubes, having a width of 10 and 18 μ, the cells being typically simple, imperforate tubes without visible internal partitions. The geno-type, *G. problematica,* was, however, at that time referred to the Rhizopods and regarded as related to the arenaceous foraminifera ("Silurian fossils in the Girvan district," 1878, p. 23). In 1888 Nicholson, in redescribing this genus in the *Geological Magazine*, compares Girvanella with the recent form *Syringammira fragillissima* of Brady.

More recently Mr. Wethered has shown that an intimate association frequently exists between Girvanella tubes and oolitic structure, and he has described several new species of Girvanella, from the Palæozoic rocks and also from certain Jurassic limestones.

The reference of Girvanella to the calcareous algæ, though not yet supported by incontestable evidence, has been advocated by several writers in recent years. Even as long ago as 1887, Bornemann, in describing examples of Siphonema (Girvanella Nich.), which he had discovered in the Cambrian rocks of the Island of Sardinia, suggested that this organism might belong to the calcareous algæ.

In 1891 Rothpletz noticed that some of the specimens of Girvanella which he had examined were characterised by dichotomous branching of the tubes; on this account he removed the genus from the Rhizopods to the calcareous algæ, placing it provisionally among the Codiaceæ. Three years later Dr. A. Brown, in summing up the evidence in favour of the inclusion of Solenopora among the nullipores, expressed the opinion that Girvanella might ultimately come to be regarded as referable to the Siphoneæ Verticillatæ.

In 1898, however, this genus was still only doubtfully placed with the calcareous algæ, for Seward, in his work on fossil plants,[7] remarks: "The nature of Girvanella, and still more its exact position in the organic world, is quite uncertain. . . . We must be content for the present to leave its precise nature still *sub judice,* and, while regarding it as probably an alga, we may venture to consider it more fittingly discussed among the Schizophyta than elsewhere."

In 1908, however, Rothpletz, in discussing the relationship of Spherocodium and Girvanella, reaffirms his opinion that the latter must be referred to the Codiaceæ.[8]

Mitcheldeania.

This genus was first described by Mr. Edward Wethered from the lower Carboniferous beds of the Forest of Dean[9] under the name of *Mitcheldeania Nicholsoni*; it was referred by him to the Hydractinidæ, and considered to be allied to the Stromatoporoids. The figure accompanying this paper unfortunately fails to show any of the characters of the organism, but a better figure of the same species was subsequently published in the Proceedings of the Cotteswold Naturalists' Field Club.[10]

[7] Vol. i, p. 125.
[8] Rothpletz. "Ueber Algen und Hydrozoen," *op. cit.*
[9] "Geol. Mag.," Dec. 3, 3, ccccxxxv, 1886.
[10] Vol. ix. p. 77, pl. v., 1886.

In 1888 Prof. H. A. Nicholson published in the *Geological Magazine* figures and descriptions of a new species of this genus (*M. gregaria*), and redefined the genus as having "the form of small, rounded, or oval calcareous masses made up of capillary tubes of an oval or circular shape, which radiate from a central point or points, and are intermixed with an interstitial tissue of very much more minute branching tubuli." He compares the larger tubes to zooidal tubes, and states that they "communicate with one another by means of large, irregularly-placed foramina resembling 'the mural pores' of the Favisitidæ, and they occasionally exhibit a few irregular transverse partitions or tubulæ."

With regard to the systematic position of this genus, Nicholson remarks: "In spite of the extreme minuteness of its tissues, the genus Mitcheldeania may, I think, be referred with tolerable certainty to the Cœlenterata . . . its closest affinities seem to be with the hydrocorallines . . . on the other hand, all the known hydrocorallines possess zooidal tubes which are enormously larger than those of Mitcheldeania; and there are other morphological features in the latter genus which would preclude its being actually placed, with our present knowledge, in the group of the Hydrocorallinæ."

Since this description by Prof. Nicholson, no further account of this organism, so far as I am aware, has been published, and its reference to the Hydrozoa rests on Prof. Nicholson's description.

During the past few years I have collected a large amount of material from both of the type localities from which Mr. Wethered and Prof. Nicholson obtained their specimens, and an examination of this material has impressed me strongly with the resemblance of Mitcheldeania to forms such as Solenopora and Girvanella, now usually classed among the calcareous algæ. In the rocks in which it occurs Mitcheldeania appears as rounded and lobulate nodules, breaking with porcellanous fracture and showing concentric structure on weathered surfaces, very similar to nodules of Solenopora; while under the microscope the branching character of the tubules and their comparatively minute size appear to separate them from the Monticuliporoids. Prof. Nicholson appears to rely on the presence of pores, which he thought he observed in the walls of both the larger and finer tubes, for the inclusion of this genus with the hydrocorallines, though he appeared to be doubtful about their occurrence in the interstitial tubuli. An examination of a large number of slides has failed to convince me of the presence of pores, even in the larger "zooidal tubes." The large "oval or circular" apertures noticed by Nicholson appear to be either elbows in the undulating tubes cut across where these bend away from the plane of the section, or places where a branch is given off from a tube at an angle to the plane of the section. If this view be accepted, there appears to be no sufficient reason why Mitcheldeania should not be ranged with Solenopora and other similar forms, and included among the calcareous algæ—a position which its mode of occurrence and general structure has led me, for some time, to assign to this organism.

In addition to the three chief forms described above from British rocks, a study of numerous thin sections from the Lower Carboniferous rocks of the north-west of England has revealed the presence of several distinct organisms, which will, I think, eventually be found to be referable to the calcareous algæ.

This meagre list appears to exhaust the genera known at the present time from the Lower Carboniferous rocks of Britain, while the only additional genus so far recorded from the Mesozoic and Tertiary rocks of this country (if we except Rothpletz's subgenus Solenoporella) is Chara from the Wealden beds of Sussex, the uppermost Jurassic of the Isle of Wight and Swanage, and the Oligocene of the Isle of Wight.

Outside of this country the literature on fossil calcareous algæ is much more extensive. The interest originally aroused on the Continent by the writings of Phillipi, of Unger of Vienna, Cohn, Rosanoff, Gümbel, Saporta, and Munier-Chalmas has been further maintained in our own time by Bornemann, Steinmann, Früh, Solms-Laubach, Rothpletz, Walther, Kiaer, and others; while the more favourable conditions which obtained for the growth of these organisms, especially during Silurian, Triassic, and Tertiary times, has afforded a much wider field for their observation.

Thus, in addition to the forms recorded from this country, an important part has been played by members of the family of the Dasycladaceæ, together with such genera as Spherocodium, Lithothamnion, and Lithophyllum.

It is now time to turn to the consideration of the part played by these organisms in the formation of the sedimentary rocks through the successive geological periods.

ARCHÆAN.

In the Archæan rocks no undoubted remains of Algæ have, so far as I am aware, yet been recorded, but Sederholm considers that certain small nodules in the Archæan schists of Finland may represent vegetable remains. I may also perhaps here refer to some curious oolitic structures which I met with in Spitsbergen in 1896 when examining the rocks of Hornsund Bay. These oolites occur on the south side of the bay, and are closely connected with massive siliceous rocks which may represent old quartzites. The whole series is much altered, and detailed structure cannot now be made out. The rocks occur apparently stratigraphically below the massif of the Hornsund Tind, and may belong either to the Archæan or the base of the Heckla Hook series. As, however, similar rocks have not been recorded from the type district of Heckla Hook, they may be referred provisionally to the Algonkian, and may represent the quartzites and earthy limestone of the Jotnian series of Scandinavia. They are mentioned here in connection with Mr. Wethered's view that oolites are essentially associated with the growth of Girvanella.

CAMBRIAN.

Passing on to the Palæozoic rocks, we find in the Cambrian deposits very few indications that calcareous algæ played any considerable part in their formation.

This is no doubt due, in part, to the conditions under which these deposits accumulated in the classical localities where true calcareous deposits are typically absent. In the Durness limestone, however, where considerable masses of dolomites occur, the conditions would appear at first sight to have been more suitable for the growth of these organisms; but even here the slow rate of accumulation and the large amount of contemporaneous solution may have militated against their preservation. At the same time, it is possible that a systematic search in the calcareous facies of the Cambrian rocks in the north of Europe and America might result in the discovery of the remains of some members of this group. That there is ground for this suggestion is shown by the recent work in the Antarctic continent.

Prof. Edgworth David and Mr. Priestly have discovered among the rocks in the north-west side of the Beardmore Glacier dark grey and pinkish-grey limestone containing the remains of Archæocyathinæ, Trilobites, and sponge spicules, together with abundant remains of a small calcareous alga referred provisionally to Solenopora; from the photographs exhibited by Prof. David on the occasion of his address to the Geological Society I have little doubt that this reference is correct.

A further occurrence is also reported from fragments of a limestone breccia collected by the Southern party from the western lateral moraine of the same glacier. Speaking of the fauna discovered in this limestone, Prof. David remarks: "The whole assemblage is so closely analogous with that found in the Lower Cambrian of South Australia as to leave no doubt as to the geological age of the limestones from which these fragments are derived."[11] This discovery, therefore, extends the vertical range of this widely spread genus down to the oldest Palæozoic rocks. It is interesting to note that the rocks in which the Solenopora occurs contain a development of pisolite and oolite, and that this is also the case in the Australian equivalents. In 1887 and again in 1891 Bornemann described and figured species of Siphonema and Confervites[12] from the Archæocyathus limestones of Sardina. As regards the former genus, it was shown by Dr. Hinde[13] to be congeneric with Girvanella (Nich and Eth). It is of interest, however, to note that Bornemann describes this form as a calcareous alga, and compares it with existing sub-aerial algæ growing on the surface of limestone rocks in Switzerland. The latter is stated by Seward to be possibly "a Cambrian algæ, but the figures and descriptions do not afford by any means convincing evidence."

More recently, in 1904, Dr. T. Lorenz has described remains of Siphoneæ from the Cambrian rocks of Tschang-duang in Northern China, for which he erects two new genera, Ascosoma and Mitscherlichia, placing them in a new family, the Ascosomaceæ. These algæ build important beds of limestone, the individuals often attaining a length of 4 cm. and a thickness of 1½ cm. In 1907 Bailey reported Girvanella associated with oolites in the lowest Cambrian Man-t'o beds in China. It is probable, therefore, that as our knowledge of these rocks is extended calcareous algæ will be found to play an important part in the Cambrian limestones of the Asiatic continent and Australia.

ORDOVICIAN.

In the Ordovician rocks, the remains of calcareous algæ become much more abundant. They are very widely distributed, and for the first time they become important rock-builders. In Britain, the chief genera met with are Girvanella and Solenopora. These two organisms occur abundantly in the Scottish Ordovician rocks of the Girvan area, where they appear to have contributed largely to the limestones of the Barr series in Llandeilo-Caradoc times.

As already mentioned, the genotype of Girvanella—*G. problematica*—was originally described by the late Prof. Nicholson and Mr. Etheridge, jun., from the Craighead limestone, where it occurs in great numbers in the Craighead limestone at Tramitchell. The officers of the Geological Survey also report it from the Stinchar limestone of Benan Hill.

It occurs in the form of small rounded or irregular nodules, varying in diameter from less than a millimetre to more than a centimetre—many of the nodules showing marked concentric structure. During a recent visit to Girvan I was much struck by the important part played by this organism in the formation of these upper compact limestones In Benan Burn, where these beds are admirably exposed, the

[11] Eleventh Inter. Congress Report, 1910, p. 775.
[12] "Nova Acta. Coes. Leop. Car.," 1887 and 1891.
[13] Hinde, "Geol. Mag.," 1887 p. 226

Girvanella nodules occur conspicuously on the weathered surfaces, being so abundant as to constitute thick layers of limestone.

Solenopora compacta, var. *Peachii*, which, likewise, forms important masses of limestone, occurs, like *Girvanella problematica*, in the Girvan area, but at a somewhat lower horizon, namely, in the nodular limestone and shales forming the lower sub-division of the Stinchar limestone. It was originally described from pebbles in the Old Red Conglomerate of Habbie's Howe by Nicholson and Etheridge, jun., under the name *Tetradium Peachii*, and was subsequently discovered to occur plentifully in the Ordovician limestone at Tramitchell and Craighead, and to be synonymous with *Solenopora compacta* (Bill). In the shales associated with the nodular limestone of Craighead it occurs as spheroidal and botryoidal nodules up to 1½ in. in diameter; while in the limestone itself the nodules may have a diameter of 3 in. On freshly fractured surfaces it appears as buff-coloured on brownish spots, having a compact porcellanous texture, while weathered surfaces often show a concentric structure. Under the microscope the tubes of this species vary in diameter from 50–80 μ.

In the Geological Survey Memoir it is also recorded, under the original name of *Tetradium Peachii*, from the Stinchar limestone of Benan Burn, Millenderdale, and Bougang, where it is accompanied by two other species, *S. filiformis* and *S. fusiformis*,[14] which contributes conspicuously to the deposit, often forming large masses of limestone. The horizon of the Stinchar limestone is correlated by Prof. Lapworth with the Craighead limestone, and considered to represent the summit of the Llandeilo or the base of the Caradoc of the Shropshire district. It is of interest to note that Solenopora is here accompanied at times by well-marked oolitic structure, and that the same is true of the pebbles with which it is associated in the conglomerate at Habbie's Howe.

Although the marked development of Solenopora found in the Stinchar limestone ceases with the advent of the Benan conglomerate, the genus appears to have survived in the district into Upper Caradoc times, for Dr. Brown describes a new species (*S. lithothamnioides*) from Nicholson's collection from the Ordovician (? Silurian) at Shalloch Mill, where it occurs in conical masses the size of a walnut. The only beds in which we might expect algæ to occur in this locality are the nodular limestones or Dionide beds of the Whitehouse group of Prof. Lapworth's classification, but there is no mention of Tetradium or Solenopora from this locality in the fossil lists cited from Mrs. Gray's collection in the survey memoir.

As this point is of some interest, I have consulted Mrs. Gray, who very kindly sent me some small nodules which she had collected from the Whitehouse beds of Shalloch Mill. On slicing one of these I find that it is undoubtedly a Solenopora, and probably the species figured by Dr. Brown as *S. lithothamnioides*. A tangential section cut from this specimen shows clearly why the original specimen of Solenopora from Craighead was mistaken for Tetradium by Nicholson and Etheridge, jun.

South of the Scottish border there is, so far as I am aware, only one locality from which calcareous algæ have been recorded in rocks of Ordovician age, namely, Hoar Edge in Shropshire. Here large examples of *Solenopora compacta* were obtained in 1888 by Prof. Lapworth from the calcareous layers near the base of the Hoar Edge sandstone. The specimens were handed to Prof. Nicholson, who records the circumstance in his description of *S. compacta* in the *Geological Magazine* for 1888. The form

[14] Brown, *op. cit.*, pp. 195–197.

occurs here at the base of the Caradoc beds, and therefore at a horizon which corresponds closely to that of the Craighead limestone of Girvan.

Prof. Lapworth also informs me that he has obtained specimens of Solenopora from a limestone in south-west Radnorshire. As the upper portion of the limestone in which it is found contains a Silurian fauna, it is possible that it is here present at a higher horizon, though the constancy with which it occurs elsewhere, in beds of Llandilo-Caradoc age, would seem to point to the possible presence of beds of Upper Ordovician age in this area. In any case, its occurrence here is of considerable interest.

Foreign Ordovician.

Outside of Britain, one of the most interesting developments of calcareous algæ in rocks of Ordovician age occurs in the Baltic provinces.

As already stated, Solenopora was first recorded from Herrküll in Esthonia, by Dybowski under the name of *Solenopora spongioides*. It occurs here in the Upper Caradoc or Borckholm beds of Schmidt's classification—where it makes up thick beds of limestone—and it is noteworthy that this horizon is practically identical with that at which *S. lithothamnioides* (Brown) occurs at Shalloch Mill.

Other specimens of *Solenopora* were collected by Prof. Nicholson in Saak, south of Reval, from the underlying Jewe beds, an horizon which corresponds very closely to that of the Craighead limestone of Girvan. Speaking of these beds, Nicholson and Etheridge remark: "At this locality *S. compacta* not only occurs as detached specimens of all sizes, but it also makes up almost entire beds of limestone; indeed, some of the bands of limestone at Saak look like amygdaloidal lavas, while others have a cellular appearance from the dissolution out of them of the little pea-like skeletons of this fossil."

In Prof. Nicholson's collection from these beds Dr. Brown afterwards distinguished two new species, namely, *S. nigra* and *S. dendriformis*. Thus in the Ordovician rocks of Esthonia, Solenopora plays quite as important a part (as a rock-forming organism) as it does in the Girvan district in Ayrshire.

In Norway again, in the Mjösen district to the north of Christiania, Solenopora occurs plentifully in Stage 5 of Kiaer's Ordovician series. Here it is very abundant and often builds entire beds, while, further east, at Furnberg, Kiaer again records the occurrence of abundant nodules of *Solenopora compacta*, var. *Peachii*.

In addition to Solenopora, however, examples of another important group of calcareous algæ, the Siphonæ, occur in great abundance in the Ordovician rocks of the Baltic region, where they play a part in the formation of calcareous rocks, scarcely less important than that played by Gyroporella and Diplopora in the rocks of the Alpine Trias.

The chief forms belong to the family of the Dasycladaceæ, represented by the recent genus Neomeris, and include the genera Palæoporella, Dasyporella, Rhabdoporella, Verimporella, Cyclocrinus, and Apidium. These algal limestones represent the beds from the Jewe to the Borckholm beds inclusive. They were originally investigated by Dr. E. Stolley, who described their occurrence in the numerous boulders which are strewn over the North German plain in Schleswig-Holstein, Pommerania, Mecklenburg, and Mark-Brandenberg. Many of these boulders can be identified by their lithological character and fossil contents as belonging to the Jewe beds of the Baltic Ordovician formations. Others have been derived from the overlying Wesenberg limestones, while yet others occur which resemble the succeeding Lyckholm beds of the Baltic succession. This assemblage proves that the boulders did not originate on the Swedish continent, but from the more easterly-lying districts, probably from a part of the Baltic between Oeland and Estland, now covered by the sea. Similar boulders are also known at Lund in Schœnen, on Bornholm, and near Wisby in the north of Gotland.

These facts appear to show that during the deposition of the Jewe and the overlying Wesenberg and Lyckholm limestones an algal facies obtained which extended from Oeland to Estland and as far north as the Gulf of Bothnia.

But even this area does not represent the full extent of the algal limestone facies in Upper Ordovician times. In Norway, Kiaer has shown by his detailed work in the Upper Ordovician rocks, Stage 5 of the Christiania district, the important part played by the Dasycladacea in this area. Here the Gastropod limestone in places forms a "phytozoan limestone," made up of Rhabdoporella, Vermiporella, and Apidium associated with a considerable development of oolite.

Again at Kuven and Valle, in the Bergen district, Reusch and Kolderup have described knolls of crystalline limestone containing abundant remains of Rhabdoporella (formerly described as Syringophyllum) associated with a gastropod and coral fauna. This horizon they have unhesitatingly referred to zone 5*a* of Kiaer's sequence, and state that it may be found stretching from Geitero in the S.S.W. by Kuven, Valle, and Trengereid to Skarfen on Ostero, while Reusch has traced it further south to Stordo, near Dyviken and Vikenes.

We have, therefore, in Upper Ordovician times, in the north of Europe, one of the most remarkable developments of algal limestones met with throughout the geological succession. In North America also algæ are represented in Ordovician times by *Solenopora compacta*, which occurs in the Trenton and Black River limestones groups, whence it was originally obtained by Billings. It therefore occurs here at about the same horizon as in Saak and Britain.

We may also note the occurrence of Girvanella in the underlying Chazy limestone originally described by the late Prof. H. M. Seeley under the name *Strephochetus ocellatus*, but now generally admitted to be a form of Girvanella.

Other forms referred to this genus have also been reported by Schuchert from rocks of undoubted Ordovician age on the east coast of the Behring Straits.[15]

Silurian.

The rocks of Silurian age in Britain, in which calcareous algæ play an important part, appear to be limited to the Wenlock limestone, from which Mr. Wethered has described the constant occurrence of Girvanella tubes, especially in the beds of this age at May Hill, at Purley, near Malvern, and Ledbury.[16] Of these beds Mr. Wethered remarks: "The most interesting result of the microscopic study of these rocks was the discovery of new and interesting forms of Girvanella and the fact that this organism has taken so important a part in building up the limestone." It may here be mentioned that it was whilst studying these forms in the Wenlock limestone that Mr. Wethered first began to favour the suggestion of Rothpletz, published two years previously, in favour of Girvanella belonging to the calcareous algæ, for he remarks: "I certainly think that the forms which I have discovered in the Wenlock limestone seem more favourable to the vegetable theory of the origin of this fossil than those described in my former paper, and possibly it may be allied to the calcareous algæ."

So far as I can ascertain, this is all that has been published up to the present time with regard to the occurrence of calcareous algæ in British Silurian rocks; but I have every confidence that a more thorough microscopic examination of these rocks will reveal the presence of many other examples of this group.

Foreign Silurian.

Outside Britain at this period we find the most marked development of an algal facies, once more in the Baltic area, where, especially in the island of Gotland, algal growths contribute enormously to several of the limestones and marls. It is an interesting fact that very shortly after the disappearance of the various members of the Dasycladaceæ which were so much in evidence in Ordovician times, we have the marked development of another group of the Siphoneæ, which quickly reached a maximum, building up in their turn abundant calcareous deposits. Nodules from these limestones have long been known from Gotland under the name of "Girvanella Rock," and have been recorded by Stolley in boulders scattered over the North German plain. In 1908, however, Prof. Rothpletz showed, in his interesting work on these Gotland deposits,[17] that the forms hitherto alluded to under the term "Girvanella" were in reality referable to two different genera. One of these he showed to be a new species of Solenopora, to which he gave the name *S. gothlandica* (distinguished from *S. compacta* by the comparatively small dimension of the tubes, which are only about one quarter of the diameter of *S. compacta*, the genotype); the other he referred to his genus Spherocodium, which he had created in 1890 for certain forms from the Alpine Trias. The survival here of Solenopora into beds of undoubted Silurian age is an interesting fact and would lead us to expect that it may also some day be found in rocks of corresponding age in this country.

Of the different forms of algæ which occur in these Gotlandian deposits, perhaps the most interesting is Spherocodium. This organism occurs at several horizons in the succession. It first makes its appearance in the marl immediately overlying the Dayi flags—approximately of Lower Ludlow age—where Spherocodium occurs in considerable masses. Through the kindness of Dr. Munthe, who has made a special study of these beds in south Gotland, I have been able to examine specimens of this interesting form. In external appearance they resemble very closely nodules of Ortonella from the Lower Carboniferous of the north-west of England; some of the nodules appear to have reached a diameter of 1½ in. The bed is overlain by sandstone and oolite, which are succeeded by an argillaceous limestone rich in nodules of *Spherocodium gotlandicum* and well exposed at Grötlingbo, where it is closely associated with oolite. Among the fossils of this limestone Spherocodium itself plays a most important *rôle*.

In the overlying Iliona limestone, Spherocodium is decidedly rare, and its place is taken by nodules of Spongiostroma. It is, however, found not infrequently forming a thin crust on some of the nodules of Spongiostroma, which have also been described by Prof. Rothpletz (*op. cit.*). In appearance, Spongiostroma resembles very closely the nodules of Spherocodium, showing the same concentric arrangement round coral fragments and total absence of the radial structure which is so characteristic of Solenopora.

The actual systematic position of this organism, if organism it be, is still undecided. In his original

17 "Ueber Algen und Hydrozoen in Silur von Gotland und Oesel" Kungl. Sven. Vet. Handl. Band 43. No. 5, 1908.

description of this genus from the Carboniferous rocks of Belgium, Gürich refers it provisionally to the Protozoa, while Rothpletz in his description of the two species *S. balticum* and *S. Holmi* from the Gotlandian of Gotland, although admitting the difficulties of assigning it to any group of the animal kingdom, decides in favour of its hydrozoan affinities.

As will be pointed out later, there appears to be no good reason why Spongiostroma may not be indirectly the result of algal growths; but whatever may be the final position assigned to it, there can be no doubt as to its importance as a rock-building form in the Iliona limestone of Gotland. The wide extent of this algæ horizon in the Upper Silurian of the Baltic area is shown by the abundance of boulders of these rocks scattered over Schleswig-Holstein, and it is probable that a careful examination will show the presence of this facies in the Silurian to the east of the Baltic provinces.

We may conclude, therefore, that the development of the Spherocodium beds of Gotland probably occupy as wide an extension in the Baltic area as that of the Rhabdoporella limestones in the Ordovician period.

With regard to other occurrences in Silurian rocks, it will be sufficient to note that of Girvanella in the Silurian limestones of Queensland, Australia, recorded by Mr. G. W. Card in 1900, and more recently by Mr. Chapman from Victoria.[18]

Quite recently Mr. R. Etheridge, jun., of Sydney,[19] has described "an organism allied to Mitcheldeania from the Upper Silurian rocks of New South Wales"; the figures given, however, and the description are not convincing that his identification can be accepted. The size of the tubes, which are from five to six times that of the largest tubes of *M. gregaria*, alone would appear to separate this organism from Mr. Wethered's genus, and almost certainly from the calcareous algæ.

Devonian.

So far as I am aware, there is only one recorded occurrence of calcareous algæ in the Devonian rocks of Britain—namely, in the Hope's Nose limestone, from which Mr. Wethered has described aggregations of tubules resembling Girvanella, but in a very poor state of preservation. It is hoped that this meagre list will be increased in the near future.

Foreign Devonian.

On the Continent the records are, so far, equally poor. At the same time, the cursory examination which I was able to make of the thin sections of the Devonian limestones exhibited in the Brussels Museum leads me to expect that a careful investigation of the Belgian Devonian limestones will yield other examples besides Spongiostroma.

Carboniferous.

We now reach the period in Paleozoic times when calcareous algæ attained their maximum development in England, a development rivalling that which obtained in the Ordovician rocks of Scotland and the Gotlandian of Scandinavia. The genera here represented include Girvanella, Solenopora, and Mitcheldeania. In addition to these, there occur several lime-secreting organisms which, though still undescribed, will, I think, ultimately come to be included among the calcareous algæ. The most interesting of these organisms I have recently figured from the Lower Carboniferous rocks of Westmorland, where it forms a definite zonal horizon or "band."[20] For this form, on account of its stratigraphical importance and for facility of reference, I propose the generic name of Ortonella.[21]

Again, at the same horizon in the North-west Province I have frequently noticed concretionary deposits of limestone which occur as finely laminated masses often lying parallel to the general direction of the bedding planes, which, on microscopic examination, show no definite or regular structure, but have every appearance of being of organic origin. Many of these puzzling forms resemble very closely the somewhat obscure structures found in the Visean limestones of the Namur basin in Belgium, of which beautiful thin sections are displayed in the Natural History Museum at Brussels,[22], and which Gürich has described and figured under various names—namely, Spongiostroma, Malacostroma, &c., and included under a new family the Spongiostromidæ,[23] and a new order, the Spongiostromaceæ. He gives the following definition of the family: "Organismes marins, incrustants, coloniaux, à structure stratifiée. La structure de la colonie est indiquée, à l'état fossile, par la disposition de petits grains opaques (granulations), entre lesquels il y a des interstices, tantôt plus étroits, tantôt plus larges—canaux du tissu et canaux coloniaux—donnant naissance à un tissu spongieux. Dans plusieurs formes, on a observé des Stercomes," and suggests that they may possibly have been encrusting foraminifera.

I must confess that neither in the original sections nor in the beautiful illustrations which accompany his work can I see any grounds for referring these structures to the protozoa.

As regards the British specimens, I have long regarded them as due, directly or indirectly, to the work of calcareous algæ, on account of their intimate association with well-developed examples of these organisms, and, secondly, on account of the entire absence of foraminifera and other detrital organisms wherever this structure occurs. As, however, I have little doubt that they are closely connected in their mode of origin with the Belgian specimens, we may conveniently speak of them under the general term Spongiostroma.

Some of the best examples known to me occur associated with Ortonella in the "*Productus globosus* band" near the summit of the "*Athyris glabristria* zone" in the Shap district. They occur here in considerable masses, often many inches in thickness, and form undulating layers parallel to the bedding, and somewhat resembling huge ripple-marks. Thin sections show little definite structure, but consist of what appears to be an irregular flocculent precipitate of carbonate of lime, the interstices being filled with secondary calcite. Some of the layers resemble almost exactly, both in hand specimens and microscopic structure, the figures of *Malacostroma concentricum* given by Gürich in plates xvii. and xx. (23). Others approach closely to the same author's figures of Spongiostroma, Aphrostroma, &c. In all cases they appear to be due to the precipitation of carbonate of lime in the neighbourhood of algal growths. I have also met with similar deposits, not only at other horizons in the Lower Carboniferous of the north of England, but also in the Forest of Dean and in the rocks of the Avon Gorge; while quite recently Mr. C. H. Cunnington has sent me examples from several horizons in the Carboniferous limestones of South Wales.

Girvanella.

This organism appears to play a considerable part in the formation of calcareous deposits in the Lower Carboniferous rocks of Britain. Its presence in these

[21] From Orton, a village between Shap and Ravenstonedale, where this organism occurs in great abundance.
[22] One of these is also exhibited at the Jermyn Street Museum.
[23] "Mem. du Musée Roy. d'Hist. Nat. de Belgique," iii, 1906.

rocks was first suggested by the late Prof. Nicholson,[24] in his paper where he remarks: "I have found some of the Carboniferous limestone of the north of England to contain largely an ill-preserved organism which will, I think, prove to be referable to Girvanella." This prophecy has turned out to be fully justified not only as regards the north of England, but also in the case of other Lower Carboniferous districts. In 1890 Mr. E. Wethered described[25] two new forms from the Lower Carboniferous of the Avon Gorge and Tortworth, viz., *G. incrustans*, with tubes having a diameter of 0·1 mm., and *G. Ducii* with a diameter of 0·02 mm. Mr. Wethered appears to rely chiefly on the size of the tubes for the differentiation of these species, but as this distinction was made at the time when Girvanella was still considered to belong to the Rhizopods, and as the size of the tubes frequently varies in the same specimen, it is doubtful whether these species can be maintained. Mr. Wethered's specimens were obtained from the limestone near where the Bridge Valley road joins the river bank, apparently at the base of Dr. Vaughan's Upper Dibunophyllum zone. The position of this limestone is of interest, as it appears to correspond very closely with the horizon of the Girvanella nodular bed, which forms a well-marked band at the base of the Upper Dibunophyllum zone throughout the whole of the north and north-west of England. Indeed, I have traced this band at intervals from the neighbourhood of Ford, near the Scottish border, southwards through Northumberland and the Pennine area to Penygent, and from the west coast at Humphrey Head through Arnside and Shap to the east coast, near Dunstanburgh. These organisms must, therefore, have flourished over an area of at least 3000 square miles.

The Girvanella tubes found associated with these nodules usually occur in two distinct sizes having diameters of 0·03 and 0·01 mm. respectively. The two forms are closely associated, but the finer tubes occur in greater abundance, and are much more closely interlaced. They resemble Mr. Wethered's description of the two species from Gloucestershire, and the figures he gives in illustration of these might serve very well to represent our northern forms.

The best exposure showing the important development of these Girvanella nodules is to be found on the dip slopes forming the eastern shore of Humphrey Head in Morecambe Bay, where the base of the Upper Dibunophyllum zone is exposed over a considerable area.

Solenopora.

The discovery of a specimen of this genus in the Lower Carboniferous rocks of Westmorland is of considerable interest, as its occurrence here gives us some insight into the history of its wanderings between the time when we last recorded it in the Gothlandian rocks of the Baltic area, and its reappearance in the Lower Oolite of Gloucestershire. Whether it lived in the Baltic area during the Devonian and Carboniferous periods is, however, still unknown. The fact of its occurrence in the Caradoc, Carboniferous, and Jurassic rocks of the British Isles would appear to point to its existence not far off during the intervening periods, and I have hopes that before long it may be found in the Silurian, and possibly also in the Devonian rocks of this country.

In Westmorland and Lancashire Solenopora occurs in considerable abundance near the local base of the Lower Carboniferous rocks, and contributes largely to the formation of limestone deposits. It is present wherever the lowest beds of the succession are exposed, as at Shap, Ravenstonedale, and Meathop, and must formerly have flourished over a considerable area.

Though bearing a general resemblance, both in hand specimens and microscopic structure to the Ordovician and Jurassic forms, it has recently been shown by Dr. G. J. Hinde to be specifically distinct.[26] It occurs as small, spheroidal nodules up to an inch in diameter, having a markedly lobulate outline embedded in compact and usually dolomitic limestones, and it is occasionally associated with oolitic structure. When fractured, it exhibits the compact porcellanous texture and pale brownish tint characteristic of specimens of the genus found at other horizons; while weathered surfaces frequently show a concentric and occasionally a radially fibrous structure. It is noteworthy that the thallus of this organism shows no trace of dolomitisation, even when embedded in limestone containing over 30 per cent. of $MgCO_3$. The profusion of this form in Westmorland would lead one to expect its occurrence in other districts where the lowest Carboniferous zones are developed; but so far as I am aware, no such occurrence has yet been recorded. It may be of interest, therefore, to mention here that a few years ago my friend, Mr. P. de G. Benson, brought me a specimen of rock from near the base of the succession in the Avon Gorge, which on cutting I found to contain several examples of Solenopora identical with the Westmorland form. It is probable, therefore, that a careful microscopic examination of the lower horizons of the Carboniferous rocks of the south-west province will lead to the discovery of other examples of this interesting genus.

Mitcheldeania.

The specimens of *Mitcheldeania Nicholsoni* originally described by Mr. Wethered were obtained from Wadley's Quarry, near Drybrook, Mitcheldean, from the lower limestone shales at the base of the succession. Prof. Sibly, who has recently made a careful study of the Lower Carboniferous succession in the Forest of Dean,[27] has traced this algal layer over a considerable area, and considers it to represent a horizon near the top of K.I. of the Bristol sequence. He has also noted examples of Mitcheldeania at a higher level, namely, in the Whitehead limestone, an horizon corresponding probably to the base of C2. During a recent visit to the Mitcheldean district I collected specimens from both the lower shales, and also from the Whitehead limestone, and, thanks to Prof. Sibly's kind directions, I was able to see numerous sections in which he has found this algal development. There can be no doubt that Mitcheldeania is here an important rock-forming organism at least at two horizons in this district, and that it occurs over a considerable area. In the case of the upper horizon it frequently contributes largely to the rock, forming in places almost entire layers in the Whitehead limestone. As regards the forms met with at these two horizons, the upper form found in the Whitehead limestone agrees exactly in general characters and mode of occurrence and also in detailed microscopic structure, with Nicholson's species, *M. gregaria*, from Kershope Foot. The character of the two sets of tubes, their size and mode of arrangement is identical, and it is impossible to distinguish between sections of well-preserved specimens from the two localities. Unfortunately, the specimens from the lower shales at Mitcheldean are very badly preserved, but if Nicholson's distinction between the two species holds, we shall have to speak of the form

24 *Op. cit.* p. 24.
25 *Q. J. G. S.*, vol. 47, p. 280, pl. 11, figs. 1 and 2. 1890.

27 *Geol. Mag.*, Dec. 5, 417.

from the lower horizon at Mitcheldean as *M. Nicholsoni,* and that from the Whitehead limestones as *M. gregaria.* Frequently associated with the latter is a curious *festoon-like* growth, while a Spongiostroma-like structure is often found in the matrix of the rock between the larger tubes of *M. Nicholsoni.* Some years ago Mr. Wethered also recorded a similar form of Mitcheldeania from the base of the middle limestones of the Avon Gorge, while I have myself collected nodules containing specimens apparently referable to *M. Nicholsoni* from the Modiola Shales near the base of the succession. Interesting as the development of Mitcheldeania in the Forest of Dean undoubtedly is, its real home in Britain is in north Cumberland and the Scottish border, where it flourished to a remarkable extent in the shallow water lagoons which spread over so large an area in the north of England during early Carboniferous times. Over the greater part of north Cumberland and the east of Roxburgh we find a remarkable development of algal limestones in the formation of which Mitcheldeania plays a very important part. They are met with especially at two horizons, an upper one, lying immediately below the Fell Sandstone, and a lower one in the middle of the underlying series of limestone and shales. The lower horizon is especially interesting on account of the thick masses of limestone composed almost entirely of algal remains. Though Mitcheldeania forms the basis of this reef-like development, it is accompanied by other algal forms, especially bundes of minute tubules of Girvanella and coarser tubes reminding one of the Spherocodium of Gotland. In places again the marked concentric coatings resemble certain forms of Spongiostroma. The substance of the reef has frequently formed round the remains of Orthoceratites; indeed, the chief layer is usually associated with remains of these Cephalopoda. With other layers occur tubes of Serpulæ, and others again with ostracod remains. In addition to the limestone of this massive reef, abundant nodules lie scattered through the calcareous shales above and below.

The upper layer, which includes examples from Nicholson's type locality, forms a compact limestone several inches thick. It is made up of small spheroidal nodules about half an inch in diameter, and occurs a short distance below the Fell Sandstone. It can be traced over the whole of north Cumberland and north-west Northumberland from near Rothbury on the east to the Scottish border at Kershope Foot, and from the head waters of the Rede in the north, to the Shopford district in the south. This layer must therefore have been originally deposited over an area of at least 1000 square miles. The horizon of the upper band is almost certainly that of the C. zone of the Bristol sequence.[28] It is quite possible, therefore, that it is contemporaneous with the Whitehead limestone of Mitcheldean. This supposition receives support from two other pieces of evidence. In the beds underlying the *Mitcheldeania gregaria* band in north Cumberland occur calcareous nodules largely made up of tubes of Serpulæ—an organism which is completely absent from the Westmorland succession, but which is reported by Prof. Sibly from the lower limestone shales containing Mitcheldeania in the Forest of Dean district. Again, this upper algal layer in Northumberland and Cumberland is almost immediately overlain by the Fell Sandstone series, while the Whitehead limestone at Mitcheldean passes immediately upwards into a sandstone, the Drybrook Sandstone of Prof. Sibly, which was originally correlated with the Millstone Grit, but was shown by Dr. Vaughan in 1905 to belong to the Lower Carboniferous series. It would be interesting if further researches should prove the existence of a former gulf at the end of Tournaisian times, running to the east of the North Wales Island, from the Forest of Dean through north Cumberland to the southern slopes of the Cheviot Isle, with a branch given off towards eastward into Westmorland.

In any case, it is a remarkable fact that we have a great development of algal deposits at this period in Gloucestershire, Westmorland, Lancashire, north Cumberland, and Northumberland.

Ortonella

This form, as already mentioned, occurs in great abundance in the algal band in the "*Athyris glabristria* zone" of the north-west province It is found in spherical nodules up to the size of a small orange. In microscopic sections it resembles Mitcheldeania in so far as it consists of a series of tubes growing out radially from a centre. It differs, however, from this genus in many important respects. All the tubes are approximately of the same size, and there is no evidence of alternating coarse and fine turfs arranged concentrically, as in the case of Mitcheldeania. Further, the tubes are not undulating as in that genus, and therefore in thin slices lie for a long distance in the plane of the section. They are much more widely spaced and show marked dichotomous branching, bifurcation making a nearly constant angle of about 40°, and there is a strong tendency for the branching to take place in several tubes at about the same distance from the centre of growth, producing a general concentric effect in the nodule.

The diameter of the tubes is decidedly less than those in Mitcheldeania, being usually little more than half the size of the tubes of *M. gregaria* The nodules of this genus occur in great profusion, contributing largely to the formation of the shaley dolomite at the base of the "*P. globosus* band" throughout the Shap, Ravenstondale, and Arnside districts and Westmorland and Lancashire.

In addition to these genera there occur also two other encrusting calcareous growths which require mention. The first of these appears in thin sections in the form of a *festoon-like growth,* surrounding fragments of calcareous algæ, especially Mitcheldeania and Ortonella. I have met with it abundantly in the "Algal band" in the north-west of England, but it also occurs not infrequently associated with Mitcheldeania in the Whitehead limestone in the Forest of Dean, while a similar structure occurs associated with *Mitcheldeania gregaria* in north Cumberland.

Although the exact nature of this growth is still undecided, I mention it here on account of its invariable association with undoubted calcareous algæ.

The other deposit is the form already alluded to under the term Spherocodium which I have found forming considerable masses of rock in many districts where the Lower Carboniferous beds are exposed; not only in Westmorland and north Cumberland, but also in the Bristol district, the Forest of Dean, and South Wales.

Foreign Carboniferous.

From its general similarity to the British deposits we might expect to find examples of an algal development in some portion of the Belgian Lower Carboniferous succession. As already mentioned, large masses of encrusting calcareous deposits have been described by Gürich[29] from the Visean limestones of the Namur basin as Spongiostroma, &c., which, though referred by him to the Rhizopoda, may very

[28] "Geology in the Field," pt. 4, p. 683, and *Q. G. S.*, vol. 73, 1912, p 547.

[29] "Les Spongiostromides du Viséen de la Province de Namur. Mem. du Musée Roy. d'Hist. Nat. de Belgique," t. iii 1906.

well be calcareous precipitates deposited by algal influence. Many of these deposits are similar to those mentioned above from British rocks.

No undoubted remains of calcareous algæ have, however, yet been recorded from these Belgian rocks. It may be of interest, therefore, to mention the recent discovery by Prof. Kaisin, of Louvain, of undoubted algal remains in the beds overlying the Psammites-de-Condroz at Feluy, on the Samme. The form found here resembles Ortonella of the Westmorland rocks, but the tubes are much finer, and it may turn out to represent a species of Micheldeania. During a recent visit to Belgium I had the pleasure of visiting the Comblain au Pont beds, in the Feluy section, with Prof. Kaisin, and, although these beds have been previously classed as Devonian, I agree with him that they probably belong to the base of the Carboniferous, and correspond approximately to K of the Bristol sequence. In the company of Prof. Dorlodot and Dr. Salée, I also visited the chief sections of the Visean, and we succeeded in discovering at least three horizons at which nodular concretionary structures, probably referable to algal growths, occurred. It is pretty certain, therefore, that careful microscopic investigation of the Belgian rocks will show the presence of calcareous algæ at more than one horizon.

One other occurrence of Girvanella may be mentioned from foreign Carboniferous rocks: that is a form described by Mr. H. Yabe from the (?) Carboniferous rocks of San-yu-tung and other localities in China under the name of *G. sinensis*.[30]

Permian and Trias.

In Britain I have met with no reference to the occurrence of calcareous algæ in rocks of this period, but quite recently Mr. Cunnington, of H.M. Geological Survey, sent me a few nodules from the base of the Permian which resemble very closely fragments of Spongiostroma from the Carboniferous limestone, and may be derived from that formation.

Abroad, masses of limestone, composed almost entirely of remains of Diplopora and Gyroporella, have long been known from the Muschelkalk and lower Keuper beds of the eastern Alps, notably the Mendola Dolomite, the Wetten limestone of Bavaria, and the Tyrolian Alps—from the Zugspitz to Berchtesgaden. In the Hauptdolomit and from the Fassa Dolomite of the north limestone Alps and the stratified Schlern dolomite of the southern Tyrol. In the Lombard Alps the same facies reappears, and *Diplopora annulata* occurs abundantly in the well-known Esino limestone above Varenna.

In 1891 Rothpletz[31] showed that certain spherical bodies in the Triassic beds of St. Cassian, formerly regarded as oolitic structures, were in reality algal growths, and referred them to a new genus, Sphœrocodium, on account of their apparent resemblance to the living form Codium. He describes them as encrusting organisms forming nodules up to several centimetres in diameter. They contribute substantially to the rocks in which they occur, and are found especially in the Raiblkalk, the Kossenerkalk, and the Plattenkalk.

Jurassic.

The Mesozoic rocks of Britain contain but few examples of marine algal limestones, and important occurrence are confined to the Jurassic Rocks. The forms met with are limited to two genera, Girvanella and Solenopora.

Tubes of Girvanella occur fairly abundantly in the British Oolites, especially in the well-known Leckhampton Pisolites, and Mr. Wethered, who has made a special study of oolitic structures, appears inclined to refer all oolitic structures to organic agency of this nature.

The examples of Solenopora met with in the Great Oolite and Coral Rag are of special interest. In both cases they attain very much larger dimensions than any species yet discovered in the Palæozoic rocks.

At Chedworth, near Cirencester, I have collected masses of *Solenopora jurassica*, measuring up to a foot across, in which the original pink tint is still so conspicuous on freshly fractured surfaces as to give rise to the local appellation of "Beetroot Stone," and the colour also reminds one of the red algæ growing in great profusion at the present day in the Gulf of Naples.

It is also recorded from the same horizon by Dr. Brown from Malton in Yorkshire, and also, on the authority of the late Mr. Fox Strangways, by Prof. Rothpletz. (*Op. cit.*)

In Yorkshire, however, a form undoubtedly occurs at a higher horizon, namely, in the Coral Rag of the Scarborough district, where it is well known to local collectors. Specimens which I have collected from this horizon at Yedmandale and Seamer also attain a considerable size—up to six inches in their longest dimension.

The name *S. jurassica* was given by Prof. Nicholson in manuscript to the specimens from Chedworth, and was adopted by Dr. Brown in his description of specimens from both Chedworth and Malton.

Prof. Rothpletz points out that specimens examined by him from Yorkshire differ from the genotype in the fact that the cells are typically rounded in cross section and by the absence of perforations in the cell-walls, and he therefore proposes to separate it as a new genus Solenoporella. It seems probable that some confusion has arisen between the specimens to which Nicholson originally gave the name of *S. jurassica* from the Great Oolite of Chedworth and other specimens from a higher horizon—the Coral Rag—examined by Dr. Brown and Prof. Rothpletz.

The former indeed figures a longitudinal section from Chedworth (Glos.) and a tangential section from Malton (Yorkshire).

I have collected specimens from both horizons and consider that whilst the Chedworth specimen, to which the name *Solenopora jurassica* was originally given, represents a species of true Solenopora, showing closely packed cells with polygonal outline in tangential section, the form from the Coral Rag of Yorkshire, with distinct circular outline to the tubes in tangential section is specifically, if not generically, distinct, and is that described by Rothpletz as Solenoporella.

If this view be correct we should continue to speak of the specimens from the Great Oolite at Chedworth as *Solenopora jurassica*, while those from the Coral Rag of Yorkshire must be known as Solenoporella *sp.* Rothpletz.

Foreign Jurassic.

It is surprising that records of the occurrence of calcareous algæ in foreign Jurassic rocks are at present very scarce.

Quite recently, however, Mr. H. Yabe[32] has described a new species of Solenopora, under the title *Metasolenopora Rothpletzi*, from the Torinosu limestone Japan. This discovery is of interest, as it carries the known occurrence of Solenopora up to the base of the Cretaceous, in which formation Lithothamnion appears and thenceforward becomes the

[30] H. Yabe, "Science Reports of the Tâhoku Imp. Univ.," Japan, 1912.
[31] "Zeitsch. d. deut Geol. Ges.," 1891.

[32] *Op. cit.*, p. 2

chief representative of the rock-building coralline algæ.

CRETACEOUS.

We here reach the period when Lithothamnion and its allies begin to make their appearance. They have not yet been recognised in British rocks, but are widely distributed in Continental deposits. They occur in the Cenomanian of France, in the Sarthe and the Var, but especially in the Danian of Petersburg, near Maestricht.

Other forms which may be mentioned are Diplopora and Triploporella. The former is met with abundantly in the lower Schrattenkalk in certain districts, especially Wildkirchli, where it plays a considerable part in the formation of the deposit.[33]

TERTIARY.

In Britain no important deposits of marine calcareous algæ have yet been reported, but considerable deposits of limestone, rich in remains of Chara, have for long been known from the Oligocene of the Isle of Wight.

Foreign Tertiary.

On the Continent, however, large deposits rich in Lithothamnion and Lithophyllum have been known for many years, among which I may mention the well-known Leithakalk of the Vienna Basin and Moravia. It will be remembered that it was these deposits which formed the subject of Unger's important monograph in 1858.

CONCLUSIONS.

The facts given above regarding the geological distribution and mode of occurrence of these organisms lead us to several interesting conclusions. In addition to the evidence of the important part they play as rock-builders, it is evident that certain forms flourished over wide areas at the same geological periods, and might well be made use of in many cases with considerable reliability as proofs of the general contemporaneity of two deposits. Thus, as general examples, we may cite the wide distribution of *Solenopora compacta* in the Baltic provinces, Scotland, England, Wales, and Canada during Llandilo-Caradoc times.

The wonderfully persistent development of the *Rhabdoporella* facies over the whole of the Baltic area at the close of Ordovician times was of so marked a character that by means of boulders scattered over the north German plain it can even be made use of for tracing the direction of flow of the ice-sheet during glacial times.

Again, to take examples nearer home. The Ortonella band found throughout Westmorland and north Lancashire near the summit of the Tournaisian occurs so constantly at the same horizon as to constitute one of the most valuable zonal indices in the succession of the north-west province, and can be used with the greatest confidence not only for correlating widely separated exposures, but also affords valuable evidence in the case of tectonic movements. Other examples are supplied by the "Girvanella nodular band" at the base of the Upper Dibunophyllum zone, and the *Mitcheldeania gregaria* beds in the north of England and the Forest of Dean.

Again, the presence of these organisms at a particular horizon furnish us with interesting evidence as to the conditions which obtained during the accumulation of these deposits.

At the present day calcareous algæ flourish best in clear but shallow water in bays and sheltered lagoons. As a good example we may take the algal banks in the Bay of Naples, described by Prof. Walther,[34] where Lithothamnion and Lithophyllum flourish to a depth of from 50–70 metres. There is seldom any muddy sediment on these banks, though detrital limestone fragments are widely distributed. Another interesting point is the constant association of fossil calcareous algæ with oolitic structure and also with dolomite.

Thus oolites occur in connection with Solenopora in the lower Cambrian of the Antarctic, in the Craighead limestone at Tramitchell in the Ordovician rocks of Christiania and the Silurian of Gotland and in the Lower Carboniferous limestone of Shap; while in the Jurassic rocks of Gloucestershire and Yorkshire it occurs in the heart of the most typical oolitic development to be met with in the whole geological succession. Though Mr. Wethered has made out a good case for the constant association of Girvanella tubes with oolitic grains, there are many cases in which their association cannot be traced. M. Cayeux,[35] in writing of a mass of Girvanella from the ferruginous oolites of the Silurian rocks of La Ferrière-aux-Etangs, expresses his opinion that Girvanella encrusts the oolite grains but does not form them, and that it is really a perforating alga of a parasitic nature.

The presence of dolomites in connection with algal deposits at different geological horizons appears to have taken place under definite physiographical conditions similar to those which obtain to-day in the neighbourhood of coral reef. Such lagoon conditions would come into existence *either* during a period of subsidence *or* elevation, and this is just what we find when we examine the periods at which these reefs are most persistent.

Thus the Girvan Ordovician reef occurred during an elevation which culminated with the deposition of the Benan Conglomerate; the Lower Carboniferous Algal band in Westmorland was laid down during the subsidence which followed the Old Red Sandstone Continental period of the Upper Girvanella; modular band occurred when the Marine period of the Lower Carboniferous was drawing to a close and a general elevation was taking place. Similar conclusions could be drawn from other periods recorded above did time permit.

In concluding this address, I wish to express the hope that however imperfect the account I have given of the succession of forms may be, that it will help to stimulate an interest in these rock-building algæ and encourage geological workers in this country to turn their attention to a hitherto neglected group of forms of great stratigraphical importance.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LEEDS.—Dr. Charles Crowther, formerly lecturer in agricultural chemistry, has been appointed professor in that subject, and will have charge of the experiments in animal nutrition, which are being supported by a grant from the Development Commissioners.

The Council of the University has granted six months' leave of absence to Prof. Smithells, who is leaving England on September 26 to proceed to Lahore, where he is to give a course of lectures and to assist the Punjab University in other ways in the promotion of scientific education and research.

The position of research chemist to the Joint Committee on Ventilation Research of the Institution of Gas Engineers and of the University of Leeds has been filled by the appointment of Mr. W. Harrison, of the Manchester Municipal School of Technology.

The medical school of the University of Leeds will hold its opening function on October 1, when Prof. C. S. Sherrington, F.R.S., will distribute the prizes and deliver an address.

LONDON.—Prof. E. W. MacBride, F.R.S., has been appointed successor to the late Prof. Adam Sedgwick in the chair of zoology at the Imperial College of Science, South Kensington.

THE presidency of Denison University has been accepted by Prof. C. W. Chamberlain, who, in consequence, has resigned the chair of physics at Vassar College.

THE new session of the Charing Cross Hospital Medical College will be opened on October 1 by an address from the dean, Dr. W. Hunter, on University medical education.

THE first Hunterian Society's lecture will be delivered at St. Bartholomew's Hospital on October 8 by Dr. F. J. Wethered, who will take as his subject "Fever in Pulmonary Tuberculosis: its Significance and Therapeutical Indications."

A CHAIR of hydrology and hygiene has been established at the Superior School of Pharmacy in Paris, which will take the place of one of mineralogy and hydrology. Prof. Délépine, the holder of the last-named chair, will occupy the new one.

DR. J. E. WODSEDALEK, of the zoological department of the University of Wisconsin, has been appointed professor of zoology and head of the department of zoology and entomology at the University of Idaho, Moscow, Idaho, in succession to Dr. J. M. Aldrich.

AN apprenticeship course in animal husbandry has been established at the Ohio State University. The course covers four years—two in the university and two in practical work on a stock farm. Many stock men in the United States are interested in the movement, and are cooperating with the University in carrying it out.

WE learn from *Science* that a bionomic laboratory has been established in connection with the University of Chicago, and that Prof. W. L. Tower, who has been appointed its curator, has left for South America to obtain material for it. The laboratory is to be equipped for the study of genetics and the problems of experimental evolution.

A SCHEME has been completed for the amalgamation of Bolton Grammar School and the High School for Girls in the town, and Sir William Lever has now endowed them as from January next with 50,000*l.* Lever Brothers 20 per cent. cumulative preferred ordinary shares, producing an income of 10,000*l.* per annum. The funds are placed at the discretion of the trustees, and it is proposed to use the first five years' income to build a new school with an administrative block.

A SCIENTIFIC and technical school of kinematography is to be inaugurated at the Polytechnic, Regent Street, W., on Wednesday, October 1. The opening meeting (which will be free) is to be followed by a course of twenty-four weekly lectures by Mr. R. Bruce Foster, who will deal with the subject under the following heads:—Historical development; modern film machines and intermittence mechanisms; films, their production and treatment; exhibiting; colour kinematography; the kinematograph combined with musical accompaniment; the Kinematograph Act and Regulations.

THE following lectures, among others, have been arranged for delivery at University College, London:—"Early Cylinders and Scarabs," Prof. Flinders Petrie, F.R.S.; "Primitive Religion in Egypt," Miss Margaret A. Murray; "The Scope of General Physiology," Prof. Bayliss, F.R.S.; "The Range of Consciousness in Organic Nature," Mr. Carveth Read; "Mental Energy," Prof. Spearman; "The Palæobotanist, his Past and Future," Dr. Marie Stopes. Particulars, syllabuses, &c., may be obtained from the Provost or the Secretary of the College.

AT University College, University of London, a course of lectures on the physical applications of the principle of relativity will be delivered on Fridays, at 5 p.m., by Dr. L. Silberstein, lecturer in natural philosophy at the University of Rome, beginning October 10. The syllabus includes consideration of the fundamental concepts and postulates of the theory of relativity, dynamics of radiation, fundamental electromagnetic equations, optical problems, the problem of gravitation, and Einstein's recent generalisation of the theory of relativity. Another course of lectures on the principle of relativity is to be given at Battersea Polytechnic by Mr. E. Cunningham, fellow of Trinity College, Cambridge, on Thursdays, at 6 p.m., beginning on October 23. The lectures will deal with the development of the principle and some consequences of the universal admission of the principle. Admission to this course is free and no ticket is required.

THE next session of Birkbeck College, which is the ninety-first, commences on September 29. The opening address will be given at 7 p.m. by Sir Francis Darwin, F.R.S., and visitors are invited to be present. The college is conducted in relation with the University of London, and classes are held both in the day and evening. We notice that thirty-two members of the staff are recognised teachers of the University of London. The courses of study provide for degrees in the faculties of arts, science, laws, and economics. It is again pointed out in the calendar, which contains full particulars of the numerous courses of study, that the usefulness of the college is curtailed by its limited accommodation. Its most pressing need is for increased space. More spacious college buildings, with additional class-rooms and larger laboratories better adapted to modern requirements, would give a great stimulus to the work of the college and add to its public utility.

THE report of the United States Commissioner of Education for the year ending June 30, 1912, has reached us from Washington. It consists of two large volumes, one dealing with educational topics in a broad way and the other devoted almost entirely to statistics. The section of the report concerned with the work of universities and colleges in the United States shows that the total amount of gifts to these institutions for higher education for the year 1911–12 was 4,956,600*l.*, excluding grants by Federal, State, and local political bodies. This amount represents an increase of 363,989*l.* over the benefactions for 1910–11. Of these gifts 1,274,960*l.* was for the increase of plant in the institutions, 745,980*l.* for current expenses, and 2,935,660*l.* for endowment. These amounts do not include subscriptions or promises received in campaigns for endowment, though they do include some property not producing an income at the present time. Fifty-four institutions reported gifts during the year of more than 20,000*l.* Five universities received more than 200,000*l.*, namely, Yale, Chicago, Harvard, Columbia, and Cornell. Columbia University seems to have been most fortunate with its 378,256*l.*

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 1.—Général Bassot in the chair.—H. **Deslandres** and L. **d'Azambuja**: Variations of the upper layer of the solar atmosphere with the approach of a sunspot minimum. An account of work done at the Observatory of Meudon from 1911 to 1913; a general account of the relations observed between spots and filaments; no general conclusions are drawn.—G. **Bigourdan**: The variable nebulæ and, in particular, the nebula G.C. 4473 = N.G.C. 6760. The observations of Borrelly on the change of luminosity of this nebula require confirmation.—A. **Laveran** and G. **Franchini**: Experimental infection of mice by *Herpetomonas ctenocephali*. The mice were infected with parasites obtained from fleas, and details are given of the changes undergone by the organism after transmission to the mouse.—Pierre **Duhem**: On the velocity of sound. A discussion of the formulæ given by Ariès and J. Moutier.—Charles **Saint-John**: Exploration of the solar atmosphere by measurements of the radial velocities in the spots. Evershed, in 1909, announced the displacement of the Fraunhofer lines in the penumbra of spots removed from the centre. The author commenced the more complete study of this phenomenon at Mount Wilson in 1910, and in the present communication summarises his results. The phenomenon is a Doppler-Fizeau effect, since the displacements are proportional to the wave-lengths. The relative levels of emission of the different lines can be determined by this method.—M. **de Séguier**: Quadratic and Hermitian groups in a Galois field.—Georges **Claude**: Influence of the diameter on the potential difference in luminescent neon tubes. The relation between the fall of potential in volts per metre of tube and the diameter of the tube was found to be hyperbolic.—Paul **Godin**: Influence of the weight of the arms on the respiratory modifications in the course of growth.—F. **Heckenroth** and M. **Blanchard**: A fixation reaction, in presence of a syphilitic antigen, in syphilis, yaws, trypanosomiasis, and phagedenic ulcer in the French Congo.

September 8.—M. **de Forcrand**: Experiments on the cupric hydrates and the heat of formation of copper nitrate. Comparison with uranyl nitrate. Calorimetric determinations on $Cu(OH)_2$, CuO, and intermediate hydrates.—J. **Guillaume**: Observations of the Metcalf comet (1913*b*) made at the Observatory of Lyons. Positions given for September 3, 5, and 6. On the 3rd the comet was of the tenth magnitude.—A. **Schaumasse**: Observations of the Metcalf comet (1913*b*) made with the Coude equatorial at the Observatory of Nice. Positions given for September 3, 4, 5, and 6. On the 3rd the comet appeared as a round nebulosity of about the tenth magnitude, about 2′ in diameter, with a badly defined nucleus.—M. **Moulin**: The terminal curves of balance springs. Influence of terms of the second order.—E. **Briner** and A. **Kuhne**: The mechanism of the formation of sulphuric acid in leaden chambers. The authors have been able to prove that pure dry nitrogen peroxide and sulphur dioxide react at 60° C., sulphur trioxide being formed. From the results of this experiment they discuss the possibility of the direct oxidation of sulphur dioxide to sulphuric acid in the leaden chamber.—J. A. **Urbain**: Morphological modifications and floral anomalies resulting from the suppression of the albumen in some plants. A study of the modifications in growth produced by removing the albumen from the seeds of various plants. Edm. **Bocquier** and Marcel **Baudouin**: The discovery and exploration of a prehistoric submarine station at the mouth of the Vie, in Vendée.—Paul **Jodot** and Paul **Lemoine**: The existence of a fault on the right bank of the Loire near Cosne.

September 15.—Général Bassot in the chair.—E. L. **Bouvier**: New observations on the larval development of the spiny lobster (*Palinurus vulgaris*). (See NATURE, August 21, p. 633.)—Jules **Andrade**: The regulation of a marine chronometer with four spirals.—Georges **Claude**: The drying of air to be liquefied by cooling. The difficulty of removing water by cooling in the ordinary heat exchanger is discussed. This can be surmounted by making the expanded gas circulate through the tubes of the exchanger instead of round them, whilst the compressed air circulates round the tubes, the path of the compressed air being composed of horizontal elements. The liquid water can be removed from the bottom without difficulty, and it is only at the end of fifteen to twenty-four hours that stoppages are produced by the hoar frost; a second exchanger is then substituted. The cost is very small compared with chemical methods of drying, and the apparatus has already been used in apparatus for the production of pure nitrogen on the large scale.—MM. **Taffanel** and **Le Floch**: The combination of gaseous mixtures and temperatures of inflammation. The combustible mixture is introduced suddenly into a vessel, the walls of which are at a known temperature, the combustion being recorded by a self-recording manometer. Results are given for mixtures of air with methane, hydrogen, carbon monoxide, acetylene, ethylene, pentane, and finely divided oil.—Maurice **Durandard**: The amylase of *Rhizopus nigricans*.

CAPE TOWN.

Royal Society of South Africa, August 20.—Dr. J. K. E. Halm in the chair.—E. J. **Goddard**: The significance of the position of the genital apertures in Hirudinea. The number of somites entering into the constitution of the Leech body is, according to one school, thirty-three, according to another thirty-four. This constitution holds good except in the doubtful exceptions of *Acanthobdella peledina* (Grube) and Semilageneta (Goddard). The ancestral stock from which the Hirudinea arose must have been Oligochætan and aquatic in nature, and having a body of 33 or 34 somites. This ancestor must have been provided with setæ, as indicated by Acanthobdella, similar to those found in aquatic Oligochæta such as Lumbriculidæ, Phreodrilidæ, &c. Further investigation may reveal a close association between the distribution of certain archaic Oligochætan families and the origin of the Hirudinea.—E. J. **Goddard**: A Phreodrilid from Sneeuw Kop, Wellington, South Africa. A new form has been discovered on the Wellington mountains. The ventral setæ are typically Phreodrilid in nature, but both are simple. Hence in Africa, which is apparently rich in Phreodrilids, all the varieties of setæ noted in the family are to be found in the African representatives.—G. C. **Scully** and A. R. E. **Walker**: Note on Spodumene from Namaqualand. The lithia-bearing mineral described in this paper was collected by the authors near Jackals Water, Steinkopf. An examination of its optical and other physical characters enables them, with confidence, to refer it to the species Spodumene. Quantitative chemical analyses of the mineral will be made, the results of which the authors hope to publish in a later paper along with a detailed account of the associated minerals.

BOOKS RECEIVED.

Botanische Jahrbücher fur Systematik, Pflanzengeschichte und Pflanzengeographie. Edited by A. Engler. Band 50. Heft 2 and 3. (Leipzig and Berlin: W. Engelmann). 14 marks.

Zeitschrift fur Wissenschaftliche Zoologie. Edited by Prof. E. Ehlers. Band 106. Heft 3. (Leipzig and Berlin: W. Engelmann.) 11 marks.

Problem Papers. Supplementary to Algebra for Secondary Schools. By Dr. C. Davison. Pp. 32. (Cambridge: University Press.) 8*d.*

Canada. Department of Mines. Mines Branch. The Nickel Industry, with Special Reference to the Sunbury Region, Ontario. By Dr. A. P. Coleman. Pp. viii+206+plates. (Ottawa: Government Printing Bureau.)

Biology. By Dr. W. D. Henderson. Pp. 92. (The People's Books series.) (London and Edinburgh: T. C. and E. C. Jack.) 6*d.* net.

Sir Williams Huggins and Spectroscopic Astronomy. By E. W. Maunder. Pp. 94. (The People's Books series.) (London and Edinburgh: T. C. and E. C. Jack.) 6*d.* net.

Spiritualism and Psychical Research. By J. A. Hill. Pp. 94. (The People's Books series.) (London and Edinburgh: T. C. and E. C. Jack.) 6*d.* net.

Entstehung der Welt und der Erde nach Sage und Wissenschaft. By Prof. D. M. B. Weinstein. Zweite Auflage. Pp. vi+116. (Leipzig and Berlin: B. G. Teubner.) 1.25 marks.

Die Dampfmaschine. By Prof. R. Vater. II., Ihre Gestaltung und Verwendung. Pp. vi+99. (Leipzig and Berlin: B. G. Teubner.) 1.25 marks.

Memoirs of the Geological Survey. England and Wales. Explanation of Sheet 339. The Geology of the Country around Newton Abbot. By W. A. E. Ussher. Pp. vi+148+iii plates. (London: H. M. Stationery Office; E. Stanford, Ltd.) 3*s.*

Viśvakarmā: Examples of Indian Architecture, Sculpture, Painting, Handicraft. Chosen by Dr. A. K. Coomaraswamy. Part v. 12 plates. (London: Luzac and Co., Ltd.) 2*s.* 6*d.*

Die Kultur der Gegenwart ihre Entwicklung und ihre ziele. Edited by Prof. P. Hinneberg. Teil iii. and Teil iv. Pp. 84. (Leipzig and Berlin: B. G. Teubner.)

Drapers' Company Research Memoirs. Biometric Series ix. A Monograph on Albinism in Man. By Karl Pearson, E. Nettleship, and C. H. Usher. Part iv. Text. Appendices. Pp. iv+136+xxiii. Part iv. Atlas. Pp. iv+lix plates. (London: Dulau and Co., Ltd.) Text and Atlas, 21*s.* net.

Department of Marine and Fisheries. Report of the Meteorological Service of Canada, Central Office, Toronto, for the year ended December 31, 1909. Pp. xxi+565+4 plates. (Ottawa.)

Handworterbuch der Naturwissenschaften. Edited by E. Korschelt and others. Lief. 54 and Lief. 55. (Jena: G. Fischer.) 2.50 marks each part.

Probleme der Entwicklung des Geistes. Die Geistesformen. By S. Meyer. Pp. v+429. (Leipzig: J. A. Barth.) 13 marks.

Quantitative Analysis in Practice. By Dr. J. Waddell. Pp. vii+162. (London: J. and A. Churchill.) 4*s.* 6*d.* net.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

" To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2292, Vol. 92] THURSDAY, OCTOBER 2, 1913 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

DEPARTMENT OF AGRICULTURE AND TECHNICAL INSTRUCTION FOR IRELAND.

ROYAL COLLEGE OF SCIENCE FOR IRELAND.

The College is an Institution for supplying Advanced Courses of Instruction in Science as applied to Agriculture and Industries, for training Teachers for Technical and Intermediate Schools, and for carrying out Scientific Research.

The Diploma of Associateship (A.R.C.Sc.I.) is awarded to students who have passed the Entrance Examination and have regularly followed a four years' course in one of the following faculties or sections, and have passed the College examinations in all subjects in the group in which they are seeking a Diploma.

Faculties.—Agriculture; Applied Chemistry; Engineering.
Sections for Science Teachers.—Experimental Science; Technology; Natural Science.

Students who show that they can profit by the courses of instruction can attend, as Non-Associate Students, courses selected by them from any portion of the curriculum, or may be admitted to the laboratories for the pursuit of special lines of scientific study or research.

Dean—Professor G. A. J. COLE.

Physics ...	... Professor W. BROWN; Dr. F. E. W. HACKETT.
Chemistry	... Professor G. F. MORGAN; Mr. A. O'FARRELLY.
Mechanical Engineering	Professor H. H. JEFFCOTT; Mr. J. TAYLOR.
Agriculture ...	Professor J. WILSON; Mr. D. HOUSTON; Mr. G. STEPHENSON.
Mathematics ...	Professor W. McF. ORR.
Geology ...	... Professor G. A. J. COLE.
Botany ...	... Professor T. JOHNSON.
Zoology ...	... Professor G. H. CARPENTER.

Particulars as to the programme of studies, fees, &c., may be obtained from the REGISTRAR.

The SESSION 1913-14 opens on OCTOBER 7.

EAST LONDON COLLEGE

(UNIVERSITY OF LONDON).

FACULTIES OF ARTS, SCIENCE, AND ENGINEERING.

FEES: TEN GUINEAS PER ANNUM.
NO ENTRY FEE AND NO REGISTRATION CHARGES.

Special fees and facilities for Post Graduate and Research Students in all Faculties.

M.A. CLASSES FOR MATHEMATICS.

Calendar, with lists of Graduates, University and College Scholarships, Academic and other distinctions, post free on application to the Registrar, or the Principal,

J. L. S. HATTON, M.A.

Telephone No.: East 3384.

BOROUGH POLYTECHNIC INSTITUTE,

BOROUGH ROAD, LONDON, S.E.

CHEMISTRY DEPARTMENT.

Under the direction of C. DORÉE, M.A., D.Sc.

The Classes—Elementary, Advanced and Honours, Inorganic and Organic Chemistry—commence September 22, 1913.

The following Special Evening Courses in Applied Chemistry have also been arranged:—

THE CHEMISTRY AND TECHNOLOGY OF THE ESSENTIAL OILS.

Lectures and Practical Work, Wednesday, 7.30. C. T. BENNETT, B.Sc., F.I.C.

THE CHEMISTRY AND MANUFACTURE OF FOODSTUFFS.

Lectures, Monday, 7.30. E. HINKS, B.Sc., F.I.C., and T. MACARA, F.I.C.

ELECTROCHEMISTRY. Wednesday and Friday, 7.30.

THE ANALYSIS AND VALUATION OF LAUNDRY TRADE MATERIALS.

A Practical Course, Monday and Friday, 7.30. C. DORÉE, M.A., D.Sc.

For full particulars apply to the Principal, C. T. MILLIS.

UNIVERSITY OF EDINBURGH.

ENGINEERING DEPARTMENT.

The next SESSION OPENS on OCTOBER 7. The Preliminary or Entrance Examination is held in September. The University provides complete COURSES in CIVIL, MECHANICAL and ELECTRICAL ENGINEERING, qualifying for the degree of B.Sc. in Engineering, and extending over a period of three years. Particulars of the Entrance Examination, Scholarships, Fees, and Courses of Instruction can be obtained from the MATRICULATION OFFICE, The University, Edinburgh.

THE SIR JOHN CASS TECHNICAL INSTITUTE,

JEWRY STREET, ALDGATE, E.C.

The following Special Course of Instruction will be given during the Autumn Term, 1913:—

COLLOIDS.

The Methods employed in their Investigation and their Relation to Technical Problems.

By E. HATSCHEK.

A course of 10 Lectures and Demonstrations on the nature and properties of Colloidal substances, of the methods employed in their investigation, and of the bearing of Colloidal phenomena on Chemical and allied Industries.

Tuesday Evenings, 7 to 8.30 p.m.

The first lecture of the Course will be held on Tuesday, October 7, at 7 p.m.

Detailed Syllabus of the Course may be had at the Office of the Institute, or by letter to the PRINCIPAL.

THE SIR JOHN CASS TECHNICAL INSTITUTE,

JEWRY STREET, ALDGATE, E.C.

EVENING CLASSES IN METALLURGY.

Lecturer in Metallurgy ...	...C. O. BANNISTER, A.R.S.M., M.I.M.M.
Lecturer on Metals used in the Motor Car Industry and Metallography	WESLEY J. LAMBERT, Assoc.Inst.C.E., late Chief Metallurgist, Royal Gun Factory, Woolwich Arsenal.
Lecturer on Iron and Steel, Mining and Mine Surveying ...	G. PATCHIN, A.R.S.M.

Elementary, Intermediate, and Advanced Metallurgy, forming a graded four years' curriculum. Special Courses on Assaying, Metallography, including Pyrometry, The Metallurgy of Gold and Silver, The Metallurgy of Iron and Steel, Metals used in the Motor Car Industry, Mining, Mine Surveying, and Mineralogy.

The Courses are suited to the requirements of those engaged in Metallurgical Industries, Assay Laboratories, and to those intending to take up Metallurgical work in the Colonies.

The Laboratories are open to students in the afternoon for practical work.

For details of the Classes apply at the Office of the Institute, or by letter to the PRINCIPAL.

COUNTY OF LONDON.

The London County Council invites applications for the position of full time LABORATORY ASSISTANT (Woman) for the Botanical and Chemical Laboratories at the County Secondary School, Putney. Candidates should be between the ages of 18 and 21 years, and the commencing salary will be 18*s.* to 25*s.* a week according to age, rising to 30*s.* a week. The person appointed will be required to take up her duties in January, 1914. Candidates should apply by letter to the Education Officer, London County Council Education Offices, Victoria Embankment, W.C., by Wednesday, October 15, 1913, and should give full particulars of their age, qualifications, and experience.

Every communication must be marked H.4 on the envelope. Canvassing, either directly or indirectly, will be held to be a disqualification for appointment. No candidate who is a relative of a member of the Advisory Sub-Committee of the school is eligible for appointment.

JAMES BIRD,
Deputy Clerk of the London County Council.

Education Offices,
Victoria Embankment, W.C.,
September 24, 1913.

UNIVERSITY OF ST. ANDREWS.

CHAIR OF CHEMISTRY IN UNIVERSITY COLLEGE, DUNDEE.

THE UNIVERSITY COURT OF THE UNIVERSITY OF ST. ANDREWS invite applications for the CHAIR OF CHEMISTRY in University College, Dundee, fallen vacant by the death of Professor. Hugh Marshall, D.Sc., F.R.S.

Letters of application, which must be accompanied by thirty printed or type-written copies of the letter of application and relative testimonials must be in the hands of the undersigned on or before Friday, November 7.

Further particulars regarding the Chair may be obtained from the undersigned.

ANDREW BENNETT,
Secretary and Registrar.

The University, St. Andrews,
September 30, 1913.

UNIVERSITY OF ABERDEEN

AND

NORTH OF SCOTLAND COLLEGE OF AGRICULTURE.

It is proposed to appoint a BIO-CHEMIST for the RESEARCH DEPARTMENT in ANIMAL NUTRITION. The salary will depend on the qualifications and experience of the person appointed. Applications from thoroughly trained and experienced investigators are invited to be sent to the SECRETARIES, Joint Committee on Agricultural Research, Marischal College, Aberdeen, from whom further information can be obtained.

THURSDAY, OCTOBER 2, 1913.

THEORY AND PRACTICE OF CHEMISTRY.

(1) *Service Chemistry: Being a Short Manual of Chemistry and Metallurgy, and their Application in the Naval and Military Services.* By Prof. V. B. Lewes and J. S. S. Brame. Fourth edition, revised. Pp. xvi+576+vii plates. (London: Edward Arnold, 1913.) Price 15*s.* net.

(2) *Handbuch der Arbeitsmethoden in der anorganischen Chemie.* By Dr. A. Stahler. Erster Band. Pp. xii+786. (Leipzig: Veit and Co., 1913.) Price 25 marks.

(3) *Cours de Chimie Organique.* By Prof. F. Swarts. 2e édition revue et augmentée. Pp. vii+751. (Paris: A. Hermann et Fils; Gand: Ad. Hoste, 1913.) Price 15 francs.

(4) *Allen's Commercial Organic Analysis.* A Treatise on the Properties, Modes of Assaying, and Proximate Analytical Examination of the Various Organic Chemicals and Products Employed in the Arts, Manufactures, Medicine, &c. Volume vii. Fourth edition. Edited by W. A. Davis and S. S. Sadtler. Pp. ix+563. (London: J. and A. Churchill, 1913.) Price 21*s.* net.

(1) TEACHERS of chemistry in colleges of applied science, who nowadays are so frequently requested to arrange specialised courses in this science suitable to the needs of students working chiefly at other subjects, will undoubtedly be interested to learn how this problem has been solved by the authors of this manual, now in its fourth edition, after long experience in the teaching of chemical science to naval officers. The writers very rightly refuse to compile a Service technology without first inculcating a knowledge of the facts and laws governing the results obtained in applied chemistry. At the same time, they carefully select their illustrations so as to arrest immediately the attention of the naval and military student, for whom the work is primarily intended.

Within the first dozen pages the topic of liquefied gases leads to a consideration of the production of "artificial ice and cold storage both on land and sea." The chemistry of galvanic batteries includes a description of Leclanché's cells used in firing torpedoes and submarine mines. The subject of combustion brings in a reference to the spontaneous ignition of coal on shipboard. Special prominence is given to explosives. The evolution of gunpowder is traced, and a concise account is given of the taming of guncotton for use as a propellant. Special sections are devoted to fuel problems, military ballooning, boiler incrustations, corrosion, protective paints, anti-fouling compositions, and many other matters arising out of Service vicissitudes.

From the doctrinal point of view, it would obviate much confusion if the term "atomicity" were employed exclusively to denote the number of atoms in an elementary molecule, and not used as a synonym for "valency." In this connection it may be mentioned that sulphur vapour at 500° C. is stated incorrectly to be hexatomic (p. 322). It is doubtful whether the affinity of the halogens for oxygen decreases regularly from iodine to fluorine. The non-existence of perbromic acid and bromine oxides rather suggests that bromine in this respect falls between chlorine and fluorine (pp. 333, 345). These points, which are open to criticism, are, however, of minor importance, and the work contains so much new material not generally found in chemical text-books that the authors are justified in hoping that the book may appeal to readers outside the circle of Service students.

(2) This work, which is the first of five volumes of a comprehensive text-book on working methods in inorganic chemistry, is a noteworthy example of the "integrated knowledge" now placed at the disposal of chemists called upon to plan the erection and organisation of laboratories for the practice of this important branch of chemical science. The information is characterised throughout by a note of thoroughness, first-hand knowledge being ensured by the author's collaboration with a staff of experts in different branches of practical chemistry. In their efforts to make every item of equipment purposive, the writers take nothing for granted, and discuss in detail such matters as the ample provision of light and space round the laboratory building, the ready accessibility of stairways and exits, the storage in cellars of volatile liquids and liquefied gases, and even the position of bicycle stands! Certain illustrations of various shapes of retort stands and specimen bottles might well be left to the dealers' catalogues.

The varieties of glass suitable for chemical purpose are fully discussed, and it may be noted that the rare alkali metal rubidium has been utilised in the production of a hard glass softening only at 1000° C. Shenstone's pioneering efforts in the production of silica ware are mentioned, and further developments are suggested by references to the use of zirconia and titania in the fabrication of crucibles and refractory apparatus. Considerable improvements have been recently made in the manufacture of porcelain, and vessels

F

of this material are now obtainable which withstand rapid fluctuations of temperature. The section on the noble metals refers not only to vessels of gold and platinum, but also to apparatus constructed of rhodium, iridium, and tantalum. The chemical and physical properties of the newer alloys (duralumin, the ternary steels, &c.) are reviewed. Scattered through the work are many valuable recipes likely to interest the practical chemist, as, for example, the use of aniline-black as a stain for woodwork, various lutings and cements for joining together chemical apparatus, and a composition for filling holes in platinum crucibles.

Special chapters are devoted to electrical fittings and to the mechanical operations of pulverisation, agitation, filtration, &c. The book affords a striking testimony of the pre-eminence of Germany in the newer industries which minister to the wants of applied chemistry. Some noteworthy products of British enterprise have, however, been overlooked, and mention may be made in this connection of Fletcher's earthenware combustion furnaces and Pilkington's glass screens with an embedded meshwork of invar steel, which form such efficient shields in working with explosive materials.

(3) In this text-book of organic chemistry the author has given prominence to the development of the theory of the subject, descriptive matter being restricted to a few substances of industrial importance. A chapter on chemical kinetics has been added because the fundamental principles of this branch of the science have been chiefly verified in connection with organic substances. From the outset stereochemical considerations are introduced, and the facts of isomerism, multiple linking, and ring formation are regarded from the point of view of the tetrahedral carbon atom. The constitution ascribed to double cyanides (pp. 174, 177) must, however, be regarded as obsolete, in view of Werner's recent researches on coordination compounds. The author omits all references to original memoirs, and the work can scarcely be recommended as a substitute for the larger English treatises on organic chemistry.

(4) This work is the seventh volume of the fourth edition of Allen's well-known treatise on organic analysis. The book is divided into seven sections, each of which is written by an expert on the subject, the entire compilation not only serving as a useful guide to the analyst, but forming also a comprehensive treatise on the general chemistry of the organic materials under review. The present volume is largely devoted to nitrogenous compounds either formed by the vital activities of plants and animals or arising from the decay of these organisms. In recent years considerable addition has been made to our knowledge of these products, among which may be mentioned the alkaloids of ergot, cyanogenetic glucosides, ptomaines, amino-acids, and purine derivatives. One section is devoted to lactic acid, and another to the bitter principles of aloes and hops, whilst the concluding chapter is a useful monograph on cyanogen and its derivatives. G. T. M.

SOME NEW ELECTRICAL BOOKS.

(1) *Electrical Photometry and Illumination: A Treatise on Light and its Distribution, Photometric Apparatus, and Illuminating Engineering.* By Prof. H. Bohle. Pp. xi + 222. (London: C. Griffin and Co., Ltd., 1912.) Price 10*s.* 6*d.* net.

(2) *The Principles of Applied Electrochemistry.* By Dr. A. J. Allmand. Pp. xii + 547. (London: Edward Arnold, 1912.) Price 18*s.* net.

(3) *Electroplating: A Treatise on the Electro-Deposition of Metals, with a chapter on Metal-Colouring and Bronzing.* By W. R. Barclay and C. H. Hainsworth. Pp. viii + 399. (London: Edward Arnold, 1912.) Price 7*s.* 6*d.* net.

(4) *The Design of Alternating Current Machinery.* By J. R. Barr and R. D. Archibald. Pp. xvi + 496 + xvi plates. (London: Whittaker and Co., 1913.) Price 12*s.* 6*d* net.

(5) *A Laboratory Manual of Alternating Currents.* By Prof. J. H. Morecroft. Pp. viii + 247. (London: Longmans, Green and Co., 1912.) Price 7*s.* 6*d.* net.

(6) *La Télégraphie et la Téléphonie Simultanées et la Téléphonie Multiple.* By K. Berger. Traduit par P. Le Normand. Pp. 134. (Paris: Gauthier-Villars, 1913.) Price 4.50 francs.

(7) *The Baudôt Printing Telegraph System.* By H. W. Pendry. Pp. iii + 147 + plates. (London: Whittaker and Co., 1913.) Price 2*s.* 6*d.* net.

(1) DURING comparatively recent years there has sprung into existence a new branch of science which is known, or knows itself, as illuminating engineering. The writer has a suspicion that if the electrical engineer who handled lighting problems had not been on the lookout for another stick with which to beat his brother gas engineer, and had not thought that stick was to be found in the greater ease with which scientific measurements can be applied to electric lamps, no such science would ever have sprung into a definite and separate existence. Be that as it may, the profession appears to be establishing itself with some degree of firmness. The illuminating engineer of theory is a man of unbiassed mind as regards the particular illuminant he employs, provided he attains his desired end in the most economical

manner: a man who instals electricity in your dining-room, gas in your kitchen, acetylene in your billiard room, and candles in your bedroom. But the illuminating engineer of practice is generally either a gas or electrical engineer with his own particular axe to grind. So much is this the case that he may show a marked preference (against all sound illuminating engineering doctrine) for a particular species of illuminant in the genus which he represents—as, for example, for flame arc lamps against all other electrical illuminants.

We do not know whether Prof. H. Bohle calls himself an illuminating engineer, but at least he has written a book (1) which claims in its subtitle to be a treatise on illuminating engineering, almost as if this were a mere appanage of electrical photometry and illumination; and, as one of the latest works on the new science, we turn to it naturally in the hope that it will more than justify that science's existence. It is disappointing to find little, if anything, more than used in our student days to be regarded as legitimately within the sphere of electrical engineering. It is disappointing, too, to find much inadequate treatment and, we are afraid, insufficient knowledge. Take, for example, the discussion of radiation laws in chapter ii. This is far from clear, and the statement on p. 21: "Coloured bodies absorb different parts of the impinged radiation: consequently they will radiate different fractions of black body radiations, according to the frequency, *i.e.* according to the temperature," is, if we understand the author's meaning rightly, not correct.

The description of the manufacture of carbon filament lamps in the same chapter must have been obtained from some out-of-date account. The criticism of the flame arc lamp on p. 97 is equally behind the times. It is stated that "on long winter evenings the lamps do not hold out until the next morning, but must be recarboned during the night." This is untrue of any flame lamps except those specially designed for short-hour lighting, and there are many flame lamps now on the market, and have been for years, which burn without recarboning for 70–100 hours, so that it will be seen that the criticisms of the author, who writes from Cape Town, would only be justified at the poles. Flame lamps burning vertical carbons are actually commended for steadiness as against lamps with inclined carbons, the exact reverse being the case. We were not surprised after this to find on p. 171 that the yellow flame arc is described as "suitable for decorative illumination," as apparently its only sphere of usefulness.

We need not, however, labour criticism of details such as these: it is only to be regretted that in discussing such a progressive subject as the manufacture and behaviour of electric lamps the author did not take more pains to bring his information up to date.

It is of interest to turn to what may be regarded as the more distinctly "illuminating engineering" sections of the book. We are told in the preface that this is a combined science of physics and physiology, and emphasis is laid on the neglect of the physiological side, which led us to expect that this would be remedied by the author. The physiological discussion in the book is, however, no more than is usually to be found in similar works. In truth, this plea for physiological investigation is, in our opinion, frequently exaggerated. The knowledge of a few elementary facts is necessary, but beyond this physiological knowledge is not needed, and it would be equally true to say that it was required as part of the equipment of a good tailor.

The last two chapters, "The Design of Reflectors and Shades" and "Illuminating Engineering," show how little the new science really has accomplished. With a few exceptions, which existed before the illuminating engineer had arrived, electric lamp shades are still, scientifically, as chaotic as ever. The design of shades is, in fact, for the most part, an art and should continue to be so: if the illuminating engineer ever succeeds in making it purely a science, he will remove what is one of the recommendations of electric lighting—that it lends itself to beauty as well as to utility. The chapter on illuminating engineering gives a number of directions for different classes of lighting which the unbiassed would admit are no more than a restatement of the common-sense practice of years—almost centuries.

We cannot omit reference to a novel procedure in the numbering of figures and equations. Thus the fifth figure in the fourth chapter is numbered Fig. 4.05: this is intended to facilitate reference. It has quite the contrary effect and we trust will not be imitated.

(2) Dr. Allmand's treatise is one of the most comprehensive and at the same time one of the best treatises on applied electrochemistry that we can call to mind in the English language. The first part, covering fourteen chapters and 194 pages, deals with the theoretical side of the subject. To write a complete exposition of the theoretical side of electrochemistry, it would almost be necessary to write a complete chemical treatise coupled with a much shorter discussion of the fundamental electrical phenomena. It is

essential, therefore, to assume a certain amount of chemical knowledge in the reader, and we are inclined to think, on the whole, that Dr. Allmand has not assumed too much.

It must be remembered however, that the student who approaches this subject from the electrical side is often seriously lacking in chemical grounding and, complete though Dr. Allmand's treatment is, we could not help feeling at times that the chemical reasoning and illustrations would be above the heads of many readers. This argument must not be given undue weight, as it is open to all who care to study the subject thoroughly to supplement the volume by the reading of other chemical and physico-chemical works, a matter which is greatly facilitated by the copious references to current literature and the bibliographical references at the end of each chapter. By the time the student has thoroughly mastered the theoretical discussion in the first part of the book he will be in a position to understand properly the reactions and phenomena involved in the various practical applications to which the second part is devoted.

The "special and technical" part of the work opens with two chapters on primary and secondary cells respectively. The treatment here is necessarily brief—whole volumes have been written dealing with each of these subjects—but it is clear and covers the more important points. An interesting discussion of the "fuel cell," a cell in which coal, or some simple derivative from coal such as carbon, or CO, is used to generate electrical energy, concludes the chapter on primary cells. There follow chapters on the electro-metallurgy of the principal metals, and on electrolytic bleaching, etc., and in chapters xxiv. to xxvi. the more important electro-thermic processes are discussed. The last two chapters deal with the oxidation of atmospheric nitrogen and the production of ozone.

Although, owing to natural conditions, this country is not to the fore in electrochemical and electrothermal development, the field for English engineers is not confined to England. There is good reason to hope, moreover, that the future, and very possibly the near future, will see much greater advances in this direction in England than one would have anticipated a few years ago. It is becoming more evident every year that not only is water power not an indispensable adjunct to electrochemical enterprises, but that other sources of power may possess decided advantages. The appearance of so thoroughly sound a treatise as Dr. Allmand's is therefore very much to be welcomed.

(3) Messrs. Barclay and Hainsworth have set out to write a thoroughly up-to-date handbook for the practical electroplater, and have succeeded admirably in realising their aim. Rightly insisting that even the most practical of practical men cannot in these days work without a more or less thorough groundwork in the theoretical side of his subject, they have devoted the first six chapters of their book to a succinct but thoroughly sound exposition of the fundamental chemical and electrical principles. These are treated in a manner well suited to the scope of the book, the elementary knowledge assumed being such as can hardly fail to be possessed by anyone seriously attempting to study the volume.

After two chapters dealing with plant and apparatus and preliminary processes such as cleaning, etc., the remaining chapters deal with the deposition of the various metals. Each of the more important metals is considered separately, and in each case the theoretical explanation of the various reactions involved is not forgotten. The composition of the various depositing baths having been considered from this viewpoint, the methods of making them up and the details of the actual electroplating process are dealt with. The book covers the deposition of all the metals of importance industrially and also of many the deposition of which has a very limited application. We can thoroughly recommend the book either to the practical electroplater or to the student anxious to familiarise himself with the details of a process of great commercial importance and great historical interest.

(4) Messrs. Barr and Archibald's volume on alternating current machinery is an advanced treatise suitable for the use of senior students and those actually engaged in the design of such machinery. The whole field is well covered: after preliminary chapters on complex wave forms and insulation, the subject of transformer design is dealt with in three chapters. These are followed by eight chapters on alternators and three on rotary converters.

(5) Mr. Morecroft's book is a collection of laboratory experiments designed to elucidate the more important current phenomena. We are glad to see that a method too frequently followed by the writers of such laboratory notes, that of confining the text to the merest statement of instructions, has been avoided and a clear exposition of the significance of the experiment has been given in each case. Although this may render the book less convenient for actual use in the test-room, it gives it much higher educational value.

(6) and (7) These two books deal with specific developments in the field of telegraphy and telephony, and may be regarded more as mono-

graphs for the specialist than as treatises for the general student. The detailed investigation of the more intricate telegraph systems is, in fact, probably outside the range of the general electrical engineer's ambitions. M. Berger's book is the more comprehensive of the two, not only because it deals with a somewhat wider subject, but also on account of the broader method of treatment which has been adopted. The subject is handled more theoretically, and there is very little purely descriptive writing. M. Pendry, on the other hand, deals mainly in description, and the book lacks something from the absence of the theoretical side. The descriptive writing is, however, clear, and numerous illustrations help to the better understanding of a very complex subject.

Maurice Solomon.

THE TEACHING OF PSYCHOLOGY.

(1) *The Learning Process.* By Prof. S. S. Colvin. Pp. xxv+336. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 5s. 6d. net.

(2) *Introduction to Psychology.* By Prof. R. M. Yerkes. Pp. xii+427. (London: G. Bell and Sons; New York: H. Holt and Co., 1911.) Price 6s. 6d. net.

(3) *Experiments in Educational Psychology.* By Dr. D. Starch. Pp. vii+183. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 4s. net.

(1) PROF. COLVIN'S book is written from the point of view of "thorough-going functionalism and pragmatism." "All learning," we are told, "both expresses itself through adjustment and is acquired through adjustment." Now it is possible to give too narrow a meaning to the term adjustment. The solving of a problem, however theoretical, is adjustment in the important sense. That movement, on the other hand, is not the one thing needful has been made evident once for all by Mr. Squeers' pedagogic system:—"W-i-n-d-o-w, window, go and clean it." In short, the essential thing is that every piece of school work should be capable of being felt as a stage in the working out of a problem.

Prof. Colvin, it is true, does not definitely commit himself to too narrow a use of the term; indeed, in places he clearly guards himself against it. Yet one cannot but feel that these passages come rather as qualifications than as explanations of other earlier ones.

One problem which lends itself particularly well to treatment from this functional point of view is that of the expression and suppression of deep-seated emotional and conative tendencies. An interesting account is given of some of Freud's main positions, and sympathy is shown with the view that the attempt simply to suppress fundamental instincts is apt to be disastrous rather than merely futile. The problem of sex education is recognised, and the possibility faced that childhood may not be so completely asexual as has been supposed. That the existence of any problem has been so completely ignored is certainly strange, but, as things are, is perhaps hardly an unmixed evil. The child has in this domain at least been spared the interference of the many well-intentioned, the parents, parsons, and pedagogues, who would otherwise surely have rushed in, fearing to tread as little as any bull in a china-shop.

Many other topics are interestingly and instructively discussed—the economy and technique of learning; the main results of recent work on testimony; the problem of the transfer of training; the comparison of child and adult as to memory and reason; "hard" versus "soft" pedagogy, and so on.

The book is clearly written, and gives, without ostentation, a large amount of information based upon modern experimental work.

(2) The most original feature of Prof. Yerkes' book is its scope and arrangement. It is intended to be an introductory outline as distinguished from a manual, that is, to arouse interest and indicate the problems with which psychology deals rather than to give a systematic account of the main facts and theories. It has the defects as well as the qualities of this plan. On one hand it contains much interesting material not commonly to be found in elementary books. On the other, its treatment is of excessively varying thoroughness. Excellent features are the texts which head each chapter, consisting of quotations, often of some length, from some more advanced book or clever piece of research, and the practical exercises, intended, however, exclusively for class work, with which the chapters end.

Special topics of which the treatment seems less satisfactory are: the difficult question of the exact theoretical difference between introspection and "external perception"; the criticism of the "tripartite division" of consciousness; the use of "sentiment" in the sense of "an emotion which attaches itself to a particular object." A sentence on the final page is apparently incomplete.

(3) Prof. Starch's little book aims at providing a course of experiments in educational psychology for a small class, the work to occupy two hours weekly through one semester. For its purpose it seems to be excellent, though the verbal material of the experiments, having been selected from an

American point of view, occasionally requires adaptation for English students, *e.g.*, some of the test words in the chapter on apperception. This would be of little consequence were it not that the actual pages of the book are intended to be used in the experiments. In spite of this drawback, however, it will be found extremely useful by anyone in charge of, or wishing to form, an experimental class of the kind indicated.

AVIATION DYNAMICS.

(1) *La Théorie de l'Aviation, son application à l'Aéroplane.* By Robert Gaston. Préface de Maurice Farman. Librairie des Sciences aéronautiques. (Paris: F. Louis Vivien.) Price 1.50 francs.

(2) *Aëroplanes in Gusts.* Soaring Flight and the Stability of Aëroplanes. By S. L. Walkden. Pp. xv+188. (London: E. and F. N. Spon, Ltd., 1912.) Price 7*s.* 6*d.* net.

It is remarkable how many books have been written in connection with problems on aviation in which the principles of elementary dynamics have been ignored, misinterpreted, or otherwise misunderstood in a way that no candidate for an intermediate B.Sc. examination would believe to be possible. These two books afford excellent examples of this disregard of elementary principles.

(1) M. Robert Gaston, who has a highly flattering preface from Mr. Maurice Farman, finds that if a body is allowed to fall and then stopped at intervals of one second, its average velocity will be 4·9 metres per second (with $g=9·81$ m/s^2). If stopped more frequently its average velocity will be less, until we come to the case when it is being stopped at every instant—*i.e.* continually supported—when its average velocity is *nil*. Having definitely proved this, he contradicts himself by saying that to maintain a body in the air an upward velocity of 4·9 metres per second must be imparted, so that if the weight is W kilograms, the rate of working must be $4·9W$ kilogram metres per second. If he had adopted a minute, instead of a second, as unit of time, he would have found that the work required was $4·9W \times 60^2$ kilogram metres per minute, or sixty times his estimate; similarly, by taking an hour as unit he would have found a result 3600 times as great as he has estimated. Can anything be more absurd? Yet Maurice Farman congratulates him on the clearness and simplicity of his book!

(2) Mr. Walkden's main theme is based on a complete misunderstanding of the physical significance of the law of composition of accelerations. He measures the effect of a gust of wind by the accelerations of the air particles relative to the aëroplane, and by compounding this acceleration reversed with gravity he gets what he calls the resultant relative gravity. But the result means nothing at all.

The only effect which a gust of wind can have on an aëroplane is due to the pressures of the air on the surfaces and other parts of the aëroplane. These are in general functions of the relative velocity components of the air rather than the accelerations. The best that Mr. Walkden's method can do is to determine their *rates of increase*, not their actual values. To solve the problem of the aëroplane in gusts it is necessary, in the first place, to determine the six force and couple components of the air pressures as functions of the six components of relative linear and angular velocity of the aëroplane, and, having done this, to investigate the six equations of motion of the aëroplane under the action of these forces and couples. This book does nothing towards solving this problem, and, on the other hand, the appearance of such books is calculated to deter competent mathematicians and physicists from attacking such problems.

OUR BOOKSHELF.

Didaktik der Himmelskunde und der Astronomischer Geographie. Verfasst von Dr. Alois Höfler. Pp. xii+414. (Leipzig and Berlin: B. G. Teubner, 1913.) Price 12 marks.

This is the second volume of a useful series of handbooks which is appearing under the general title of "Didaktische Handbücher für den Realistischen Unterricht an Höheren Schulen," and arranged by Professor A. Höfler of Vienna and Professor F. Poske of Berlin. This volume follows that from the pen of the first named, which dealt with mathematical instruction, and its object, like its predecessor, is to reform the teaching of astronomy and astronomical geography in the schools. The volume is essentially for teachers and displays a graduated series of courses of instruction for students commencing when eleven years old and finishing at eighteen. The book is divided into four stages, each stage arranged to cover two years of the student's training. The author strives at great length to impress on the teacher the importance of leading the students to observe for themselves as much as possible, and to show them simple experiments whenever the opportunity arises.

No pains seem to have been spared to provide the teacher with numerous references to works that may be consulted by him, and to draw his attention to numerous points which are not often sufficiently clearly explained to the youthful student.

While the full course here suggested would be difficult to carry out under the conditions of education in this country, our teachers could nevertheless, provided they are sufficiently well conversant with the German language, gather a large amount of useful hints, even if only from the method of treatment of the material. For use in Germany we have no doubt that the teachers will hail gladly the appearance of this volume, and the distinguished list of co-workers with Prof. Höfler is sufficient indication to stamp the volume as one of a high order.

Einführung in die Agrikulturmykologie. By Prof. Dr. A. Kossowicz. 1. Teil: Bodenbakteriologie. Pp. vii+143. (Berlin: Gebrüder Borntraeger, 1912.) Price 4 marks.

Prof. Kossowicz is to be congratulated on having condensed into such a small book a review of the chief publications on soil mycology. The book partakes, in fact, more of the nature of an introduction to the literature of the subject than to the subject itself. The mere enumeration of the various workers for and against a hypothesis, without any criticism from the author, is not calculated to afford much help to a beginner. The subject-matter is divided into sections dealing with the part played by bacteria in the cycle of the elements carbon, oxygen, hydrogen, nitrogen, sulphur, phosphorus, and iron; the mycology of soil; the mycology of manure; and the influence of the manurial treatment on the micro-flora of the soil. For such a small book the bibliography is very comprehensive, constituting, as it does, about one-fourth of the total number of pages. The book is well illustrated, and as a short work of reference ought to prove of value to agricultural chemists and mycologists.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Piltdown Skull.

It had been my intention not to add anything further in print to my preliminary note (Quart. Journ. Geol. Soc., vol. lxix., 1913, p. 145) on the cranial cast obtained by Dr. Smith Woodward from his reconstruction of the Piltdown skull until I was in a position to make a full and comprehensive statement as to the precise significance of the information afforded by the cranial fragments as to the kind of brain possessed by the earliest known human inhabitant of Britain. But, although my investigations are now sufficiently advanced to permit me to undertake the writing of my report, it will be some months before it can be published; and in the meantime it is most undesirable that the present widespread misunderstandings should be allowed to breed further trouble and confusion for those who are interested in the elucidation of Mr. Charles Dawson's momentous discoveries.

Recent events have made it difficult for those who have relied wholly upon what has appeared in print to form any accurate conception of the meaning and importance of the Piltdown skull-fragments. It is quite certain that they afford the first evidence we have obtained of a hitherto unknown group of the Hominidæ, so fundamentally distinct from all the early fossil men found in Europe as to be worthy of generic distinction—a "dawn-man" of a very primitive and generalised type. Certain features are so clearly ape-like as definitely to confirm the generally admitted kinship to the African anthropoid apes, as well as to distinguish Eoanthropus sharply and clearly from all other human remains. In other respects, however, there is a closer resemblance to the features of modern man than is found in the specialised group of Neanderthaloid palæolithic men. This curious association of features is not paradoxical, as some people pretend. The small and archaic brain and thick skull are undoubtedly human in character, but the mandible, in spite of the human molars it bears, is more simian than human. So far from being an impossible combination of characters, this association of human brain and simian features is precisely what I anticipated in my address to the British Association at Dundee (Nature, September 26, 1912, p. 125), some months before I knew of the existence of the Piltdown skull, when I argued that in the evolution of man the development of the brain must have led the way. "The growth in intelligence and in the powers of discrimination no doubt led to a definite cultivation of the æsthetic sense, which, operating through sexual selection, brought about a gradual refinement of the features." Just as the young child still uses its teeth for purposes of attack, so in the dawn of human existence teeth suitable for offensive purposes were retained long after the brain had attained its distinctively human status and had made the hands even more serviceable instruments for attack.

That the ape-like conformation of the chin region signifies the inability to speak is surely a patent fallacy. Articulate speech must have come while the jaws were still simian in character; and the bony changes that produced a chin were the result mainly of that process of refinement to which I have already referred, to the reduction of the teeth, which was part of the same process, and, quite in a minor degree, to that process of growth and specialisation of the genio-glossi muscles which resulted from their use in speech.

A great source of misunderstanding will be got rid of if these obvious facts and the considerations based upon them be admitted.

In conclusion, I may answer many questioners by affirming that I still hold to every word of my preliminary note published in the Quarterly Journal of the Geological Society, as well as of the statements made in my lectures delivered before the Royal Dublin Society and the Manchester Literary and Philosophical Society last winter, and also to the facts demonstrated in my exhibit at the Royal Society's soirée in May.

G. Elliot Smith.

University of Manchester, September 23.

Solar Electrical Phenomena.

In a lecture last January to the Christiania Academy, Prof. Birkeland[1] gave an interesting summary of his recent researches on solar and planetary electrical phenomena. He describes how in a study intended to elucidate the evolution of celestial bodies he examined the nature of the electric discharge taking place *in vacuo* in a large discharge vessel from a magnetisable globe serving as kathode. The experiments, which were made under widely differing conditions, were on a scale more ambitious than anything hitherto attempted. Two vessels of 300 and 1000 litres' capacity respectively were employed. In the larger of these the globe used was of 36 cm. diameter,

[1] "De l'origine des mondes," par K. Birkeland, Arch. Sci. phys. et nat. Genève. Quatrième Periode, t. xxxv., Juin, 1913.

and discharges up to nearly half an ampere were obtained. Some of the published photographs are very remarkable. One of them showing the electric corona and streamers round the magnetised globe might easily be mistaken for a genuine photograph of a typical solar eclipse. Many of the phenomena of sunspots are also very strikingly imitated in the experiments.

Birkeland proceeds to discuss the cause of the general magnetic field of the sun, the fact of the existence of which has been established by Hale. He attributes it to induced currents circulating in the interior of the rotating mass, which, he argues, can only have a comparatively feeble electric conductivity. He says (*loc. cit.* p. 540):—

"We know that electric currents circulating in large globes formed of good electric conductors are of great persistence. Lamb found that for a globe of copper as large as the earth, ten million years would elapse before the currents fell to $1/\epsilon$ of their former intensity. The induction effects produced by electric rays emanating from sunspots may therefore give rise to currents of long duration if circumstances permit. It is probable that as regards the sun, we shall be obliged to suppose a somewhat feeble conductivity of the gaseous interior, to the intent that the electric currents created and circulating within it are reduced with a fairly high rapidity and are transformed into heat."

In a recent communication to the Royal Astronomical Society,[2] the writer brought forward some evidence deduced from laboratory experiments, which led to a contrary conclusion, namely, that the gaseous matter composing the sun must be a highly conducting medium. The experiments of Kaye[3] and the writer showed that carbon and a number of metals emit on heating ionisation currents of a relatively very high order of magnitude, and this in absence of any external applied potential and at atmospheric pressure. The currents are almost certainly carried by swarms of negatively charged particles of relatively considerable mass, the emissivity of the emitting surface increasing very rapidly with increase of temperature.

In the interior of a carbon-tube resistance-furnace heated by alternating current, the apparent gaseous resistance of the order of megohms at 1400° C. fell at the highest attainable temperature to a small fraction of an ohm, due to the emission from carbon alone. In one series of experiments where temperature measurements were made, the conductivity increased exponentially nearly two hundred-fold for each rise of 1000° C. Impurities such as iron and silicon, which are generally present in ordinary samples of carbon, may further increase the conductivity four or five fold during the first heating of a new furnace. Though influenced somewhat by the surrounding gas, the emissivity appears to be invariably present in neutral or reducing media. The experiments of King, briefly referred to by Hale in his paper in the current number of *The Astrophysical Journal*, show that though the emissivity of carbon falls with increase of pressure, it is still apparent at 20 atmospheres.

Seeing that the temperature of the sun is probably between 5600° and 6000° abs. and that of those elements shown to possess an appreciable electric emissivity, carbon, and iron at any rate are present in the solar atmosphere in considerable quantity, it is difficult to avoid the conclusion that the degree of ionisation, and consequently of electric conductivity, must be very high; probably at least as good as that of the globe of copper considered in Lamb's computation.

The bearing of these conclusions on Birkeland's solar theory seemed worthy of some consideration.

A New Aquatic Annelid.

About the middle of September I received from Dr. H. F. Parsons, of Croydon, a fresh-water Annelid which had been found in the water supply of Ringwood, Hants, and sent to the Local Government Board for identification. It proved to be an immature but very beautiful specimen of *Rhynchelmis limosella*, Hoffm., a member of the Lumbriculidæ. It is of peculiar interest, inasmuch as it confirms a suspicion expressed by Beddard in 1895. He remarks ("Monograph of the Order Oligochæta," p. 215) that "the genus Rhynchelmis is, so far as our present knowledge goes, confined to the fresh waters of Europe. . . . I have seen a specimen from some part of England, but cannot give any details. I believe this specimen to be in the Oxford Museum. There is every probability that it is a native of this country."

I have collected annelids in almost every part of the British Isles, but hitherto have never had the good fortune to come across the species here named. It is, therefore, very gratifying to be able to record it as a new addition to our Annelid fauna.

MODERN ELECTROMETERS.

Recent research on the electron and radioactivity has necessitated so many refined electrostatic measurements that much attention has been directed to the design of electrometers, and several different instruments distinguished by their sensitiveness and convenience in working have been devised. Two types have served as the starting-points for modern improvements, the first being the gold-leaf electroscope, and the second the quadrant electrometer of Lord Kelvin; great progress has been made by bettering the insulation, the sensitiveness, and the accuracy and ease of observation, and further by important modifications of design. Polished amber or ambroid, a substance made from compressed fragments of amber, is now generally used as insulating substance, and for the first type of instrument the deflection is now measured with a reading microscope; for the second the mirror and scale is employed.

The gold-leaf instrument is used in many forms. In a modification by Exner a leaf is fastened on either side of a narrow, vertical, insulated metal plate, while opposite each leaf is a metal plate the distance of which from the central plate can be adjusted, thus controlling the sensitiveness; for potentials of some hundred volts this is a convenient form. For higher potentials of thousands of volts Braun's pattern, with a light rigid needle pivoted a short distance above its centre of mass, is much used. For very sensitive measurements C.T.R. Wilson has recently modified the gold-leaf electroscope in his so-called "tilted electrometer." In this instrument a single hanging gold leaf is attracted out of the vertical by an inclined insulated plate, which is kept charged at a constant potential. On varying the inclination of the plate by tilting the instrument, a position can be found for which the leaf is only just in stable equilibrium; slightly increasing the tilt would cause the leaf to fly over to the plate. In such a case, as is well known, the sensitiveness of an instrument is very high, a familiar example being the suspended magnet galvanometer, in which, by adjusting the field magnet, the controlling field is so arranged that the magnet is only just in stable equilibrium. The capacity of this instrument of Wilson's is very small, and a reading microscope attached to the stand enables accurate readings to be taken. Fig. 1 shows in section the instrument as made by the Cambridge Scientific Instrument Co.

To avoid difficulties, known to all physicists, which occur in working with a gold leaf, Wulf

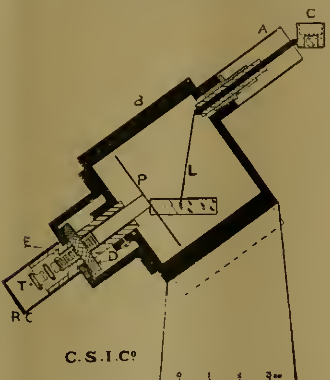

FIG. 1.—The tilted gold leaf electrometer.

has devised a very effective instrument, put on the market by the firm of Günther and Tegetmeyer, in which the leaf is replaced by quartz fibres rendered conducting by sputtering with a thin film of platinum in a kathode-ray tube. Two such fibres hang side by side, loaded with a minute weight: on being charged the fibres repel one another, and the separation is read with a microscope. The fibres give a very sharp image, and thus all difficulty connected with reading by one irregular edge of a gold leaf is avoided. The capacity is smaller than that of the smallest leaf instrument, and practically independent of the potential. The sensitiveness never approaches that of the tilted electrometer, but this instrument is excellent for measuring potentials of either a few volts or a few hundred volts, according to the fineness of the fibres, the size of the weight, and other details of construction. It fills the gap between the tilted and the Braun electrometer, and is very convenient and portable. A somewhat similar design is the Einthoven string electrometer, in which a silvered quartz fibre is stretched between, and parallel to, two metal plates, kept at a constant difference of potential.

The pattern of quadrant electrometer devised by Dolazalek is so widely used at present that it suffices to mention very briefly the improvements introduced, the small dimensions of the needle and quadrants, the quartz suspension, the amber insulations, and the light needle of silvered paper, rendered rigid by its peculiar form. Dolazalek has, however, recently devised an instrument differing in many important particulars from that familiar to English physicists, which he calls the binant electrometer, from the fact that the four

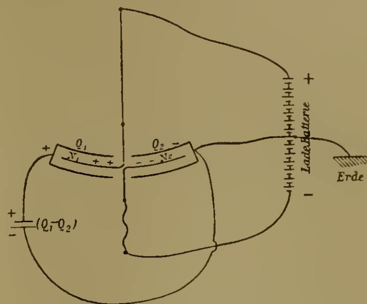

FIG. 2.—The binant electrometer.

quadrants are replaced by two semicircular "binants"[1]; it is made by Herr Georg Bartels, of Göttingen. This instrument has many advantages over the quadrant pattern, and is being widely used in Germany, although at present it seems to be unknown in England. The "needle" is a disc formed of two semicircular segments of the thinnest sheet-aluminium, stiffened by means of embossed ridges, and insulated from one another with amber. The box which encloses them is likewise made up of two semicircular parts supported on amber, arranged so that their line of separation is perpendicular to the line of separation of the needle segments. Needle and box are not plane, but formed from shallow concentric spherical shells, the centre of which coincides with the point of suspension of the needle. Owing to this simple device an oscillation of the needle does not bring it any nearer to the enclosing walls, and the needle is stable at very much higher potentials than in the case of the quadrant electrometer; this form also lends increased rigidity to the delicate needle. When in use, one of the segments of the needle is charged positively, the other negatively, by earthing the middle of the battery used for charging; contact is made for the one segment through the suspension, which is an exceedingly fine Wollaston wire, and for the other through a still finer coiled wire arranged

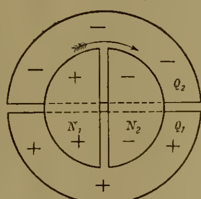

FIG. 3.—The binant electrometer. Plan.

[1] "Annalen der Physik," (iv) 26, 1908. F. Dolazalek, "Binantelektrometer." Figs. 2, 3, and 4 are from this paper.

in a similar way to the lower connection in a moving-coil galvanometer. The binants of the box are connected to the potential difference to be measured.

Advantages of the instrument are the wide proportionality between deflection to one side and potential difference, and the large range of potential which may be given to the needle with satisfactory results; in addition we have the stability of the needle already mentioned. The deflections to one side are proportional to the applied potential difference over a range seven times as great as is the case when, with the quadrant instrument, readings to both sides are taken. This property has led to the construction of a portable binant instrument with a pointer, which can be used as a voltmeter, measuring directly potentials to a fraction of a volt without passage of current. If used idiostatically, the deflections are, of course, proportional to the square of the potential, and, connected in this way, the instrument measures alternating potentials very effectively.

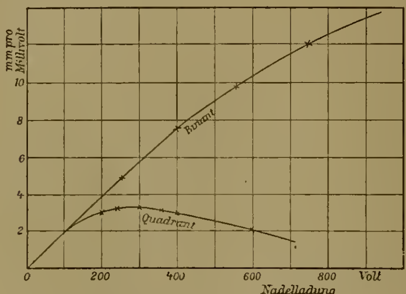

FIG. 4.—The sensitiveness of the "binant" and quadrant electrometer compared.

The potential of the needle in the binant instrument can be taken as small or as large as may be desired. The variation of the sensitiveness with the potential of the needle is shown in the diagram (Fig. 4) for a quadrant and a binant instrument of similar dimensions throughout. The abscissæ are the difference of potential of the two halves of the needle for the binant, the potential of the needle above earth for the quadrant, and the ordinates are millimetres deflection per millivolt applied potential. With the binant form the deflection is proportional to the potential of the needle up to about 400 volts, and still continues increasing up to 1500 volts (off the diagram); in the case of the quadrant instrument the sensitiveness increases slowly with the potential of the needle, and reaches a maximum at about 300 volts, after which increasing the potential of the needle is disadvantageous. Further, for the quadrant electrometer the potential of the needle cannot be taken very small, as in this case the readings are too asymmetrical on reversal, as will be seen from the ordinary formula of the text-books. For the binant the potential of the needle may be taken as small as desired; in fact, by altering the potential of the needle alone measurements of potential can be made over a region of five powers of ten.

The cause of the peculiar variations of the sensitiveness of the quadrant electrometer with the potential of the needle, increasing to a maximum and then decreasing again, is to be found in the fact that the change of capacity per unit angular displacement is not constant, as assumed in Maxwell's accepted treatment, but decreases with increasing needle potential and increasing displacement. This is due to the lines of force from the radial edges of the needle, which are to a large extent diffused not perpendicularly to the top and bottom of the box, but horizontally. The connection of such horizontal lines of force with one of the quadrants is unaltered by the displacement of the needle, and this influences the changes of capacity. The form of the needle and its position avoid these disturbances in the binant instrument; the narrow gap between the two halves of the needle, and their opposite potentials, cause the lines of force from the diametral edges to spring from one half to the other, instead of to the walls of the box, and the position of the gap perpendicularly to the gap in the box further diminishes the effect. The wide proportionalities of the binant electrometer are largely attributable to this result of its peculiar construction.

E. N. DA C. ANDRADE.

THE TECHNICAL PRODUCTION AND UTILISATION OF COLD.[1]

THE appearance of an English translation of the work by Georges Claude (1), the successful French inventor in the field of the liquefaction and rectification of air, affords an occasion for reviewing the progress made in this, which seems destined to become one of the leading departments of twentieth-century scientific industry. Eighteen years have elapsed since the inventions of Linde and Hampson solved the problem of the production of liquid air in quantity, and extended the range of low temperatures practically attainable to as great an extent as the electric furnace did in the opposite direction. It is sufficient to recall the names of Faraday, Andrews, Dewar, Hampson, and Ramsay to show that this country has not been behindhand in pioneers in this field, both in regard to the attainment of low temperatures and to their utilisation for scientific investigation. But there, as in other cases, progress in this country seems to have come to a standstill, and the commercial application and utilisation of these results has been developed entirely abroad, in this case chiefly in Germany and France.

It is on this side of the subject that the present book furnishes much information difficult to acquire easily elsewhere. Part i., dealing with elementary principles and the history of the subject, and part iii., with the properties of liquid

[1] (1) "Liquid Air, Oxygen, Nitrogen." By Georges Claude. Translated by H. E. P. Cottrell. With a Preface by D'Arsonval. Pp. xxv.+418. (London: J. and A. Churchill, 1913.) Price 18s. net.
(2) "Le Froid industriel." By L Marchis. Pp. xx+328+104 figs. (Paris: Félix Alcan, 1913.) Price 3.50 francs.

air, are popular presentations of a hackneyed theme, almost painfully familiar in this country, where liquid air long since descended to the level of a music-hall turn. But in parts ii. and iv. the author deals in an interesting and original way with the theory and practice of actual processes for the technical liquefaction of air, and its separation into oxygen and nitrogen. Naturally an author must be allowed to tell his story in his own way, and fight his battles over again, when these battles have resulted in success, though almost everyone may now be supposed to know that working at $-200°$ C. does not confer upon liquids any peculiar behaviour or render the separation of oxygen and nitrogen from the air a problem essentially different in its scientific principles from that of the separation of alcohol and water in one of the oldest of chemical operations.

The English translation certainly retains to the full the racy style of the original, but sadly needs careful revision, especially in the mathematical expressions. As many as six slips have been noted, for example, on pp. 132-4. The units employed should be defined to render them intelligible to English readers, and misleading contractions like *calorie* for *kilogramcalorie,* and *Kgms.* for *Kilogram-metres,* avoided. In more than one instance the real meaning of the author, just where it is important, is obscured by some slip or looseness of expression, as on p. 184, where an improvement is stated to increase the yield of liquid air in Claude's process *by* 0·85 litre per H.P. hour, when apparently *to* 0·85 litre is intended. In a preface by D'Arsonval yields of "finally 0·95 litres per H.P. hour" in Claude's process are referred to, but in the text, apart from the above imperfect statement, we are left in doubt as to the best that Claude has so far been able practically to achieve.

Dealing first with the problem of air liquefaction Claude's especial contribution is the solution of the problem of expansion with external work, following the suggestion made by Lord Rayleigh so long ago as 1898. As is well known, Linde's and Hampson's processes depend only on the "internal work," that is, on the relatively minute cooling effect—the Joule-Thomson effect—produced on the expansion of an imperfect gas, like air, due to the work done by the molecules in increasing their distances apart against their own feeble attraction. As in the whole of these processes, the Siemens exchanger of temperature, fifty-six years old, is employed, and enables this cooling to be used regeneratively until ultimately the liquefaction temperature is reached. But at the expansion jet, or, at least, inside the exchanger, just where it is emphatically not wanted, the enormous mechanical energy of the escaping gas is quantitatively reconverted into heat. The expansion is adiabatic, and temperatures, as in Cailletet's apparatus, far below the liquefaction temperature are instantaneously attained, but, in distinct inferiority to Cailletet's simple process, are not made use of because the work is quantitatively reconverted into heat inside the system. At first sight, but at first sight only, it appears that an enormous improvement might be effected in this direction, increasing the yield of liquid air some ten times, and regaining thereby a substantial proportion of the work employed in compression. Lord Rayleigh's suggestion was that the air on expansion should drive a turbine, which, however inefficient, could not fail both to increase the cooling effect and recover some of the power employed.

Claude has successfully employed the energy of expansion to do work in a compressed air motor capable of working below $-100°$ C. We read that "while the makers have troubles, which are relatively frequent, with the ever well-known but still somewhat barbarous and brutal appliances which air compressors are, they have, so to speak, none at all with the new-born appliances, the expansion machines for liquid air." At first petrol and even liquid air itself were employed as lubricants in the cylinders of the compressed air machines. Lubrication troubles seem, however, now to have been entirely avoided, owing to a discovery (1912) of the unique properties of leather, which, after being suitably treated, preserves all its good qualities at low temperatures. In the present machines the pistons of the expanders are provided with stamped leathers instead of metallic rings, and do not require any lubrication. The chief advantage of the system is that lower pressures—40 atmospheres, the critical pressure of air—can be employed, whereas the Linde and Hampson processes depend on the use of a pressure of 200 atmospheres. But the yield, spoken of in the preface as finally 0·95 litre per H.P. hour, is not very greatly superior. In the Linde process a practical yield of 0·6 litre per H.P. hour is realised in large machines, which is some three times better than in the Hampson laboratory machine.

The evolution of Claude's system has many points of interest. Exchangers are employed, and the gas arrives at the expander at a temperature of about $-100°$ C. Now if this process of exchange is carried too far, for example to $-140°$ C, "the air which enters the machine is not yet a liquid, but it is almost no longer a gas; its expansive properties are, so to speak, done away with, and the external work of expansion becomes detestable." Even were air a perfect gas, it can readily be seen that the more it is cooled before expansion the less energy it has to lose when expanded, and the smaller the cooling effect obtained. Enormously more of it is required to fill the cylinder the lower the temperature, whilst all the time the external work it can do, and the cooling effect it can produce, are steadily vanishing. But actually, at $-140°$ under 40 At., the volume is already only one-fourth of that of a perfect gas. This, of course, though Claude does not say so, is tantamount to admitting that the defect in the "internal work" processes in not utilising the energy of expansion is more apparent than real, and that the advantages of utilising the external work are to a large extent illusory. The practical solution was found in admitting the compressed gas to the expander at a temperature as high as is consistent with the attainment of a final temperaure below the critical temperature. This is effected by passing the cold expanded air at about $-140°$ around tubes supplied by a T branch from the intake of the machine, *i.e.* with air at 40 At. and at $-100°$ C. It liquefies part of this compressed air, and is warmed up thereby to about $-130°$, at which temperature it is admitted to the exchanger. A further improvement is obtained, much as in multiple expansion steam engines, by expanding in stages and warming up the expanded gas in between by making it circulate over coils filled with air above its critical pressure.

Thus at the present time liquid air may be produced in large machines for an expenditure of power perhaps one-fourth to one-fifth of that required in the Hampson simple laboratory machine, but it must still be regarded as a somewhat expensive and troublesome commodity to base a process upon. Naturally the question arises how it is that such great results may be confidently anticipated of its use. It has already displaced all other processes for the production of oxygen and nitrogen on a large scale, and, in the same field, the preparation of pure hydrogen and carbon monoxide from water gas offers no insurmountable difficulty. The industry can supply oxygen to-day, in plants of 1000 cubic metres per hour, at 0·2*d*. per cubic metre, and this means that to burn coal in pure oxygen rather than in air would increase the cost of the fuel only some four times. The saving in certain cases, through not having to heat at the same time a mass of nitrogen at least two and a half times greater than that of the coal and oxygen together, is evident. But this to-day's figure gives no conception of what could be done if chemists really set themselves to separate the oxygen and nitrogen of the atmosphere before use, even in such common processes as the combustion of fuel. It can be stated confidently that the cost of the oxygen would not exceed that of the coal, without taking into account the possible use of the nitrogen produced at the same time. When it is considered how all industrial chemistry has been based upon the necessity of taking oxygen always diluted with some five times its volume of nitrogen, the revolution in methods that these facts suggest is obvious. A blast furnace, for example, consuming oxygen instead of air, would be very different from the present affair.

The reason why the liquefaction of the atmosphere and its subsequent rectification holds out such great industrial possibilities, in spite of the somewhat expensive character of liquid air, is, of course, that the cold is used regeneratively. There is an apparatus into which air at ordinary temperatures passes, and out of which oxygen and nitrogen, at a few degrees only from that temperature, issue. In other words, the losses of cold through the issuing gas being at slightly lower temperature than the entering gas are so small that in the rectification of thirty litres of liquid air into its components some twenty-nine litres would be recovered. Actually, there is a very slight expenditure of power required, amounting theoretically to 0·1 H.P. hour per cubic metre of oxygen separated. In addition, the losses through heat entering the well-insulated apparatus from outside must be considered, but these, naturally, are the smaller the larger the scale of operations. The yield of pure oxygen, the nitrogen being left with 2·4 per cent. of oxygen, per H.P. hour is, for a plant of 50 cubic metres per hour, about 1 cubic metre; of 100 cubic metres per hour, 1·2 cubic metres. For larger plants 1·5 cubic metres is confidently predicted. For the purpose of the industries fixing atmospheric nitrogen, naturally, great purity of the nitrogen rather than that of the oxygen is aimed at, and in these a purity of 99·9 per cent. can be realised, the oxygen testing some 80 per cent.

Space does not permit any detailed discussion of the factors which have enabled the older Linde process to compete successfully, and now to cooperate with, the newer processes utilising the principle of external work, though, as admirably set forth in this book, these are fascinating enough. Nothing less than real genius could have enabled Linde eighteen years ago to grasp and work out the intrinsic possibilities of success in the "internal work" method, which appears theoretically to be so barbarously wasteful, or to have designed the apparatus which, as Claude remarks, strikes one at first sight like a coach with five wheels. It furnishes a most interesting example, in this region of topsy-turvy thermodynamics, of how thoroughly the theoretical aspect of a problem may change the more deeply and completely it is examined.

(2) The volume by Prof. Marchis is complementary to the other, and does not deal with the production of the extreme temperatures necessary for the liquefaction of air. It gives a most readable and useful account of the science of refrigeration as applied to the preservation of perishable commodities. It is packed full of practical information about refrigerating machines and insulating materials, the construction and management of cold-storage chambers and ice factories, and the preservation of the great variety of comestibles dealt with nowadays, each of which requires its special treatment if the best results are to be attained. The book can be confidently recommended as being in itself almost sufficient for an engineer without experience to undertake this field of work. At the same time, it contains much recent information of general utility to all interested in the subject. A description of the recent high-speed rotary compressors of M. Leblanc, with vanes of ramie fibre, agglutinated by the solution of acetate of cellulose in acetone, and running in a casing with practically no play at a peripheral speed of 500 metres per second, ends an abundantly illustrated section dealing with the various types of refrigerating machines. In the last two chapters the special cases of the preservation of meat and of fish are treated in detail. The author combats the prevalent idea that cold storage

tends to make food go bad more quickly when it is re-exposed to the ordinary temperature. Cold does not improve articles already commencing to decompose; but, on the other hand, if scientifically carried out—that is, if the food is in excellent condition to begin with, and is preserved with all due precautions as regards the correct temperature, its uniform maintenance, and the proper hygrometric condition and frequent renewal of the air in the store-room, and if the lowering and raising of the temperature do not take place too suddenly—no harmful consequences follow refrigeration.

F. SODDY.

THE NATURAL HISTORY OF A LONDON SUBURB.[1]

THE increasing demand for works on local natural history, of which class of publication the present volume is an excellent specimen, must have been noted by workers in science as a healthy sign of popular awakening. But while in the eighteenth century it was possible for a Gilbert White to cover the whole ground so far as concerned his own district, the great development of specialised knowledge in modern times necessitates the cooperation of many workers to produce such a volume as that under consideration. Thus, in addition to the opening chapter on topography, by Messrs. Maynard and Findon (the hon. sec. of the natural history section of the society), there are ten chapters by different authors dealing respectively with the geology, climate, plant-life (three chapters), bird-life, mammals, &c., insects, molluscs, and pond-life together with a very useful bibliographical appendix.

A commendable feature of the present work is the general introductory section heading many of the chapters. By this treatment the reader is enabled to pass from the general to the special—a method which may be condemned by some critics as an inversion of scientific method but, in a local natural history, has the distinct advantage of enabling the general reader and the would-be student to realise that the local and restricted data supplied by his own district fit in to the larger and more comprehensive generalisations which scientific observers have built up from detailed observations over wider fields. The chapter by Mr. A. G. Tansley dealing with the vegetation (chap. iv.) is a very good example of the treatment referred to, as he begins with the ecology, shows the relationship of the vegetation to the geological features, and then groups vegetation generally under the various types of "associations" before dealing with the particular plant-associations of the district. The lists of species then come as natural sequences to the various "associations." A living interest is thus imparted to a subject which in former times was presented

Badger Earths in Ken Wood. From "Hampstead Heath: Its Geology and Natural History."

in the uninteresting form of a catalogue of names, amounting, in fact, to nothing more than the statement of the occurrence of a certain species in a particular district, without any relationship to its environment or to its associates. The chapter on the trees and shrubs (chapter v.), by Mr. Hugh Boyd Watt, will surprise many readers as a revelation of the extreme richness of the district, all

[1] "Hampstead Heath: Its Geology and Natural History." Prepared under the Auspices of the Hampstead Scientific Society. Pp. 328+xi plates+3 maps. (London; T. Fisher Unwin, n.d.) Price 10s. 6d. net.

the native English trees, and also a large number of foreign species, finding the conditions suitable for their growth. How long these conditions will remain favourable is problematical, a remark which applies also to Mr. Whitton's goodly list of some 300 species of flowering plants given in chapter vi.

The geology of the district is necessarily "tame," but since Mr. F. W. Rudler is responsible for that chapter (chap. ii.), it is perhaps scarcely necessary to say that it will be found both interesting and instructive. The only regret is that the author did not "let himself go" more freely in discussing some of the generalisations which have of late years been based upon the detailed study of gravels and superficial deposits generally. In connection with the climate of Hampstead (chap. iii., by Mr. E. L. Hawke), it is of interest to note that the sunshine record, as compared with that of the city, more nearly approaches that of Berkhamstead, which is tolerably clear of London influence. Thus the total number of hours of bright sunshine during 1910 was 1372, as compared with 1348 at the Hertfordshire station, 1183 at Camden Square, and 993 at Bunhill Row. So much for the effects of atmospheric pollution in the City of London! Bird-life (chap. vii.) is dealt with by Mr. Herbert Goodchild, who gives a very clear account of the particular conditions favourable and unfavourable to an avifauna. One of his observations is very significant: "Adjoining the heath are several private woods, a form of ownership which tends to the preservation of species that might otherwise be lost to the district, since in such woods and coppices the birds are safer from molestation. As some of these woods adjoin the public domain, an observer may see on the latter many species of birds that might be driven away if all the woods were public." The writer of this notice has long ago come to the conclusion that the preservation of open spaces solely from the point of view of the "recreation and enjoyment of the public" is in many cases quite the reverse of a boon from the point of view of the naturalist. Mr. Goodchild is, of course, an advocate of the study of bird-life by the modern method —*i.e.* the field-glass and camera, and not by the gun. It is fortunate for the district, also, that it comprises the Brent reservoir, and that that well-known observer Mr. J. E. Harting was a former resident, and kept observations of the birds for many years.

The chapter on mammals, fishes, and reptiles, by Mr. Hugh Findon, will also surprise many readers who are unprepared for the survival of such a number of species within sight of the metropolis. The existence of badger-earths, still apparently tenanted, is certainly remarkable, but here, again, the preservation of this notoriously shy animal is due to the inclusion of the earths (a figure of which we reproduce) in the private grounds of Ken Wood, the owner of which estate has always been a sympathetic conservator of this interesting denizen. Dr. O'Brien Ellison's chapter on insect-life serves to emphasise the complaint so frequently made by entomologists in this country that local collectors so generally concentrate their attentions upon the Lepidoptera to the neglect of other orders. There are surely more than twenty-seven species of Coleoptera in the district, to say nothing of Hymenoptera, Diptera, and Microlepidoptera. The list of Lepidoptera, by the way, is marred by a number of misprints. It only remains to add that there are chapters on molluscs and on pond-life by Mr. Hugh Findon and Mr. James Burton respectively.

The Hampstead Scientific Society has certainly done good service in publishing this volume, which is a typical specimen of the kind of work which local societies should undertake. For a district such as that dealt with—viz. within the three-mile radius from the flagstaff on the summit of the heath—a book like that before us is not only of immediate utility, but is certain to acquire increased value as time moves on and the influence of urbanisation becomes more and more pronounced. Already many of the species recorded are taken from old publications, and are now extinct. The general impression produced by the perusal of the volume is one of marvel at the persistence of so much that is "natural" in the area described.

R. M.

PROF. HUGH MARSHALL, F.R.S.

BY the untimely death of Prof. Hugh Marshall, which took place in London on September 5, chemistry has lost, at the early age of forty-five, one of the nowadays comparatively few prominent men who devoted their energies to the investigation of subjects connected with the inorganic and mineralogical branches of the science, and the University of St. Andrews an active and useful member of the professorial staff of Dundee University College.

It is not a disparagement to say that Dr. Marshall's most brilliant discovery—that of the persulphates, in 1891—was due to one of those fortunate chances, not infrequent in science, where experiments designed to elucidate a certain definite question lead to some new discovery of a wholly different description and often of much greater consequence; for, no sooner was the discovery made than its author was quick to discern that substances of far-reaching importance had fortuitously presented themselves to him and to prosecute their examination with exceptional vigour and success. The subject under immediate investigation was the oxidation of cobalt salts by electrolysis in the then comparatively little employed "divided" electrolytic cell, and on passing a current of electricity through "a fairly acid solution of cobalt and potassium sulphates," with a view to prepare potassium cobalt alum, small crystals slowly separated, which proved on analysis to consist of potassium persulphate. The discovery of the persulphates at once brought Dr. Marshall's name into prominence, while the assiduity and skill with which he continued his examination of them speedily marked him as a rising inorganic chemist.

Having a distinct leaning towards mineralogy and crystallography, he devoted a considerable amount of study to these subjects also, and published several useful crystallographical papers; but inorganic chemistry claimed most of his attention, and his later papers as a rule savoured more or less of persulphates in some of their varied interactions. Thus, either alone or in collaboration with others, he published papers describing the action of persulphates on iodine, silver salts, thiosulphates, &c.; and the neat modification of Crum's test for manganese, in which potassium persulphate is employed as oxidising agent instead of lead peroxide, was devised and elaborated into a quantitative colorometric method by him. Other papers dealt with thallic sulphate; rubidium, cæsium, and thallium persulphates; quantitative analysis by electrolytic methods; succinic acid and succinates; the compound of iodine with thiocarbamide, &c.

In addition to his chemical investigations he found time to examine some technical subjects, and his work upon the burning of mixtures of air and light hydrocarbon vapour led to the perfecting of the "Petrolite" safety incandescent lamp, for which he was awarded prizes by the Edinburgh Association of Science and Art, and the Royal Scottish Society of Arts. He also devised a simplified form of Bunsen burner which was particularly suitable for use by beginners in laboratory practice. The Keith prize and gold medal for the period 1899–1901 was awarded to him by the Council of the Royal Society of Edinburgh for his researches on persulphates. He was elected to fellowship of the Royal Society in 1904, and to the chair of chemistry in Dundee in 1908. With, to all appearance, many years for good work still before him, Dr. Marshall was a man whom inorganic chemistry could ill afford to lose.

LEONARD DOBBIN.

NOTES.

REUTER'S Agency is informed that Sir David Bruce will leave England on November 1 for the purpose of concluding his sleeping sickness investigations in Central Africa. He will be accompanied by Lady Bruce, who is herself a member of the Commission. Sir David and Lady Bruce will sail in the *Edinburgh Castle* from Southampton, and will proceed to Cape Town, whence they will travel by train to Beira. From that place they intend to go up the Zambesi and Shire rivers to Lake Nyasa.

The Paris correspondent of *The Times* reports the death of the toxicologist, Dr. Jules Ogier, at sixty years of age. Our contemporary gives the following particulars of Dr. Ogier's career:—After some years' work with Berthelot, during which period his writings on arsenic and other poisons attracted considerable attention, he was appointed director of toxicology at the Prefecture of Police, where his work was of the greatest value to justice. He planned most of the large water systems in France, and his labours in connection with the purification of drinking water have been of great service to public health. He was in a way the creator of modern toxicological chemistry, and his many works include a treatise which has become a classic in that branch of science.

THE seventeenth annual autumn foray of the British Mycological Society was held at Haslemere on September 22–27, the Haslemere Educational Museum, founded by the late Sir Jonathan Hutchinson, serving as headquarters during the meeting. A well-arranged programme of excursions was planned by Mr. E. W. Swanton, and a large number of fungi were collected, including many rare and interesting forms. The mornings were generally devoted to the examination and arrangement of specimens, some of the most noteworthy of which were:—*Rhizopogon rubescens, Hydnum melaleucum, H. Queletii, Sparassis laminosa, Clavaria formosa, Cortinarius bolaris, Mycena crocata*, and *Sclerotinia baccarum*, and also the Mycetozoa, *Licea pusilla, Hemitrichia clavata, Oligonema nitens*, and *Diderma simplex*. On Wednesday evening, September 24, Mr. A. D. Cotton (president for the year) delivered an address entitled "Suggestions as to the Study and Critical Revision of Certain Genera of Agaricaceæ," pointing out the urgent need of critical work, and emphasising the diagnostic value of certain microscopic characters. Other members contributed papers, namely, Mr. F. T. Brooks, on pure cultures of several Basidiomycetes and Ascomycetes; Prof. Buller, on the hymenium-structure in Hymenomycetes; and Mr. J. Ramsbottom, on the history of the classification of Discomycetes. In passing a vote of thanks to the trustees of the museum, the hope was expressed that the scientific and educational work hitherto carried on there would be continued, and that it would be possible to establish the museum upon a permanent basis. The officers elected for 1914 were:—President, Prof. A. H. R. Buller; vice-president, Miss G. Lister; honorary secretary and treasurer, Mr. Carleton Rea; the localities for the spring and autumn meetings being the Forest of Dean and Doncaster respectively.

AT a conference held on September 19 in the rooms of the Linnean Society, Burlington House, Dr. A. B. Rendle, F.R.S., gave an account of the inception and activities of the plant protection section of the Selborne Society, under the auspices of which the meeting had been called, and outlined the various causes at work tending to the diminution or extermination of native plants in Britain—the building over of suburban and rural districts, drainage of marshes and bogs, smoke pollution, excessive collecting of rare plants by botanists and their agents, the wholesale digging up of both rare and common species by hawkers, &c. A brisk discussion followed regarding the proposed remedial measures for the preservation of the British flora; and though this was marked by considerable divergences of opinion, it was generally agreed that on one hand much remained to be done in the way of arousing public interest in the matter, while on the other there was much to be said for the introduction of legislation which should secure at least the same degree of protection and scheduling of plants as that afforded to bird-life by the Wild Birds Protection Acts. Several speakers pointed out that much might be done with the powers now possessed by local authorities but rarely exercised by them, and that in many cases small areas might be secured as nature reserves by public-spirited persons interested in the local flora before such areas were destroyed as plant habitats.

Dr. J. Mitchell Bruce will deliver the Harveian oration at the Royal College of Physicians of London on Saturday, October 18.

Under the auspices of the National Association for the Feeble-Minded, a conference of public authorities upon the subject dealt with by the association will be held at the Guildhall, London, on October 23.

The first Italian congress of radiology will be held at Milan on October 12–13. In connection with the congress there will be an exhibition of apparatus connected with Röntgen rays and investigations in radioactivity.

The twenty-first James Forrest lecture of the Institution of Civil Engineers will be delivered in the lecture theatre of the new building of the institution, Great George Street, Westminster, on Thursday, October 23, at 9 p.m., by Mr. Alexander Gracie, upon the subject of "Progress of Marine Construction."

The death is reported, at the early age of forty-two, of Mr. E. L. Morris, the biologist and curator in natural science in the museum of the Brooklyn Institute of Arts and Sciences. In addition to holding this office, Mr. Morris was one of the special plant experts of the U.S. Herbarium and the U.S. Department of Agriculture.

Mr. W. A. Tookey is to lecture to the Junior Institution of Engineers to-morrow—October 3—on gas-engine testing. On October 20 a paper is to be read by Mr. G. S. Cooper on modern coke-ovens. The new president of the institution, Sir Boverton Redwood, will deliver his presidential address on December 5, taking as his subject "The Future of Oil Fuel."

The Russian Government, reports *The Japan Chronicle* (September 11), has decided to establish a physical observatory at Vladivostok and experimental stations on the Pacific coast with the view of co-operating with the authorities of meteorological stations in China and Japan. Mr. S. D. Griboyedov, a prominent meteorologist, has been commissioned to investigate suitable sites for the proposed structures and to submit a report thereon.

It was announced in *The Times* of September 22 that a Malay python (*Python reticulatus*) in the Zoological Society's Garden had laid a number of eggs some days previously, which, after a considerable delay, she eventually brooded in the manner distinctive of this group of snakes. Unfortunately, there is every reason to believe that the eggs were not fertilised. A similar event took place in the Tower Menagerie so long ago as 1828, a second at the Jardin des Plantes in 1841, a third in the Society's Gardens in 1881, and a fourth in the Colombo Gardens in the autumn of 1904.

In *The Times* of September 25 it is stated, on the authority of a local correspondent, that steps are being taken, under the auspices of the Resident-General of France and of his Highness the Bey of Tunis, to establish in Tunisia a reserve in which the fast disappearing fauna of the country may find immunity from persecution. For this purpose some 4000 acres of wild mountainous country, with an adjoining marsh of 5000 acres, have been secured; and as this area already contains representatives of many of the wild animals of the country, the work of stocking the reserve will be much less heavy than would otherwise have been the case.

The first general meeting of the London Wireless Club was held on Tuesday of last week at the City of Westminster School, Mr. F. Hope Jones in the chair. Prof. Silvanus P. Thompson, F.R.S., Mr. A. A. Campbell Swinton, and Sir John Macpherson-Grant, Bart., have consented to become vice-presidents of the club. The honorary secretary is Mr. R. H. Klein, 18 Crediton Road, West Hampstead, N.W. The objects of the society were explained by the chairman to be the guarding of the interests of all experimenters in wireless telegraphy and telephony, and the organisation of desultory and for the most part useless work into co-operative scientific research. The committee was authorised to negotiate for the acquisition of suitable club-rooms, and their equipment with suitable aërial and instruments. A letter was read from Sir A. F. King, K.C.B., on behalf of the Postmaster-General, welcoming the formation of such a society, and indicating that certificates of its advisory committee would be accepted by him as qualification for the granting of licences. There will be two classes of members and full membership will be limited to persons having scientific qualifications. The subscriptions are at present 10*s.* 6*d.* for London members, and 5*s.* for members living outside a 25 miles' radius. The entrance fee is fixed at 2*s.* 6*d.*

A National Gas Congress and Exhibition will be held at Shepherd's Bush, London, during the whole of October, under the presidency of Sir Corbet Woodall. Space will be devoted in the exhibition to special exhibits related to hygienic and scientific lighting, the raw materials used in gas manufacture, the preparation and uses of residual products, the application of scientific apparatus, and to engineering in relation to gas manufacture, gas distribution, and gas measurement. A comprehensive series of conferences and popular lectures has been arranged. Among the subjects of the conferences are smoke abatement, to discuss the use of gas for fuel in relation to the problem of the smoke nuisance; food and cookery, to consider means for increasing knowledge of economical and correct methods of preparing and cooking food; the hygienic aspect of gas for lighting, heating, cooking, and ventilation; the lighting, heating, and ventilation of schools; the physiological and mental disadvantages of unscientific illumination; the teaching of cooking in schools; the economic value of adequate illumination; the use of gas as a fuel for industrial purposes; the use of gas for power; and the principles of scientific illumination in their relation to the use of gas for lighting.

MANY ways have already been suggested and demonstrated for causing each eye to see its appropriate picture of a stereoscopic pair, but we learn from *The Times* of September 26 that Messrs. Friedmann and Reiffenstein are showing yet another at the Austro-German Medical Congress now being held in Vienna. The new method depends upon the fact that a white image is invisible on a white background, and a black image is invisible on a black background, while both are visible if the backgrounds are reversed. The authors therefore bleach the negative of one of the pair, make an ordinary transparency from the other, and superpose the two plates. This compound plate will show either the one or the other picture according as the background put behind it is light or dark, and if the background is arranged so that it appears light to one eye and dark to the other—that is, light or dark according to the side that it is viewed from—then each eye will see its own picture without any instrumental means. A background that serves this purpose is a sheet of glass that is "ribbed convexly," while its back surface is "prepared in a special manner" that is not described. The great advantage of such stereoscopic pictures is that they only need looking at as if they were single pictures to show the full stereoscopic effect. It is stated that the few specimens shown are very satisfactory.

THE provisional programme of the Royal Geographical Society for the coming session has just been issued. We learn from it that the following papers have been arranged:—"The Work and Adventures of the Northern Party of Capt. Scott's Antarctic Expedition," R. E. Priestley (November 10); "Explorations in the Eastern Karakoram," Mrs. Bullock Workman and Dr. Hunter Workman (November 24); "Is the Earth Drying up?" Prof. J. W. Gregory, F.R.S. (December 8); "An Expedition to Dutch New Guinea," A. F. R. Wollaston (December 16). In addition to the foregoing, the following papers may be expected:—"Famous Maps in the British Museum," J. A. J. de Villiers; "Journey through Arabia," Capt. G. E. Leachman; "Geographical Aspects of Two Sub-Expeditions in the Antarctic," Griffith Taylor; "The Federal District and Capital, Camberra, of the Commonwealth of Australia," Griffith Taylor; "Journeys in the Upper Amazon Basin," Dr. Hamilton Rice; "The Gulf Stream," Commander Campbell Hepworth, C.B.; "The Red Sea and the Jordan," Sir William Willcocks, K.C.M.G.; "Fresh Discoveries in the Eket District, Southern Nigeria," P. A. Talbot; "The Panama Canal," Dr. Vaughan Cornish; "The Atlantic Ocean," Prof. E. Hull, F.R.S.; "The Anglo-German Boundary Survey in West Africa," Capt. W. V. Nugent.

IN *L'Anthropologie*, vol. xxiv., Nos. 2 and 3, Prof. G. H. Luquet proposes an explanation of the rock markings at Gavr'inis. Comparing the figures with those on the megalithic monuments in Brittany and Ireland, he suggests that they are ultimately based on an anthropomorphic attempt to represent the human figure, particularly of the eyes and eyebrows. This contribution is lavishly illustrated by woodcuts, and the explanation now offered well deserves respectful study by archæologists in this country.

MR. ANANDA COOMARASWAMY'S useful periodical, *Visvakarma*, devoted to the reproduction of examples of Indian architecture, sculpture, painting, and handicrafts, has reached its fifth number. We have a fine series of photographs, among which the most noticeable are the splendid lion column from Sarnath, the Trimurti or sacred triad from the Caves of Elephanta, and interesting figures of deer, monkeys, a cat and mice from Mamallapuram. The Asokan statue from Besnagar is one of the most remarkable sculptural remains of the period.

THE *National Geographic Magazine* for September is devoted to Egypt, and contains a large collection of beautiful photographs. Perhaps the most interesting contribution is the account by Mr. C. M. Cobern of the sacred ibis cemetery and jackal catacombs at Abydos. The ibises are as carefully mummified as the royal personages at Deir-el-Bahari, and were it not for the ravages by white ants, hundreds of these sacred birds could now be examined in as perfect a state as when they were buried. The jackals were preserved because they were sacred to Anubis, the friend of the righteous dead, who guided the soul across the trackless desert to the fields of Aalu, the land of the dead.

THE excavation of the Roman city of Corstopitum, the modern Corbridge, begun by the Northumberland County History Committee and the Corbridge Excavation Committee in 1906, was actively prosecuted during the past season. Among the objects unearthed were forty-eight gold coins and a gold ring, probably deposited about A.D. 385, several altars, a vast quantity of pottery, a bronze pig containing 160 gold coins ranging from Nero to Marcus Aurelius, the well-known Corbridge lion, a smithy with arrow-heads and other articles of iron. Thus a vast amount of material for the study of Roman pottery has been found, and the buildings include some of the most imposing relics in Roman Britain, as well as some of the worst walls ever erected by human hands. The animal remains are of high scientific value, and some addition has been made to our knowledge of Roman metallurgy. The museum has been rearranged, and now contains a collection of Roman remains unequalled in the north of England, except, perhaps, at York.

WE have to acknowledge the receipt from Messrs. Dulau and Co., Ltd., of a copy of a catalogue of works and papers on various groups of the lower invertebrates.

IN the report of the museums of the Brooklyn Institute for 1912, reference is made to the large increase in the zoological collections, and the mounting of a group of marsh-hawks for the series illustrating the fauna of Long Island. Of the fauna and flora of that island a popular account is in course of publication in vol. ii. of the Science Bulletin of the Institute, the first portion of this dealing with the bats, and the second with two species of molluscs.

In the September number of *The American Naturalist*, Prof. H. H. Newman, of Chicago University, discusses at length the remarkable phenomenon of polyembryonic development exhibited by *Dasypus novemcinctus* and certain other species of armadillos, and its bearing on sex-determination. The females of these species, when pregnant, invariably develop four embryos, enclosed in a single chorionic envelope, which are always of the same sex, the process of development being summarised by the author as follows:—"The ovogenesis is normal; a single egg is fertilised by a single spermatozoon; the cleavage is apparently normal, and gives rise to a blastodermic vesicle similar to that of other mammals, especially the rodents; germ-layer-inversion affords an easy mechanism for producing several embryos in a single chorion, for the quadruplets arise by means of dichotomous budding of the inner ectodermic vesicle without affecting the enveloping membranes of the vesicle, which form the common chorion; the subsequent embryonic development of the several embryos is as independent as it can be under monochorial conditions, since each individual has its own separate amnion, allantois, umbilicus, and placenta."

M. Fujioka contributes an elaborate study of the structure of the wood in the Japanese conifers to the Journal of the College of Agriculture, University of Tokyo, vol. iv., No. 4. The detailed descriptions of the wood in the various species examined are followed by a key to the Japanese genera of Coniferæ based upon the history of their wood, and the memoir is illustrated by seven plates containing eighty-four very fine photomicrographs.

We have received a copy of the Proceedings and Transactions of the Croydon Natural History and Scientific Society, 1912–13, which contains various items of interest. Among these there is an account of the organisation of the Regional Survey of Croydon, which the society have undertaken, and which, when completed, will form one of the most elaborate records of the natural history of a limited area that has been made. The volume also includes reports of addresses given by Dr. H. F. Parsons and Mr. A. G. Tansley, dealing respectively with "Plant Growth and Soil Conditions" and with "Practical Study of Vegetation in the Field." There is an extensive appendix containing the records of the Meteorological Committee, and giving the daily rainfall throughout the year 1912 at various stations in the district.

Miss M. C. Knowles, in a paper on the maritime and marine lichens of Howth (Sci. Proc. Royal Dublin Soc., August, 1913), gives an interesting account of the lichen vegetation of Howth Head, Dublin Bay, illustrated by several beautiful photographs by Mr. R. Welch. More than half of the memoir is occupied by a detailed description of the ecology of the lichens which inhabit the siliceous rocks on the coast and form more or less sharply defined belts or zones dominated, from above downwards, by species of Ramalina, orange-coloured lichens, species of Lichina, *Verrucaria maura*, and marine Verrucarias. Three new species are described, and notes are given on some remarkable forms of Ramalina, while the memoir as a whole may be regarded as the most important contribution that has yet been made to the ecology of the littoral lichen vegetation of this country.

We have received a Spanish edition of the "International Codex of Resolutions adopted at Congresses, Conferences, and at Meetings of the Permanent Committee, 1872–1910," translated by the Central Observatory of Manila from the second German edition. The preparation of this useful work was recommended by the International Meteorological Committee at the meeting at Southport in 1903, and Drs. Hellmann and Hildebrandsson were requested to undertake it. At the conference at Innsbruck, in 1905, a manuscript copy of the Codex was presented, and its publication in English, French, and German was urged as "a most valuable means for promoting international meteorological work." In view of the extended use of Spanish in central and southern America, and also in eastern Asia, Señor J. Algué was thanked for his offer to arrange for its publication in that language. It should be mentioned that due reference was made by Dr. Hellmann to a somewhat similar work published by Dr. Wild (then president of the International Meteorological Committee) in the *Repertorium für Meteorologie*, vol. xvi., which contained particulars for 1872–1891, and was at the time of considerable value.

In a well-known experiment of De la Rive's, one end of an electromagnet projects into an evacuated bulb containing two electrodes, one of which takes the form of a ring. When a discharge is passed the luminous column is seen to rotate round the magnet pole. This experiment receives various interesting extensions in a paper by Prof. Righi on "Rotazioni Ionomagnetiche (R. Accad. di Bologna, February, 1913). In a typical experiment the two electrodes, which are here cylindrical, are placed in the same vertical line, and the lower one is surrounded by a suspended metal cylinder. An external magnet produces a field parallel to the line joining the electrodes. When the discharge passes it is found that the cylinder rotates. The theory shows that the effect is due to the oblique impact, on the cylindrical walls, of the ions carrying the discharge.

We have received a copy of Dr. P. W. Bridgman's paper on the thermodynamic properties of twelve liquids between 20° C. and 80° C. and up to 12,000 kilograms per sq. cm. The work was carried out at the Jefferson Physical Laboratory of Harvard University by the aid of the Rumford Fund. The liquids used were methyl, ethyl, propyl, isobutyl, and amyl alcohols, ethyl ether, acetone, carbon bisulphide, phosphorus trichloride, and ethyl bromide, all of which were obtained in an approximately pure state. The liquid was contained in a cylinder closed by a piston, the motion of which determined the change of volume. The pressure applied was measured by the change of electrical resistance of a standardised manganine wire.

The whole was enclosed in a bath the temperature of which could be varied between the limits stated above. Dr. Bridgman finds that the compressibility and thermal expansion of a liquid may decrease with increasing temperature and may increase with increase of pressure. He is disposed to attribute these remarkable results to deformation of the actual molecules when forced into contact at these high pressures.

PROBABLY no branch of the community is more open to be defrauded than those who must perforce exclude carbohydrates from their diet. The unsuspecting patient purchases foods which are not only glaringly misrepresented, but also may be positively harmful to him. It is to be feared, moreover, that the medical adviser is often but little better informed, though in default of a source of trustworthy information as to the nature of the commercial products he can scarcely be held responsible. The Connecticut Agricultural Experiment Station has done great service, therefore, in issuing a lengthy report dealing with the composition and merits of all the so-called diabetic flours, breads, biscuits, and other diabetic foods of both European and American origin—the list is an exhaustive one. To all but the few initiated the result of the inquiry must be very startling. By far the greater number of the foods examined were definitely fraudulent in that they did not fulfil the claims made for them, and many of them indeed contained as much starch as is present in ordinary white bread. The report also deals with the excessive cost of such foods, which has, in the past, rendered their use almost prohibitive to the poor man. A select list of genuine diabetic foods, which return good value, is given, in which it is satisfactory to find the products of British firms of repute. Our chief purpose in directing attention to the report is, however, to urge the necessity of some control being exercised over the indiscriminate misrepresentation of foodstuffs of which this is a type with its attendant menace to the public health. The report merits the widest possible publication.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR OCTOBER :—

Oct. 2. 3h. 0m. Mars at quadrature to the Sun.
,, 14h. 0m. Jupiter at quadrature to the Sun.
6. 6h. 21m. Jupiter in conjunction with the Moon (Jupiter 4° 51′ N.).
8. 3h. 37m. Uranus in conjunction with the Moon (Uranus 3° 35′ N.).
13. 14h. 0m. Uranus stationary.
14. 9h. 0m. Venus nearest the Sun.
19. 9h. 19m. Saturn in conjunction with the Moon (Saturn 6° 56′ S.).
21. 13h. 7m. Mars in conjunction with the Moon (Mars 3° 55′ S.).
,, 18h. 0m. Neptune at quadrature to the Sun.
22. 7h. 54m. Neptune in conjunction with the Moon (Neptune 4° 53′ S.).
27. 5h. 0m. Uranus at quadrature to the Sun.
,, 8h. 31m. Venus in conjunction with the Moon (Venus 3° 17′ N.).
30. 20h. 17m. Mercury in conjunction with the Moon (Mercury 2° 2′ N.).
31. 13h. 0m. Neptune stationary.

COMETS 1913*b* (METCALF) AND 1913*c* (NEUJMIN).—Prof. H. Kobold's ephemeris for comet Metcalf during the present week is as follows (*Astronomische Nachrichten*, No. 4682):—

M.T. Berlin.

	R.A. (true) h. m. s.		Dec. (true) ° ′		Mag.
Oct. 2 ...	23 18 26	...	+72 6·0	...	8·2
3 ...	22 54 25	...	69 52·2		
4 ...	22 34 49	...	67 23·4		
5 ...	22 18 45	...	64 42·1	...	8·0
6 ...	22 5 26	...	61 51·4		
7 ...	21 54 26	...	58 53·3		
8 ...	21 45 16	...	55 50·0		
9 ...	21 37 9	...	+52 43·7	...	8·0

This comet is now in Cepheus and rapidly reducing its northern declination, moving towards the constellation of Cygnus. It is well up above the horizon and gaining in magnitude.

On the other hand, comet Neujmin is decreasing in magnitude, becoming fainter than magnitude 12. This comet seems to be moving in an elliptical orbit, and Prof. Cohn finds a period of nine years. Its appearance has attracted the attention of numerous observers, since while the nucleus has appeared quite stellar, the gaseous envelope has been alternating between visibility and disappearance.

ANOTHER COMET.—A Kiel telegram, dated September 27, distributes the information communicated by Prof. Hussey that Mr. Delaren on September 26, 10h. 29·2m. M.T. Laplata, discovered a comet of the tenth magnitude, its position being given as R.A. 21h. 54m. 16s. and declination 2° 34′ 27″ S. In the issue of *The Times* for September 30 it is suggested that probably this comet may be identical with Westphal's comet, which is now due, and for which a search has been continually made. If it be Westphal's, then it will move northward during the next month and will increase considerably in brightness, possibly becoming visible to the naked eye. At its appearance in 1852 it was a fairly conspicuous naked eye object.

THE SPECTRUM OF α-CANUM VENATICORUM.—In two previous notes in this column (June 5 and July 24) reference has been made to Prof. Belopolsky's observations of the spectrum of this star, the lines in the spectrum showing striking variations of a periodic nature. The *Astronomische Nachrichten*, No. 4681, contains now the preliminary discussion of a large number of spectrograms, sixty-seven in number, which he has been able to secure in the interval between April 15 and June 23. All the photographs were taken with the 30-inch and a three-prism spectrograph, the exposures lasting one hour; an iron comparison was photographed twice at each exposure. In the present communication Prof. Belopolsky first describes in detail the appearance of the lines observed. From the measures of the intensity of the line λ4131·00 he finds a period of 5·50 days, and he places several other lines in the same category, *i.e.* they become bright at the same time as λ4131·00. Another group of lines behaves in an opposite manner, disappearing when the former group become more intense; the period is also very near 5·50 days. Other lines such as hydrogen, magnesium, calcium, and iron display little if any change. From the line of sight measures he finds a certain group of lines, which includes H., Mg., and Fe., which indicate no changes dependent on the 5·5 day period, while other lines display variations of radial velocity equal in period to that of the intensity of the lines. Prof. Belopolsky suggests as an explanation of the above and other observations that a gaseous satellite or a gas ring moves round a central body, but he finds that there are several details that are difficult to explain which will perhaps be cleared up when more material has been collected.

THE WAVE-LENGTHS OF CERTAIN IRON LINES.—It is important for the accurate determination of wave-lengths in a spectrum to have available a large number of standard wave-lengths well distributed over the whole length of the spectrum. The work which the Solar Union initiated in this respect has been most valuable, and the task of determining more constants and of securing greater accuracy is no light one. By the aid of a grant of the Martin Kellogg fellowship in the Lick Observatory and of the generosity of MM. Buisson and Fabry, who placed the necessary apparatus and also constant help and advice at his service, Mr. Keivin Burns has been able to make a series of interference measures of standards in the iron spectrum between the limits λλ5434A and 8824A. The results of this research are recorded in Lick Bulletin, No. 233, and, in addition to the international standards already determined between the above-mentioned limits, he has added another one hundred and nineteen lines in regions which were lacking in international standard lines. Small discrepancies in different measures of some standard lines have led to the consideration of their variability of wave-length. Mr. Burns has had access to the manuscript of Dr. Goos, in which a special study has been made of the source of this variability, and he agrees entirely with the view, namely, that "Dr. Goos insists on the necessity of determining exactly what conditions the arc is to used." In this journal for September 11 last, further details will be found regarding the specified conditions for the determinations of further standards which were recommended by the committee of the Solar Union on standard wave-lengths at the recent meeting in Bonn.

THE ANTIQUITY OF MAN IN SOUTH AMERICA.[1]

THE problem of the antiquity of man in South America has given rise to many papers and much discussion in various languages, and it became necessary for a trained anthropologist and geologist to study on the spot the human remains and the exact mode of their occurrence. Dr. A. Hrdlička was undoubtedly the anthropologist best fitted for the investigation, as he has an unequalled knowledge of the physical anthropology of the American Indian and had already summarised his own investigations on the antiquity of man in North America in Bulletin 33 of the Bureau of American Ethnology (1907), where he states his conclusion that "no human bones of undisputed geological antiquity are known," and that the remains exhibit a "close affinity to or identity with those of the modern Indian."

Mr. Bailey Willis, of the U.S. Geological Survey, who had done important work on the loess and related formations in North America and China, accompanied Dr. Hrdlička to Argentina in May, 1910. The Argentine men of science received them very cordially, and facilitated their work. Most of the specimens they were to examine had been described by Prof. F. Ameghino, to whose energy and enthusiasm South American palæontology owes so much, and it must have saddened his last hours to know—if indeed he admitted it—that zeal is a poor substitute for knowledge when the details of human anatomy are in question.

[1] "Early Man in South America." By Ales Hrdlička, in collaboration with W. H. Holmes, Bailey Willis, Fred E. Wright, and Clarence N. Fenner. Pp. xv+405+68. (Smithsonian Institution, Bureau of American Ethnology, Bulletin 52. Washington, 1912.)

Mr. Bailey Willis gives an excellent account of the geology of central eastern Argentina, more especially of the Pampean terrane, which is a remarkably uniform deposit of fine-grained earth, probably an eolian formation of desert plateau origin, transported by rivers to the lowlands, but during arid episodes the alluvium was partially converted into eolian loess. There is no evidence at present that man lived during Pampean times, but his remains have been found in the Upper Pampean and Post Pampean, also mainly eolian loess formations, which lie in hollows sculptured in the surface of the Pampean, also in many cases there is a distinct unconformity beneath the deposits of the Upper Pampean. A great deal has been written about the *tierra cocida*, or burnt earth which occurs in the Pampean terrane at various horizons; many of these may have been due to the burning of grasses, but there is nothing to connect the burnt earths of the Pampean with man.

Messrs. F. E. Wright and C. N. Fenner present details of their petrographic studies of specimens of the loess, tierra cocida, and scoriæ. They state that many specimens of tierra cocida are so large and compact that one is forced to assume long-continued and confined heating at a fairly high temperature, such as would be encountered near the contact of an intrusive igneous or volcanic mass, but not beneath an open fire made of grass or small timber.

Dr. Hrdlička discusses the peculiar stone industries of the Argentine coast. Ameghino considered that the "split-stone" industry "is in certain respects more primitive than that of the eoliths of Europe," referring it to the Middle Pliocene, and that it was preceded by a "broken-stone" industry. Dr. F. F. Outes denied the distinctiveness and great antiquity of these techniques, and Hrdlička confirms him. Dr. W. H. Holmes supplies a valuable critical study of the stone implements collected by the expedition, which should be read by European archæologists, as it contains information of general interest.

The greater part of the book consists of a discussion by Dr. Hrdlička of the human remains; his system is to note the history and earlier reports, then to give the result of his own examination, and to conclude with critical remarks. He first deals with the dolichocephalic skulls found in the caves at Lagoa Santa, Brazil, and states that there is no evidence that they belonged to a race which lived contemporaneously with the extinct species of animals found in the same caves. Similarly the Carcaraña, Rio Negro, Saladero, Fontezuelas, and other remains have no solid claims to geological antiquity. The *Homo caputinclinatus* and *H. sinemento* of Ameghino prove to be skulls of ordinary Indian type, with no title to antiquity; the same holds good for *H.* (*Prothomo*) *pampaeus*, despite Ameghino's statement that it is the "earliest human representative—if not even a predecessor of man." Concerning the fragmentary calvarium, *Diprothomo platensis*, of reputed Lower Pliocene origin, Hrdlička supports Schwalbe's statement that "all the features dwelt upon by Ameghino are referable to a *wholly false orientation* of the specimen." Bailey Willis cannot give his support to the statement that the calvarium was really dug out of undisturbed ancient Pampean. Finally, the atlas and femur of *Tetraprothomo argentinus*, of supposed Upper Miocene age, have been subjected to a searching analysis by Hrdlička, with the result that there is nothing to distinguish the former from the atlas of a modern Indian, and the femur is that of a carnivore, probably of an extinct form of one of the Felidæ. Bailey Willis "does not consider the age of the so-called Monte Hermoso formation [in which the remains were found] definitely established," nor does he "attach any significance to the occurrence of burnt earth as an evidence of man's existence in the Miocene (?) 'Monte Hermosean.'" "The conclusions of the writers with regard to the evidence thus far furnished are that it fails to establish the claim that in South America there have been brought forth thus far tangible traces of either geologically ancient man himself or of any precursors of the human race." A. C. Haddon.

PAPERS ON INVERTEBRATES.

Unusual interest attaches to the description by Dr. A. Brinkmann, in the *Bergens Museum Aarbok* for 1912, part 3, of a new genus and species of deep-sea nemertine worm—*Bathynectes murrayii*—which differs from all previously known forms in the external position of the male genitalia. A single example was obtained so long ago as 1895, while sixteen others were collected by the *Michael Sars* in 1910. The length of females ranges from 43 to 61 mm., with a breadth of from 7·5 to 10 mm., but males are considerably smaller. Although the new organism, of which figures are given, represents an entirely new type, it forms in some degree a connecting link between Planktonemertes and Nectonemertes.

In connection with the above may be noticed a paper by Dr. M. v. Gedroyć, in *Bull. Ac. Sci. Cracovie* for February, 1913, on certain new European leeches, referred to the genera Trocheta and Hæmentaria, special interest from a distributional point of view attaching to the second determination, owing to the fact that while the genus was originally described from South America, it is now known to occur in the United States, Canada, Lapland, and Poland.

The death-feigning instinct (*Katalepsie*) among stick-insects (Phasmidæ), as exemplified by the species *Cerausius morosus,* forms the subject of a very interesting article by Mr. Peter Schmidt in *Biol. Centralblatt* of April 20. These insects, it appears, are extremely prone to assume the cataleptic phase, and may do so in almost any pose—sometimes lying flat on one side, with the limbs and antennæ stretched out parallel with the body, sometimes with the legs straddled outwards and the head and thorax raised, and at other times standing on the head. As these insects are specially modified to imitate vegetation, it seems that the cataleptic condition is another adaptation—of the muscular and nervous structures—to the same end.

The beetles, spiders and scorpions, earwigs, and flies collected during the Abor Expedition of 1911–12 form the subject of four articles by specialists in part 2 of vol viii. of Records of the Indian Museum, a number of new forms being described. In vol. iii., part 4, of Annals of the Transvaal Museum, Mr. L. B. Prout and Mr. E. A. Meyrick respectively describe new local Geometridæ and Micro-Lepidoptera.

We have received a copy of a concise "Synopsis of the Classification of Insects," drawn up by Prof. Maxwell Lefroy, and published by Messrs. Lumley, of Exhibition Road, at the price of one shilling. The arrangement of the orders is the one adopted by Messrs. Sharp and Shipley, and a brief, but apparently sufficient, definition is given of each order and family. The lack of an index is a decided drawback to the value of the work.

To the May number of *The Entomologist's Monthly Magazine* the Hon. Charles Rothschild contributes a note on the extremely rare bugs of the genus Cacodemus, which are parasitic on Old World bats. Three species are mentioned, one from South Africa, a second from India, and a third of which the home is at present unknown. Mr. Rothschild, it may be added, employs the name Clinocoridæ for the bugs, whereas Prof. Lefroy, in the synopsis just mentioned, uses Cimicidæ. R. L.

THE BRITISH ASSOCIATION AT BIRMINGHAM.

SECTION D.

ZOOLOGY.

Opening Address by H. F. Gadow, F.R.S., President of the Section.

"Address your audience about what you yourself happen to be most interested in, speak from the fullness of your heart, and make a clean breast of your troubles." That seemed good advice, and I shall endeavour to follow it, taking for my text old and new aims and methods of morphology, with special reference to resemblances in function and structure on the part of organs and their owners in the animal kingdom. First, however, allow me to tell you what has brought me to such a well-worn theme. Amongst the many impressions which it has been my good luck to gather during my travels in that enchanting country Mexico are the two following:—

First, the poisonous coral snakes, Elaps, in their beautiful black, red, and yellow garb; it varies in detail in the various species of Elaps, and this garb, with most of the variations too, occurs also in an astonishing number of genera and families of semi-poisonous and quite harmless Mexican snakes, some of which inhabit the same districts. A somewhat exhaustive study of these beauties has shown incontestably that these often astoundingly close resemblances are not cases of mimicry, but due to some other cooperations.

Secondly, in the wilds of the State of Michoacan, at two places, about twenty and seventy miles from the Pacific coast, I myself collected specimens of Typhlops which Dr. Boulenger without hesitation has determined as *Typhlops braminus*. Now, whilst this genus of wormlike, blind little snakes has a wide circum-tropical distribution, *T. braminus* had hitherto been known only from the islands and countries of the Indian Ocean basin, never from America, nor from any of the Pacific Islands which possess other kinds of Typhlops. Accidental introduction is out of the question. Although the genus is, to judge from its characters, an especially old one, we cannot possibly assume that the species *braminus*, if the little thing had made its way from Asia to Mexico by a natural mode of spreading, has remained unaltered even to the slightest detail since that geological epoch during which such a journey could have taken place. There remains the assumption that amongst the of course countless generations of Typhlops in Mexico some have hit off exactly the same kind of permutation and combination of those characters which we have hitherto considered as specific of *braminus,* just as a pack of cards may in a long series of deals be dealt out more than once in the same sequence.

The two cases are impressive. They reminded me vividly that many examples of very discontinuous distribution—which anyone who has worked at zoogeography will call to mind—are exhibited by genera, families, and even orders, without our knowing whether the groups in which we class them are natural or artificial. The ultimate appeal lies with anatomy.

Introduced to zoology when Haeckel and Gegenbaur were both at their zenith, I have been long enough a worker and teacher to feel elated by its progress and depressed by its shortcomings and failures. Perhaps we have gone too fast, carried along by methods which have yielded so much and therefore have made us expect too much from them.

Gegenbaur founded the modern comparative anatomy by basing it upon the theory of descent. The leading idea in all his great works is to show that transformation, "continuous adjustment"

(Spencer), has taken place; he stated the problem of comparative anatomy as the reduction of the differences in the organisation of the various animals to a common condition; and as homologous organs he defined those which are of such a common, single origin. His first work in this new line is his classical treatise on the Carpus and Tarsus (1864).

It followed from this point of view that the degree of resemblance in structure between homologous organs and the number of such kindred organs present is a measure for the affinity of their owners. So was ushered in the era of pedigree of organs, of functions, of the animals themselves. The tracing of the divergence of homogenous parts became all-important, whilst those organs or features which revealed themselves as of different origin, and therefore as analogous only, were discarded as misleading in the all-important search for pedigrees. Functional correspondence was dismissed as "mere analogy," and even the systematist has learnt to scorn these so-called physiological or adaptive characters as good enough only for artificial keys. A curious view of things, just as if it was not one and the same process which has produced and abolished both sets of characters, the so-called fundamental or "reliable," as well as the analogous.

As A. Willey has put it happily, there was more rejoicing over the discovery of the homology of some unimportant little organ than over the finding of the most appalling unrelated resemblance. Morphology had become somewhat intolerant in the application of its canons, especially since it was aided by the phenomenal growth of embryology. You must not compare ectodermal with endodermal products. You must not make a likeness out of another germinal layer or anything that appertains to it, because if you do that would be a horror, a heresy, a homoplasy.

Haeckel went so far as to distinguish between a true homology, or homophyly, which depends upon the same origin, and a false homology, which applies to all those organic resemblances which derive from an equivalent adaptation to similar developmental conditions. And he stated that the whole art of the morphologist consists in the successful distinction between these two categories. If we were able to draw this distinction in every case, possibly some day the grand tree of each great phylum, maybe of the whole kingdom, might be reconstructed. That would indeed be a tree of knowledge, and, paradoxically enough, it would be the deathblow to classification, since in this, the one and only true natural system, every degree of consanguinity and relationship throughout all animated nature, past and present, would be accounted for; and to that system no classification would be applicable, since each horizon would require its own grouping. There could be definable neither classes, orders, families, nor species, since each of these conceptions would be boundless in an upward or downward direction.

Never mind the ensuing chaos; we should at least have the pedigree of all our fellow-creatures, and of ourselves among them. Not absolute proof, but the nearest possible demonstration that transformation has taken place. Empirically we know this already, since, wherever sufficient material has been studied, be it organs, species, or larger groups, we find first that these units had ancestors, and, secondly, that the ancestors were at least a little different. Evolution is a fact of experience, proved by circumstantial evidence. Nevertheless we are not satisfied with the conviction that life is subject to an unceasing change, not even with the knowledge of the particular adjustments. We now want to understand the motive cause. First, What, then How, and now Why?

It is the active search for an answer to this question (Why?) which is characteristic of our time. More and more the organisms and their organs are considered as living, functional things. The mainspring of our science, perhaps of all science, is not its utility, not the desire to do good, but, as an eminently matter-of-fact man, the father of Frederick the Great, told his Royal Academicians (who, of course, were asking for monetary help) in the following shockingly homely words: "Der Grund ist derer Leute ihre verfluchte Curieusiteit." This blamed curiosity, the beginnings of which can be traced very far back in the lower animals, is most acutely centred in our desire to find out who we are, whence we have come, and whither we shall go. And even if zoology, considering the first and last of these three questions as settled, should some day solve the problem: Whence have we come? there would remain outside zoology the greater Why?

Generalisations, conclusions, can be arrived at only through comparison. Comparison leads no further where the objects are alike. If, for instance, we restrict ourselves to the search for true homologies, dealing with homogenes only, all we find is that once upon a time some organism has produced, invented, a certain arrangement or *Anlage* out of which that organ arose, the various features of which we have compared in the descendants. Result: we have arrived at an accomplished fact. These things, in spite of all their variety in structure and function, being homogenes, tell us nothing, because according to our mode of procedure we cannot compare that monophyletic *Anlage* with anything else, since we have reduced all the homogenous modifications to one. Logically it is true that there can have been only one, but in the living world of nature there are no such iron-bound categories and absolute distinctions. For instance, if we compare the organs of one and the same individual, we at once observe repetition, *e.g.* that of serial homology, which implies many difficulties, with very different interpretations. Even in such an apparently simple case as the relation between shoulder girdle and pelvis we are at a loss, since the decision depends upon our view as to the origin of the paired limbs, whether both are modified visceral arches, and in this case serially repeated homogenes, or whether they are the derivatives from one lateral fin, which is itself a serial compound, from which, however, the proximal elements, the girdles, are supposed to have arisen independently. What is metamerism? Is it the outcome of a process of successive repetitions so that the units are homogenes, or did the division take place at one time all along the line, or is it due to a combination of the two procedures?

The same vagueness finds its parallel when dealing with the corresponding organs of different animals, since these afford the absolute chance that organs of the same structure and function may not be reducible to one germ, but may be shown to have arisen independently in time as well as with reference to the space they occupy in their owners. As heterogenes they can be compared as to their causes. In the study of the evolution of homogenes the problem is to account for their divergencies, whilst the likeness, the agreements, so to speak their greatest common measure, is *eo ipso* taken to be due to inheritance. When, on the contrary, dealing with heterogenes, we are attracted by their resemblances, which since they cannot be due to inheritance must have a common cause outside themselves. Now, since a leading feature of the evolution of homogenes is divergence, whilst that of heterogenes implies convergence from different starting points, it follows that the more distant are these respective starting points (either in time or in the material) the better is our chance of extracting the greatest common measure out of the unknown number of causes which combine in the production of even the apparently simplest organ.

These resemblances are a very promising field, and the balance of importance will more and more incline towards the investigation of function, a study which, however, does not mean mere physiology with its present-day aims in the now tacitly accepted sense, but that broad study of life and death which is to yield the answer to the question Why?

Meantime, comparative anatomy will not be shelved; it will always retain the casting-vote as to the degree of affinity among resemblances, but emphatically its whole work is not to be restricted to this occupation. It will increasingly have to reckon with the functions, indeed never without them. The animal refuses to yield its secrets unless it be considered as a living individual. It is true that Gegenbaur himself was most emphatic in asserting that an organ is the result of its function. Often he held up to scorn the embryographer's method of muddling cause and effect, or he mercilessly showed that in the reconstruction of the evolution of an organ certain features cannot have been phases unless they imply physiological continuity. And yet how moderately is function dealt with in his monumental text-book and how little is there in others, even in text-books of zoology!

> Habt alle die Theile in der Hand,
> Fehlt leider nur das geistige Band—Life!

We have become accustomed to the fact that like begets like with small differences, and from the accepted point of view of evolution *versus* creation we no longer wonder that descendants slowly change and diverge. But we are rightly impressed when unlike comes to produce like, since this phenomenon seems to indicate a tendency, a set purpose, a *beau idéal*, which line of thought or rather imperfect way of expression leads dangerously near to the crassest teleology.

But, teleology apart, we can postulate a perfect agreement in function and structure between creatures which have no community of descent. The notion that such agreement *must* be due to blood-relationship involved, among other difficulties, the dangerous conclusion that the hypothetical ancestor of a given genuine group possessed in potentiality the *Anlagen* of all the characters exhibited by one or other of the component members of the said group.

The same line of thought explained the majority of human abnormalities as atavistic, a procedure which would turn the revered ancestor of our species into a perfect museum of antiquities, stocked with tools for every possible emergency.

The more elaborate certain resemblances are, the more they seem to bear the hall-mark of near affinity of their owners. When occurring in far-related groups they are taken at least as indications of the homology of the organs. There is, for instance, a remarkable resemblance between the *bulla* of the whale's ear and that of the *Pythonomorph Plioplatycarpus*. If you homologise the mammalian tympanic with the quadrate the resemblance loses much of its perplexity, and certain Chelonians make it easier to understand how the modifications may have been brought about. But, although we can arrange the Chelonian, Pythonomorph, and Cetacean conditions in a progressive line, this need not represent the pedigree of this *bulla*. Nor is it necessarily referable to the same *Anlage*. Lastly, if, as many anatomists believe, the reptilian quadrate appears in the mammals as the *incus*, then all homology and homogeny of this *bullae* is excluded. In either case we stand before the problem of the formation of a *bulla* as such. The significant point is this, that although we dismiss the *bulla* of whale and reptile as obvious homoplasy, such resemblances, if they occur in two orders of reptiles, we take as indicative of relationship until positive evidence to the contrary is produced. That this is an unsound method is brought home to us by an ever-increasing number of cases which tend to throw suspicion on many of our reconstructions. Not a few zoologists look upon such cases as a nuisance and the underlying principle as a bugbear. So far from that being the case, such study promises much beyond the pruning of our standard trees—by relieving them of what reveal themselves as grafts instead of genuine growth—namely, the revelation of one or other of the many agencies in their growth and structure.

Since there are all sorts and conditions of resemblances, we require technical terms. Of these there is abundance, and it is with reluctance that I propose adding to them. I do so because unfortunately some terms are undefined, perhaps not definable; others have not "caught on," or they suffer from that mischievous law of priority in nomenclature.

The terms concerning morphological homologies date from Owen; Gegenbaur and Haeckel rearranged them slightly. Lankester, in 1870, introduced the terms homogenous, meaning alike born, and homoplastic, or alike moulded. Mivart rightly found fault with the detailed definition and the subdivisions of homoplasy, and very logically invented dozens of new terms, few of which, if any, have survived. It is not necessary to survey the ensuing literature. For expressing the same phenomenon we have now the choice between homoplasy, homomorphy, isomorphy, heterophyletic convergence, parallelism, &c. After various papers by Osborn, who has gone very fully into these questions, and Willey's "Parallelism," Abel, in his fascinating "Grundzüge der Palæobiologie," has striven to show by numerous examples that the resemblances or "adaptive formations" are cases of parallelism if they depend upon the same function of homologous organs, and convergences if brought about by the same function of non-homologous organs.

I suggest an elastic terminology for the various resemblances indicative of the degree of homology of the respective organs, the degree of affinity of their owners, and lastly the degree of the structural likeness attained.

Homogeny.—The structural feature is invented once and is transmitted, without a break, to the descendants, in which it remains unaltered, or it changes by mutation or divergence, neither of which changes can bring the ultimate results nearer to each other. Nor can their owners become more like each other, since the respective character made its first appearance either in one individual, or, more probably, in many of one and the same homogenous community.

Homoplasy.—The feature or character is invented more than once, and independently. This phenomenon excludes absolute identity; it implies some unlikeness due to some difference in the material, and there is further the chance of the two or more inventions, and therefore also of their owners, becoming more like each other than they were before

CATEGORIES OF HOMOPLASY.

Isotely.[1]—If the character, feature, or organ has been evolved out of homologous parts or material, as is most likely the case in closely related groups, and if the subsequent modifications proceed by similar stages and means, there is a fair probability or chance of very close resemblance. *Iso-tely*: the same mark has been hit.

Homoeotely.—Although the feature has been evolved

[1] *Cf.* "Isotely and Coralsnakes." By H. Gadow, Zoolog. Jahrbücher, Abt. f. Syst., xxxi., 1911.

from homologous parts or material, the respective modifications may proceed by different stages and means, and the ultimate resemblance will be less close and deficient in detail. Such cases are most likely to happen between groups of less close affinity, whether separated by distance or by time. *Homoeo-tely*: the same end has been fairly well attained. The target has been hit, but not the mark.

Paratelv.—The feature has been evolved from parts and material so different that there is scarcely any or no relationship. The resulting resemblance will at best be more or less superficial; sometimes a sham, although appealing to our fancy. *Para-tely*: the neighbouring target has been hit.

EXAMPLES.

Isotely: Bill of the Ardeidæ Balæniceps (Africa) and Cancroma (tropical America).

Zygodactyle foot of cuckoos, parrots, woodpeckers $\left(\frac{2\ 3}{1\ 4}\right)$.

Patterns and coloration of Elaps and other snakes.

Parachute of Petaurus (marsupial); Pteromys (rodent) and Galeopithecus.

Perissodactylism of Litopterna and Hippoids.

Bulla auris of Plioplatecarpus (Pythonomorphe) and certain whales; if tympanic = quadrate.

Grasping instruments or nippers in Arthropods: pedipalps of Phryne; chelæ of squill; first pair of mantis' legs.

General appearance of moles and Notoryctes, if both considered as mammals; of gulls and petrels, if considered as birds.

Homoeotely: Heterodactyle foot of Trogons $\left(\frac{3\ 4}{2\ 1}\right)$.

Jumping foot of Macropus, Dipus, Tarsius.

Intertarsal and cruro-tarsal joint.

Fusion and elongation of the three middle metarsals of Dipus and Rhea.

Paddles of Ichthyosaurs. Turtles, whales, penguins.

"Wings" of Pterosaurs and bats.

Long flexible bill of Apteryx and snipes.

Proteroglyph dentition of cobras and Solenoglyph dentition of vipers.

Loss of the shell of Limax and Aplysia.

Complex molar pattern of horse and cow.

Parately: Bivalve shell of Brachiopods and Lamellibranchs.

Stretcher-sesamoid bone of Pterodactyls (radial carpal); of flying squirrels (on pisiform); of Anomalurus (on olecranon).

Bulla auris of Pythonomorph (quadrate) and Wale (tympanic); if *incus* = quadrate.

"Wings" of Pterosaurs, or bats, and birds.

The distinction between these three categories must be vague because that between homology and analogy is also arbitrary, depending upon the standpoint of comparison. As lateral outgrowths of vertebræ all ribs are homogenes, but if there are at least hæmal and pleural ribs, then those organs are not homologous even within the class of fishes. If we trace a common origin far enough back we arrive near bedrock with the germinal layers. So there are specific, generic, ordinal, &c., homoplasies. The potentiality of resemblance increases with the kinship of the material.

Bateson, in his study of Homœosis, has rightly made the solemn quotation: "There is the flesh of fishes . . . birds . . . beasts, &c." Their flesh will not and cannot react in exactly the same way under otherwise precisely the same conditions, since each kind of flesh is already biased, encumbered by inheritances. If a certain resemblance between a reptile and mammal dates from Permian times, it may be homogenous, like the pentadactyle limb which as such has persisted; but if that resemblance has first appeared in the Cretaceous period it is Homoplastic, because it was brought about long after the class division. To cases within the same order we give the benefit of the doubt more readily than if the resemblance concerned members of two orders, and between the phyla we rightly seek no connection. However, so strongly is our mode of thinking influenced by the principle of descent that, if the same feature happen to crop up in more than two orders, we are biased against Homoplasy.

The readiness with which certain Homoplasies appear in related groups seems to be responsible for the confounding of the potentiality of convergent adaptation with a latent disposition, as if such cases of Homoplasy were a kind of temporarily deferred repetition, *i.e.* after all due to inheritance. This view instances certain recurring tooth patterns, which, developing in the embryonic teeth, are said not to be due to active adaptation or acquisition, but to selection of accomplished variations, because it is held inconceivable that use, food, &c., should act upon a finished tooth. It is not so very difficult to approach the solution of this apparently contradictory problem. Teeth, like feathers, can be influenced long before they are ready by the life experiences of their predecessors. A very potent factor in the evolution of Homoplasies is correlation, which is sympathy, just as inheritance is reminiscence. The introduction of a single new feature may affect the whole organism profoundly, and one serious case of Isotely may arouse unsuspected correlations and thus bring ever so many more homoplasies in its wake.

Function is always present in living matter; it is life. It is function which not only shapes, but creates the organ or suppresses it, being indeed at bottom a kind of reaction upon some stimulus, which stimuli are ultimately all fundamental, elementary forces, therefore few in number. That is a reason why nature seems to have but few resources for meeting given "requirements"—to use an everyday expression which really puts the cart before the horse. This paucity of resources shows itself in the repetition of the same organs in the most different phyla. The eye has been invented dozens of times. Light, a part of the environment, has been the first stimulus. The principle remains the same in the various eyes; where light found a suitably reacting material a particular evolution was set going, often round about, or topsy-turvy, implying amendments; still, the result was an eye. In advanced cases a scientifically constructed dark chamber with lens, screen, shutters, and other adjustments. The detail may be unimportant, since in the various eyes different contrivances are resorted to.

Provided the material is suitable, plastic, amenable to prevailing environmental or constitutional forces, it makes no difference what part of an organism is utilised to supply the requirements of function. You cannot make a silk purse out of a sow's ear, but you can make a purse, and that is the important point. The first and most obvious cause is function, which itself may arise as an incidental action due to the nature of the material. The oxydising of the blood is such a case, and respiratory organs have been made out of whatever parts invite osmotic contact of the blood with air or water. It does not matter whether respiration is carried on by ecto- or by endodermal epithelium. Thus are developed internal gills, or lungs, both of which may be considered as referable to pharyngeal pouches; but where the outer skin has become suitably osmotic, as in the naked Amphibia, it may evolve external gills. Nay, the whole surface of the body may become so osmotic that both lungs and gills are suppressed, and the creature breathes in a most pseudo-primitive fashion. This arrangement, more or less advanced, occurs in many Urodeles, both American and European, belonging to several sub-families, but not in every species of the various genera. It is therefore a case of apparently recent Isotely.

There is no prejudice in the making of a new organ except in so far that every organism is conservative, clinging to what it or its ancestors have learnt or acquired, which it therefore seeks to recapitulate. Thus in the vertebrata the customary place for respiratory organs is the pharyngeal region. Every organism, of course, has an enormous back history; it may have had to use every part in every conceivable way, and it may thereby have been trained to such an extent as to yield almost at once, like a bridle-wise horse to some new stimulus, and thus initiate an organ straight to the point.

Considering that organs put to the same use are so very often the result of analogous adaptation, homoplasts with or without affinity of descent, are we not justified in accusing morphology of having made rather too much of the organs as units, as if they were concrete instead of inducted abstract notions? An organ which changes its function may become a unit so different as to require a new definition. And two originally different organs may come to resemble each other so much in function and structure that they acquire the same definition as one new unit. To avoid this dilemma the morphologist has, of course, introduced the differential of descent, whether homologous or analogous, into his diagnoses of organs.

The same principles must apply to the classification of the animals. To group the various representative owners of cases of isotely together under one name, simply because they have lost those characters which distinguished their ancestors, would be subversive of phyletic research. It is of the utmost significance that such "convergences" (rather "mergers," to use an administrative term) do take place, but that is another question. If it could be shown that elephants in a restricted sense have been evolved independently from two stems of family rank, the convergent terminals must not be named Elephantinæ, nor can the representatives of successive stages or horizons of a monophyletic family be designated and lumped together as subfamilies. And yet something like this practice has been adopted from Cope by experienced zoologists with a complete disregard of history, which is an inalienable and important element in our science.

This procedure is no sounder than would be the sorting of our Cartwrights, Smiths, and Bakers of sorts into as many natural families. It would be subversive of classification, the aim of which is the sorting of a chaos into order. We must not upset the well-defined relative meaning of the classificatory terms which have become well established conceptions; but what such an assembly as the terminal elephants should be called is a new question, the urgency of which will soon become acute. It applies at least to assemblies of specific, generic, and family rank, for each of which grades a new term, implying the principle of convergence, will have to be invented. In some cases geographical terms may be an additional criterion. Such terms will be not only most convenient, but they will at once act as a warning not to use the component species for certain purposes. There is, for instance, the case of *Typhlops braminus*, mentioned at the beginning of this address. Another case is the dog species, called *Canis familiaris*, about which it is now the opinion of the best authorities that the American dogs of sorts are the descendants of the coyote, while some Indian dogs are descendants of a jackal, and others again are traceable to some wolf. The "dog," a definable conception, has been invented many times, and in different countries and out of different material. It is an association of converged heterogeneous units. We have but a smile for those who class whales with fishes, or the blind-worm with the snakes; not to confound the amphibian Cœcilians with reptilian Amphisbænas requires some training; but what are we to do with creatures who have lost or assimilated all those differential characters which we have got used to rely upon?

In a homogeneous crowd of people we are attracted by their little differences, taking their really important agreements for granted; in a compound crowd we at once sort the people according to their really unimportant resemblances. That is human nature.

The terms "convergence" and "parallelism" are convenient if taken with a generous pinch of salt. Some authors hold that these terms are but imperfect similes, because two originally different organs can never converge into one identical point, still less can their owners whose acquired resemblance depresses the balance of all their other characters. For instance, no lizard can become a snake, in spite of ever so many additional snake-like acquisitions, each of which finds a parallel, an analogy in the snakes. Some zoologists therefore prefer contrasting only parallelism and divergence. A few examples may illustrate the justification of the three terms. If out of ten very similar black-haired people only two become white by the usual process, whilst the others retain their colour, then these two diverge from the rest; but they do not, by the acquisition of the same new feature, become more alike each other than they were before. Only with reference to the rest do they seem to liken as they pass from black through grey to white, our mental process being biased by the more and more emphasised difference from the majority.

1 A B C D E F

Supposing A and B both acquire the character x and this continues through the next ten generations, while in the descendants of C the same character is invented in the tenth generation, and whilst the descendants of D, E, F still remain unaltered. Then we should be strongly inclined, not only to "key together $C\frac{x}{10}$ with $A\frac{x}{10}$ and $B\frac{x}{10}$, but take this case for one of convergence, although it is really one of parallelism. If it did not sound so contradictory it might be called parallel divergence. The inventors diverge from the majority in the same direction: Isotely.

Third case.—Ten people, contemporaries, are alike but for the black or red hair. Black A turns white and red E turns white, not through exactly identical stages, since E will pass through a reddish-grey tinge. But the result is that A and E become actually more like each other than they were before. They *converge*, although they have gone in for exactly the same divergence with reference to the majority.

In all three cases the variations begin by divergence from the majority, but we can well imagine that all the members of a homogeneous lot change ortho-genetically (this term has been translated into the far less expressive "rectigrade") in one direction, and if there be no lagging behind, they all reach precisely the same end. This would be a case of transmutation (true mutations in Waagen's and Scott's sense), producing new species without thereby increasing their number, whilst divergence always implies, at least potentially, increase of species, genera, families, &c.

If for argument's sake the mutations pass through the colours of the spectrum, and if each colour be deemed sufficient to designate a species, then, if all the tenth generations have changed from green to yellow and those of the twentieth generation from yellow to red, the final number of species would be the same. And even if some lagged behind, or remained stationary, these epistatic species (Eimer) are produced by a process which is not the same as that of divergence or variation in the usual sense.

The two primary factors of evolution are environment and heredity. Environment is absolutely inseparable from any existing organism, which therefore must react (adaptation) and at least some of these results gain enough momentum to be carried into the next generation (heredity).

The life of an organism, with all its experiments and doings, is its ontogeny, which may therefore be called the subject of evolution, but not a factor. Nor is selection a primary and necessary factor, since, being destructive, it invents nothing. It accounts, for instance, for the composition of the present fauna, but has not made its components. A subtle scholastic insinuation lurks in the plain statement that by ruthless elimination a black flock of pigeons can be produced, even that thereby the individuals have been made black. (But, of course, the breeder has thereby not invented the black pigment.)

There can be no evolution, progress, without response to stimulus, be this environmental or constitutional, *i.e.* depending upon the composition and the correlated working of the various parts within the organism. Natural selection has but to favour this plasticity, by cutting out the non-yielding material, and through inheritance the adaptive material will be brought to such a state of plasticity that it is ready to yield to the spur of the moment, and the foundation of the same new organs will thereby be laid, whenever the same necessity calls for them. Here is a dilemma. On one hand, the organism benefits from the ancestral experience; on the other, there applies to it de Rosa's law of the reduction of variability, which narrows the chances of change into fewer directions. But in these few the changes will proceed all the quicker and farther. Thus progress is assured, even hypertely, which may be rendered by "over-doing a good thing."

Progress really proceeds by mutations, spoken of before, orthogenesis, and it would take place without selection and without necessarily benefiting the organism. It would be mere presumption that the seven-gilled shark is worse off than its six- or five-gilled relations; or to imagine that the newt with double trunk-veins suffers from this arrangement, which morphologically is undoubtedly inferior to the unpaired, azygous, &c., modifications. The fact that newts exist is proof that they are efficient in their way. Such orthogenetic changes are as predictable in their results as the river which tends to shorten its course to the direct line from its head waters to the sea. That is the rivers Entelechy and no more due to purpose or design than is the series of improvements from the many gill-bearing partitions of a shark to the fewer, and more highly finished comb-shaped gills of a Teleostean fish.

The success of adaptation, as measured by the morphological grade of perfection reached by an organ, seems to depend upon the phyletic age of the animal when it was first subjected to these "temptations." The younger the group, the higher is likely to be the perfection of an organic system, organ, or detail. This is not a platitude. The perfection attained does not depend merely upon the length of time available for the evolution of an organ. A recent Teleostean has had an infinitely longer time as a fish than a reptile, and this had a longer time than a mammal, and yet the same problem is solved in a neater, we might say in a more scientifically correct, way by a mammal than by a reptile, and the reptile in turn shows an advance in every detail in comparison with an amphibian, and so forth.

A few examples will suffice:—

The claws of reptiles and those of mammals; there are none in the amphibians, although some seem to want them badly, like the African frog Gampsosteonyx, but its cat-like claws, instead of being horny sheaths, are made out of the sharpened phalangeal bones which perforate the skin.

The simple contrivance of the rhinocerotic horn, introduced in Oligocene times, compared with the antlers of Miocene Cervicornia and these with the response made by the latest of Ruminants, the hollow-horned antelopes and cattle. The heel-joint; unless still generalised, it tends to become intertarsal (attempted in some lizards, pronounced in some dinosaurs and in the birds) by fusion of the bones of the tarsus with those above and below, so that the tarsals act like epiphysial pads. Only in mammals epiphyses are universal. Tibia and fibula having their own, the pronounced joint is cruro-tarsal, and all the tarsals could be used for a very compact, yet non-rigid arrangement. The advantage of a cap, not merely the introduction of a separate pad, is well recognised in engineering.

Why is it that mammalian material can produce what is denied to the lower classes? In other words, why are there still lower and middle classes? Why have they not all by this time reached the same grade of perfection? Why not indeed, unless because every new group is less hampered by tradition, much of which must be discarded with the new departure; and some of its energy is set free to follow up this new course, straight, with ever-growing results, until in its turn this becomes an old rut out of which a new jolt leads once more into fresh fields.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY PROF. H. N. DICKSON, PRESIDENT OF THE SECTION.

SINCE the last meeting of this Section the tragic fate of Captain Scott's party, after its successful journey to the South Pole, has become known; and our hopes of welcoming a great leader, after great achievement, have been disappointed. There is no need to repeat here the narrative of events, or to dwell upon the lessons afforded by the skill, and resource, and heroic persistence, which endured to the end. All these have been, or will be, placed upon permanent record. But it is right that we should add our word of appreciation, and proffer our sympathy to those who have suffered loss. It is for us also to take note that this last of the great Antarctic expeditions has not merely reached the Pole, as another has done, but has added, to an extent that few successful exploratory undertakings have ever been able to do, to the sum of scientific geographical knowledge. As the materials secured are worked out it will, I believe, become more and more apparent that few of the physical and biological sciences have not received contributions, and important contributions, of new facts; and also that problems concerning the distribution of the different groups of phenomena and their action and reaction upon one another—the problems which are specially within the domain of the geographer—have not merely been extended in their scope but have been helped to their solution.

The reaching of the two poles of the earth brings to a close a long and brilliant chapter in the story of geographical exploration. There is still before us a vista of arduous research in geography, bewildering almost in its extent, in such a degree indeed that "the scope of geography" is in itself a subject of perennial interest. But the days of great pioneer discoveries in topography are definitely drawn to their close. We know the size and shape of the earth, at least to a first approximation, and as the map fills up we know that there can be no new continents and no new oceans to discover, although all are still, in a sense, to conquer. Looking back, we find that the qualities of human enterprise and endurance have shown no change; we need no list of names to prove that they were alike in the days of the earliest explorations, of the discovery of the New World or of the sea route to India, of the "Principall Navigations," or of this final attainment of the Poles. The love of adventure and the gifts of courage and endurance have remained the same: the order of discovery has been determined rather by the play of imagination upon accumulated knowledge, suggesting new methods and developing appropriate inventions. Men have dared to do risky things with inadequate appliances, and in doing so have shown how the appliances may be improved and how new enterprises may become possible as well as old ones easier and safer. As we come to the end of these "great explorations," and are restricted more and more to investigations of a less striking sort, it is well to remember that in geography, as in all other sciences, research continues to make as great demands as ever upon those same qualities, and that the same recognition is due to those who continue in patient labour.

When we look into the future of geographical study, it appears that for some time to come we shall still be largely dependent upon work similar to that of the pioneer type to which I have referred, the work of perfecting the geographer's principal weapon, the map. There are many parts of the world about which we can say little except that we know they exist; even the topographical map, or the material for making it, is wanting; and of only a few regions are there really adequate distributional maps of any kind. These matters have been brought before this Section and discussed very fully in recent years, so I need say no more about them, except perhaps to express the hope and belief that the production of topographical maps of difficult regions may soon be greatly facilitated and accelerated with the help of the new art of flying.

I wish to-day rather to ask your attention for a short time to a phase of pioneer exploration which has excited an increasing amount of interest in recent years. Civilised man is, or ought to be, beginning to realise that in reducing more and more of the available surface of the earth to what he considers a habitable condition he is making so much progress, and making it so rapidly, that the problem of finding suitable accommodation for his increasing numbers must become urgent in a few generations. We are getting into the position of the merchant whose trade is constantly expanding and who foresees that his premises will shortly be too small for him. In our case removal to more commodious premises elsewhere seems impossible—we are not likely to find a means of migrating to another planet—so we are driven to consider means of rebuilding on the old site, and so making the best of what we have, that our business may not suffer.

In the type of civilisation with which we are most familiar there are two fundamental elements—supplies of food energy, and supplies of mechanical energy. Since at present, partly because of geographical conditions, these do not necessarily (or even in general) occur together, there is a third essential factor, the line of transport. It may be of interest to glance, in the cursory manner which is possible upon such occasions, at some geographical points concerning each of these factors, and to hazard some speculations as to the probable course of events in the future.

In his presidential address to the British Association at its meeting at Bristol in 1898, Sir William Crookes gave some valuable estimates of the world's supply of wheat, which, as he pointed out, is "the most sustaining food-grain of the great Caucasian race." Founding upon these estimates, he made a forecast of the relations between the probable rates of increase of supply and demand, and concluded that "Should all the wheat-growing countries add to their (producing) area to the utmost capacity, on the most careful calculation the yield would give us only an addition of some 100,000,000 acres, supplying, at the average world-yield of 12·7 bushels to the acre, 1,270,000,000 bushels, just enough to supply the increase of population among bread-eaters till the year 1931." The president then added, "Thirty years is but a day in the life of a nation. Those present who may attend the meeting of the British Association thirty years hence will judge how far my forecasts are justified."

Half the allotted span has now elapsed, and it may be useful to inquire how things are going. Fortunately this can be easily done, up to a certain point at any rate, by reference to a paper published recently by Dr. J. F. Unstead (*Geographical Journal*, August, 1913), in which comparisons are given for the decades 1881–90, 1891–1900, and 1901–10. Dr. Unstead shows that the total wheat harvest for the world may be estimated at 2258 million bushels for the first of these periods, 2575 million for the second, and 3233 million for the third, increases of 14 per cent. and 25 per cent. respectively. He points out that the increases were due "mainly to an increased acreage," the areas being 192, 211, and 242 million acres, but also "to some extent (about 8 per cent.) to an increased average yield per acre, for while in the first two periods this was 12 bushels, in the third period it rose to 13 bushels per acre."

If we take the period 1891–1900, as nearly corresponding to Sir William Crookes's initial date, we find that the succeeding period shows an increase of 658 million bushels, or about half the estimated increase required by 1931, and that attained chiefly by "increased acreage."

But signs are not wanting that increase in this way will not go on indefinitely. We note (also from Dr. Unstead's paper) that in the two later periods the percentage of total wheat produced which was exported from the United States fell from 32 to 19, the yield per acre showing an increase meanwhile to 14 bushels. In the Russian Empire the percentage fell from 26 to 23, and only in the youngest of the new countries—Canada, Australia, the Argentine—do we find large proportional increases. Again, it is significant that in the United Kingdom, which is, and always has been, the most sensitive of all wheat-producing countries to variations in the floating supply, the *rate* of falling-off of home production shows marked if irregular diminution.

Looking at it in another way, we find (still from Dr. Unstead's figures) that the total amount sent out by the great exporting countries averaged, in 1881–90, 295 million bushels, 1891–1900, 402 millions, 1901–10, 532 millions. These quantities represent respectively 13·0, 15·6, and 16·1 per cent. of the total production, and it would appear that the percentage available for export from these regions is, for the time at least, approaching its limit, *i.e.* that only about one-sixth of the wheat produced is available from surpluses in the regions of production for making good deficiencies elsewhere.

There is, on the other hand, abundant evidence that improved agriculture is beginning to raise the yield per acre over a large part of the producing area. Between the periods 1881–90 and 1901–10 the average in the United States rose from 12 to 14 bushels; in Russia from 8 to 10; in Australia from 8 to 10. It is likely that, in these last two cases at least, a part of the increase is due merely to more active occupation of fresh lands as well as to use of more suitable varieties of seed, and the effect of improvements in methods of cultivation alone is more apparent in the older countries. During the same period the average yield increased in the United Kingdom from 28 to 32 bushels, in France from 17 to 20, Holland 27 to 33, Belgium 30 to 35, and it is most marked in the German Empire, for which the figures are 19 and 29.

In another important paper (*Geographical Journal*, April and May, 1912) Dr. Unstead has shown that the production of wheat in North America may still, in all likelihood, be very largely increased by merely increasing the area under cultivation, and the reasoning by which he justifies this conclusion certainly holds good over large districts elsewhere. It is of course impossible, in the present crude state of our knowledge of our own planet, to form any accurate estimate of the area which may, by the use of suitable seeds or otherwise, become available for extensive cultivation. But I think it is clear that the available proportion of the total supply from "extensive" sources has reached, or almost reached, its maximum, and that we must depend more and more upon intensive farming, with its greater demands for labour.

The average total area under wheat is estimated by Dr. Unstead as 192 million acres for 1881–90, 211 million acres for 1891–1900, and 242 million acres for 1901–10. Making the guess, for we can make nothing better, that this area may be increased to 300 million acres, and that under ordinary agriculture the average yield may eventually be increased to 20 bushels over the whole, we get an average harvest of 6000 million bushels of wheat. The average wheat-eater consumes, according to Sir William Crookes's figures, about four and a half bushels per annum; but the amount tends to increase. It is as much (according to Dr. Unstead) as six bushels in the United Kingdom and eight bushels in France. Let us take the British figure, and it appears that on a liberal estimate the earth may in the end be able to feed permanently 1000 million wheat-eaters. If prophecies based on population statistics are trustworthy, the crisis will be upon us before the end of this century. After that we must either depend upon some substitute to reduce the consumption per head of the staple foodstuff, or we must take to intensive farming of the most strenuous sort, absorbing enormous quantities of labour and introducing, sooner or later, serious difficulties connected with plant-food. We leave the possibility of diminishing the rate of increase in the number of bread-eaters out of account for the moment.

We gather, then, that the estimates formed in 1898 are in the main correct, and the wheat problem must become one of urgency at no distant date, although actual shortage of food is a long way off. What is of more immediate significance to the geographer is the element of change, of return to earlier conditions, which is emerging even at the present time. If we admit, as I think we must do, that the days of increase of extensive farming on new land are drawing to a close, then we admit that the assignment of special areas for the production of the food-supply of other distant areas is also coming to its end. The opening up of such areas, in which a sparse population produces food in quantities largely in excess of its own needs, has been the characteristic of our time, but it must give place to a more uniform distribution of things, tending always to the condition of a moderately dense population, more uniformly distributed over large areas, capable of providing the increased labour necessary for the higher type of cultivation, and self-supporting in respect of grain-food at least. We observe in passing that the colonial system of our time only became possible on the large scale with the invention of the steam-locomotive, and that the introduction of railway systems in the appropriate regions, and the first tapping of nearly all such regions on the globe, has taken less than a century.

Concentration in special areas of settlement, formerly chiefly effected for military reasons, has in modern times been determined more and more by the distribution of supplies of energy. The position of the manufacturing district is primarily determined by the supply of coal. Other forms of energy are, no doubt, available, but, as Sir William Ramsay showed in his presidential address at the Portsmouth meeting in 1911, we must in all probability look to coal as being the chief permanent source.

In the early days of manufacturing industries the main difficulties arose from defective land transport. The first growth of the industrial system, therefore, took place where sea transport was relatively easy; raw material produced in a region near a coast was carried to a coalfield also near a coast, just as in times when military power was chiefly a matter of "natural defences," the centre of power and the food-producing colony had to be mutually accessible. Hence the Atlantic took the place of the Mediterranean, Great Britain eventually succeeded Rome, and eastern North America became the counterpart of northern Africa. It is to this, perhaps more than to anything else, that we owe our tremendous start amongst the industrial nations, and we observe that we used it to provide less favoured nations with the means of improving their system of land transport, as well as actually to manufacture imported raw material and redistribute the products.

But there is, of course, this difference between the supply of foodstuff (or even military power) and mechanical energy, that in the case of coal at least it is necessary to live entirely upon capital; the storing up of energy in new coalfields goes on so slowly in comparison with our rate of expenditure that it may be altogether neglected. Now in this country we began to use coal on a large scale a little more than a century ago. Our present yearly consumption is of the order of 300 millions of tons, and it is computed (General Report of the Royal Commission on Coal Supplies, 1906) that at the present rate of increase "the whole of our available supply will be exhausted in 170 years." With regard to the rest of the world we cannot, from lack of data, make even the broad assumptions that were possible in the case of wheat supply, and for that and other reasons it is therefore impossible even to guess at the time which must elapse before a universal dearth of coal becomes imminent; it is perhaps sufficient to observe that to the best of our knowledge and belief one of the world's largest groups of coalfields (our own) is not likely to last three centuries in all.

Here again the present interest lies rather in the phases of change which are actually with us. During the first stages of the manufacturing period energy in any form was exceedingly difficult to transport, and this led to intense concentration. Coal was taken from the most accessible coalfield and used, as far as possible, on the spot. It was chiefly converted into mechanical energy by means of the steam-engine, an extremely wasteful apparatus in small units, and hence still further concentration; thus the steam-engine is responsible in part for the factory system in its worst aspect. The less accessible coalfields were neglected. Also, the only other really available source of energy—water-power—remained unused, because the difficulties in the way of utilising movements of large quantities of water through small vertical distances (as in tidal movements) are enormous; the only easily applied source occurs where comparatively small quantities of water fall through considerable vertical distances, as in the case of waterfalls. But, arising from the geographical conditions, waterfalls (with rare exceptions such as Niagara) occur in the "torrential" part of the typical river-course, perhaps far from the sea, almost certainly in a region too broken in surface to allow of easy communication or even of industrial settlement of any kind.

However accessible a coalfield may be to begin with, it sooner or later becomes inaccessible in another way, as the coal near the surface is exhausted and the workings get deeper. No doubt the evil day is postponed for a time by improvements in methods of mining—a sort of intensive cultivation—but as we can put nothing back the end must be the same, and successful competition with more remote but more superficial deposits becomes impossible. And every improvement in land transport favours the geographically less accessible coalfield.

From this point of view it is impossible to overestimate the importance of what is to all intents and purposes a new departure of the same order of magnitude as the discovery of the art of smelting iron with coal, or the invention of the steam-engine, or of the steam-locomotive. I mean the conversion of energy into electricity, and its transmission in that form (at small cost and with small loss) through great distances. First we have the immediately increased availability of the great sources of cheap power in waterfalls. The energy may be transmitted through comparatively small distances and converted into heat in the electric furnace, making it possible to smelt economically the most refractory ores, as those of aluminium, and converting such unlikely places as the coast of Norway or the West Highlands of Scotland into manufacturing districts. Or it may be transmitted through greater distances to regions producing quantities of raw materials, distributed there widespread to manufacturing centres, and reconverted into mechanical energy. The Plain of Lombardy produces raw materials in abundance, but Italy has no coal supply. The waterfalls of the Alps yield much energy, and this transmitted in the form of electricity, in some cases for great distances, is converting northern Italy into one of the world's great industrial regions. Chisholm gives an estimate of a possible supply of power amounting to 3,000,000 horse-power, and says that of this about one-tenth was already being utilised in the year 1900.

But assuming again, with Sir William Ramsay, that coal must continue to be the chief source of energy, it is clear that the question of accessibility now wears an entirely different aspect. It is not altogether beyond reason to imagine that the necessity for mining, as such, might entirely disappear, the coal being burnt *in situ* and energy converted directly into electricity. In this way some coalfields might conceivably be exhausted to their last pound without serious increase in the cost of getting. But for the present it is enough to note that, however inaccessible any coalfield may be from supplies of raw material, it is only necessary to establish generating stations at the pit's mouth and transport the energy to where it can be used. One may imagine, for example, vast manufactures carried on in what are now the immense agricultural regions of China, worked by power supplied from the great coal deposits of Shan-si.

There is, however, another peculiarity of electrical power which will exercise increasing influence upon the geographical distribution of industries. The small electric motor is a much more efficient apparatus than the small steam-engine. We are, accordingly, already becoming familiar with the great factory in which, instead of all tools being huddled together to save loss through shafting and belting, and all kept running all the time, whether busy or not (because the main engine must be run), each tool stands by itself and is worked by its own motor, and that only when it is wanted. Another of the causes of concentration of manufacturing industry is therefore reduced in importance. We may expect to see the effects of this becoming more and more marked as time goes on, and other forces working towards uniform distribution make themselves more felt.

The points to be emphasised so far, then, are, first, that the time when the available areas whence food supply as represented by wheat is derived are likely to be taxed to their full capacity within a period of about the same length as that during which the modern colonial system has been developing in the past; secondly, that cheap supplies of energy may continue for a longer time, although eventually they must greatly diminish; and, thirdly, there must begin in the near future a great equalisation in the distribution of population. This equalisation must arise from a number of causes. More intensive cultivation will increase the amount of labour required in agriculture, and there will be less difference in the cost of production and yield due to differences of soil and climate. Manufacturing industries will be more uniformly distributed, because energy, obtained from a larger number of sources in the less accessible places, will be distributed over an increased number of centres. The distinction between agricultural and industrial regions will tend to become less and less clearly marked, and will eventually almost disappear in many parts of the world.

The effect of this upon the third element is of first-rate importance. It is clear that as the process of equalisation goes on the relative amount of long-distance transport will diminish, for each district will tend more and more to produce its own supply of staple food and carry on its own principal manufactures. This result will naturally be most marked in what we may call the "east-and-west" transport, for as climatic controls primarily follow the parallels of latitude, the great *quantitative* trade, the flow of foodstuffs and manufactured articles to and fro between peoples of like habits and modes of life, runs primarily east and west. Thus the transcontinental functions of the great North American and Eurasian railways, the east-and-west systems of the inland waterways of the two continents, and the connecting links furnished by the great ocean ferries, must become of relatively less importance.

The various stages may be represented, perhaps, in some such manner as this. If **I** is the cost of producing a thing locally at a place A by intensive cultivation or what corresponds to it, if **E** is the cost of producing the same thing at a distant place B, and **T** the cost of transporting it to A, then at A we may at some point of time have a more or less close approximation to

$$\mathbf{I}=\mathbf{E}+\mathbf{T}.$$

We have seen that in this country, for example, **I** has been greater than **E+T** for wheat ever since, say, the introduction of railways in North America, that the excess tends steadily to diminish, and that however much it may be possible to reduce **T** either by devising cheaper modes of transport or by shortening the distance through which wheat is transported, **E+T** must become greater than **I**, and it will pay us to grow all or most of our own wheat. Conversely, in the 'seventies of last century **I** was greater than **E+T** in North America and Germany for such things as steel rails and rolling-stock, which we in this country were cultivating "extensively" at the time on more accessible coalfields, with more skilled labour and better organisation than could be found elsewhere. In many cases the positions are now, as we know, reversed, but geographically **I** must win all round in the long run.

In the case of transport between points in different latitudes the conditions are, of course, altogether dissimilar, for in this case commodities consist of foodstuffs, or raw materials, or manufactured articles, which may be termed luxuries, in the sense that their use is scarcely known until cheap transport makes them easily accessible, when they rapidly become "necessaries of life." Of these the most familiar examples are tea, coffee, cocoa and bananas, indiarubber and manufactured cotton goods. There is here, of course, always the possibility that wheat as a staple might be replaced by a foodstuff produced in the tropics, and it would be extremely interesting to study the geographical consequences of such an event as one-half of the surface of the earth suddenly coming to help in feeding the two quarters on either side; but for many reasons, which I need not go into here, such a consummation is exceedingly unlikely. What seems more probable is that the trade between different latitudes will continue to be characterised specially by its variety, the variety doubtless increasing, and the quantity increasing in still larger measure. The chief modification in the future may perhaps be looked for in the occasional transference of manufactures of raw materials produced in the tropics to places within the tropics, especially when the manufactured article is itself largely consumed near regions of production. The necessary condition here is a region, such as (*e.g.*) the monsoon region, in which there is sufficient variation in the seasons to make the native population laborious; for then, and apparently only then, is it possible to secure sufficient industry and skill by training, and therefore to be able to yield to the ever-growing pressure in more temperate latitudes due to increased cost of labour. The best examples of this to-day are probably the familiar ones of cotton and jute manufacture in India. With certain limitations, manufacturing trade of this kind is, however, likely to continue between temperate and strictly tropical regions, where the climate is so uniform throughout the year that the native has no incentive to work. There the collection of the raw material is as much as, or even more than can be looked for—as in the case of mahogany or wild rubber. Where raw material has to be cultivated—as cotton, cultivated rubber, &c.—the raw material has to be produced in regions more of the monsoon type, but it will probably—perhaps as much for economic as geographical reasons—be manufactured at some centre in the temperate zones, and the finished product transported thence, when necessary, to the point of consumption in the tropics.

We are here, however, specially liable to grave disturbances of distribution arising from invention of new machinery or new chemical methods; one need only mention the production of sugar or indigo. Another aspect of this which is not without importance may perhaps be referred to here, although it means the transference of certain industries to more accessible regions merely, rather than a definite change of such an element as latitude. I have in mind the sudden conversion of an industry in which much labour is expended on a small amount of raw material into one where much raw material is consumed, and by the application of power-driven machinery the labour required is greatly diminished. One remembers when a fifty-shilling Swiss watch, although then still by tradition regarded as sufficiently valuable to deserve enclosure in a case constructed of a precious metal, was considered a marvel of cheapness. American machine-made watches, produced by the ton, are now encased in the baser metals and sold at some five shillings each, and the watch-making industry has ceased to be specially suited to mountainous districts.

In considering the differences which seem likely to arise in what we may call the regional pressures of one kind and another, pressures which are relieved or adjusted by and along certain lines of transport, I have made a primary distinction between "east-and-west" and "north-and-south" types, because both in matters of food supply and in the modes of life which control the nature of the demand for manufactured articles climate is eventually the dominant factor; and, as I have said, climate varies primarily with latitude. This is true specially of atmospheric temperature; but temperature varies also with altitude, or height above the level of the sea. To a less extent rainfall, the other great element of climate, varies with latitude, but the variation is much more irregular. More important in this case is the influence of the distribution of land and sea, and more especially the configuration of the land surface, the tendency here being sometimes to strengthen the latitude effect where a continuous ridge is interposed, as in Asia, practically cutting off "north-and-south" communication altogether along a certain line, emphasising the parallel-strip arrangement running east and west to the north of the line, and inducing the quite special conditions of the monsoon region to the south of it. We may contrast this with the effect of a "north-and-south" structure, which (in temperate latitudes especially) tends to swing what we may call the regional lines round till they cross the parallels of latitude obliquely. This is typically illustrated in North America, where the angle is locally sometimes nearly a right angle. It follows, therefore, that the contrast of "east-and-west" and "north-and-south" lines, which I have here used for purposes of illustration, is necessarily extremely crude, and one of the most pressing duties of geographers at the present moment is to elaborate a more satisfactory method of classification. I am very glad that we are to have a discussion on "Natural Regions" at one of our sederunts. Perhaps I may be permitted to express the hope that we shall concern ourselves with the types of region we want, their structure or "grain," and their relative positions, rather than with the precise delimitation of their boundaries, to which I think we have sometimes been inclined, for educational purposes, to give a little too much attention.

Before leaving this I should like to add, speaking still in terms of "east-and-west" and "north-and-south," one word more about the essential east-and-west structure of the Old World. I have already referred to the great central axis of Asia. This axis is prolonged westward through Europe, but it is cut through and broken to such an extent that we may include the Mediterranean region with the area lying further north, to which indeed it geographically belongs in any discussion of this sort. But the Mediterranean region is bounded on the other side by the Sahara, and none of our modern inventions facilitating transport has made any impression upon the dry desert; nor does it seem likely that such a desert will ever become a less formidable barrier than a great mountain mass or range. We may conclude, then, that in so far as the Old World is concerned, the "north-and-south" transport can never be carried on as freely as it may in the New, but only through certain weak points, or "round the ends," *i.e.* by sea. It may be further pointed out that the land areas in the southern hemisphere are so narrow that they will scarcely enter into the "east-and-west" category at all—the transcontinental railway as understood in the northern hemisphere cannot exist; it is scarcely a pioneer system, but rather comes into existence as a later by-product of local east-and-west lines, as in Africa.

These geographical facts must exercise a profound influence upon the future of the British Isles. Trade south of the great dividing line must always be to a large extent of the "north-and-south" type, and the British Isles stand practically at the western end of the great natural barrier. From their position the British Isles will always be a centre of immense importance in *entrepôt* trade, importing commodities from "south" and distributing "east and west," and similarly in the reverse direction. This movement will be permanent, and will increase in volume long after the present type of purely "east-and-west" trade has become relatively less important than it is now, and long after the British Isles have ceased to have any of the special advantages for manufacturing industries which are due to their own resources either in the way of energy or of raw material. We can well imagine, however, that this permanent advantage of position will react favourably, if indirectly, upon certain types of our manufactures, at least for a very long time to come.

Reverting briefly to the equalisation of the distribution of population in the wheat-producing areas and the causes which are now at work in this direction, it is interesting to inquire how geographical conditions are likely to influence this on the smaller scale. We may suppose that the production of staple foodstuffs must always be more uniformly distributed than the manufacture of raw materials, or the production of the raw materials themselves, for the most important raw materials of vegetable origin (as cotton, rubber, &c.) demand special climatic conditions, and, apart from the distribution of energy, manufacturing industries are strongly influenced by the distribution of mineral deposits, providing metals for machinery, and so on. It may, however, be remarked that the useful metals, such as iron, are widely distributed in or near regions which are not as a rule unfavourable to agriculture. Nevertheless, the fact remains that while a more uniform distribution is necessary and inevitable in the case of agriculture, many of the conditions of industrial and social life are in favour of concentration; the electrical transmission of energy removes, in whole or in part, only one or two of the centripetal forces. The general result might be an approximation to the conditions occurring in many parts of the monsoon areas—a number of fairly large towns pretty evenly distributed over a given agricultural area, and each drawing its main food supplies from the region surrounding it. The positions of such towns would be determined much more by industrial conditions, and less by military conditions, than in the past (military power being in these days mobile, and not fixed); but the result would on a larger scale be of the same type as was developed in the central counties of England, which, as Mackinder has pointed out, are of almost equal size and take the name of the county town. Concentration within the towns would, of course, be less severe than in the early days of manufacturing industry. Each town would require a very elaborate and highly organised system of local transport, touching all points of its agricultural area, in addition to lines of communication with other towns and with the great "north-and-south" lines of world-wide commerce, but these outside lines would be relatively of less importance than they are now. We note that the more perfect the system of local transport, the less the need for points of intermediate exchange. The village and the local market-town will be "sleepy" or decadent as they are now, but for a different reason; the symptoms are at present visible mainly because the country round about such local centres is overwhelmed by the great lines of transport which pass through them; they will survive for a time through inertia and the ease of foreign investment of capital. The effect of this influence is already apparent since the advent of the "commercial motor," but up to the present it has been more in the direction of distributing from the towns than collecting to them, producing a kind of "suburbanisation" which throws things still further out of balance. The importance of the road motor in relation to the future development of the food-producing area is incalculable. It has long been clear that the railway of the type required for the great through lines of fast transport is ill-adapted for the detailed work of a small district, and the "light" railway solves little and introduces many complications. The problem of determining the direction and capacity of a system of roads adequate to any particular region is at this stage one of extraordinary difficulty; experiments are exceedingly costly, and we have as yet little experience of a satisfactory kind to guide us. The geographer, if he will, can here be of considerable service to the engineer.

In the same connection, the development of the agricultural area supplying an industrial centre offers many difficult problems in relation to what may be called accessory products, more especially those of a perishable nature, such as meat and milk. In the case of meat the present position is that much land which may eventually become available for grain crops is used for grazing, or cattle are fed on some grain, like maize, which is difficult to transport or is not satisfactory for bread-making The meat is then temporarily deprived of its perishable property by refrigeration, and does not suffer in transport. Modern refrigerating machinery is elaborate and complicated, and more suited to use on board ship than on any kind of land transport. Hence the most convenient regions for producing meat for export are those near the sea-coast, such as occur in the Argentine or the Canterbury plains of New Zealand. The case is similar to that of the "accessible" coalfield. Possibly the preserving processes may be simplified and cheapened, making overland transport easier, but the fact that it usually takes a good deal of land to produce a comparatively small quantity of meat will make the difficulty greater as land becomes more valuable. Cow's milk, which in modern times has become a "necessary of life" in most parts of the civilised world, is in much the same category as meat, except that difficulties of preservation, and therefore of transport, are even greater. That the problem has not become acute is largely due to the growth of the long-transport system available for wheat, which has enabled land round the great centres of population to be devoted to dairy produce. If we are right in supposing that this state of things cannot be permanent, the difficulty of milk supply must increase, although relieved somewhat by the less intense concentration in the towns; unless, as seems not unlikely, a wholly successful method of permanent preservation is devised.

In determining the positions of the main centres, or rather, in subdividing the larger areas for the distribution of towns with their supporting and dependent districts, water supply must be one of the chief factors in the future, as it has been in the past; and in the case of industrial centres the quality as well as the quantity of water has to be considered. A fundamental division here would probably be into districts having a natural local supply, probably of hard water, and districts in which the supply must be obtained from a distance. In the latter case engineering works of great magnitude must often be involved, and the question of total resources available in one district for the supply of another must be much more fully investigated than it has been. In many cases, as in this country, the protection of such resources pending investigation is already much needed. It is worth noting that the question may often be closely related to the development and transmission of electrical energy from waterfalls, and the two problems might in such cases be dealt with together. Much may be learned about the relation of water supply to distribution of population from a study of history, and a more active prosecution of combined historical and geographical research would, I believe, furnish useful material in this connection, besides throwing interesting light on many historical questions.

Continued exchange of the "north-and-south" type and at least a part of that described as "east-and-west" gives permanence to a certain number of points where, so far as can be seen, there must always be a change in the mode of transport. It is not likely that we shall have heavy freight-carrying monsters in the air for a long time to come, and until we have the aërial "tramp" transport must be effected on the surfaces of land and sea. However much we may improve and cheapen land transport, it cannot in the nature of things become as cheap as transport by sea. For on land the essential idea is always that of a prepared road of some kind, and, as Chisholm has pointed out, no road can carry more than a certain amount; traffic beyond a certain quantity constantly requires the construction of new roads. It follows, then, that no device is likely to provide transport indifferently over land and sea, and the seaport has in consequence inherent elements of permanence. Improved and cheapened land transport increases the economy arising from the employment of large ships rather than small ones, for not only does transport inland become relatively more important, but distribution along a coast from one large seaport becomes as easy as from a number of small coastal towns. Hence the conditions are in favour of the growth of a comparatively small number of immense seaport cities like London and New York, in which there must be great concentration not merely of work directly connected with shipping, but of commercial and financial interests of all sorts. The seaport is, in fact, the type of great city which seems likely to increase continually in size, and provision for its needs cannot in general be made from the region immediately surrounding it, as in the case of towns of other kinds. In special cases there is also, no doubt, permanent need of large inland centres of the type of the "railway creation," but under severe geographic control these must depend very much on the nature and efficiency of the systems of land transport. It is not too much to say (for we possess some evidence of it already) that the number of distinct geographical causes which give rise to the establishment and maintenance of individual great cities is steadily diminishing, but that the large seaport is a permanent and increasing necessity. It follows that aggregations of the type of London and Liverpool, Glasgow and Belfast will always be amongst the chief things to be reckoned with in these islands, irrespective of local coal supply or accessory manufacturing industries, which may decay through exhaustion.

I have attempted in what precedes to direct attention once more to certain matters for which it seems strangely difficult to get a hearing. What it amounts to is this, that as far as our information goes the development of the steamship and the railway, and the universal introduction of machinery which has arisen from it, have so increased the demand made by man upon the earth's resources that in less than a century they will have become fully taxed. When colonisation and settlement in a new country proceeded slowly and laboriously, extending centrifugally from one or two favourable spots on the coast, it took a matter of four centuries to open up a region the size of England. Now we do as much for a continent like North America in about as many decades. In the first case it was not worth troubling about the exhaustion of resources, for they were scarcely more than touched, and even if they were exhausted there were other whole continents to conquer. But now, so far as our information goes, we are already making serious inroads upon the resources of the whole earth. One has no desire to sound an unduly alarmist note, or to suggest that we are in imminent danger of starvation, but surely it would be well, even on the suspicion, to see if our information is adequate and trustworthy and if our conclusions are correct; and not merely to drift in a manner which was justifiable enough in Saxon times, but which, at the rate things are going now, may land us unexpectedly in difficulties of appalling magnitude.

What is wanted is that we should seriously address ourselves to a stocktaking of our resources. A beginning has been made with a great map on the scale of one to a million, but that is not sufficient; we should vigorously proceed with the collection and discussion of geographical data of all kinds, so that the major natural distributions shall be adequately known, and not merely those parts which commend themselves, for one reason or another, to special national or private enterprises. The method of Government survey, employed in most civilised countries for the construction of maps, the examination of geological structure or the observation of weather and climate, is satisfactory as far as it goes, but it should go further, and be made to include such things as vegetation, water supply, supplies of energy of all kinds, and, what is quite as important, the bearings of one element upon others under different conditions. Much, if not most, of the work of collecting data would naturally be done as it is now by experts in the special branches of knowledge, but it is essential that there should be a definite plan of a *geographical* survey as a whole, in order that the regional or distributional aspect should never be lost sight of. I may venture to suggest that a committee formed jointly by the great national geographical societies, or by the International Geographical Congress, might be entrusted with the work of formulating some such uniform plan and suggesting practicable methods of carrying it out. It should not be impossible to secure international cooperation, for there is no need to investigate too closely the secrets of anyone's particular private vineyard—it is merely a question of doing thoroughly and systematically what is already done in some regions, sometimes thoroughly, but not systematically. We should thus arrive eventually at uniform methods of stock-taking, and the actual operations could be carried on as opportunity offered and indifference or opposition was overcome by the increasing need for information. Eventually we shall find that "country-planning" will become as important as town-planning, but it will be a more complex business, and it will not be possible to get the facts together in a hurry. And in the meanwhile increased geographical knowledge will yield scientific results of much significance about such matters as distribution of populations and industries, and the degree of adjustment to new conditions which occurs or is possible in different regions and amongst different peoples. Primary surveys on the large scale are specially important in new regions, but the best methods of developing such areas and of adjusting distributions in old areas to new economic conditions are to be discovered by extending the detailed surveys of small districts. An example of how this may be done has been given by Dr. Mill in his "Fragment of the Geography of Sussex." Dr. Mill's methods have been successfully applied by individual investigators to other districts, but a definitely organised system, marked out on a carefully matured uniform plan, is necessary if the results are to be fully comparable. The schools of geography in this country have already done a good deal of local geography of this type, and could give much valuable assistance if the work were organised beforehand on an adequate scale.

But in whatever way and on whatever scale the work is done, it must be clearly understood that no partial study from the physical, or biological, or historical, or economic point of view will ever suffice. The urgent matters are questions of distribution upon the surface of the earth, and their elucidation is not the special business of the physicist, or the biologist, or the historian, or the economist, but of the geographer.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Leeds.—In connection with the work on animal nutrition which is being conducted under a grant from the Development Commissioners, Dr. H. W. Dudley, of the Herter Research Laboratory, New York, has been appointed lecturer in biochemistry. The experimental station in flax growing, which is also supported by the Development Commissioners, has been placed under the direction of Mr. F. K. Jackson, formerly of the agricultural departments of the Universities of Leeds and Cambridge.

London.—The following courses of advanced science lectures are announced:—"The Cytology and Affinities of the Higher Fungi," by Dr. Gwynne-Vaughan, at University College, beginning on October 23; "The Physiological Significance of Acidosis," by Drs. Kennaway and Poulton, at Guy's Hospital, beginning on October 9; "The Cerebro-spinal Fluid," by Profs. Halliburton and Dixon, at King's College, beginning on November 3; "Mechanism and Teleology," by Prof. Hans Driesch, at King's College, beginning on October 21; "The Theory of Heat in Relation to Atmospheric Changes," by Dr. W. N. Shaw, F.R.S., at the Meteorological Office, beginning on January 23. All the lectures are free.

The Maharaja Scindia of Gwalior has contributed 25,000 rupees to the Yunani Vedic Medical College at Delhi.

Dr. T. Franklin Sibly, lecturer in geology at King's College, London, has been appointed professor of geology in the University College of South Wales and Monmouthshire, Cardiff.

The report by cable that Mr. W. Robbie, a pioneer gold-digger, who died at Ballarat a short time ago, had left a large bequest to the University of Aberdeen, has been confirmed by mail. The estimated amount of the bequest, however, is 23,000*l.*—not 30,000*l.* as at first reported—and it is to be applied for scholarships in mathematics, natural philosophy, and chemistry.

SOCIETIES AND ACADEMIES.

New South Wales.

Linnean Society, July 30.—Mr. W. S. Dun, president, in the chair.—T. G. **Sloane**: Revisional notes on Australian Carabidæ. Part iv., The genus Notonomus. The number of species recognised is eighty-nine, of which fifteen are proposed as new.—J. J. **Fletcher**: A case of natural hybridism in the genus Grevillea (N.O. Proteaceæ. *Grevillea laurifolia*, Sieb., and *G. acanthifolia*, A. Cunn., are two common and characteristic members of the flora of the higher portion of the Blue Mountain area. Certain other rare forms are sometimes associated with one or both of them, some of which have been described under the name of *G. gaudichaudii*, R. Br. The object of this paper is to justify the contention, that the rare plants to which the name *G. gaudichaudii*, R. Br., has been applied, or is applicable, form one group only of a series of transitional forms between *G. laurifolia and G. acanthifolia*, of which another, equally remarkable, group has escaped notice; that the entire series is one series of naturally related forms; and that the explanation of their real relationship is, that they are hybrids between the two species mentioned. Seven recognisably different types are described. The two parent-species are markedly contrasted in most of their morphological characters, in their habit of growth, and in being members of two different plant-associations and consequently in their habitats; but cross-pollination is possible, because the racemes of both are of the same pattern (elongated and secund). As the two species belong to different plant-associations, the conditions favouring cross-pollination arise only at or close to the boundary between them, while circumstances prevent the hybrids from spreading laterally.

HAUSA FOLK-LORE AND CUSTOMS.

Hausa Folk-Lore, Customs, Proverbs, &c., Collected and Transliterated with English Translation and Notes. By R. Sutherland Rattray. With a preface by R. R. Marett. Vol. i., pp. xxiv+327; vol. ii., pp. 315. (Oxford: Clarendon Press, 1913.) Price, 2 vols., 30*s.* net.

THIS book is intended to serve two distinct objects: to serve as a chrestomathy of the Hausa language, and as a collection of the local folk-lore and custom. It contains a series of lithographed Hausa texts, with a transliteration in Roman characters and a literal English translation. The method employed is to reproduce the MSS. written by a learned Hausa Málam or scribe, who wrote down or translated from Arabic sources such information as was required, and this was subsequently translated into Hausa. By this process the primary intention of the work is satisfactorily attained. Mr. Rattray is obviously a competent scholar, and in the course of the work he has been able to correct or extend the work of previous writers on Hausa grammar and phonology.

These admirably printed volumes thus represent a substantial contribution to linguistics, but the attempt to collect folk-lore and custom is not quite so satisfactory. The learned native scribe, like the Indian Pundit or Moulvi, is not the best agent for exploring the peasant beliefs and usages. He is apt to regard popular tradition and custom as of little value when they do not happen to conform to his standard of orthodoxy, and to introduce into his material something which is of purely literary origin and does not smell of the soil. In this respect Major Tremearne, in his recently published "Hausa Superstition and Custom," seems to have followed a sounder method by recording in his own hand the tales and superstitions which he heard from the lips of privates in the Nigeria Regiment, peasants, women and children.

Mr. Rattray has arranged his material in five divisions: traditionary accounts of the origin of the Hausa nation and of their conversion to Islam; tales of heroes and heroines; animal tales; customs and arts; proverbs. Among the tales we find many familiar *motifs* and incidents—the cannibal giant with his "Fee-fo-fum"; Beauty and the Beast, and so on. The animal tales are decidedly the best in the collection, and well illustrate the naïve cunning and wit which characterise the race. The formulæ introducing and closing the tales are interesting. They begin with "This is a story about" so and so; "a tale, let it go, let it come," ending with "Off with the rat's head!" that is, "that is the end of him."

The accounts of custom are rather disappointing, because, unless the Málam is mistaken, Islam has crushed down most of the indigenous practices. Perhaps the most valuable chapters are those describing, from native sources, the *cire perdue* process of brass-casting, as it appears in the remarkable figures from Benin, and an account of the primitive method of tanning skins.

The book, as a whole, deserves hearty commendation. But in his next attempt to add to his stores of local folk-lore and usage Mr. Rattray might with advantage dispense with the services of his Málam and depend upon himself for the task of collection.

INDIAN CHRONOGRAPHY.

Indian Chronography: An extension of the "Indian Calendar," with working examples. By Robert Sewell. Pp. xii+187. (London: George Allen & Co., Ltd., 1912.) Price 31*s.* 6*d.* net.

HINDU chronology appears extremely complex at first glance, but this complexity is more apparent than real, being largely due to the fact that so many different systems of reckoning were used in different places and at different times. Each single system is comparatively simple, and—save for the neglect of the effects due to precession—fairly accurate. The standard work on the subject is the "Indian Calendar," by Messrs. Sewell and Dikshit (NATURE, vol. liv., No. 1393), to which the present volume forms a supplement.

We have here a condensed account of those systems of chronology usually met with in inscriptions and documents, which are more fully treated in the previous work. Some space is devoted to the tropical year in view of the fact that this unit is occasionally met with, while the method of reckoning by Jovian Saṁvatsaras is fully described.

The volume contains a very large number of carefully worked examples and numerous tables, numbered to run consecutively with those of the previous volume. These include tables for the conversion of the moment of Mēsha Saṁkrānti by the First Arya Siddhānta into the same moment of the Present Sūrya Siddhānta; tables of the sixty- and twelve-year cycles of Jupiter, &c. Table I. of the "Indian Calendar" is carried forward to A.D. 1950; while Tables W, Y, Z (now XXXIII., XXXIV., XXXV.) of the Additions and Corrections to the "Indian Calendar" reappear. In Table XXXIII., "For finding the mean place of Jupiter," the argument is now the time interval from the epoch of the Kaliyuga, so that the table is available for more than 3000 years further back; while Table XXXIV. is now given for days, hours, and minutes, instead of days, ghatikās, and palas.

The tables are clearly printed and the volume is furnished with a comprehensive index. To the Indian epigraphist and many others the volume should prove a welcome supplement to the "Indian Calendar."

R. J. Pocock.

THE ANTIQUITY AND EVOLUTION OF MAN.

(1) *Man and His Forerunners.* By Prof. H. v. Buttel-Reepen. Incorporating Accounts of Recent Discoveries in Suffolk and Sussex. Authorised Translation by A. G. Thacker. Pp. 96. (London: Longmans, Green and Co., 1913.) Price 2*s.* 6*d.* net.

(2) *The Origin and Antiquity of Man.* By Dr. G. Frederick Wright. Pp. xx+547. (London: John Murray, 1913.) Price 8*s.* net.

(3) *L'Uomo Attuale una Specie Collettiva.* By V. Giuffrida-Ruggeri. Pp. viii+192+xiii plates. (Milano: Albrighi, Segati e C., 1913.) Price 6 lire.

(4) *Die Rehobother Bastards und das Bastardierungsproblem beim Menschen.* Dr. Eugen Fischer. Pp. vii+327+19 plates. (Jena: Gustav Fischer, 1913.) Price 16 marks.

(1) IN this excellent translation of Prof. Buttel-Reepen's little book, with the German title altered to "Man and His Forerunners," the statement occurs that "general treatises on Pleistocene man published before 1908 are now almost valueless." Such a statement implies that our knowledge regarding the ancestry and evolution of man has been revolutionised in the last five years —a statement which no one familiar with the subject could support for a moment. Yet in that space of time certain events have occurred which do materially alter our conception of how and when mankind came by its present estate.

There is, in the first place, the discovery of definite types of worked flints beneath the Red Crag of East Anglia by Mr. J. Reid Moir. Prof. von Buttel-Reepen does not question that the sub-Crag flints show human workmanship, but he seeks to minimise their antiquity by withdrawing the Red Crag from the Pliocene formations and setting it at the commencement of the Pleistocene series—a change which we believe geologists will not be inclined to countenance. Even if the place of the Red Crag be changed to the commencement of the Pleistocene, the sub-Crag flints may still claim a respectable antiquity, for the author quotes with approval Penck's estimate of 500,000 to 1,500,000 years as the duration of the Pleistocene period, and 25,000 years as the time which has elapsed since the Pleistocene closed.

It is during the last five years that we have come to realise fully the significance of Neanderthal man. He was formerly regarded as our Pleistocene ancestor. The recent discoveries in France and a more exact study of prehistoric remains have made amply clear that Neanderthal man is so sharply differentiated in all his features from modern man that we must regard him not as an ancestor, but as a totally different and collateral species, and that in past times there was not one species of man—subdivided into varieties as at present—but that there existed several, perhaps many, different species of man.

We note that Prof. von Buttel-Reepen gives his adhesion to the theory of multiple human species. On the other hand, we also observe that Dr. Frederick Wright, in the "Origin and Antiquity of Man," adopts the view, usually held by geologists, that Neanderthal man is merely a variant of modern man, and brings forward the time-worn examples of Robert the Bruce and the mediæval Bishop of Toul as representatives of Neanderthal man in modern times. The difference between the crania of Robert the Bruce and Neanderthal man is almost as great as that which separates the skulls of the chimpanzee and gorilla.

The third event which has altered our conception of man in the past is the discovery made by Mr. Charles Dawson in a pocket of gravel by the side of a farm-path, at Piltdown, Sussex. The discovery is noted by three of the authors whose books are here reviewed, and it is interesting to see what opinion each of them has formed of *Eoanthropus dawsoni.* Prof. von Buttel-Reepen gives us the first surprise; he places this new species of humanity with Neanderthal man, between the second and third glacial phases of the Pleistocene. It is true that Mr. Dawson and Dr. Smith Woodward did use the term Chellean—which refers to the stage of flint workmanship usually supposed to have been reached between the second and third of Penck's glacial phases—but they were also careful to explain that they regarded the Piltdown gravel as having been deposited and the skull imbedded at a period long anterior to the Chellean age—namely, at the early part of the Pleistocene period—perhaps earlier.

As to the position of Eoanthropus in the human lineage, all our authors show circumspection. Prof. von Buttel-Reepen is "inclined to think that the anterior curve of the jaw passed more sharply upwards than in Woodward's reconstruction, and that the whole front of the jaw, and consequently the front teeth, were somewhat smaller and more human than he believes." There is no doubt this is the case; a close study of the faithful replicas of the jaw which are now freely in circulation will show that there is neither indication of, nor accommodation for, the large canine tooth postulated by Dr. Smith Woodward. It is true the conformation of the chin is purely simian. It is a feature never before observed in a human skull, but a simian chin does not necessarily indicate a large canine tooth.

The discovery at Piltdown evidently puzzled the author of "l'Uomo Attuale"—Prof. Giuffrida-Ruggeri, of Naples, one of the most expert anthropologists in Europe. He is naturally puzzled by the statement of the discoverers that they regard Eoanthropus as a contemporary of the Heidelberg man, and that flints of the Chellean type were found with the remains—flints of that type belonging to a much later date than that of the Heidelberg jaw. He adds that it was impossible for him to make any further statement regarding the nature of Eoanthropus until figures, or, better still, actual models of the remains were at his disposal. By this time such models are probably at the Neapolitan professor's disposal, and he will have noted, as students of anatomy are certain to observe, that owing to the manner in which the bones of the skull-case have been put together, the brain-size of Eoanthropus has been greatly under-estimated. The size of brain is that of modern man—somewhere about, or a little above, 1500 cubic centimetres. The importance of the discovery of Eoanthropus will be thus apparent. At an early part of the Pleistocene period, perhaps much earlier, there existed human beings with a brain of the modern size, but a chin which was purely simian in conformation.

(2) In discovering the evidence on which the long-past history has to be based three classes of men are involved—the geologist, the archæologist (or lithologist), and the anatomist. It is unlikely that any one man could attain such a knowledge as to become an expert in all three lines of investigation. The geologist must be our time-keeper and time-marker, especially as regards the Pleistocene—the geologist who has paid special attention to the evidence relating to the phases of glaciation. For this reason a work on the origin and antiquity of man, by Dr. Frederick Wright, who has been a life-long student of the glacial phenomena of North America, is of especial value. There is nothing concerning the origin of man in Dr. Wright's book, but much which bears on the length of the Pleistocene period and the relation of man to that period. Penck, from his studies of the glacial deposits in Europe, estimates that the Pleistocene was at least half a million years in duration, perhaps a million and a half. Dr. Frederick Wright's investigations in America have led him to infer that 80,000 years is an ample estimate of the duration of the Ice age from its inception to its close. He admits the existence of pre-Glacial man. "Large areas," he writes, "in Europe and North America which are now principal centres of civilisation were buried under glacial ice thousands of feet thick, while the civilisation of Babylonia was in its heydey (5000 B.C.). . . . Both in its inception and in its close the Glacial epoch was a catastrophe of the most impressive order. No reasoning from present conditions can apply to the Glacial epoch without great reservation."

It will thus be seen that Dr. Frederick Wright has returned to the manner of thinking which was prevalent before the days of Lyell. He is an advocate of "Paroxysms of Nature." By a paroxysm of human evolution—one is inclined to substitute the word "miracle"—he thinks the early civilisation of Babylon and of Egypt may have hurriedly arisen and primitive mankind become separated into the well-marked varieties which are seen in our present-day world. It must also be noted that the duration assigned to the last phase of glaciation by Dr. Wright is in complete agreement with the computations given by the late General Drayson. In one matter especially anthropologists are much beholden to Dr. Wright. He has no hesitation in declaring that the human skeletons found under the loess at Lancing on the Missouri and at Omaha, Nebraska, lay under undisturbed glacial deposits, and the remains were those of men who lived in America in the Glacial period. The importance of the statement lies in the fact that these men were of the modern type—in one case exactly of the Red Indian type.

(3) Prof. Giuffrida Ruggeri's book deals with another aspect of the problem of man's origin. Its inception dates from his visit to London two years ago, when he attended the Universal Races Congress. He was surprised to hear the speculations of Prof. Klaatsch regarding the independent origin of human races—brought forward by those who took part in the discussions of the congress—as if they were facts accepted by all anthropologists. It will be remembered that Prof. Klaatsch saw fanciful resemblances between certain races of mankind and certain anthropoids, and supposed such races and anthropoids had sprung together from a common stock. In the process of dismembering Prof. Klaatsch's theory, the Neapolitan pro-

fessor has done anthropologists a great service by bringing together and systematising all recent investigations concerning the origin and nature of modern races of mankind. He regards the human race not as an "ideal" species—one composed of a predominant single variety: it would become so if one race prevailed and exterminated all the others—but as a collective species comprising many varieties of equal value in the eye of the classifier. His classification of modern races is a very practical one.

(4) We have kept the most important of the four books here reviewed to the last—for there can be no doubt, from every point of view, that Prof. Eugen Fischer's book merits such commendation. What happens when two diverse races of mankind interbreed throughout a long series of generations? Is a new race of mankind thus produced—a race which will continue to reproduce characters intermediate to those of the parent stocks? At the present time such an opinion is tacitly accepted by most anthropologists. It was to test the truth of such an opinion that Dr. Eugen Fischer, professor of anthropology at Freiburg, with financial assistance from the Royal Academy of Sciences of Berlin, set out to investigate the Bastard people in the Rehoboth district of German South-West Africa. The Rehoboth Bastards form a community of 2500–3000 souls, and are the result of intermarriage between early Boer farmers and Hottentot women—an intermixture which began more than a century ago.

This book contains the results of Prof. Fischer's investigations and is a model for those who will follow in his footsteps. His observations have convinced him that a new and permanent human race cannot be formed by the amalgamation of two diverse forms of man—not from any want of fertility—for amongst the Bastards there is an average of 7·4 children to each family—but because certain characters are recessive, others are dominant, and the original types tend to reassert themselves in the course of generations, according to Mendel's law. Although the mean head-form of the Bastards is intermediate to those of the two parent races—Hottentot and Boer—yet in each generation a definite number of the Bastards tend to assume the head-form of the one or of the other of the parent races. There are certain facts relating to head-form known to English anthropologists which can be explained only on a Mendelian basis and are in harmony with Dr. Fischer's observations. Between three and four thousand years ago England was invaded by a race with peculiarly formed, short and high heads. During those thousands of years the Bronze age invaders have been mingling their blood with that of the older and newer residents of England. Yet in every gathering of modern Englishmen—especially of the middle classes—one can see a number of pure examples of the Bronze age head-form. On the Mendelian hypothesis the persistence of such a head-form is explicable.

Dr. Eugen Fischer's study of the Rehoboth Bastards will be welcomed by all students of heredity. No race has so many peculiar human traits as the Hottentots, and hence the laws of human inheritance—as Prof. Fischer was the first to recognise—can be advantageously studied in their hybrid progeny.

"FLORAS" AND PLANT MONOGRAPHS.

(1) *A Manual Flora of Egypt.* By Dr. Reno Muschler. With a preface by Prof. Paul Ascherson and Prof. Georg Schweinfurth. Two volumes. Pp. xii+1312. (Berlin: R. Friedländer und Sohn, 1912.)

(2) *Bush Days.* By Amy E. Mack. With illustrations from photographs by J. Ramsay and L. Harrison. Pp. xii+132. (Sydney: Angus and Robertson, Ltd.; London: Australian Book Company, 1911.) Price 3*s*. 6*d*. net.

(3) *The Flora of Bristol: Being an account of all the Flowering Plants, Ferns, and their Allies that have at any time been found in the district of the Bristol Coal-Fields.* By J. W. White. Pp. ix+722+3 plates+map. (Bristol: John Wright & Sons, Ltd.; London: Simpkin, Marshall and Co., Ltd., 1912.) Price 13*s*. 6*d*. net.

(4) *Pflanzengeographische Monographie des Berninagebietes.* By Dr. E. Rübel. Pp. x+615+xxxvi plates. (Leipzig: W. Engelmann, 1912.) Price 8 marks.

(5) *Das Pflanzenreich: Regni vegetabilis conspectus.* Herausgegeben von A. Engler. 53 Heft. iv. 129. Geraniaceæ. By R. Knuth. Pp. 640. Price 32 marks. 54 Heft. iv. 277 u. 277*a*. Goodeniaceæ und Brunoniaceæ. By K. Krause. Pp. 207+6. (Leipzig: W. Engelmann, 1912.) Price 10.80 marks.

(1) DR. MUSCHLER'S "Flora of Egypt" has grown from the work of Ascherson and Schweinfurth, whose "Illustration de la flora d'Egypte," published in 1887, was the first modern account of the vegetation of the country. In this work 1215 species were enumerated, and the number was increased in a supplement, issued two years later, to 1316. In the preparation of the present work, Dr. Muschler has had the advantage of the unpublished additional notes by the two veteran workers and also the use of their extensive herbarium. The number of species (of flowering plants and ferns) is brought up to 1505,

which, however, includes about 180 cultivated plants.

The work is in English and comprises adequate descriptions of the families, genera, species, and varieties; the systematic arrangement is that of Engler's Syllabus. Under each species references are given to relevant synonymy, and the distribution in the area under consideration is worked out in detail. About one-third of the second volume is occupied by a series of appendixes, including (1) a brief account of botanical work in Egypt; (2) a phytogeographical subdivision of the area into five districts—Mediterranean, Nile-delta, Oases of the Libyan Desert, Desert region, and Red Sea region; (3) a tabulated list of all the species and their distribution in these districts; (4) a similar table showing the distribution of Egyptian species in the Mediterranean basin; (5) a list of the commoner cultivated and garden plants; (6) a glossary; and (7) a list of Arabian names. The "Flora" forms a useful working handbook to the plants of Lower Egypt, and will be much valued by those interested in the botany of this ancient land.

(2) Miss Mack's "Bush Days" is a readable little volume consisting of short chapters on the plants and birds, and their habitats, which are still to be found within easy reach of Sydney. The letterpress is illustrated by numerous well-executed photographic reproductions, and the book, though obviously written for the author's near neighbours, may be read with interest and profit by lovers of nature in other parts of the world.

(3) Mr. White's "Flora of Bristol," described as "the outcome of an ideal hobby, cultivated in the spare moments of a business career," is a good example of a modern local flora. As no descriptions of genera and species are given, it must be used in association with a general "British Flora," but it is rich in critical notes on the plants and their occurrence within the limits of the area under consideration. Full details of habitat are given—a circumstance which will, it is hoped, not lead to the extinction of some of the rarer forms by greedy or over-zealous collectors. 1138 flowering plants are recorded as native or colonists, and a number of aliens are also included in smaller type. Ferns and Characeæ bring the total up to 1178. The number is likely to decrease, as some of the rarer plants are noted as less common than formerly and as extinct in former localities. Mr. White mentions 193 species as rare or local and 218 as very rare. Three, formerly native, are now extinct, namely, sea-kale (*Crambe maritima*), the rare galingale (*Cyperus longus*), which, formerly abundant in a single locality, has been exterminated by draining and cultivating, and a sedge (*Carex Davalliana*), found a century ago near Bath, but long since destroyed by drainage. The last species is of interest as having supplied the figured specimen for "English Botany."

In addition to the systematic portion, Mr. White gives a valuable introduction, including notes on the geology of the district and an analysis of the flora in relation to the different geological areas. There is also an interesting history of Bristol botany, with biographical notices of botanists, from William Turner, the father of English botany, who as Dean of Wells spent some years in the district, onwards to recent workers.

(4) Botanists who have visited the Engadine will turn with interest to Dr. Rübel's exhaustive account of the plant-geography of the Bernina district. The author is a pupil of Dr. Schröter, and his book is a tribute to the well-known zeal of his teacher in the ecological study of the botany of the Swiss Alps. Factors of climate, soil, and position are studied in detail, and a useful account is given of the various plant-formations. There is also a complete flora of the district, including flowering plants and cryptogams, in the elaboration of which Dr. Rübel has had the help of specialists in the various groups. A notable feature of the book are the beautiful photographic reproductions; and there is also an excellent folding map.

(5) Dr. R. Knuth's contribution to "Das Pflanzenreich"— a monograph of the Geraniaceæ —is one of the most important of this series. It is of interest to the horticulturist as well as to the botanist, as it includes an elaborate account of the hybrids of the genus Pelargonium, the source of the so-called geraniums and zonal pelargoniums of our gardens. The plan of the volume is similar to that of the other monographs of the series—a general account of the vegetative and floral morphology and the distribution of the family, followed by a detailed systematic description of the genera, species, and varieties, a fair proportion of which are illustrated in the eighty plates. Dr. Knuth recognises about 600 species, 259 of which are included in Geranium (to which belong our crane's-bills), while 232 belong to the great South African genus Pelargonium. Erodium—including our stork's-bill—has sixty species. These three great genera, with two less important, form the tribe Geranieæ, characterised by the twisted beak of the fruit—the remaining six genera, the fruit of which is not beaked, show greater diversity of floral structure, and are distributed among four small tribes.

Dr. Krause has elaborated for the same series of monographs the two families Goodeniaceæ and

Brunoniaceæ, members of the sympetalous series Campanulatæ. The former is a small but important Australian family with about 300 species; the latter is a monotypic group, restricted to a single species, *Brunonia australis*, a small perennial herb of somewhat daisy-like habit, widely distributed in Australia. It is interesting to note that the wealth of Australian material preserved in the great herbaria at the British Museum and Kew have supplied a large proportion of the material on which Dr. Krause's monographs are based. A. B. R.

OUR BOOKSHELF.

Le Monde Polaire. By Otto Nordenskjöld. Traduit du Suédois par G. Parmentier and M. Zimmermann. Préface du Dr. J. Charcot. Pp. xi+324+xx plates. (Paris: Librairie Armand Colin, 1913.) Price, 5 francs.

Here is a handbook to the Polar regions, dealing, not with the exploration (of such there are plenty), but with the physical conditions of the regions, for which there was a vacant place. It is well for readers outside Scandinavia that it has been translated from the original Swedish into French: it might well be so into English. In a sense it treats the two polar regions as one, for it is comparative throughout, and for that reason the chapters are not arranged in a topographical sequence. Thus we have successive chapters devoted to Greenland, Iceland, and Spitsbergen; the next chapter deals with the Antarctic lands. The writer ranges widely enough to include among "sub-antarctic" lands Patagonia and Tierra del Fuego, the Falkland and other islands, and New Zealand, so far as that Dominion can be considered to lie under such conditions; correspondingly we find chapters on Arctic America (including Labrador), on Siberia, and on north-western Europe. Numerous photographs and sketch-maps accompany the text, and the French translation, which is prefaced by an introduction by Dr. J. Charcot, appears to have been excellently carried out by MM. G. Parmentier and M. Zimmermann. Dr. Nordenskiöld's chapters deal with the relief of land, ice conditions and effects, plant and animal distribution, climatic conditions and human life, and, where appropriate, with economic products.

Coast Erosion and Protection. By E. R. Matthews. Pp. xiv+147+33 plates. (London: C. Griffin and Co., Ltd., 1913.) Price 10*s*. 6*d*. net.

The author of this book writes with a practical knowledge of the subject with which he deals. He holds the position of Borough Engineer of Bridlington, and has constructed sea walls, promenades, and sea defence works of considerable magnitude, which are good examples of what such work should be.

The book follows much the same lines as that on the Destruction, Littoral Drift, and Protection of the Sea Coast, published by Messrs. Longman and Co. in 1902, but it does not treat the question of Littoral Drift with the same detail. As that book is now out of print, and the author of the present book has had the advantage of the large body of evidence laid before the Royal Commission on Coast Erosion, this work will be a valuable aid to engineers called upon to take charge of sea defence works.

The text is very fully illustrated with numerous plates showing the effect of waves on sea walls and cliffs in course of erosion, and illustrations of sea walls, groynes, and other sea defence works. As these latter are clearly drawn, and have the dimensions of the several parts marked on, they cannot fail to be of great practical use.

The book is divided into twelve chapters, the subjects dealt with being: wave action; erosion and accretion of the shore; types and designs of sea walls; groynes; reinforced concrete; and the action of sea water on cement and concrete.

In his account of the erosion of the Yorkshire coast, the author repeats the old fallacy of the material eroded from those cliffs being carried southward by the tides and being deposited on the Lincolnshire shore, and also as being carried up the Humber. This subject was fully dealt with in a paper on the source of warp in the Humber, read before the Geological Section of the Glasgow meeting of the British Association in 1901, in which it was shown that it is practically impossible for this eroded material to be carried so far southward; and samples of water taken on several occasions of the water entering the Humber on the flood tide give no indication of alluvial matter being carried into that river.

I Fenomeni Magnetici Nelle Varie Teorie Elettro-Magnetiche. Note Storico-Critiche. By Silvio Magrini. Pp. 165. (Bologna: Nicola Zanichelli, 1912.)

The scope of this interesting little volume, by an Italian author, is novel to English readers; at least, the present writer cannot recollect any other book devoted entirely to the history of the theory of magnetism. Oersted's fundamental discovery that an electric current gives rise to a magnetic field in surrounding space was important, not only as the starting point of electromagnetism, but also because, in the hands of Ampère, it became the basis of a theory designed to explain the physical nature of magnetism. Beginning at this point, the author passes in review the work of Poisson; Faraday's conception of lines of force, with its necessary recognition of the part played by the medium; the successful development of this idea in mathematical form by Maxwell; the theories of Weber and Ewing; the experimental work of Curie on diamagnetic and feebly magnetic substances; and finally, the modern electronic theory of magnetism as extended by Langevin, Weiss, Gans, and others. The various stages in the historical development are clearly displayed, and, although more elementary in its treatment, the book is a worthy companion of Whittaker's well-known "History of the Theories of Elasticity and the Ether." An English volume of similar scope would be a very desirable addition to current text-books. R. S. W.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Theory of Radiation.

The natural unit of angular momentum postulated by Dr. Niels Bohr, of Copenhagen, in his researches on the theory of spectral lines actually exists. It is the angular momentum of the magneton. Rejecting entirely the idea of magnetic or electric substance, the magneton may be regarded as an inner limiting surface of the æther, formed like an anchor-ring. The tubes of electric induction which terminate on its surface give it an electric charge, the magnetic tubes linked through its aperture make it a permanent magnet.

I find that the angular momentum of any such system, whatever its shape or dimensions, about its axis of symmetry is $(8\pi^2 V)^{-1}\epsilon\mu$. V is the velocity of light, ϵ the electric induction over the surface, and μ the magnetic induction over the aperture. I shall consider elsewhere the applications to the theory of complete radiation, spectral series, and the asymmetrical emission of electrons in ultra-violet light. Only this need be mentioned. If an electron (charge ϵ) be thrown off from a magneton like a speck of dust from a flying wheel, then the angular momentum of the magneton changes by the amount $-1(2\pi V)^{-1}\mu$. This is therefore the angular momentum of the ejected electron about the axis of the magneton. Taking the velocity of ejection to be proportional to the angular velocity in the magneton, we have Ladenburg's result that the energy of the emitted rays varies as the frequency.

Dr. Bohr, by first insisting on the fact that Planck's h is an angular momentum, has done something of the greatest importance, whatever the ultimate fate of his particular interpretation. Dr. Nicholson has, I think, used the same idea.

G. B. McLaren.

University College, Reading, September 20.

Stability of Aëroplanes.

In his experiments on the resistance of the air to spheres, M. Eiffel showed that for a certain critical velocity for a given sphere the resistance suddenly fails. The critical velocity appears to be very different for different spheres; *e.g.* in his paper (*Comptes rendus*, December 30, 1912) the sudden change is shown to begin at velocities of 12, 7, and 4 metres per second for spheres of diameter 16·2, 24·4 and 33·0 cm. respectively.

Suppose we make a triangular frame with one of these spheres at each corner and allow the frame to fall from a height. It would appear that if the weights of the spheres were so adjusted that the frame would maintain a horizontal position for a part of its flight, it must reach some velocity at which the equilibrium of the resisting forces would be destroyed, and rotation would ensue, tending to make the frame take up a vertical position.

If such a law holds for bodies of other shapes than spheres, it would appear that an aëroplane would have a much better chance of being stable in winds of great variety of velocities, if the resisting surfaces were all of the same size and shape.

I do not know whether this case has already been dealt with by others, and I make the suggestion for what it may be worth.

G. A. Shakespear.

The University, Birmingham.

The Pancreatic Treatment of Tuberculosis and Malaria.

There are two points in Dr. Saleeby's remarks upon p. 61 of Nature (September 18, 1913) which I should like to notice briefly. In my letter to you on the same page I did not refer to Baetzner's brilliantly successful results in the treatment of tuberculosis by pancreatic enzymes (*The Practitioner*, January, 1913, pp. 203–219), because after his prolonged investigations the thing is *an accomplished fact*, which cannot be disputed by any interested in its operative treatment. I am neither a medical practitioner nor the apostle of a new faith, but merely a scientific investigator. I foresaw, and foretold, the complete success of this treatment of tuberculosis in 1907; and with the fulfilment of this scientific forecast at the hands of Dr. M. A. Cleaves in that year and of Dr. W. Baetzner more recently, my concern with the matter has ended. Moreover, I have taught medical students for more years than I care to think of, and I know how hopeless it is to try to teach something new of a scientific nature to the medical profession.

As to the *sexual phases* of the life-cycle in malaria, they are of no practical importance at all in the treatment of malaria by enzymes. A reference to Major Lamballe's original manuscript shows that the presence of such *sexual* phases had been verified in several of his cases. Like all the clinical symptoms, such as in grave cases, delirium and coma, these sexual phases vanished and did not return, when the Fairchild injections of trypsin and amylopsin were administered. These sexual phases, the so-called "crescents," have a scientific interest, but scarcely a clinical importance, as Major Lamballe also recognises. The disease is not continued by them any more than cancer is continued by the cells, to which Prof. Farmer gave the name of "gametoid tissue." Probably they are got rid of by the leucocytes, but, in any case, in ordinary circumstances the pancreatic ferments would be devoid of action upon such *sexual* phases, as my experiments upon various non-pathogenic micro-organisms demonstrated (*vide* Beard, J., on the occurrence of dextrorotatory albumins in organic nature, *Biol. Ctrlblatt.* vol. xxxiii., pp. 150–170, 1913). J. Beard.

8 Barnton Terrace, Edinburgh, October 1.

Relative Productivity of Farm Crops in Different Countries.

In view of the repeated statements that British farming is declining and that the world is threatened with a shortage of wheat supplies, the following extract from the results of an investigation into the facts regarding both these questions may be of interest. Lack of space precludes reference to the sources of information, the statement of the results for all countries, details as to the method of investigation, and so on, but the condensed tabular summary which follows is typical of the results as a whole:—

—		Wheat			Oats			Barley			Potatoes		
		(*a*)	(*b*)	(*c*)	(*a*)	(*b*)	(*c*)	(*a*)	(*b*)	(*c*)	(*a*)	(*b*)	(*c*)

World changes in yield per acre ...		100	103	113	100	112	122	100	106	115	100	108	114

Decades—(1) = 1881–1890. (2) = 1891–1900. (3) = 1901–1910.
(*a*) Percentage of world's acreage. (*b*) Percentage of world's crop.
(*c*) Ratio of (*b*) to (*a*) = relative productivity per acre.

Column (*a*) gives the average percentage acreage for the three last decades, and column (*b*) the average percentage total crop; France is typical of the countries which have declined, and Russia of those which have improved under these heads. Column (*c*) measures relative productivity, which has been practically constant all the world over for the three decades. Information is added to show the increases which have taken place for the world as a whole in relative yield per acre.

The end of the nineteenth century may be considered as the close of a commercial revolution due to improved communications and transport, &c., and therefore the period under review is notably distinct from earlier epochs, so that the relative constancy of the productivity of these and other crops may be held to be a characteristic of this revolutionary period. Farming is a world business; improved results are common to all countries. The figures are instructive with reference to the threat of a world famine, *e.g.* if Russia only improved to the level of the United States, there would be an increase of 6 per cent. in the world's crop of wheat. At the same time it becomes obvious that the British farmer is the most successful farmer in the world; he always obtains a higher yield for each acre of land he tills. These are but the most important conclusions to which these results point; others may suggest themselves to your readers.

The Elephant Trench at Dewlish—Was it Dug?

I was not aware that it had occurred to Mr. Clement Reid, before it had done so to me, whether the Elephant Trench might have been excavated by man. He does not refer to this in his survey memoir on the Dorchester district; and so far as I can recollect he did not mention it when I described the trench with lantern slides at the meeting of the British Association at Cambridge in 1904. He now states (Nature, Sept. 25) that he is convinced that the trench was due to *natural agencies*, and suggests that it was "probably wind-cut by the swirl of the fine dust-like quartz sand which, mixed with polished flints, now fills the lower part."

For my part I cannot imagine how such a trench could have been formed in that manner. He says that he found the sides of the trench "curiously smooth, and no tool marks nor rubbings such as might be made by man working in the trench, or by wild beasts," and also that the flint nodules projected into the cavity from either side as though the softer chalk had been scoured away. The fine sand which partially fills the trench is, I think, to all appearances wind-borne; and during the long interval which probably elapsed before the trench had become filled up by natural agencies the surface of its walls would have become weathered away, and, possibly abraded by the sand, leaving the courses of flints projecting, and completely obliterating any tool marks.

Mr. Reid remarks: "If this sand-filled fissure is found to continue downwards, but is too narrow for a man to work in, it will show that the trench is not artificial." On the other hand, my late lamented friend the Rev. R. Ashington Bullen wrote to the *Geological Magazine* (July, 1910, p. 334), describing a pitfall to catch antelopes. It was 10 ft. deep, 2 ft. wide at the top, narrowing at the bottom to a *few inches.*

I may, however, say that when I dug at the end of the trench on the hill-face I came to the conclusion that the bottom of the trench was a flat chalk surface, and near the bottom I found some angular coarse gravel, and among it a nearly worn-down molar along with the polished flints. If, as Mr. Reid suggests, the trench was excavated by wind, which appears to me impossible, all the flints corresponding to the chalk so removed ought to lie, now, unbroken at the bottom, but in my notebook I find the remark that the flints in this gravel did not appear to have come "from the chalk direct."

I am extremely glad that Mr. Reid's interesting reply to my letter shows that I have succeeded in directing the attention of geologists to this, as I believe, important question.

O. Fisher.

Graveley, Huntingdon, September 26.

Referring to Mr. Clement Reid's letter on the origin of the Elephant Trench at Dewlish, in Nature of September 25, on the Yorkshire wolds holes are not infrequently scooped out of the chalk by what are locally termed "cloudbursts." One such, 13 ft. deep, occurred in the parish of South Cave last year.

A New Poet of Nature.

Readers of *The English Review* must be inured to shocks; but among the revolutionary visions which its young men have seen, surely nothing more startling has been recorded than this, which I extract from a short poem entitled "Early One Morning":—

"Have you heard what the young moon said to me
As I walked in the morning early?
. . . .
She lay on her back and laughed at me
As I walked in the morning early."

W. D. E.

TRAVEL IN TIBET.

(1) IN a third volume Dr. Sven Hedin concludes the popular account of his Tibetan expedition of 1905–8, of which the main instalment was published four years ago. The present volume collects "all the material for which there was no room" in the previous two tomes. This includes a description of the explorer's journey northwards from the Mānasarowar Lake to the source of the Indus, which Dr. Hedin was the first European actually to penetrate, and of the well-known route from that lake along the Sutlej Valley back to Simla. Added to this are miscellaneous extracts from the books of previous writers and travellers on a variety of Tibetan topics, also a polemical defence of the author's discovery of the "Trans-Himalaya," a claim which has been disputed by a writer in the *Geographical Journal*, on the ground that the existence of that range was undoubtedly known in a general way over a generation ago. The breezy, rollicking narrative reflects the abounding enthusiasm of the author, and couched largely in dialogue form it reads almost like a romance, conveying at times the impression of a holiday romp rather than a rigorous journey achieved only by the painful toil of man and beast.

Of the scientific results, "which will shortly be issued," it is mentioned that the geological specimens (1170 in number) have enabled Prof. A. Hennig, of Lund, to say that the older sedimentary rocks of the Trans-Himalaya generally resemble those found on the northern flanks of the Himalayas near Gyantse and Lhasa in Central Tibet. They consist of Jurassic quartzites and phyllitic schists, with subordinate beds of slaty crystalline limestone, which is so strongly metamorphosed that if it did originally contain fossil remains these are quite destroyed. The series is penetrated by an intrusive formation which has suffered metamorphosis by pressure, and therefore is older than the other. The eruptive formation is obviously part of that found in both the eastern and western Himalayas, and ascribed to the Eocene age, and consists in the Trans-Himalaya of intrusive granites, pegmatites, porphyries, &c., with vitrified surface lavas, basalts, and sub-aërial volcanic tuffa. It is noteworthy that the Brahmaputra Valley, which separates the Himalayas from the Trans-Himalaya, must be considered as "a deeply excavated *erosion*-valley, and that faults do not play the leading part here which Oswald has assigned to them in his article based on Dr. Sven Hedin's preliminary communications."

FIG. 1.—"I dangle between Heaven and the murderous Sutlej." From "Trans-Himalaya."

Some mistakes are noticeable in respect to the legends and etymologies of the names of the great rivers rising in the vicinity of Mount Kailas, the Hindu Olympus, and require emendation. They

[1] (1) "Trans-Himalaya: Discoveries and Adventures in Tibet." By Sven Hedin. Vol. iii. Pp. xv+426+plates+maps. (London: Macmillan and Co., Ltd., 1913.) Price 15s. net.

(2) "The Land of the Blue Poppy: Travels of a Naturalist in Eastern Tibet." By F. Kingdon Ward. Pp. xii+283+xxxix+plates+5 maps. (Cambridge University Press, 1913.) Price 12s. net.

are perhaps due to the indirect process made use of in interrogating the Tibetans, of which the author states "I spoke Jagatai Turkish with my men, and Rabsang translated for me into Tibetan." Thus, we read "Mānasarowar means 'Mīnasa the most beautiful of lakes.' Mānasa means 'created by the soul,' for the lake was created by the soul of Buddha." In this equation our author has evidently confused Brahmā with Buddha. For there is no authentic Buddhist legend associating Sakya Muni or his "soul" with the creation of this lake; indeed, that teacher as an elementary part of his doctrine denied the existence of a soul altogether. On the other hand, Brahmā in Hindu myth is often linked with this lake, doubtless because "*Mānasa*," meaning in Sanskrit "mental or spiritual," or "produced by the mind," is an epithet of Brahmā, and Kailas, the Olympian abode of the other gods created by Brahmā, adjoins this lake. To say that *sarowar* means "the most beautiful of lakes" is neither literally correct nor appropriate. No photograph of that lake is given in the present volume, but no one who has seen this desolate lake, as the writer of this note has, could think of calling it "most beautiful." The word really means "the great lake," or literally "the best or sacred lake," but with no sense whatever of "beautiful." Similarly, the Brahmaputra, the source of which is known to the Tibetans as "the river of the horse's mouth," is, we are told, "so named in honour of Buddha's steed," though, as a fact, neither Buddha nor his steed are denoted in this name, nor is there any authentic legend of such relationship current amongst Tibetans. Again, the statement that "'Singi-kamba' [='the lion's mouth'] the Indus, refers rather to the tiger than the lion," is a mistake, as "*Sing*" means only "lion," and not tiger; and lions are not even yet extinct in the mid-Indus valley, where they are believed to have been formerly generally distributed. The volume is enriched by numerous excellent photographs and sketches, which are admirably reproduced, and add greatly to the attractiveness of the book.

(2) Under the title of the "Land of the Blue Poppy," Mr. Ward, son of the late Professor of Botany at Cambridge, describes his travels on the Chinese border of Eastern Tibet, as a collector of decorative plants for a firm of florists. In this work he spent several months in 1911 in the upper valleys of the Yangtse, Mekong, and Salwin, with his headquarters at the missionary station of "A-tun-tsi" (the A-tun-tzu of the maps), on the north-west frontier of Yunnan. As a result he gathered many rare plants, including more than twenty new species, amongst which was the *Meconopsis*, named after him, and giving the title to his book; also two new voles. Although he displays no very intimate acquaintance with the writings of previous travellers in those regions, his narrative is pleasantly written, and contains some observations of general interest.

The extensive cultivation of opium-poppy, in "solid fields" and otherwise, which he noticed in Western Yunnan, is of political importance at the present time, when India is depriving herself of enormous revenue from opium solely in the interests of assisting China to stamp out the vice of opium-eating, and on the express condition that China herself ceased all cultivation of that drug. On one of the occasions on which Mr. Ward lost his way, and wandered alone for several days in the wilds, he ate a quantity of rhododendron corollas for their nectar, and was surprised to find them poisonous—forgetful of the toxic Pontine honey described by Xenophon, and usually ascribed to rhododendron or azalea. With the exception of *R. arboreum* the Himalayan species are generally regarded as poisonous.

Of the Tibetan character and hospitality he

Fig. 2.—The Salween Forests in Summer, Mekong-Salween Divide, 8,000 feet. From "The Land of the Blue Poppy."

speaks with much enthusiasm. In the dress of the Tibetan men he remarks as "very curious a section of an elephant's tusk threaded on to the queue"—this doubtless is the thumb-ring of the ancient bowmen, whose dress the modern Tibetan dandy imitates, and binds the ring on his coiled pigtail when not worn on the thumb on ceremonial occasions. Other border tribes of much ethnological interest amongst which he passed were Lissu, Lutzu, Minchia, "Lama," Pe-tzu, Chu-tzu, and Mosso. The last-named is of especial interest as possessing an elementary hieroglyphic writing, somewhat like that of the Hittite, the origin and development of which is still unsolved, though specimens have been published by Captain Gill, Prince Henri, and Mr. Forrest. Yet our author makes no reference to this matter. He encountered several hot-springs, but unfortunately took no record of the temperature, nor indicated their location exactly, as a guide to future travellers desirous of making precise scientific observations.

The oft-discussed question of the geological causation of that remarkable wrinkling of the surface of south-east Tibet into a series of parallel valleys, through which the great rivers rush southwards, is not advanced nearer to a solution by the vague theories indulged in in the last chapter. These hypotheses, which are not even new, are not based on examination of the actual rocks, and are uninformed by the many facts collected by the experts of the Indian Geological Survey and others. The great river of Central

Fig. 3.—The Salween in the arid region, below La-Kor-ah. From "The Land of the Blue Poppy."

Tibet is not usually spelt "Bramapootra" nowadays. Notwithstanding its scientific deficiencies as "the journal of a naturalist," the book gives a lively popular account of adventurous travel off the beaten tracks, and the numerous photographs convey a good idea of the country traversed.

THE OCCURRENCE OF OIL SHALE AMONG THE JURASSIC ROCKS OF RAASAY AND SKYE.[1]

THE Geological Survey of Great Britain in the course of their investigations in the Isle of Skye have discovered an oil-shale which may ultimately prove of economic importance, and as notices of the discovery have appeared in the daily Press, it is desirable that the facts so far as they are known to the Geological Survey should be placed on record without further delay. The discovery was made by Dr. G. W. Lee, who has written the following account:—

The stratigraphical position of the shale is at the very base of the Great Estuarine Series, a group which succeeded strata containing a fauna of Garantiana age (high in the Inferior Oolite),

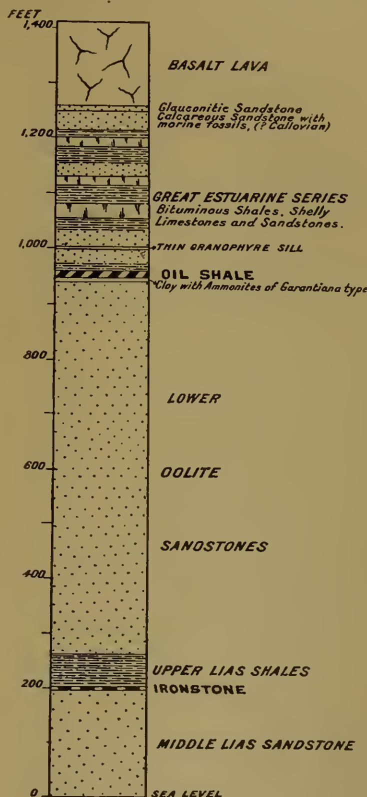

Diagram section illustrating the sequence of the Jurassic rocks below Dùn Caan, Isle of Raasay.

and is overlain by Kellaways Rock. The shale itself yields fossils. They include Entomostraca, a flattened lamellibranch, and plant remains. Since it rests immediately on the marine Garantiana clay, it follows that the incoming of estuarine conditions must have been a sudden one.

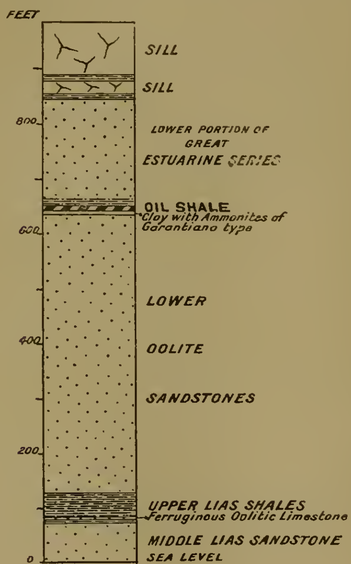
The shale is brownish in colour, fine in grain, gives a wooden sound under the hammer, and has a brown streak. It is tough and resists disintegration by weathering, a character which

[1] Communicated by the Director of the Geological Survey of Great Britain.

distinguishes it from the bituminous shales found throughout the Estuarine Series, all of which crumble into small fragments. It is so far known only from natural exposures, where through weathering, it assumes a lilac or yellowish coating.

The thickness of the seam at the outcrops may be taken to be from seven to ten feet, but its passage into the overlying sediments is gradual.

The samples so far analysed were much weathered, so that we are not yet in possession of exact data concerning the yield of oil and bye-products from the fresh shale. That the fresh shale might be expected to yield more than weathered portions seems probable, but to what



Diagrammatic section illustrating the sequence of the Jurassic rocks in the cliff between Holm and Prince Charles's Cave, Isle of Skye.

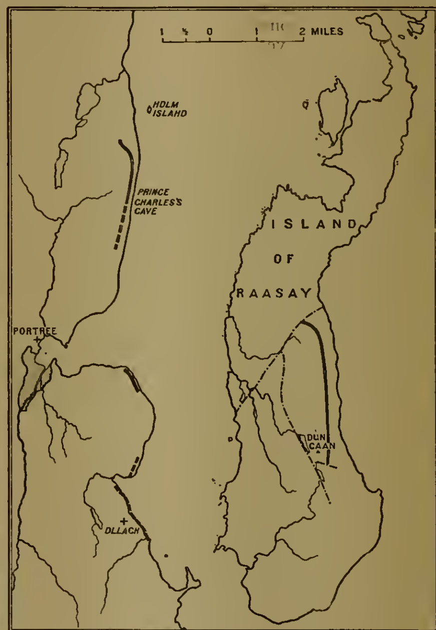
extent is not known, and it is on that that the industrial possibilities of the find depend.

A sample from the outcrop where the shale was first detected in Raasay gave 12 gallons of crude oil per ton of shale, with 6·2 lbs. of sulphate of ammonia, which is equivalent to at least 12 lbs. in a works retort.

A compound sample from the Skye coast between Holm and Prince Charles' Cave yielded 12·8 gallons of crude oil per ton, and 7·4 lbs. of sulphate of ammonia. Mr. D. R. Steuart, who kindly undertook these tests, states that the samples were so weathered that he did not expect to get any oil. Consequently these results indicate that the shale is worth further investigation.

Before the period of denudation which removed so much of the Scottish Jurassic rocks, the shale probably extended over a large area. Still, the portions that escaped denudation are not inconsiderable. In Raasay the field occupies an oblong area stretching from Dun Caan northwards to the boundary fault which throws the Mesozoic rocks against the Torridonian. It is three miles long, with an average width of seven-eighths of a mile, which diminishes southwards. The strata are not folded, but have a dip of about 10 degrees to the west.

In the Portree district of Skye there was once



Sketch map showing the outcrops of the Oil Shale.

——— Oil Shale.

– – – – Oil Shale, where burnt by contact action of igneous rocks.

—·—·– Faults.

an extensive field, of which much has been destroyed by the contact action of intrusive rocks. The crop has been traced from Ollach—five miles south of Portree—to the Holm burn—five miles north of Portree. The outcrop south of Portree shows much alteration from heat, except between the Tom cave and the Clach Dubh. North of Portree the destructive action of the intrusions is felt as far as Prince Charles' cave, but between that point and the Holm burn—one and a half miles further north—the shale has escaped the action of igneous rocks. There is no inland exposure of the oil shale horizon, which is everywhere covered by higher beds; consequently the probable extent of the field towards the west cannot be estimated. But the dip being low the shale would be within practicable reach for some distance inland. In the cliff section between Bearreraig and Upper Tote, that is north of the point just considered, the shale facies is replaced by a sandstone facies.

THE ADDRESSES AT THE MEDICAL SCHOOLS.

THE first of October is the opening day of the winter session of our medical schools; and in many of them it is made the occasion of an address, given by some person of high authority. The addresses this year include a wide range of subjects. Mr. Handley, at the Middlesex Hospital, gave a very pleasant discourse on the "renegades of medicine," the men who have forsaken medicine for some other profession, not without advantage to themselves and us—Keats, Goldsmith, Bridges, Huxley, Livingstone, and many more. It is a new subject, and worth working out; but we are not sure that Mr. Handley got hold of the right end of the moral. Sir William Osler at St. George's, Dr. Hunter at Charing Cross, and Prof. Sherrington at Leeds, spoke on certain problems of medical education. Sir John McFadyean, at the Royal Veterinary College, spoke on the working of the new Tuberculosis Order of the Board of Agriculture. He stated that the number of milking or dairy herds in England and Scotland free from tuberculosis was practically negligible; and he urgently advised the owners of valuable pedigree herds, as a matter of their own profit, to eradicate the disease among their animals. He also advised that contagious abortion in cows, and Johnes's disease, should be brought under the Contagious Diseases of Animals Act.

Two of the October addresses this year are of especial interest—one, at the London School of Medicine for Women, by Sir Charles Lukis, Director-General of the Indian Medical Service; the other, at St. Mary's, by Sir John Hewett, sometime Lieut.-Governor of the United Provinces. These two addresses, by men of profound experience and unquestioned authority, should be read carefully by all who want to know what the medical profession is accomplishing, and what it hopes to accomplish, for the peoples of India.

Sir Charles Lukis, speaking to women students, appealed to them for personal service. His appeal, full of wisdom and of sympathy, ought not to fail: for the work done in India by medical women is some of the very best work in the world. He spoke, especially, of the imperative need of more teaching and more acceptance of ordinary rules of sanitation, not only for the prevention of the spread of malaria, plague, and tuberculosis, but for the prevention of food-infection, and water-infection. It is our medical women who alone can get the women of India to help in this good work. "Ladies who have spent all their lives in England are apt to regard their Indian sisters as being very downtrodden and oppressed. This is a grave mistake. Out of doors the man is lord of creation, but once he is inside the house he is absolutely controlled by his wife and mother in all matters concerning domestic economy and the family life. Indeed, I know of no country where the woman is more absolutely the mistress of the house than she is in India; and I am convinced that we shall never make any real headway in promoting the knowledge of domestic and personal hygiene until we have convinced the women of India as to its necessity, and they have thrown their powerful influence into the scale. Here the medical man is useless—the *purdah* bars the way, and it is to the medical woman that we must look." Sir Charles Lukis went on to speak of infant mortality in India, and of its relation to early marriage, and to the native methods of midwifery. Then he described fully the improved scheme for a women's medical service for India, and the plan for a medical college for women to be established in Delhi. Every word of his address is worth reading.

So is every word of Sir John Hewett's address on the work of the medical profession in India. He spoke first of the improved health in the Army, and in the jail population. "The mortality among the wives of soldiers has been reduced to one-third of what it formerly was, and that among their children to one-half." The death-rate among the native troops has come down from more than 20 per thousand in 1871–1880 to less than 7 per thousand in 1911. The death-rate among the jail population has come down from 71 per thousand in 1831–1856 to 18 or 19 per thousand in 1911. Sir John Hewett then spoke, with strong feeling, of the errors of anti-vaccination and anti-vivisection. Truly, in view of the facts of India, they are worse than errors. "It is surely calamitous that the opponents of vaccination in England should have set themselves to make the people of India hostile to a process which has brought them so much benefit." To the anti-vivisectionist, we commend Sir John Hewett's statement of the results of the protective treatment against plague, typhoid, and hydrophobia in India. These results are not only a final verdict against anti-vivisection; they are a magnificent record of the saving of the lives of men, women, and children.

SCOTTISH ORNITHOLOGY IN 1912.[1]

THIS report supplies in an epitomised form the results of the activities of Scottish ornithologists during the past year. It is a comprehensive and well-arranged booklet of ninety-six pages, and is both useful and important, since it affords much information hitherto unpublished, as well as a *résumé* of all that has appeared in serial literature during the period covered. A pleasing feature is to be found in the fact that these well-known lady ornithologists have themselves contributed materially to the year's opera-

[1] Report on Scottish Ornithology in 1912, including Migration. By Leonora Jeffrey Rintoul and Evelyn V. Baxter, hon. members of the British Ornithologists' Union. (Edinburgh: Oliver and Boyd; London: Gurney and Jackson. Price 1s 6*d*. net.

tions by their investigations made during a two months' residence in the lighthouse at the Isle of May—a famous bird observatory situated in the North Sea off the mouth of the Firth of Forth. There are also contributions from nearly one hundred observers, posted between the Muckle Flugga (the northernmost limit of the British Isles) and the shores of the Solway and Tweed. This vast amount of material has been arranged under the following headings: birds new to Scotland; uncommon visitors and species new to faunal areas; extension of breeding range; hybrids; summer and nesting; winter; ringing; plumage; food, habits, &c.; and migration.

Much that is interesting is recorded under all these headings, but the special feature of the report lies in the wealth of data from the numerous islands—the most important, in some respects, of all bird stations.

These insular records relate mainly to the spring and autumn passage-movements of those feathered voyagers which traverse our shores when *en route* between their accustomed northern summer haunts beyond our isles, and their winter retreats lying to the south of them. These birds form by far the most numerous class of migrants that visit the British area. At such stations, especially the northern stations, the comings and goings of these travellers are to be observed free from the complications that arise on the mainland through the presence of birds of the same species which are simply local natives or engaged in local movements. In addition, the recent attention devoted to island stations has resulted in the garnering of a remarkable crop of records on the occurrence of rare visitors, some of them mere waifs, while others formerly considered such have unexpectedly proved to be annual in their appearances—among others the yellow-browed warbler, red-spotted bluethroat, little bunting, ortolan bunting, and grey-headed wagtail.

The year 1912 was remarkable for the number of rare species detected at Scottish stations. These included the black chat, northern bullfinch, scarlet grosbeaks, little buntings, Richard's pipit, red-breasted flycatchers, Blyth's reed warblers, icterine warblers, barred warblers, snowy owl, Tengmalm's owl, broad-billed sandpiper, Temminck's stints, little bustard, &c., the visits of which are duly recorded along with the particulars relating to their occurrence.

In conclusion Scottish ornithologists have every reason to be satisfied with the results of the year's investigations and may congratulate themselves on the able and excellent manner in which these results are set forth in the report.

W. E. C.

NOTES.

A few days ago (October 2) the daily Press published sensational paragraphs to the effect that Sir Frederick Treves had announced, at the Radium Institute, "a complete revolution in the future of radium." When analysed, the "revolution" amounts to little more than a statement that the Radium Institute has begun to collect radium emanation in sealed glass tubes, and to issue the tubes to doctors for the treatment of their patients. It was assumed by the literary young men who write the leaders and notes in the daily papers that radium emanation had just been discovered instead of being known and named for ten years or more, so they let their enthusiasm overstep the bounds of their knowledge. Even the method referred to by Sir F. Treves is not new; it was published in *The Lancet* on December 11, 1909, p. 1742 ("On the Use of Radium for Local Application within the Body," by Dr. Alfred C. Jordan), and this paper is quoted and fully abstracted by Dr. Dawson Turner in his book on "Radium: its Physics and Therapeutics" (Baillière, Tindall and Cox, 1911), pp. 27 and 28. In *The Lancet* the glass tube containing the emanation was directed to be enclosed in a tube of lead "compo" of 1 mm. thickness, and this in its turn in a length of rubber tubing. Of course, these tubes must be used at once, for the emanation decays to one-half its initial strength in three and a half days. A tube of initial strength equal to 10 mg. of radium may be placed in contact with a tumour, and left to "decay" there. It will be understood that emanation used in this way (in sealed tubes surrounded by 1 mm. of lead) depends for its action on its γ rays and its hardest β rays, the glass stopping all the α radiation, while the lead absorbs most of the β rays. Very different is the action of free radium emanation, as in radio-active waters. In the latter case the α particles are able to bombard the tissues at close quarters; the action of the β and γ radiation then becomes negligible, possessing no more than one-hundredth part of the energy of the α radiation. Great care must be used in applying α radiation to the tissues, for the destructive action is most pronounced. Good results have been obtained with radium in many diseases, but the hopes of the public as well as the medical profession are centred round the treatment of cancer. Even in this dreaded disease many favourable results have been reported both with radium and with the Röntgen rays, but unfortunately disappointments are far more frequent than cures.

The year 1914 is the centenary of the birth of Sir John Lawes, and 1917 is that of Sir Henry Gilbert; and it is proposed by the Society for Extending the Rothamsted Experiments to raise the sum of 6000*l.* by public subscription for the purpose of erecting a suitable commemoration laboratory at the Rothamsted Experimental Station. It is understood that if 6000*l.* is raised in this way, a further grant of 6000*l.* can be obtained, making a total of 12,000*l.* altogether, for which sum an adequate building could be put up. The rapid development of agricultural chemistry and bacteriology, and particularly of the special branches associated with Rothamsted—the composition of crops and the study of the soil in relation to the plant—has necessitated further increases in the laboratory staff, and has attracted a number of voluntary workers. For all these more modern accommodation is required than can be obtained in the older part of the present buildings. The work of Lawes and Gilbert not only laid the foundations of agricultural chemistry as a science in this country, but did much to improve British agriculture and raise it to its present high level. It also played a great part in developing the artificial fertiliser industry, which has remained an essentially British industry and has now assumed vast dimensions. The whole country has gained enormously through the work of these two men. It is therefore felt that the appeal should be national, and several committees have been formed for the purpose. Men of science have many calls on them, but it is hoped, nevertheless, that the sympathy which everyone feels with the Rothamsted work will manifest itself by practical assistance towards its development. Subscriptions should be sent to the Secretary, Rothamsted Experimental Station, Harpenden, Herts.

It is with great regret that we record the disappearance of Dr. Rudolph Diesel from the G.E.R. steamer *Dresden* on her voyage from Antwerp to Harwich on the night of September 29; the circumstances are such as to leave no hope of his being alive. Dr. Diesel will be remembered as the inventor of the oil engine which bears his name. Born in Paris in 1858, of German parentage, his training included courses at the Augsburg technical schools and at the Munich Technical College. His first published description of the Diesel engine appeared in 1893; aided financially by Messrs. Krupp and others, the next few years were spent in arduous efforts to realise the principle of his engine in a commercially successful machine. The difficulties to be overcome were very great. In the earliest attempt, compression of the air was effected in the motor cylinder and the fuel injected direct. This engine exploded with its first charge and nearly killed the inventor. The modern Diesel engine compresses the air in the motor cylinder to a pressure above 400 lb. per square inch, during which process the air becomes hot enough to ignite the fuel. At the end of compression, the fuel is injected by means of a separate air supply at a pressure higher than that in the cylinder. Nothing of the nature of an explosion occurs in the cylinder; the oil burns as it is injected, and, as the piston is moving outwards at the same time, the pressure does not rise to any extent. The fuel consumption of these engines is remarkable, being roughly one-half of any other type of oil motor. Engines both of a two-stroke cycle and of a four-stroke cycle are now being developed by many firms both on the Continent and in Britain. In Dr. Diesel's opinion the two-stroke engine would probably be the standard type for marine purposes. Marine Diesel engines of very large power have not yet been constructed, but many important experiments in this direction are being made. Dr. Diesel's loss will be regretted by men of science on account of his efforts to interpret practically the Carnot ideal cycle, and by engineers on account of the immense strides which his untiring energy and indomitable pluck have made possible.

Sir William Christie, K.C.B., F.R.S., formerly Astronomer-Royal, has been elected Master of the Clockmakers' Company.

The death is announced, at fifty-four years of age, of Dr. W. Carnegie Brown, joint secretary of the Society of Tropical Medicine and Hygiene, and author of papers on malaria and diseases of the tropics.

It is announced in *The Athenaeum* that in consequence of the efforts of Dr. C. Holder and others, extending over many years, the Legislature of California has constituted the island of Santa Catalina a fish refuge. In future there will be no netting within three miles of the shore of the island.

The first ordinary meeting of the Medical Society of London for the session 1913–14 will be held on Monday next, October 13, when the new president, Sir David Ferrier, F.R.S., will deliver his inaugural address. The Lettsomian lectures of the society will be given on February 2 and 16 and March 2 by Dr. F. M. Sandwith, who will treat of the subject of dysentery.

According to *The Electrical Review*, a wireless receiving installation has been set up in the cathedral at Florence by the director of the Florence Observatory. All the parts of the equipment are within an enclosed space, the antennæ being within the building. Messages have been received from Paris, Toulon, and Madrid, the efficiency of the receivers being, it is stated, only slightly less than if in the open air.

A public meeting in connection with the ninth quinquennial festival of the Royal Albert Institution, Lancaster, will be held at Lancaster on Tuesday, October 21, when the following addresses will be given:—"The Feeble-minded: Historical Retrospect," Sir T. Clifford Allbutt, K.C.B., F.R.S.; "The Future of the Royal Albert Institution," Sir J. Crichton Browne, F.R.S.; "The After-care of the Feeble-minded," Dr. C. H. Bond.

The fourth exhibition of models, tools, and scientific apparatus, organised by the proprietors of *The Model Engineer*, will be held at the Royal Horticultural Hall, Westminster, S.W., on October 10–18. Special rooms are to be devoted to wireless telegraphy in operation, and to aëroplane models of all kinds, while a completely equipped workshop will be manned by members of the London Society of Model and Experimental Engineers, who will give demonstrations of model-making and workshop operations.

A conference of members of the Museums Association and others interested in similar work is to be held at the Warrington Museum on Thursday afternoon, October 30, for the purpose of discussing subjects of common interest to those concerned in the work of museums, art galleries, and kindred institutions. Offers of papers or suggestions of suitable subjects for discussion should be sent to Mr. C. Madeley, director of the Warrington Municipal Museum.

A demonstration of the results of his researches into the pathology of rabies will be given on Monday next to the Royal Society of Medicine by Dr. Hideyo Noguchi, of the Rockefeller Institute. Dr. Noguchi proposes to show pure cultures of various pathogenic and saprophytic spirochætæ; to demonstrate the presence of treponema pallidum in the brain in cases of general paralysis; to show experimental general paralysis in rabbits; and to give a demonstration of cultural studies of the virus of rabies.

IN response to numerous requests, it has been decided to defer until October 31 the closing of the Historical Medical Museum, referred to in our issue of July 3 (vol. xci., p. 456). During the month of October the exhibition will remain open from 10 a.m. to 6 p.m. daily, and from 10 a.m. to 1 p.m. on Saturdays. After this date it will be closed for a few months for re-arrangement as a permanent museum. It is proposed to reopen the museum in its permanent form in the spring of next year.

A MODERATELY strong earthquake was felt in the neighbourhood of the Panama Canal during the night of October 1–2, and has evidently caused some concern with regard to the safety of the canal from future shocks. It would seem, however, that there is little need for anxiety. Though other adjoining districts are frequently visited by destructive earthquakes, the isthmian zone itself is singularly free from such disturbances. Moreover, as Milne and Omori have shown, earthquake vibrations are much less intense in excavations than on the surface of the surrounding land.

IT is announced in *Science* that the Walker prizes in natural history of the Boston Society of Natural History for the present year have been awarded as follows:—The first prize of 100 dollars to Dr. R. A. Spaeth for a paper on an experimental study concerning the chromatophores of fishes, and the second of 50 dollars to Prof. O. D. von Engeln for a paper on the effects of continental glaciation on agriculture. Prizes for 1914 and 1915 will be awarded for original and unpublished research work in any biological or geological subject. Competing essays must reach the secretary of the society on or before April 1 next.

MAJOR BARRETT-HAMILTON, accompanied by Mr. Stammwitz, one of the taxidermists on the staff of the British Museum (Nat. Hist.), sailed in a whaler on Saturday last for South Georgia, on a mission from the Colonial Office, to report on the whaling stations leased by the British Government to a Norwegian firm. The species hunted at the South Georgian stations are chiefly rorquals, of which the slaughter is reported to be very heavy; and we understand that the main object of the mission is to ascertain whether the whales stand in danger of extermination. The taxidermist will endeavour to obtain specimens (not, of course, entire whales) for the museum.

MR. ALVIN LANGDON COBURN's exhibition of camera pictures, which is to be seen at the Goupil Gallery, 5 Regent Street, until October 25, is well worth a visit from anyone interested in artistic photography. The series of pictures of the Grand Canyon exhibit this remarkable region in a new light. Mr. Coburn's photographs, all enlargements from quarter-plate negatives, are as far apart from Hayden's well-known topographical drawings as could well be imagined; the latter faithfully delineate the grandeur of the vast spaces and lofty walls of the great valley by delicacy and accuracy of line and by their panoramic outlook. Mr. Coburn, limited by his apparatus to a smaller field, conveys the same sensations of vastness by his artistic use of atmosphere and the great shadows cast by hill and cloud. Clouds indeed are made the most of in all these pictures, and No. 44, "The Cloudburst," is not only a striking photograph, but a valuable record of this phenomenon.

AT the recent International Congress of Pharmacy held at the Hague, a proposal to form an international pharmacopœial bureau was discussed, and a commission was appointed to consider the question, and to submit to the International Pharmaceutical Federation at an early date a scheme for the establishment of such a bureau. The commission is composed of seven members, representing respectively Great Britain, the United States, Germany, France, Holland, Belgium, and Switzerland; most of the members are associated with the revision of their national pharmacopœias, the English representative being Prof. H. G. Greenish, joint editor of the "British Pharmacopœia," and the American, Prof. J. P. Remington, editor of the "United States Pharmacopœia." As the outcome of the deliberations of such a strong committee, a useful plan may be expected. Among the duties of such a bureau as that proposed would be the collection and examination of all literature relating to pharmacopœial revision and the experimental investigation of new drugs and preparations, and no doubt the influence of the bureau would tend to encourage the work already commenced in the direction of the unification of pharmacopœias.

The South African Journal of Science for September, being the organ of the South African Association for the Advancement of Science, reports the business proceedings of the meeting of the association held at Lourenço Marques in July last, under the presidency of Dr. A. W. Roberts. The following officers were elected for 1913–14:—President, Prof. R. Marloth; vice-presidents, Prof. L. Crawford, Mr. S. Evans, Dr. W. Johnson, and Mr. A. F. Williams; general secretaries, Dr. C. F. Juritz and Mr. H. E. Wood; general treasurer, Mr. A. Walsh. Invitations to hold the next annual meeting were received from the mayors and councils of both Kimberley and Pretoria; and the final decision as to the place was left to the council. A resolution was passed "that the Government of the Union be asked to pass legislation declaring that meteorites are Government property, and when found should be delivered to the nearest magistrate, for transmission to the nearest museum under Government control." The sixth award of the South Africa Medal, together with a grant of 50*l.*, was made to Dr. A. W. Rogers, assistant director of the Geological Survey of the Union, in recognition of his geological work in the Cape Province. In connection with the grant of 100*l.* made to Dr. A. W. Roberts by the association in 1905 for the reduction of his variable star observations, Dr. Roberts reported that he has had the observations, some 60,000 in number, reduced, copied in dulplicate, and indexed. The question of printing has, however, been a difficulty.

THE Board of Agriculture and Fisheries has issued a "Horses (Importation and Transit) Order of 1913" in accordance with powers conferred by the Diseases of Animals Acts, 1894 to 1911. The Order came into force on October 1; it provides for the proper accommodation of horses, asses, and mules on all vessels on which such animals are carried to or from any port in Great Britain, and for the proper construction of railway trucks used for conveying such animals in Great Britain. Provision is made for the proper feeding and watering at places of unloading and during transit. It is made illegal to convey any horse, ass, or mule by boat or train if, in the opinion of an inspector of the Board and notified by him, the animal cannot, owing to infirmity, illness, injury, fatigue, or any other cause, be so carried without unnecessary suffering. The above regulations, together with instructions as to disinfection, &c., have all been provided for by previous Orders, which have been revoked and re-enacted in the present Order. The principal reason for the present Order is to provide the following most necessary amendment, namely, that horses, asses, and mules brought to Great Britain from abroad are required henceforth to be accompanied by a veterinary certificate of freedom from symptoms of glanders (including farcy), epizootic lymphangitis, ulcerative lymphangitis, dourine, horse-pox, sarcoptic mange, psoroptic mange, influenza, ringworm, or strangles, instead of as heretofore from symptoms of glanders (including farcy) only.

WE have to acknowledge the receipt of a copy of a pamphlet issued by the Department of Lands and Survey, Victoria, on various methods of destroying rabbits and other "vermin" employed in that colony, and also containing the regulations with regard to fences of wire-netting.

THE National Equine Defence League has issued a fourth edition of a pamphlet on docking and nicking horses. The fact that Parliament has passed a law, to come into operation on January 1, 1915, making the practice of "docking" horses illegal, and that the purchase of docked remounts for the army is to be discontinued as soon as practicable, seems to render the pamphlet somewhat superfluous—at any rate, in this country.

WE have been favoured with an extract from *Neue Weltanschauung* for 1913, Heft 913 (pp. 321–332), in which Dr. W. Breitenbuch directs attention to the fact that the present year is the jubilee (fiftieth year) of Prof. Ernst Haeckel's work on evolution. The article includes a chronological account of the learned professor's studies during that long period, with brief notes on the numerous memoirs and works which have made his name famous.

To the series of biographical memoirs issued by the National Academy of Sciences, Washington, Prof. H. F. Osborn has contributed an exceedingly interesting account of the life and work of Prof. Joseph Leidy, the founder of vertebrate palæontology in America, and the last great naturalist of the type who made the entire subject of zoology their study, and published papers and works of permanent value in almost every branch. That such encyclopædic knowledge and broad grasp of the whole field of natural history can, as his biographer remarks, never reappear, is a matter for regret, as the specialised lines on which zoology is now, from necessity, studied cannot fail, in many cases at any rate, to result in narrowness of view. Although his study of the rhizopods was sufficient of itself to establish a great reputation, Leidy will chiefly be remembered as a palæontologist, and especially by his descriptions of Poëbrotherium and the so-called oreodonts, or "ruminating hogs," which paved the way for the discovery of the phylogeny of the camels and other artiodactyle ungulates.

To vol. vii., part 2, of *Annotationes Zoologicae Japonenses* Mr. B. Aoki contributes a list of Japanese and Formosan mammals. The island of Saghalien is also stated to come within the scope of the list, but no mention is made in the introduction that Korea is likewise included, although in the text we find (p. 272) a Korean shrew. On the other hand, Korea is not in the range of the tiger (p. 312), although the animal abounds in that country. The total number of forms, inclusive of subspecies, is 197. If trustworthy, the identification of three foxes with American, rather than with Asiatic or European, races is of considerable interest; but it may be noted that one of these races—the black or silver fox (*Vulpes pennsylvanicus argentatus*)—is not recognised as such in Mr. G. S. Miller's list of North American mammals (1912). In a footnote on p. 317 "Arctocyonidæ" should be "Arctoidea + Cynoidea." Mammals collected in Korea form the subject of an article by Messrs. Allen and Andrews in Bull. Amer. Mus. Nat. Hist., vol. xxxii. (pp. 427–36). In connection with the above may be noted a paper by Messrs. Jordan and Thompson on fishes from the island of Shikoku, Japan, published as No. 2011 of the Proceedings of the U.S. National Museum.

THE Proceedings of the South London Entomological and Natural History Society for the past year contain matter of much interest, and give proof of continued activity on the part of the members of this well-known association of naturalists. Mr. A. E. Tonge's presidential address, delivered at the beginning of the present year, includes some excellent observations on the external characters of British lepidopterous ova. Mr. R. Adkin's communication on the subject of varietal names is marked by strong common sense, and the same may be said of his paper on the labelling of entomological specimens—a matter that was often neglected by the naturalists of a former generation, to the detriment of many results of their labours. Mr. A. E. Gibbs's paper on the genus Cœnonympha gave occasion for some interesting exhibits of the local variation to which species of that genus are subject. A useful account, well illustrated by photographs and drawings, of the British species of Forficulodea is contributed by Mr. W. J. Lucas. Perhaps the most important of the papers printed *in extenso* is Mr. C. J. Gahan's excellent memoir on mimicry in the Coleoptera. The author is a well-known authority on this order, and the great extent of his special knowledge enables him to treat the subject in a comprehensive and convincing manner. It is noteworthy to find that he considers it "hopeless to try to explain the facts of mimicry in any other way than as the result of natural selection." The reports of the field excursions and the discussions held at the meetings contain some valuable records, and the volume as a whole furnishes good evidence of the excellent work that may be done by local societies, such as the present, in encouraging an intelligent interest in the objects of natural history.

Petermann's Mitteilungen for September contains a characteristic portrait of the late Prof. H. Credner, the well-known geologist of Leipzig. Dr. K. Andrée discusses the important question of the correlation of sedimentary rocks with conditions of deposition, as a guide in the formation of palæogeographic maps.

Mr. C. A. Cotton, of Wellington, N.Z., publishes a paper on the physiography of the Middle Clarence Valley, New Zealand (*Geographical Journal*, vol. xlii., p. 225), in which the influence of Prof. W. M. Davis is apparent in the lucid illustrations of local earth-structure and surface features. The author contests Park's view that an ice-sheet passed across the district, which lies in the north-east of the south island.

Messrs. W. Hanns, A. Rühl, H. Spethmann, and H. Waldbaur, who accompanied Prof. W. M. Davis on a European tour in 1912, have published "Eine geographische Studienreise durch das westliche Europa" (Leipzig: Teubner, price 2.40 marks), a brochure which should well illustrate modern methods of investigation. The regions selected include Snowdonia, Cornwall, central France, and the famous Kirchet of Meiringen.

The Journal of the Meteorological Society of Japan for May contains, *inter alia*, a useful article on the amount of evaporation of water, by Mr. Y. Horiguti, in which he gives some results of his investigation of the subject with a circular atmometer 8 in. in diameter, 4 in. in depth, and a small layer of water, the instrument being freely exposed to wind and sunshine. The determination of evaporation is a very uncertain operation, and in a recent essay (Strachan, "Basis of Evaporation") it is noted that the methods hitherto tried with tanks have been more or less failures, although, with the assistance of theory, better results ought eventually to be obtained. Many formulæ by well known men of science already exist, and Mr. Horiguti has added another to the number. The result of his investigations shows that his formula, together with others referred to, will fairly well represent evaporation in the shade, but that in the open air this is not the case. He concludes that "there remains an ample space for further studies."

In 1881 a MS. known as the Bakhshâli, from a village of that name in the Peshawar district, was discovered. If the view of Dr. Hoernle be accepted, that it belongs to the third or fourth century A.D., it would be of unique value as pushing back the mathematical knowledge of the Hindus to a date much earlier than has hitherto been admitted. The question of date has been reopened by Mr. G. R. Kaye in vol. viii., No. 9, of the Proceedings Asiatic Society of Bengal for 1912. After a careful review of its contents he arrives at the conclusion that it is later than the time of Brahmagupta, or even later than Bhâskara. "The literary form and the mathematical form of the manuscript point to a comparatively late period; the script is not ancient; the notation used and the rules and examples have nothing ancient about them, and my general conclusion is that the manuscript was not written much before the twelfth century A.D. It may have been an adaptation of a more ancient work, but it is certainly not a faithful copy of any work composed much before the twelfth century." It will be interesting to await Dr. Hoernle's reply to this communication.

In the Proceedings of the Tokyo Mathematico-Physical Society (2), vii., 5, Mr. S. Yokota gives an analytical solution of the stress distribution in a riveted plate due to a simple push applied to a rivet, the surfaces being smooth. The lines of principal stress are plotted.

In addition to the usual lists of students and degree proceedings, the Johns Hopkins University Circular contains interesting mathematical notes edited by Prof. Frank Morley. Mr. J. E. Rowe, in a note on Fermat's classical theorem, shows that the sum of two powers of integers cannot be the same power of another integer (excluding, of course, the case of second powers) unless the index is greater than 100 and the largest integer greater than the twenty-ninth power of 10; and further, considering next the two types in which the greatest integer is odd or even respectively, the author says, "Also it is shown that one-half of all possible solutions of each of the two types just described are impossible" (!). In a note on self-dual rational quartics, Mr. L. E. Wear shows that the only quartic curves which reciprocate into themselves are the limaçon and the obvious case of two conics.

Prof. E. B. Wilson, writing in the July Bulletin of the American Mathematical Society on the unification of vector notations, expresses a doubt whether the several steps which have been taken in this direction recently have been steps "backward or forward, sideways or up in the air." The committee appointed at Rome in 1908 has not yet presented a report, so that not much of a step in any direction can be attributed to it. There has been great activity in the use of vector methods in Italy, which has served to stereotype the notations of Burali-Forti and Marcolongo, which differ from those in vogue in Germany and America. A valuable report by the late Dr. Macfarlane has been published in the Bulletin of the International Association for Promoting the Study of Quaternions and Allied Systems of Mathematics for June, 1912, and Prof. Wilson hopes "that the place of publication may not prove a burial ground for the essay." Lastly, Langevin's article in the French Mathematical Encyclopædia proposes a system of notations in which vectors are distinguished by interlineal superscripts, no special founts being used, and this seems likely to be widely adopted in France.

In the *Journal de Physique* for August, M. A. Henry, physics master at the Reims Lycée, describes how he has applied a well known form of micromanometer to make measurements in a number of directions in which a manometer is not often utilised. The manometer consists of a U tube with wide limbs joined by a horizontal capillary tube. The limbs are about half-filled with carbon tetrachloride, and the capillary contains a small bubble of air Any slight difference of pressure at the ends of the capillary produces a considerable motion of the bubble. The instrument is calibrated by tilting the tube support by means of a screw at one end. M. Henry shows how the instrument may be used to measure the excess of pressure in a soap-bubble and the effect of charging the bubble electrically, a small volume, a mass of a few grams, the density of a gas or of a solid, small amounts of heat, specific inductive capacity, difference of potential, a flow of gas, and the pressure exerted by a sound-wave.

The determination of sulphur in illuminating gas is the subject of Technologic Paper No. 20 of the Bureau of Standards, by R. S. McBride and E. R. Weaver, issued by the Department of Commerce, Washington. Experiments were made with the gas referees' apparatus and the apparatus designed by Elliot, Hinman-Jenkins, Drehschmidt and Somerville. The results of a series of comparisons are given, in which many variations were made to determine the best conditions of operation and the sources of error. The referees' apparatus appears to be most used in America as well as here, and possesses the advantages of simplicity and convenience; the accuracy obtainable with this, as with other forms, has been often over-estimated. The concluding portion of the pamphlet deals with the estimation of the sulphate in the liquid condensate, and details are given of the gravimetric determination, a rapid turbidimetric method, and a volumetric method based on that due to Holliger. Although most gas companies in this country are now free from any restriction as to the amount of sulphur present in their gas other than sulphuretted hydrogen, the pamphlet will be very useful to any chemists having to deal with this problem.

In the *Bulletin de la Société d'Encouragment* (No. 6, p. 805) Prof. Camille Matignon discusses in an interesting paper some of the less known recent processes for the industrial fixation of atmospheric nitrogen. The well known methods utilising an electric flame are only briefly touched upon, but especial reference is made to Schloesing's process of absorbing the nitrous gas so obtained with lime at a temperature of 300°. The principal processes dealt with are those of Haber, in which nitrogen and hydrogen are made to combine directly under the influence of a catalytic agent, and that of Serpek based on the formation of aluminium nitride by heating a mixture of alumina and carbon in a current of pure nitrogen at a temperature of 1800°. The latter method has a particularly bright industrial outlook owing to the fact that by decomposing the nitride with dilute alkali not only is ammonia obtained, but it is possible by means of it to transform bauxite into alumina suitable for the aluminium industry at a much reduced cost. The action between the alumina and carbon is effected in revolving cylinders, which are lined with aluminium nitride itself, as being the only sufficiently refractory material which will withstand the high temperatures employed.

Red Book No. 182 of the British Fire Prevention Committee contains an account of tests on three window openings filled in with Luxfer electro-glazing. The record gives the effect of a fire of ninety minutes' duration, the temperature reaching 1500° F. and not exceeding 1650° F., followed by the application of water for two minutes on the fire side. This test again indicates that forms of special glazing are being produced commercially that can serve most efficiently to stop the spread of a fire of considerable severity. It is the second occasion upon which "lights" presented for test by the British Luxfer Prism Syndicate, Ltd., have met the strain of a ninety minutes' test at temperatures exceeding 1500° F. Red Book No. 183 contains records of tests on two steel-cased reinforced concrete doors by Messrs. Chubb and Sons, one hung on runners and made to slide, the other hung on hinges, fixed in a reveal. The latter door secured "full protection" (Class B). The partially successful efforts to produce a single door able to do the work of two iron doors required under the London Building Act are of considerable technical importance. The radiation through the doors was very small. Doubtless the problem of making a sliding door flame-proof around the edges will be overcome.

OUR ASTRONOMICAL COLUMN.

A New Comet.—A Reuter message from Perth, W.A., dated October 7, reports that a faint new comet has been observed in the position R.A. 2h. 31m.; Dec. 3° 48′ N.

The Return of Westphal's Comet.—The identification of Mr. Delaran's comet with Westphal's comet of 1852 is now complete, its positions being in accord with those predicted on the assumption of the object being the return of the comet of Westphal.

The following ephemeris for the current week is given by Prof. H. Kobold in a Supplement to the *Astronomische Nachrichten*, No. 4684:—

12h. M.T. Berlin.

	R.A. h. m. s.	Dec. ° ′	Mag.
Oct. 9	21 16 24	+ 8 18·2	8·4
10	13 52	9 7·9	
11	11 25	9 57·1	
12	9 2	10 45·6	8·4
13	6 44	11 33·8	
14	4 32	12 21·3	
15	2 25	13 8·3	
16	21 0 24	+13 54·8	8·4

After observations on September 28, the corrections to the above ephemeris are as follows:—R.A. −34s., Dec. +9·9′.

As this comet does not reach perihelion until November 26, and as it is slowly approaching the earth, its brightness will be increased. In appearance the nucleus is described as well defined but elongated, and surrounded by a nebulosity 20′ in diameter. The tail has been observed to be 1·2° in length, while a photograph taken of it at Bothkamp on September 28 records a tail 3·5° long.

The comet is in a good position for observation in the evening, and its movement northwards will make the conditions more favourable. It is at present passing through the constellations of Equuleus and Delphinus, but later will reach Vulpecula and Cygnus.

In *The Times* of October 2 we read that Westphal's comet is the fourth member of the Neptune group of comets that has been observed at a second apparition, the others being those of Halley, Olbers, and Pons. Two other members of the group appeared in 1846 and 1847, and are expected back about 1921 and 1927. Westphal's comet has much the shortest period (61·118 years) of any member of the group, its aphelion being at almost exactly the same distance from the sun as the orbit of Neptune.

Photographic Study of the Solar Photosphere.—In an abstract from the Annals of the Observatory of Zô-sé (Tome iii., 1912), M. S. Chevalier, S.J., describes the results of his research on the solar photosphere as studied photographically. He first of all describes the early observations of the solar surface by Sir W. Herschel, and rapidly surveys those who followed him, concluding with the photographic researches of M. Janssen at Meudon. M. Chevalier points out that on these latter photographs the famous granules observed by Secchi, Dawes, &c., were recorded.

He then directs attention to the possibility of errors creeping in when photography is employed. Is the image recorded on the photographic plate necessarily a faithful representation of the object photographed? M. Chevalier says it is not, and in the present investigation he attempts to show that the *réseau photosphérique* discovered on Janssen's clichés is not solar. The phenomenon, he says, is chiefly due to deviations undergone by the luminous rays refracted in an abnormal manner. This abnormal refraction takes place in the interior of the telescope, and more especially in the neighbourhood of the secondary magnifier. M. Chevalier accompanies his memoir with a series of fine reproductions from photographs of the solar surface which he has taken to demonstrate his views, and it is by an examination of these that his conclusions must be studied.

Statistics of Nebulæ and Clusters.—In the *Arkiv för Matematik, Astronomi och Fysik* (Band 9, No. 15), Prof. C. V. L. Charlier has published a preliminary paper on the statistics of nebulæ and clusters. This contribution is part of the work of the Lund Observatory, which has undertaken a discussion of the position of the nebulous stars in space, and these statistics form a preliminary part of the investigation. In this publication Prof. Charlier represents both in statistical and graphical form, the information collected on card catalogues of the coordinates, brightness, size, and form of nebulæ, as well as other observations of interest. The base of the card catalogues was the three great catalogues of Dreyer. In these pages the results are given purposely without any discussion regarding their bearing upon the question of the distribution of the nebulæ in space. He remarks, however, that while in many respects they speak for themselves, in others conclusions must be drawn with great caution. The main interest here are the relations between the Milky Way and the positions and numbers of the nebulæ.

When it is remembered that distinction is made between five different classes of nebulous objects, namely, clusters, globular clusters, planetary nebulæ, annular nebulæ, and nebulæ, and that the objects number 13,223, some idea of the work involved in the investigation will be gathered.

Spectroheliographic Results from Meudon.—A memoir by MM. H. Deslandres and L. d'Azambuja, appearing in No. 9 of the *Comptes rendus* of the Paris Academy of Sciences, contains an interesting historical survey of the spectroheliographic work carried out at Meudon. The paper is more especially concerned with the *qualitative* results obtained by examination of the spectroheliograms secured since 1908, when the spectroheliograph of high dispersion was erected. Whilst careful to point out that the evidence does not permit the formulation of general laws, the authors are content to state that during the period in question the "filaments" (dark and definite stream-like markings seen in hydrogen and calcium light) have followed, but with a distinct lag, more pronounced in the case of the polar disturbances, the sun-spot variations. In this regard the polar disturbances recall the secondary maximum of high-latitude prominences. On the other hand, the "alignments" (markings somewhat less dark and sharp seen only in calcium light) have been without noticeable variations.

AN EXHIBITION OF PROGRESS IN LIGHTING AND HEATING BY COAL GAS.

THE National Gas Exhibition at Shepherd's Bush, which will be open during the whole of October, affords the best object lesson in gas lighting that the public has ever had the opportunity of studying, and the fascination is greatly increased by the absence of competing stalls, the exhibits being shown in model rooms, shops, studios, &c., under all the conditions in which they are likely to be used in practice.

It is something of an achievement to have induced the leading gas undertakings, municipal and private, and the leading manufacturers of gas appliances in the United Kingdom, to sink their individuality and rivalry and to cooperate in a coherent exhibition of the varied uses to which gas can be efficiently and profitably applied. The result should be of benefit both to the industry and to the public generally.

The exhibition impresses one with the enormous strides that have been made during the last few years in the application of gas for manufacturing, domestic, and public purposes. The introduction of vertical retorts, improved methods of purification, and the resulting greater yield of gas, coke, and by-products obtained from the coal carbonised, have resulted in its price being kept down in spite of the gradual rise in the cost of coal, whilst the enormous progress that has been made in the methods employed in its combustion has popularised it to an extent that could hardly have been foreseen a few years ago.

There is not the least doubt but that the introduction of the atmospheric burner and the incandescent mantle has been the real factor which has made gas the most important fuel for both heating and lighting, and in the present exhibition the progress that has been made from the inception of the union jet by Nielson in 1820, which gave less than one candle per cubic foot of gas consumed, to the modern high-pressure incandescent burner, with its sixty candles per cubic foot of gas, is demonstrated in a striking manner.

Various apparatus for raising gas to the pressure of several pounds per square inch, necessary in high-pressure lighting, is to be seen at work in the Industrial Hall, and the bearing which the high-pressure distribution has upon commercial applications is shown by the exhibition of a number of furnaces for a multiplicity of purposes, such as melting metals and hardening steel. In these cases it is necessary to concentrate the temperature over a defined area, and by increasing the pressure at which the gas is supplied very high temperatures under perfect control can be attained. Specimens of these different types of furnaces are also to be seen in other sections of the exhibition.

In domestic heating the grasping of the conditions necessary to make gas a hygienic domestic fuel has been the great factor that has led to progress. In the early days of the gas fire, only 25 to 33 per cent. of the heat was given out as radiant heat, and convection was relied upon largely to give the heating effect, this giving hot air to breathe, and at the same time leaving the objects in the room often so far below the body temperature as to lead to chill; whilst the capacity for moisture of the heated air caused a degree of discomfort that led to prejudice being raised against this method of warming living-rooms.

When, however, it was realised that a stove to be hygienic must always give a larger amount of radiant heat than of convected heat, advance was at once made, and the severe competition in which, in the last three years, the different makers of gas fires have indulged has resulted in the production of gas stoves which give a high radiant efficiency. Further advances are being made constantly, and it is anticipated that in a short time the percentage of radiant heat given by gas fires will be more than double that which was possible even three years ago. Meantime, the claim that there are gas fires in the exhibition which can transmit 50 per cent. of the heat energy into the room in the form of radiant heat is undoubtedly true, whilst in one case as high as 70 per cent. is claimed. Apparently there is no exhibit of Prof. Bone's interesting "flameless combustion" stove, which would have proved very attractive, but the steam used in the kitchens is generated by a Bonecourt boiler, which is a modification of the same principle.

A very fine collection of products from tar and ammonia liquor are shown in the shops that serve to illustrate the best methods of show-window lighting. These are divided into three classes, tar, ammonia, and cyanogen products, the first class especially being worthy of attention.

Another very suggestive exhibit is a series of compartments illustrating the effect of the colour and surface of wall-papers on the amount of illumination obtained from equal sources of light. Some valuable conferences have been arranged to take place during the period that the exhibition remains open, and especial interest will be felt in the promised discussion on the sanitary influence of gas lighting and heating, whilst the influence of gas as a fuel on smoke abatement will also receive its due share of attention.

CARNEGIE SCHOLARSHIP MEMOIRS.

Vol. v. of the Carnegie Scholarship Memoirs has just been issued by the Iron and Steel Institute. The volume contains six papers which differ very widely in merit and interest, but on the whole it represents a considerable amount of important research work. It is unfortunate, however, that the practice of publishing these papers in a separate volume tends to relegate them to oblivion, and at all events robs them of the advantages of discussion even by correspondence, thus lessening materially the value of the work done under the Carnegie scheme.

The preservation of iron is dealt with by Dr. Newton Friend; his results, if confirmed by future practical experience, are of considerable importance. He finds that the addition of small quantities of paraffin wax to paint lessens very materially corrosion in iron and steel merely exposed to the air, but rather assists corrosion in the case of plates actually immersed in water. Increasing the number of coats of paint beyond two also appears not only to offer no increased protection, but actually to promote corrosion. This result leads one to inquire whether the constant repainting of iron-work often practised on ships may not actually do more harm than good; at all events, an examination of some of these thickly painted surfaces should afford interesting evidence on the point. Finally, Dr. Friend finds that painting over a slightly rusted surface, from which, however, all lumps of scale, dirt, &c., have been removed, is actually more effective as against further rusting than the same paint applied to a completely cleaned surface—the only advantage of thoroughly cleaning the iron before painting lying in a better surface finish of the painted work.

Another paper of special interest is that by Mr. J. A. Pickard dealing with the determination of oxygen in steel. This is a question of steadily increasing importance, and the older methods are known to be quite unsatisfactory. Mr. Pickard's method consists in heating the drillings to be analysed in an atmosphere of hydrogen which is simultaneously kept in contact with phosphorus pentoxide, so that the concentration of water-vapour always remains very low. His results indicate a very satisfactory degree of accuracy, and the further application of his method will be awaited with interest.

A lengthy paper by Mr. A. Kessner deals with the development of the drill test for ascertaining the machining properties of steel; the author, working at Charlottenburg, has developed a form of apparatus whereby the rate of cutting under standard conditions can be measured with a considerable degree of accuracy, and has used this to study the effect of several factors upon the machining properties of metals and to compare the ball-hardness and tensile properties of materials with their machining properties. That ball-hardness is not a guide to machining properties is a result which might have been anticipated, but whether the author's form of drill test does not depend upon the measurement of a quantity which depends upon too large and complicated a system of factors yet remains to be proved.

Of the more theoretical papers, that of Mr. Humfrey, dealing with the influence of the intercrystalline cohesion of metals upon their mechanical properties is perhaps the most interesting. It is another step in the development of our conceptions of the internal mechanical constitution of metals, and although to some extent speculative, it is certainly suggestive, particularly as it offers the first attempt at explaining the mechanism of the effects of mechanical overstrain, which, while it raises the elastic limit in tension, and thus apparently hardens the metal, at the same time lowers the elastic limit in compression. Humfrey explains this by the development of severe internal stresses residing in the amorphous matter at the intercrystalline boundaries, these stresses tending to resist further deformation in the direction of previous strain, but assisting stresses tending to produce deformation in the opposite sense.

The remaining papers, by Messrs. Hailstone and Swinden, are less satisfactory. The latter attacks the problem of the constitution of molybdenum steels by means of numerous cooling-curves and other data, but does not make use of the well-known methods of discussing and considering the equilibria of a ternary system. As a result of this lack of general theoretical guidance in the work, the data lead to no satisfactory conclusion. This want of systematic attack is typical of much of the work which has been done on steel, and especially on alloy steels, and probably accounts for the confusing differences of opinion which still exist in regard to their nature and constitution.

ENTOMOLOGICAL NOTES.

ACCORDING to a note by Mr. J. J. Walker in the September number of *The Entomologists' Monthly Magazine*, 1913 is to rank as a "clouded yellow" year, immigrant specimens of these butterflies (*Colias edusa*) having reached our southern counties in June, and given rise to native broods in August. No British specimen of *C. hyale* had been recorded this year up to the date of the note.

In order to enable planters in Trinidad to cope effectually with the native sugar-cane frog-hopper (*Tomaspis varia*), a member of the family Cercopidæ, the Board of Agriculture of Trinidad and Tobago has issued a pamphlet (Circular No. 9), drawn up by Mr. F. W. Urich, the official entomologist, in which the life-histories of this and certain other members of the same group are very fully described. Three beautifully coloured plates illustrate all the stages of the species forming the main subject of the pamphlet and the adults of its Trinidad relatives. Although reported to have been originally described from Guiana, *T. varia* cannot be identified elsewhere than in Trinidad, and is accordingly regarded as a native of that island. Two charts show that it is most numerous in January, when the rainfall is at its lowest. This mischievous insect is attacked by two kinds of fungus, one of which affords, at present, the best means of keeping it in check; and, with this and other agents, the author is hopeful that the "plague may be stayed" in the near future.

Although holiday-makers roundly cursed the heavy rains of the summer of 1912, they were highly beneficial, in the opinion of Mr. G. H. Carpenter, as expressed in an article on injurious insects observed in Ireland during that year (Economic Proceedings Royal Dublin Society, August) in reducing the great development of insect life due to the abnormally hot summer of 1911.

The editor is indebted to the Rev. R. P. Longinos Navas, S.J., for a copy of a synopsis of the Ascalephides, published in the *Arxius de l'Institut de Ciencias, Barcelona*, vol. i., No. 3. Although these Neuroptera, which are related to the lace-wing flies, are generally classed as a subfamily of the Hemerobiidæ, the author follows MacLachlan in regarding them as representing a family by themselves—Ascalaphidæ. None of these flies are found in the British Islands, but they are abundant in many parts of the Continent, and enjoy an almost cosmopolitan distribution. The present synopsis includes diagnoses of all the known generic and specific types, several of which are named and described for the first time.

Several important entomological articles have recently appeared in the Proceedings of the Philadelphia Academy, notably one in the May and June issues on the grasshoppers of the genus Nemobius. Other papers are published in the July issue of Records of the Indian Museum, in which Mr. J. J. Kieffer reviews the chironomid flies in the collection of the museum, while Mr. K. Jordan does the same for the beetles of the family Anthribidæ.

In describing a new species (*Clomaciella subfusca*) of the mantispid group of Neuroptera in vol. viii., part 2, of *Annotationes Zool. Japon.*, Mr. W. Nakahara takes the opportunity of reviewing the Japanese representatives of the group—eleven in number.

Copies of two entomological papers from vol. xlvi. of the Proceedings U.S. National Museum have been received recently, namely one by Mr. F. Knab on new species of moth-flies bred from bromelias and other plants, and one by Prof. T. D. A. Cockerell on new parasitic Hymenoptera of the genus Eiphosoma.

To the Journal of the College of Agriculture, Tohoku Imperial University, Japan, vol. v., parts 4 and 5, Mr. Yos'himo Tanaka communicates articles, illustrated by one plain and one coloured plate, on Mendelian factors and gametic coupling and repulsion in silkworms.

THE BRITISH ASSOCIATION AT BIRMINGHAM.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. GISBERT KAPP, PRESIDENT OF THE SECTION.

ENGINEERING, the subject with which Section G is concerned, covers so wide a field that it has been found convenient to introduce a rough subdivision into the three branches of civil, mechanical, and electrical engineering. By applying any such term to a particular piece of engineering work we do not necessarily exclude the others; we merely characterise a predominant feature. There is often a considerable amount of overlapping between the three branches, and that is especially the case with mechanical and electrical engineering. Sometimes the boundary-line even becomes indistinct, and then it is difficult to say which branch of our science is the predominant feature. Is the equipment of a works with electric power mechanical or electrical engineering? It is both, but not necessarily to the same degree. The mere replacement of a steam engine by an electric motor to drive the main shafting of a works can scarcely be called a piece of electrical engineering; but if special electric appliances are introduced to perform duties which cannot be done, or not done as well, by purely mechanical machinery, then we have electrical engineering in the true sense of the term.

Electricity has invaded almost every branch of our industrial activity, sometimes as a rival to older methods, but often also as a helpmate, stimulating progress all round. Electricity is a "great source of power in nature," and the "art of directing it for the use and convenience of man" belongs to our generation. Yet, like all new things, it has had to fight its way in the face of strenuous opposition—generally an absolutely honest opposition, not in any way traceable to self-interest, but simply to inability to see things in the right perspective. Let me illustrate my meaning by an example. Shortly after Charles Brown had established the first electric-power transmission between Kriegstetten and Solothurn I happened to visit a well-known mechanical engineer in Zürich, who had in his time been professionally (not financially) interested in so-called teledynamic transmission of power by wire-rope, first introduced into Alsatia by the celebated Prof. Hirn, of thermodynamic fame, about the middle of last century, and then also imported into Switzerland. To my old friend these transmission systems appeared to be the acme of perfection; and on my pointing out that the range was necessarily very limited, he replied that transmission to longer distances would be useless, since there would be no market for the power. My friend was not able to look at the subject in the right perspective; he failed completely in appreciating the fundamental conditions of the problem, and although it is easy for us now, fortified as we are by experience, to appreciate electric transmission of power correctly and feel contempt for the old gentleman's narrow-mindedness, yet we should be careful not to fall into the same error about electrical developments which are new to us, as the transmission of power was new to my Swiss friend.

It is not so very long ago that mechanical engineers thought there was no advantage in electrifying textile mills; and I do not feel quite certain whether a good many and very capable engineers are not still of the same opinion. A commission has been investigating this subject, and its first report was by no means encouraging to the electrical engineer. Yet at the very time when that report was issued hundreds of motors were being installed in Continental mills. The spinners there had found out that by using a motor with very delicate speed regulation they could speed-up their frames and increase the output considerably. In the long run a good thing must win through, and the electrification of English textile mills is no exception to this economic law; but in some cases it would almost seem that the way is made longer by the narrowness of the mental horizon of opposing experts. This process of gradually overcoming the opposing expert had to be gone through in all applications of electricity, but the opposition being generally honest, once it is overcome, the very men who opposed become strong friends. There is no question now that electricity can do some things better than could be done formerly. The separation of magnetic from non-magnetic material; the lifting of hot pigs, ingots, plates, and scrap by electromagnets; the production of high-grade steel in the electric furnace; the sinking of shafts by electrically-driven pumps; in mines the use underground of electromotors instead of steam engines, in shipyards the use of magnetically-fixed and electrically-driven tools; the electric driving of rolling mills, and the use of electric traction on tube and other underground railways are familiar examples of the application of electricity in which unanimity as to its advantages has been reached between the electrical engineer and what, without any intention of being disrespectful, we may call the old school of mechanical engineers. There are, however, other applications of electricity where the old and new school of engineers have either not at all, or only partially, reached unanimity of opinion, and it is with one of these applications—namely the electrification of railways—that I propose to deal in this Address.

As regards urban and suburban lines, not only the possibility of electric traction, but its immense superiority over steam traction, is fairly generally admitted. Where we get on debatable ground is when we begin to discuss main-line traffic. Here the process of overcoming opposition, of which I spoke a moment ago in connection with other applications of electricity now generally approved, has only just begun. Will it lead to the same result, or will the electrician have to confess himself beaten by the steam locomotive? The answer each one of us would give to this question must necessarily be biassed by our early training. Most engineers love their profession, and are enthusiasts; being enthusiasts, they are necessarily biassed. This applies as well to the electrical engineer as to the mechanical engineer—perhaps to the electrical engineer most. In many cases he is so biassed that he will not admit any virtue in any other but his own pet scheme of electric traction. A modern steam locomotive is a beautiful and efficient engine, and one can well understand its designer looking at it with the pride of a father whose son has turned out a good man. One can also understand that this engineer will not readily admit the superiority of an electric locomotive. The mental horizon of each of us must necessarily be narrowed by previous training and professional enthusiasm; let us, then, try to forget for a moment that we are engineers, and let us put out of our minds all questions of mechanical or electrical detail, focussing our thoughts merely on what we see going on all around us as regards electrification of railways. We see year by year more lines being electrified. Some are failures; but the very fact that in spite of these failures the process of electrification is going on, shows that the failures are remediable.

In some cases it is easy to understand why a line should be electrified. If fuel is dear, if the trains must be heavy and frequent, if there are steep grades and long tunnels, then obviously steam is at a disadvantage and electricity can beat it easily. But the electrification is not limited to cases where there are such obvious advantages. We see a military State like Prussia electrifying a fairly long line where the traffic is not extremely heavy, where there are very gentle grades, and only few and short tunnels. Moreover, one of the stock arguments against electrification is that in case of war the whole system may be broken down by the enemy cutting the wires; yet this consideration, if it has any weight—a matter on which I cannot pronounce an opinion—does not deter a military State from at least experimenting with electric traction on a large scale. We see suburban lines growing longer and longer, until they might almost be classed as short main lines, and we see the Swiss Government buying up water-powers with the object of utilising these powers in the electrification of its most important main lines. We see in America the electrification of large systems taking place, not only for passenger service, but also for the goods service, comprising trains of 2000 and more tons weight, and of goods yards, to the complete exclusion of steam.

One need not be an engineer to appreciate the significance of such a general development. No Government department, and certainly no board of railway directors, will spend money merely for the sake of an interesting scientific experiment, and, although it is conceivable that in an isolated case such an experiment may be undertaken under a miscalculation as to its possible success, it is not conceivable that such a miscalculation should be the general rule. When we see that in all countries a vast amount of labour is devoted to, and capital is spent on, the electrification of main lines, we cannot but come to the conclusion that this new application of electricity is bound to progress, and that the persons who tell you that electric traction is all right for tramways and urban railways, but will never be able to compete against steam traction on main lines, are very much in the position of my old Swiss friend, whose conception of power transmission was entirely limited to the use of ropes and pulleys.

It is just thirty years since the first electric railway was opened for public use. That was a small line in Ireland, known as the Portrush-Bushmills Railway. In those days only the continuous-current motor was available, and that only at a very moderate pressure and power. These restrictions were from the first felt to be a serious drawback, and inventors tried to overcome them in various ways. Of these, two may be here noted, in passing. Ward Leonard in 1891 made the suggestion of carrying on the train a converting station. He argued, quite correctly, that for the transmission of power to long distances the alternating current was eminently suitable, and that, consequently, the power should be sent to the train in the shape of high-pressure alternating current. On the other hand, such a current was, in those days, quite unsuitable for motors; hence the necessity of its conversion into continuous current, with which the then available motors could alone deal. Ward Leonard suggested to put on the first vehicle of the train a synchronous motor, which drives an exciter and continuous-current generator. The current obtained from this generator was to be used to drive the train-motors, which might be distributed in a number of motor coaches. The regulation of speed and tractive force was to be effected entirely by suitable adjustment of excitation, and therefore without rheostatic loss. It will be admitted that this proposal has some attractive features. It is essentially a long-distance system, and at the same time it offers the possibility of great and uniform acceleration, a matter of great importance in urban traffic, so that it is equally suitable for both kinds of service. Moreover, the current can be taken with unity-power factor. Unfortunately the extra weight which has to be carried in the shape of converting machinery is a serious drawback; and for this reason the Ward Leonard system (excellent as it has proved in other applications of electric power) has in the domain of traction never got beyond the experimental stage.

The experiment has been made on a fairly large scale, but with this difference, that the traction-motors were placed not only into motor coaches, but on the first vehicle itself, which thus became an electromotive; also, in order to save the weight and cost of starting and synchronising gear, the asynchronous type of single-phase motor was adopted, thus sacrificing the advantage of unity-power factor. The electromotive developed at the hour-rating 200 horse-power, and weighed 46 tons. This is not a very brilliant achievement, and it was beaten by a sister engine of the same power, but using alternating-current motors. This electromotive weighed only 40 tons.

It is probable that a better weight efficiency could be obtained nowadays with this system if carried out on a larger scale, and if the motor-generator were replaced by a converter, in which case the step-down transformer would have tappings on its secondary side for starting and regulation. It is, however, doubtful whether even then it could compete with electromotives using the alternating current in the motors directly. Motors of this type have recently been so much improved that the margin of weight that could be saved by the use of continuous-current motors is probably less than the excess weight of the converting machine.

The other attempt to combine high trolley-voltage with low motor-voltage has shared the same fate. This consisted in the application of the three-wire principle of continuous-current supply to electric traction. It is in successful operation at a moderate voltage on a London tube railway, but as far as main-line working is concerned it has not got beyond an application on two small lines in Bohemia. The principle adopted is to make the trolley wire of the up-line the positive and that of the down-line the negative side of the system, whilst the rails take the place of the zero wire. Each electromotive is fitted with four motors, of which at least two are in series, taking 1500 volts. Thus, whilst the voltage of one motor is kept within the customary limit of 750 volts, the pressure of the whole system is 3000 volts. The objection to this arrangement is that its fundamental supposition of a fairly close balance between the two halves of the three-wire system must in actual railway working be rather the exception than the rule, and that the obvious remedy of combining both halves of the system in one and the same train would involve the use of two overhead trolley wires, and thus introduce the very feature which the advocates of the continuous-current system find so objectionable in three-phase traction. Moreover, the recent improvements made in continuous-current motors has reduced the importance of the three-wire principle. Continental makers are prepared to build motors for 1200 volts, and one English maker is actually building motors for 1750 volts, so that with two motors in series a trolley-pressure of 2400 and 3500 volts respectively can be used.

The present tendency in electric traction is in the direction of simplicity, in the sense that mixing up of different types of current and dependence of one train on another is avoided. Only three types of current are used—namely continuous, three-phase, and single-phase. The two first-named are used direct; the last through the intervention of a transformer. In a large measure the different systems have already become standardised. As regards the C.C. system, up to 750 volts the process of standardisation has been completed long ago. It is almost generally adopted for urban and suburban lines of moderate length, unless there are local difficulties as regards the third rail, or it is desired to work the suburban and the main-line service on the same system. The three-phase system has also been fairly well standardised, but the single-phase system is still in a process of development—a development which, however, takes place on a fairly large scale. In France the Compagnie du Midi is electrifying on the single-phase system nearly 400 miles of track; the German Government have already electrified the Dessau-Bitterfeld of the Leipzig-Magdeburg line, and are electrifying the line Lauban-Koenigszelt in Silesia, to say nothing of some smaller private lines in the south of Germany, which have been in operation for some years. In Switzerland the Berne-Loetschberg-Simplon Railway, already in operation, and the Rhætian Alp Railway, nearing completion, also employ single-phase electromotives. Both in France and Germany the type of electromotive to be finally adopted has not yet been settled, but half a dozen different types, supplied by as many different makers, are being tried, and it is in this respect that one may look on single-phase traction as still in the process of development. As regards the Loetschberg the period of trial is over. Three years ago the railway company ordered a 2000 horse-power electromotive, and have had it at work ever since with such satisfactory results that they have decided to adopt this type definitely, and have ordered thirteen more engines, but of the slightly larger power of 2500 horse-power on the 1½-hour rating. Of these I shall have to say something more presently; but before entering into the details of single-phase traction it is expedient to glance briefly at the present position of the rival system of three-phase traction.

The first application of this method of working dates back to the end of last century, and took place on a small Swiss line; then followed the well-known Valtellin line, and, later still, when the Italian Government took over the railways, the Government engineers decided to extend the application of three-phase traction to some other lines—a decision which practical experience has shown to have been perfectly justified. The total power represented by three-phase electromotives either at work or on order in Italy to-day exceeds 200,000 horse-power (95,000 horse-power in service, and 120,000 horse-power building). Ten years ago the three-phase system was the only possible one for main-line working, but later on there came on the scene the single-phase, and, later still, the high-pressure continuous-current systems, and I need scarcely mention that between the advocates of the three systems there has been waged a fierce battle, each claiming that his is the best and the others very inferior. I am afraid that battle is still raging; but it is a futile war, for there is no such thing as a best system generally. One system is the best for one set of conditions and another for another set. Thus the German railway engineers found that the single-phase system would serve them best, and they adopted it. There is in this matter no question of personal feeling or national prejudice. I have no intention to enter the lists as an advocate for any one of the three possible systems for main-line traction; each has its special features and special merits, and all I can do is to place before you some of these. As the three-phase system is the oldest, it will be convenient to take it first.

It is curious to note that the three most obvious objections which have been raised against three-phase electromotives by theorists have been found to have but little weight in practical work. These objections were: the complication of a double overhead wire, the danger that the motors would not share the load fairly, and the inability to run without rheostatic waste at intermediate speeds, or to run at a higher than synchronous speed to make up for lost time.

That an overhead wire is inconvenient must be readily admitted, but the inconvenience applies to all methods of main-line working, for the so-called third rail is not applicable to high pressure, and even if it were, the consideration of the safety of the platelayer would preclude its use. The question then is: are two wires twice as objectionable as one? Possibly, but the most objectionable feature is not the wire itself, but the posts or gantries on which it is carried, and the number of posts is the same, whether we use three-phase, single-phase, or continuous current. There is a little more complication at the cross-over points and at the switches; but this is not a serious matter, if one may judge from the perfectly smooth working of so extended a yard as that at Busalla, where there are five miles of track, connected by thirty-seven switches and crossings. The other objection—as to the motors not sharing the load equally—is theoretically sound. The torque developed by the motor is proportional to the slip, and in order that the two motors on an electromotive shall share the load equally their slips, and consequently also their speeds, must be the same. Now, it is conceivable that, owing to a slight difference in the size of the drivers, that motor which is geared to the larger drivers will, by reason of its lower speed and consequently greater slip, take more than its fair share of the load. In practice this difficulty does, however, not arise. With reasonably good workmanship there should be no sensible difference in the size of the wheels; but even if we admit the possibility of there being a difference of ½ per cent. in the diameter of the wheels, this would, with the usual slip of 3 per cent., only mean that the motor geared to the larger wheels develops 8 per cent. more, and the other 8 per cent. less, than its normal power. The larger wheels will develop 16 per cent. more tractive effort than the smaller wheels, and having thus a greater wear, the difference originally existing will diminish in service. For the same reason, any tendency to wear unequally, say, in consequence of unequal material, is counteracted by the slip-adjustment of the motors. This point has been tested practically by the makers of the Simplon three-phase electromotives. It was found that if originally a slight difference in diameter of the drivers had been permitted to exist, after a short time this had vanished. That is as regards the condition on one electromotive; but if we come to the case of a train being hauled by two engines, then a sensible difference in the size of their wheels may exist. In this case it is necessary artificially to adjust the slip so as to make each motor take half the load.

This problem has been solved by Mr. v. Kando in the electromotives which he designed for the Italian State railways. In these engines only liquid resistances are used in the rotor circuit for starting and speed regulation. The liquid is raised or lowered in the rheostat chambers so as to cover more or less of the contact plates, and the level of the liquid is controlled by a solenoid under the influence of the working current. The working current, and therefore also the tractive effort exerted by each motor, is thereby automatically kept constant, notwithstanding any difference that may exist in the size of the drivers on the two electromotives. Incidentally, it may be mentioned that this method of liquid rheostat control has also the advantage of a perfectly constant acceleration during the starting period—a point which makes for comfort of travel in a three-phase train.

The third objection advanced by theorists against three-phase traction is against the waste of energy consequent on rheostatic speed control and the inability to run at more than synchronous speed so as to make up for lost time. The obvious remedy for the last-named difficulty is to fix the time-table so that the synchronous speed should be high enough for making up lost time and to employ motors which can run economically at less than synchronous speed. As a matter of practical experience, three-phase trains are not more unpunctual than any other kind, steam not excluded. A train pulled by a series motor (C.C. or A.C.) runs slower on an up-grade or if abnormally heavy; this is one of the characteristics of the series motor, and it is valuable, because it limits the excess load thrown on to the source of power; but it is clearly not a condition making for good time-keeping. With a series motor time lost cannot be recovered on an up-grade, whilst with a three-phase motor the speed on an up-grade may be kept practically the same as on the level or on down-grades, so that the process of gaining time is not restricted to the easy parts of the line.

The problem of speed control without rheostatic waste has been solved in various ways. One of the simplest and generally adopted solutions is that of cascade and single working. If the two motors are put into cascade connection the speed is halved. The cascade is used in starting and on heavy grades (unless time has to be made up), and on the easy grades or on down-grades the motors work singly—that is to say, in simple parallel connections. Intermediate speeds may be obtained by some pole-changing device. Ordinarily, such devices have to be applied to stator and rotor, but in some of the Simplon electromotives only the stator is arranged for pole-changing, the rotor being a squirrel cage. In this arrangement the advantage of cascade-working has to be given up, but the system has the merit of great simplicity. The number of poles may be changed from twelve at starting to eight, six, and four at top speed. Thus, four different speeds, all without rheostatic waste, are possible. The single bars in the squirrel cage rotor are connected at their ends by resistance-connectors made of an alloy having a high temperature coefficient. At starting the rotor current is large and heats up these strips, thus automatically providing what is technically termed a starting-resistance. When the motor is running the current is less, and by reason of the fanning action of the connecting-strips these get cooled so as to bring their resistance down to a permissible amount. Thus the efficiency of the motor when running under load is only a few per cent. less than that of a motor with a wound rotor.

A valuable feature of the three-phase system is the automatic recuperation of current whenever the speed exceeds synchronous speed by a few per cent.: and, connected with this property is the further advantage that it is impossible for a train to race on a down-grade. Obviously recuperation can only take place if power is given to the motor. This is provided partly by the electromotive itself and partly by the train pushing it on a down-grade. This means that the train is braked in front only, and railway engineers have raised the objections that such a method is contrary to the accepted rules for safe working, which require that even on a down-grade all the couplings should remain in tension, which means that each coach must be independently braked. Here we have again a case where the theorists' objections have been proved to be without foundation in actual practice. It is no doubt objectionable to brake a train in front only, if the braking action is jerky; but with the automatically controlled liquid rheostat the braking comes in quite gradually, and is throughout so even that it has been found possible to permit a higher down-grade speed with recuperation than with ordinary braking. On the Italian State railways the regulation permits on heavy down-grades a speed of thirty kilometres per hour for steam trains, but the electric goods trains on the Giovi line are permitted to run at forty-five kilometres per hour. This concession is not extended to passenger trains. Nevertheless the economic effect is considerable. Recuperation saves 17 per cent. on the coal bill, and this amount is sufficient to provide for interest and sinking fund on the electrical plant at the generating station.

One advantage of three-phase traction over steam traction is the lessened weight of the locomotive in comparison with its tractive force and power. As an example, we may take the Giovi line in Italy where steam trains, consisting of 310 tons of rolling-stock and 202 tons of locomotive (one in front and the other at the back), have been replaced by three-phase trains, consisting of 380 tons of rolling-stock and two electromotives, each weighing 60 tons (also placed front and rear). Thus there has been a saving in total weight of 12 tons, and at the same time an increase in useful weight hauled of 70 tons. The average grade of this line, over which passes the whole traffic between the Port of Genoa and the Plain of Lombardy, is 27 per mille, and the maximum is 35 per mille. This traffic is now worked with forty electromotives, each of 60 tons weight. These engines have five driving-wheels connected to two eight-pole motors by gear-wheels and rods. The pressure on each driving-axle is 12 tons. Each electromotive develops 2000 horse-power at the hour-rating; thus 1 horse-power is obtained for each 30 kilogramme weight of engine.

The number of patented designs for single-phase traction motors is very large; but, notwithstanding considerable difference in matters of detail, all motors which have been successfully applied in practice may be ranged under three great groups—namely, the so-called repulsion type, the repulsion type with additional excitation of the rotor, and the straightforward series motor. The present tendency is rather in favour of the series motor, and the practical results obtained with it are certainly very promising. The latest design made by Dr. Behn-Eschenburg shows a remarkable weight efficiency. His 2500 horse-power electromotives (the power being at a one and a half-hour rating) weigh only 108 tons, so that at this rating 1 horse-power is obtained with a total weight of 43 kilogrammes. This compares favourably with the high-pressure C.C. system, where 50 to 70 kilogrammes per horse-power may be taken as normal values.

The so-called "repulsion motor" invented by Prof. Elihu Thomson has been applied to railway work in the slightly modified form due to Mr. Deri, where, instead of there being only two brushes per pair of poles, double the number is provided, and the adjustment for speed and torque is made more accurate, whilst at the same time the commutation, being split up into two steps, becomes easier. In the matter of simplicity, an electromotive fitted with Deri motors cannot be surpassed by any other arrangement. There are no rheostats, contactors, control switches, or other gear; all the regulation is effected by mechanical transmission of the movement of a hand-wheel placed in the driver's cab to the brushes of the motors. At one time it was hoped that this system would win its way to a general application; but, unfortunately, the motor must run somewhere near synchronous speed, and becomes therefore rather heavy with the low frequencies alone possible in traction. Moreover, as the power-factor obtainable is only about 0·80, that is, considerably below the value obtainable with other motors, there does not seem to be any great future for this system for heavy work, although its great simplicity may still turn the balance in its favour on lines with a light traffic. For heavy lines the choice at present lies between the induction motor, with direct rotor excitation, and the straightforward conduction-motor, where rotor and stator are traversed in series by the same current. The former type of motor—also called the Latour-Winter-Eichberg motor—depends for its working current in the rotor on electromagnetic induction, which produces the working current in the rotor much in the same way as the current in the secondary circuit of a transformer is produced by induction. Since the motor has in part the character of a transformer its weight would, as is the case with any transformer, be unduly augmented by too great a reduction in the frequency. Experience has shown that a frequency of twenty-five periods per second is high enough to render the transformer action effective, and at the same time not so high as to introduce serious difficulties as regards e.m.f. of self-induction and commutation. This frequency has been adopted in most cases where electrification of main lines has been carried out by motors of this class.

One valuable feature of this motor is that at a speed slightly exceeding synchronism the power-factor may be brought up to unity. At this speed the commutation takes place under conditions which may be described as theoretically perfect. A fair number of Continental lines have been electrified by using these motors, and they have also been adopted, with very satisfactory results, in the electrification of the London, Brighton and South Coast lines between Victoria and London Bridge and to some distance south of London. On this line no locomotives are used, but only motor coaches. It is therefore not possible to make a direct comparison as to weight efficiency with a locomotive. The latter has only to carry the propelling machinery, whilst the former has to provide accommodation for passengers as well. The 600 horse-power motor coaches on the Brighton line weigh 50 tons, or at the rate of 83 kilogrammes per horse-power. A 1000 horse-power C.C. electromotive taking current at 1200 volts weighs 74 tons.[1] By making a suitable reduction for the extra weight of the passenger accommodation in the A.C. coach, its weight per horse-power comes out at something like 60 kilogrammes, against 62 kilogrammes in the C.C. engine.

Series motors are employed on the electrified lines of the Midland Company between Heysham, Morecambe, and Lancaster. Also in this case motor coaches, and not electromotives, are used. At the hour-rating a motor coach develops 420 horse-power, and as its total weight is about 35 tons, we have here the same weight-efficiency as on the Brighton lines—namely, 83 kilogrammes per horse-power for the whole coach.

Of high-pressure continuous-current lines there are many examples, both in Europe and America. The term high-pressure does, of course, not imply the same order of magnitude as in single-phase A.C. lines. There high-pressure may mean anything up to 15,000 volts, the pressure which is likely to become a standard in future electrifications; but in C.C. work one must class anything over 1000 volts or 1500 volts as high-pressure. The general rule is to employ motor coaches, and not electromotives; but there is a private line belonging to a steel-works in Lorraine, where two electromotives, each of 600 horse-power (four C.C. motors of 150 horse-power) are working the mineral trains under a pressure of 2000 volts. The Southern Pacific Railway also employs C.C. electromotives of 1000 horse-power each. Each engine weighs 74 tons, and hauls a train of 270 tons on grades of 40 per mille. This is a remarkable performance, rendered possible by the fact that with the even torque exerted by the electric motor a much large co-efficient of friction than is possible in steam traction may safely be permitted. Electrical engineers generally base their calculation of the possible tractive effort on a co-efficient of 0·17, without sand, and as high as 0·25, or even 0·28, if sand is used. The voltage in the case of the Southern Pacific engines is only 1200 volts, taken by two motors in series, and there is provision made to change over from the overhead wire to third rail, with 600 volts, when the motors are all in parallel.

On European C.C. lines the voltage is higher—generally 2000 volts, as on the Chur-Arosa and some other Swiss lines—and the tendency is still in the direction of higher pressures. Continental makers are now prepared to go as far as 1200 volts per motor, so that with the usual system of series-parallel control a line-pressure of 2400 volts becomes possible. The greatest step in advance in this direction has, however, been made in England, where Messrs. Dick Kerr, Ltd., have adopted a line-pressure of 3500 volts as their standard, involving the use of motors constructed for 1750 volts. After having experimented with this high-pressure system for two years, they have undertaken the electrification of a short section of the Lancashire and Yorkshire Railway with continuous current at 3500 volts. I am indebted to the firm for the following particulars: The current is collected by pantograph from an overhead wire with catenary suspension. The train consists of a motor coach and two trailers. The motor coach is equipped with four 300 horse-power motors, and weighs 62 tons; the trailers weigh each 26 tons. From these figures it will be seen that the weight of the motor coach per horse-power is only 52 kilogrammes, and thus considerably below what the weight of an equivalent single-phase motor coach would be. It is especially the saving in weight and the avoidance of any telephonic disturbances which renders the C.C. system so attractive that, in spite of

1 See Gratzemueller's paper read at the Paris meeting of the I. E. E. and S. Intern. des Electr. (Paris, May, 1913).

a natural reluctance against the use of high-pressure on a commutator, designers are giving increased attention to the use of continuous current for electric traction. The difficulties which some engineers anticipate with commutator and brushes seem, however, rather imaginary than real, if we may judge from the experience with the 3500-volt motor coach. The makers inform me that they estimate the mileage for a set of carbon brushes at 50,000 miles. The motors drive the car-axles by single reduction gear, and are controlled by contactors operated from a master controller. The current for operating the contactors, driving the air-pump motor, and for the general service of lighting and heating is obtained from a small motor-generator, fed on the primary side at 3500 volts, and delivering C.C. at 210 volts. All motors have commutating poles—a practice which has become universal in C.C. traction work.

From the figures quoted above it will be seen that where motor coaches are employed the C.C. system has an advantage in point of weight over the single-phase A.C. system. But main-line traction, including goods trains, is not going to be done by motor coaches, and if we come to large electromotives of some 2000 to 3000 horse-power, then this advantage is likely to vanish. No high-pressure C.C. electromotive has as yet been built for so large a power, and it is therefore not possible to make a direct comparison; but, if we may judge from the largest engines yet built for moderate-pressure C.C. there is little probability that the C.C. system for high-pressure can beat the single-phase system, and none whatever that it can beat the three-phase system.

In the early days of single-phase traction some trouble has been experienced in the matter of telephonic disturbance. A systematic investigation carried on for over a year on the Seebach-Wettingen line, chiefly by means of the oscillograph, showed that this trouble was due, not as had originally been suspected, to the commutator, but to the employment of open slots in the rotor, and the trouble nearly ceased when new rotors with semi-closed and spiralled slots were used. To improve the telephonic service further the usual remedy of metallic return and drilling the telephone lines was employed. Although by these means it is possible to render telephonic speech over a line alongside a single-phase railway nearly, and perhaps quite, as clear as it is along a C.C. railway, there still remains the danger that the telephone lines may, by electrostatic induction, acquire a very high potential. The remedy against this danger, first applied on some Swedish experimental lines, is to short-circuit the two wires of each circuit by a choking coil of very high inductance, the centre of which is earthed. The static charge is thus carried off to earth, whilst the telephonic currents are only inappreciably weakened.

One of the advantages possessed by the alternating over the continuous current is the simplicity of regulation. There are no contactors and no rheostats used, the power and speed of the motors being adjusted by the use of tappings on the secondary side of the transformers. As transformers are necessary in any case in order to work with a high voltage on the trolley, the introduction of tappings does not materially increase the weight, whilst at the same time it effects a great reduction in the primary starting current. The only difficulty that still remains is that of sparkless commutation, and inventors have evolved many, and sometimes very complicated, arrangements for overcoming it. As so often happens with engineering problems, the most simple solution is, after all, found to be the best in practice; and of all the ingenious inventions patented during the last ten years very little use is made by the designer of traction motors.

Broadly speaking, only two methods are in use; the one is the method first made known by Messrs. Winter and Eichberg, where the working field is produced by direct excitation of the rotor and the transformer e.m.f. in the coils short-circuited by the main brushes is balanced by an e.m.f. of rotation due to a transverse field; and the other method applicable to the straightforward series motor, where a non-inductive shunt is connected to the terminals of the compensating or commutating winding. The effect of a non-inductive shunt is to make the armature field slightly leading over the field produced by the compensating winding. The resultant of these two fields is in position coincident with the brush axis, but has in point of time a phase difference of a quarter period over the working current, thus balancing the e.m.f. of self-induction, which lags by a quarter period. Obviously this balancing effect can only take place when the motor is running, since it depends on the balance between an e.m.f. of self-induction which is independent of speed and an e.m.f. of rotation which is proportional to speed. At starting, when there is no speed, there is no compensation. Thus there would appear to be a new difficulty in the way of the use of single-phase current; but also this has been overcome in quite a simple manner. Experience has shown that a potential difference of 7 volts between heel and toe of brush, and a current density of 15 A. per sq. cm. is permissible.

If, then, we use narrow brushes, covering at any time not more than three segments, use coils of only one turn to each segment, and work at a reasonably low frequency, and not too high a total flux, it is possible to keep the transformer voltage and current density well within the above limits. This is not a severe limitation, for it enables the designer to use a flux out of one pole of 2·4 megalines if the frequency is 25, and 3·6 megalines if it is 15. The number of poles has then to be selected in accordance with the power desired. Obviously the lower periodicity is to be preferred, because the motor may be built with a lesser number of poles, and will then occupy less room—a matter of considerable importance considering the limited space which is available in an electromotive. The frequency of 15 has also some other advantages over that of 25. The e.m.f. of self-induction is proportionately less, and, in consequence, the power-factor is about 5 per cent. better. The skin effect in the rails is much reduced, and also disturbances on neighbouring circuits which may be due to inductive or capacity effects. On the other hand, the generators become a little more expensive and the transformers on the electromotives a little heavier. But, notwithstanding these drawbacks, the balance of advantage is with the lower frequency, and that is the reason why the Commission of Experts called together in 1904 by the Swiss Government to establish standards for the electrification of the Swiss railways has decided that 15 shall be the standard frequency, with a tolerance down to 14, and up to 16⅔. Since then other States have fallen into line, so that 15 is now the standard frequency nearly all over the continent of Europe. The standard pressure is likely to be 15,000 volts. For three-phase tractions the standard pressure is 3000 to 3300 volts.

The subject of electric main-line traction is so vast that in the limited time at my disposal I have only been able to mention a few of the important features of this interesting problem. A detailed account of all that has been done in electrification would take far more time than we can spare; but, by way of example, I give below two tables referring to the Italian State Railways. I am indebted for the information to Mr. v. Kando, who may justly be described as the father of three-phase traction.

Italian State Railways Electrified on the Three-phase System.

Location of line	In service			In construction

Method of speed regulation	—	Cascade	Cascade	Cascade	Cascade and pole-changing

The most recent example of single-phase electrification is that of the Loetschberg line establishing direct communication between Berne and the Simplon line. I am indebted to Dr. Behn-Eschenburg, the designer of the electromotives, for the following information. The power at the one-and-a-half-hour rating is 2500 horse-power, and the total weight of the engine is 108 tons, of which 85 tons is taken by the five driving axles. At the normal speed of 50 kilometres per hour the tractive effort is 10 tons. This can be increased at starting to 18 tons. On the heaviest grade (27 per mille) the tractive effort is 13·5 tons, which suffices for a train of 310 tons. The maximum speed is 75 kilometres per hour. There are two 1250 horse-power motors on each engine. Each has its own transformer and controller, the principle of duplication being carried out in all the details, so that in the event of a defect to any one part the other remains serviceable. The potential difference between tappings is 45 volts, and the last step gives with 15,000 volts on the trolley 520 volts. This is in excess of what is required by the motor, and thus provides for the event that the trolley-voltage should for some reason fall below the standard pressure. The normal voltage of the motors is 420, and the full-load current 2700 A. At starting on the level the line-current is about one-third of the full load-current, and the power 10 per cent. of the full power. When starting on an up-grade of 27 per mille with a train of 310 tons, the current taken from the trolley is 40 per cent. of the normal full-power value, and the acceleration 0·05 metres per second per second. The current is taken from the overhead trolley by two pantographs, the pressure being 15,000 volts, and the frequency 15. The controller drums are each worked by an electromotor and rocking pawls under the electric control of a master controller, so that the driver is relieved of any physical exertion in attending to the regulation of the motors. These have 16 poles, a compensating winding to increase the power-factor, and commutating poles shunted by a non-inductive resistance to insure sparkless collection. The power-factor is about 0·95 over a wide range of load. The motor is geared by double helical wheels (ratio 1 : 2·23) to a blind axle, from which the turning moment is transmitted to the drivers by cranks and connecting-rods. The weights are as follows: Motor, 11·8 tons; gear, 2 tons; transformer, 7·5 tons; and controller, 1 ton; total, 22·3 tons; or at the rate of 17·8 kilogrammes per horse-power on the one-and-a-half-hour rating. The total weight of the electromotive is at the rate of 43 kilogrammes at the same rating. This is a remarkably high weight-efficiency, which has up to the present not been reached by any continuous-current electromotive, and has only been surpassed by the three-phase 2000 horse-power electromotives (taken at the one-hour rating) of the Italian State railways, which works out at 30 kilogrammes per horse-power.

In conclusion, let us briefly glance at what is being done in the electrification of the Gothard line, that main link of commerce between Germany and Italy. I am indebted for the following notes on the subject to Mr. Huber-Stocker, the scientific adviser to the Swiss Government in the matter of railway electrification: The part to be electrified first is that between Erstfeld and Bellinzona, a total length of 110 kilometres, of which about 29 per cent. is in tunnel. This part also contains the longest and heaviest grades, so that the limitations of steam as compared with electric traction are here most prominent and a relief most urgent. On this section the average daily train movement, taking both directions together, was, in 1911, not less than 1,680,000 kilometre-tons, and the maximum on any day 2,282,000 kilometre-tons. It is estimated that in 1918 the average train movement will have increased by 35 per cent. over 1911, and in 1928 by a further 30 per cent. In the 45 kilometres on the north side of the tunnel the train climbs 569 metres, and in the 65 kilometres on the south it descends to Bellinzona 900 metres, with a steepest grade of 27 per mille. The section Erstfeld-Airolo is to be opened for electric traction in four years from now, and the southern section one year later. The present arrangements are made with the intention of extending the electric service on the north to Lucerne (60 kilometres), and on the south to Chiasso (55 kilometres) at some future date not yet fixed. There will be two large power-stations, one at Amsteg, where at first 32,000 horse-power will be available on the turbine shafts, and 56,000 to 60,000 when the station is completed; and the other at Piotta, where at first 40,000, and finally 50,000 horse-power will be available. The head of water in the northern power-house is 267 metres down to the Reuss, and an accumulation of one million cubic metres is provided for to compensate for diurnal variations. In the southern power-house the head of water is 900 metres, and there the Ritom Lake offers a natural reservoir, with 19 million cubic metres, to mpensate for annual variation in the water-supply. he power-current will be sent along the line by two dependent cables, each capable of carrying the full ower at twice 30,000 volts, with earthed neutral. The urrent will be transformed down to 7500 volts at first, nd 15,000 volts later on, if the experience gained with the lower pressure should warrant the increase to double pressure. This will not involve any additional plant, since the secondary winding of transformers both along the line and on the locomotives can from the first be arranged with this alteration in view. It is also contemplated to establish sub-stations in Biasca, Goeschenen, Lavorgo, and Bellinzona The trolley wires will be suspended from gantries, each wire independently insulated. The section varies according to the gradient from 100 to 160 square millimetres. The feeders are separate for the up and down line, and are 100 square millimetres in section. At all railway stations there are change-over switches for trolley wire and feeders. In the tunnels the wires are carried by brackets fastened to the crown of the tunnel. The rails will be bonded, and, in addition, there will be a bare return conductor either laid in the ground or placed between the trolley wires. A variation in the supply of voltage of from plus 10 to minus 15 per cent. is allowed for. There will be no motor coaches used, only electromotives. It is intended to haul express trains weighing 420 tons with a speed of 50 kilometres per hour on grades of 26 per mille, for which service the electromotive will have to develop 3000 horsepower on the rails. Goods trains weighing up to 670 tons will run with a speed of from 27 to 28 kilometres per hour, and have two electromotives. one in front and one in the rear, each rated at 2800 horse-power. Passenger trains will be heated by steam, the boiler being carried in a special heating coach. Except for the stipulation that the traction must be single-phase at 15 frequency and a voltage of 7500, which may eventually be raised to 15,000, no definite type of electromotive has as yet been selected, but there can be no doubt that several of the already existing types of mono-phase electromotive can be adapted to the special requirements of the Gothard line.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—Prof. P. F. Frankland, F.R.S., has been elected dean of the faculty of science in succession to Prof. S. M. Dixon.

Dr. F. C. Lee has been nominated to the chair of civil engineering vacated by Prof. S. M. Dixon.

Cambridge.—The director of the psychological laboratory has appointed Mr. Cyril Burt, psychologist to the London County Council, to be assistant in experimental psychology.

The professor of zoology and comparative anatomy has appointed Mr. T. J. Saunders to be demonstrator of comparative anatomy.

At Emmanuel College, Mr. J. B. Peace, bursar of the college, resigned the tutorship in mathematics at Michaelmas, and Mr. P. Worsley Wood has been appointed his successor. The exhibition of 50*l.* offered to a research student commencing residence this October has been awarded to Mr. J. Conway Davies for research in history. An additional exhibition of 30*l.* has been awarded to Mr. H. Ogden for research in physics.

The next combined examination for fifty-six entrance scholarships and a large number of exhibitions, at Pembroke, Gonville and Caius, Jesus, Christ's, St. John's, and Emmanuel Colleges, will be held on Tuesday, December 2, and following days. Mathematics, classics, natural sciences, and history will be the subjects of examination at all the above-mentioned colleges. Most of the colleges allow candidates who intend to study mechanical sciences to compete for scholarships and exhibitions by taking the papers set in mathematics or natural sciences. A candidate for a scholarship or exhibition at any of the six colleges must not be more than nineteen years of age on October 1. Forms of application for admission to the examination at the respective colleges may be obtained from the masters of the several colleges, from any of whom further information respecting the scholarships and exhibitions and other matters connected with the colleges may be obtained.

Glasgow.—Prof. Archibald Barr has resigned the Regius chair of civil engineering and mechanics, which he has held since 1889. The magnificent James Watt engineering laboratories, in which the department is accommodated, were erected and equipped under his direction. The Crown has appointed Prof. J. D. Cormack, dean of the faculty of engineering in University College, London, and a governor of the Imperial College of Science and Technology, to the vacant chair. Prof. Cormack is a graduate of Glasgow, and was formerly a lecturer in the engineering department.

Mr. C. R. Bury has been appointed assistant lecturer and demonstrator in chemistry at the University College of Wales, Aberystwyth.

A gift of ten lakhs of rupees for the promotion of scientific technical knowledge has been made by Dr. Rash Bahari Ghosh to the University of Calcutta.

The McCosh professorship of philosophy at Princeton University has been resigned by Prof. A. T. Ormond, who has accepted the presidency of Grove City College.

We learn from *Science* that by the will of Miss Katherine Allen, of Worcester, the Worcester Polytechnic Institute has received a bequest amounting to about 20,000*l.*

Mr. L. C. Plant has resigned his position as head of the department of mathematics in the University of Montana on accepting a similar post in the Michigan Agricultural College. He is succeeded by Dr. N. J. Lennes, of Columbia University.

By a trust settlement of Dr. Gavin P. Tennent, of Bath Street, Glasgow, the sum of 25,000*l.* is bequeathed to the governing body of the University of Glasgow, to be applied for such objects or object in connection with the faculty of medicine as the trustees may determine.

The Gresham lecturer on astronomy, Mr. Arthur R. Hinks, F.R.S., will deliver a course of four lectures on astronomy in daily use on October 14, 15, 16, and 17, at 6 p.m., at the City of London School, Victoria Embankment. The subjects of the four lectures are respectively:—The determination of time; the distribution of time; the determination of position; and measurement of the size and shape of the earth. The lectures are free to the public.

A strong committee, mainly consisting of old students of the Royal Agricultural College, Cirencester, is about to issue a special appeal with the view, in the first place, of collecting the balance of 1685*l.* still required to complete the 5000*l.* necessary to secure the advance of a similar sum from the Development Fund for erection of King Edward's wing of the college. When this sum has been subscribed, the appeal will still be continued so as to provide for further much needed extensions The honorary secretary of the committee is Mr. A. Goddard, Surveyors' Institution, 12 Great George Street, Westminster.

THE London County Council has arranged for three courses of free lectures at the Horniman Museum, Forest Hill, S.E., during the autumn, viz.:—On Saturday afternoons, at 3.30 p.m., beginning October 11, a course of ten lectures as follows: Nature study in a Croydon garden, E. Lovett; folk-lore of the Balkan peoples (II.), A. R. Wright; native arts and crafts in British New Guinea, Dr. H. S. Harrison; weeds and their influence, Dr. E. Marion Delf; the origin and nature of teeth, Dr. W. A. Cunnington; a folk-lore tour in the southern counties of England, E. Lovett; the history of coined money, A. R. Wright; the evolution of man in the light of recent discoveries, Dr. H. S. Harrison; animal life in the great caves, H. N. Milligan; the stone monuments of prehistoric times, A. L. Lewis. On Wednesday evenings, beginning October 29, a course of five lectures by Mr. H. N. Milligan on the animal life of the sea-shore. On Saturday mornings, beginning October 11, a course of ten lectures to teachers by Dr. A. C. Haddon, F.R.S., on the ethnology of India. Tickets are required only for the Saturday morning lectures, and may be obtained from the museum.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 22.—Général Bassot in the chair.—**A. Chauveau**: Comparison of vigorous and feeble organisms from the point of view of their aptitude for receiving and cultivating virulent organisms. According to the views at present generally held, a strong, healthy man is less readily attacked by tuberculosis or other contagious diseases than cases where the body has been weakened by alcoholism or other causes. This view is strongly controverted by the author, who refers to the experimental infection in 1868 of sixty healthy animals by tubercle; not one escaped the infection. Additional experiments on the transmission of scab to sheep are now given. Neither the healthy nor enfeebled subjects escaped.—T. **Levi-Civita**: Torricelli's theorem and the commencement of flow.—Edouard **Heckel** and Cl. **Verne**: Cultural bud mutations of *Solanum immite, S. Jamesii*, and *S. tuberosum*.—R. **Lépine** and **Boulud**: The intra-renal resorption of chlorides in various states of the kidney.—P. **Chofardet**: Observations of the Metcalf comet 1913*b*, made at the observatory of Besançon with the bent equatorial. Data given for September 7 and 11. The comet was of the ninth magnitude, nucleus badly defined, and no tail visible.—P. **Chofardet**: Observations of the Neujmin comet 1914*c*, made at the observatory of Besançon with the *coudé* equatorial. Data given for September 10 and 11. The comet was of the eleventh magnitude, with a small brilliant nucleus and a nebulous tail.—D. **Mirimanoff**: Remarks on a communication of Eugène Fabry. Pointing out an error in a demonstration of Fermat's theorem.—Paul **Lebard**: Remarks on the affinities of the principal genera of the group of ligulate flowers.—P. **Mazé**, M. **Ruot**, and M. **Lemoigne**: Lime chlorosis of green plants. Rôle of the root excretions in the absorption of iron from chalky soils. The presence of excess of chalk in the soil may produce chlorosis by rendering the iron insoluble. The addition of organic acids permitting the solution of small quantities of iron in presence of calcium carbonate removes the chlorosis at once.—Eugène **Pittard**: The comparative analysis of some of the body dimensions in Tartars of both sexes.—Ch. **Dhéré** and L. **Ryncki**: The absorption of visible and ultra-violet rays by carotinoid pigments.

MINERALOGY—CRYSTALLOGRAPHY—PETROGRAPHY—GEOLOGY.

Ask for our new

GENERAL CATALOGUE XVIII.

(2nd Edition)

for the use of Middle and High Schools and Universities.

Part I, 260 pages, 110 Illustrations.

This catalogue has been prepared with the view of making an exhaustive compilation of **all educational appliances for the teaching of Mineralogy and Geology** from a **scientific** as well as from a **practical** point of view. All the subjects are treated typically, and instructive specimens have been selected with the greatest care. A close examination of the catalogue will show, that owing to its careful composition it gives the opportunity of procuring the most complete outfit for the various schools for instruction in and the study of the subjects named.

Catalogue No. 18, Part I, will be sent free on application.
Part II will appear within the course of the year.

(Collections and single specimens of Minerals and Fossils, Meteorites bought and exchanged.)

Dr. F. KRANTZ,

RHENISH MINERAL OFFICE, BONN-ON-RHINE, GERMANY.

Established 1833. Established 1833.

ROCK SECTIONS FOR THE MICROSCOPE

New List of over 600 well cut Rock and Mineral Sections now ready, post free from

JAMES R. GREGORY & CO.,

Mineralogists, &c.,

139 FULHAM ROAD, SOUTH KENSINGTON, S.W.

Telegrams: "Meteorites, London." Telephone: 2841 Western.

LIVING SPECIMENS FOR THE MICROSCOPE.

Volvox, Spirogyra, Desmids, Diatoms, Amœba, Arcella, Actinosphærium, Vorticella, Stentor, Hydra, Floscularia, Stephanoceros, Melicerta, and many other specimens of Pond Life. Price 1s. per Tube, Post Free. Helix pomatia, Astacus, Amphioxus, Rana, Anodon, &c., for Dissection purposes.

THOMAS BOLTON,

25 BALSALL HEATH ROAD, BIRMINGHAM.

MARINE BIOLOGICAL ASSOCIATION OF THE UNITED KINGDOM.

THE LABORATORY, PLYMOUTH.

The following animals can always be supplied, either living or preserved by the best methods:—

Sycon; Clava, Obelia, Sertularia; Actinia, Tealia, Caryophyllia, Alcyonium; Hormiphora (preserved); Leptoplana; Lineus, Amphiporus, Nereis, Aphrodite, Arenicola, Lanice, Terebella; Lepas, Balanus, Gammarus, Ligia Mysis, Nebalia, Carcinus; Patella, Buccinum, Eledone, Pecten, Bugula, Crisia, Pedicellina, Holothuria, Asterias, Echinus, Salpa (preserved), Scyllium, Raia, &c., &c.

For prices and more detailed lists apply to Biological Laboratory, Plymouth. THE DIRECTOR.

BRITISH FISH PARASITES.

The British Parasitic Copepoda. By Dr. Thomas Scott and Andrew Scott. Vol. i. Pp. x+256. Vol. ii. Pp. xii+72 plates. (London: The Ray Society; Dulau and Co., Ltd., 1913.) Price 15*s.* net.

DR. THOMAS SCOTT has long been recognised as a leading authority on the smaller crustacea of the British seas, and his son, Mr. Andrew Scott, has also made important contributions to our knowledge of the same subject. It is fortunate, therefore, that the Ray Society has found these experienced investigators ready to undertake the preparation of a monograph on the British parasitic Copepoda, of which these two volumes, dealing with the species parasitic on fishes, form the first instalment.

The parasitic Copepoda have hitherto been somewhat neglected from a systematic and faunistic point of view. The student wishing to identify British specimens of fish-lice has had little to help him beyond Baird's "British Entomostraca," published by the Ray Society so long ago as 1850. The inadequacy of this help is shown by the fact that only thirty-four species of fish-parasites are described in Baird's volume, while the authors of the present monograph are able to record no fewer than one hundred and thirteen. The practical importance of a knowledge of the parasites of fishes in connection with fishery research hardly needs to be pointed out, and the careful descriptions and abundant illustrations now provided will prove a most useful foundation for future work in this department.

The authors have not attempted to deal seriously with the morphology and classification of the animals that they describe. For this course they can plead plenty of precedents, and it will meet with little condemnation from those zoologists of the younger generation who are so ready to proclaim the vanity of morphological research. It is likely, however, to cause the student some trouble when he finds, for instance, the term "fifth pair of thoracic feet" applied, in one family, to the appendages of the pre-genital somite, and transferred in the next family, without explanation or discussion, to those of the genital somite.

There are a number of minor blemishes throughout the work that might have been removed by more careful editing; specific names appearing for the first time are sometimes followed by the indication "sp. nov.," as on p. 202, sometimes not, as on p. 135; there is a lack of uniformity in the way in which references are made to the list of literature at the end of vol. i., and some of the references are obviously wrong; and the generic name *Phyllothyreus* appears on p. 92 and elsewhere as *Phyllothreus*. The colouring of some of the plates is very diagrammatic, and adds neither to their beauty nor their usefulness.

From a faunistic point of view, however, the work is of the highest importance, and it is to be hoped that it will attract other students to the many complex problems presented by the life-histories and bionomics of these strangely-modified parasites.

DISEASE AND ITS PREVENTION.

(1) *Prevention and Control of Disease.* By Prof. F. Ramaley and Dr. C. E. Giffin. Pp. 386. (Boulder, Colo.: The University, 1913.)

(2) *Practical Bacteriology, Microbiology and Serum Therapy (Medical and Veterinary).* A Text-book for Laboratory Use. By Dr. A. Besson. Translated and adapted from the fifth French edition by Prof. H. J. Hutchens, D.S.O. Pp. xxx+892. (London: Longmans, Green and Co., 1913.) Price 36*s.* net.

(3) *A Monograph on Johne's Disease (Enteritis Chronica Pseudotuberculosa Bovis).* By F. W. Twort and G. L. Y. Ingram. Pp. xi+179+ix plates. (London: Baillière, Tindall and Cox, 1913.) Price 6*s.* net.

(1) THE authors of this book have undertaken the task of describing, in language intelligible to the educated man without special medical training, the present state of knowledge and opinion respecting the origin, nature, and methods of preventing important diseases. In the earlier chapters the principles of bacteriology and the meaning of terms employed in describing the phenomena of immunity are detailed and explained. In later chapters most of the common diseases are passed in review and the duty of an intelligent citizen in the presence of any such disease succinctly stated.

The vastness of the field attempted to be covered and the necessity of avoiding technical discussion in a work of this kind must needs result in portions of it appearing incomplete to a specialist reader. Thus the student of hereditary influences might doubt whether the authors sufficiently recognise the importance of the soil in the genesis of disease, while the statistician will feel that the face value of various sets of figures quoted differs from their intrinsic worth. Such criticisms as these, however, could be directed against any similar book, and we have no doubt that the present work will satisfactorily achieve the aim its authors had in view. Some suggestions for the improvement of future editions may not be out of place.

Vital statistics necessarily form the principal medium through which the layman acquires a knowledge of the prevalence of disease. The remarks on pp. 8-9 might be amplified with advantage. In particular the methods by which corrections for the age and sex constitutions of different populations are made can be readily explained to an intelligent reader, and such an explanation would enable him to avoid many fallacies in comparing mortality rates.

(2) This translation of Besson's well-known treatise forms a notable addition to the list of text-books on bacteriology available to the English student and laboratory worker, and we may say at the outset that Prof. Hutchens has admirably performed the undoubtedly difficult task of translating and emendating a foreign text-book in such a manner as to render it palatable to the English reader. The translator, while adhering closely to the French text, has wisely decided to reproduce the sense rather than the letter of the original, with the result that the text betrays little or no sign of its foreign origin. The present translation has been made from the last French edition, which appeared in 1911, and consequently numerous additions have been made by the translator so as to bring the matter up to date. The most extensive of these additions are the chapters embodying recent work on the relationships of the Gaertner-Paratyphoid group of bacilli, to which subject English writers have made important contributions, also on the work of the English Royal Commission on Tuberculosis, in which Prof. Hutchens formerly participated. The chapter on the microscope has also been entirely rewritten and contains a most complete account of the working of the modern microscope, including the principle of dark-ground illumination and its practical applications.

Besides these major additions to the French original, there is scarcely a page of the text which does not bear evidence of the work of the emendator. This generally takes the form of bracketed paragraphs or footnotes, which the translator has interpolated where the views of the French author, or the French school generally, happen to conflict with current English or German opinion. By the advanced laboratory worker these interpolations will be readily appreciated, but it is possible that the student may become bewildered by the multiplicity of these interpolations, which not infrequently contain opinions at variance with those of the French author. Short of rewriting the whole book, however, such defects are, of course, inevitable, and it is to be hoped that the translator, with the experience he has now gained, may see his way to compile an equally comprehensive and purely English text-book, in which greater scope for the exercise of criticism would be available than is possible in a work written at second hand. It is doubtful whether the French original was really the best foundation on which to build an English text-book. The English mind is essentially practical, and there is no doubt that many of the methods so minutely described by the French author and many of the complicated media recommended for the isolation of various micro-organisms are either antiquated, superfluous, or unworthy of mention. The arrangement of the matter in the book may justly be considered a model, and the prominent headings of the various sections are most helpful to the reader.

The book is well bound and beautifully printed, and the illustrations are excellent. The only important misprint we have noticed is the curious but consistent employment of "an" before such words as "homogeneous," "herd," and "horse."

As a most comprehensive treatise on bacteriology, we can confidently assert that Dr. Besson's book in its English dress has unique claims on English workers in bacteriology.

(3) The great merit of this monograph rests on the important contributions which the authors have made during the past four years to our knowledge of the etiology of Johne's disease.

This disease is one which affects cattle (and possibly also sheep and goats) in various countries, and it is only recently that serious attention has been directed to it in Great Britain. The chief pathological lesion in affected cattle is an irregular thickening of the bowel, generally in the neighbourhood of the ileo-cæcal valve, and the symptoms to which this lesion gives rise are chiefly diarrhœa and extreme emaciation. The disease leads to serious economic loss, and the name by which it goes in this country is that of Prof. Johne, of Dresden, who in 1895, in conjunction with Dr. Frothingham, first directed attention to the presence of acid-fast bacilli in the thickened intestine. For many years all attempts to cultivate these acid-fast organisms on artificial media either failed entirely or the cultures that were obtained from the lesions proved to be incapable of reproducing the disease in experimental animals. In 1910 Dr. Twort and Mr. Ingram started an investigation of this question and ultimately succeeded in obtaining a growth of the organism on an egg-medium in which killed tubercle bacilli were incorporated. Later it was found that the addition of killed Timothy grass bacilli, or glycerine extracts of these bacilli, gave equally good results.

These experiments have been repeated and confirmed by other workers.

Further, attempts to reproduce the disease by inoculation of artificial cultures have been successful. The authors have also carried out a considerable number of experiments with the view of obtaining a preparation of Johne's bacillus suitable for diagnostic purposes on the same lines as those on which the tuberculin test is at present applied. The results have been distinctly encouraging, and we may express the hope that lack of funds may not impede the further effective prosecution of the author's researches. The book has been very carefully written throughout, and concludes with a valuable bibliography. To all scientific veterinarians and stockbreeders this monograph may be heartily recommended.

MATHEMATICAL TEXT-BOOKS.

(1) *Elementary Algebra.* By C. Godfrey and A. W. Siddons. Vol. ii. Pp. xi+227–530+xlvi. (Cambridge University Press, 1913.) Price 2*s.* 6*d.*

(5) *Mathematics, Science, and Drawing for the Preliminary Technical Course.* By L. J. Castle. Pp. vii+149. (London: George Routledge and Sons, Ltd., 1913.) Price 1*s.* net.

(6) *Nomography, or the Graphic Representation of Formulae.* By Captain R. K. Hezlet. Pp. iv+54. (Woolwich: Royal Artillery Institution, 1913.) Price 2*s.* 6*d.*

(7) *The Principles of Projective Geometry Applied to the Straight Line and Conic.* By J. L. S. Hatton. Pp. x+366. (Cambridge University Press, 1913.) Price 10*s.* 6*d.*

(1) THE second volume of this treatise, which is intended to include as much as the pupil of average ability will assimilate in a full school course, opens with a treatment of indices and logarithms. The next two chapters deal with variation of functions of one or more variables. This is followed by harder equations, surds, proportion, and progressions. The next four chapters contain an excellent introduction to the differential and integral calculus. Although confining themselves to very simple functions, x^2, x^3, $1/x$, the authors have illustrated all the important ideas of the subject. The educational value of such work as this is very great, and we have little doubt that in a few years' time it will be accepted as a regular part of the non-specialist course. This and the chapter on progressions are the outstanding features of a book which is admirable throughout. An appendix is added containing such parts of the subject as are still required by various conservative examining bodies, but which the authors hope further reform will soon render unnecessary. There is an excellent set of test papers.

(2) We welcome the issue of this set of four-figure tables chiefly on account of their low price. Now that their use has become so general, it is important that students should be able to procure them in an inexpensive form. There is little to note in regard to their contents, which include, in addition to squares, square-roots, reciprocals and logarithms, the usual trigonometrical tables. In our opinion it is unfortunate that the table of logarithms is not placed at the beginning. Coming as it does at p. 22, some time will always be lost in finding it. The arrangement of the table of square-roots is new and distinctly ingenious; for instance, opposite to 42, printed one below the other are the numbers 2049, 6481, thus making it impossible for the pupil to take the square-root from the wrong page.

(3) This collection of papers, set under the new regulations for the first part of the mathematical tripos, besides being of use to undergraduates at Cambridge, is interesting as showing the change in character of the work required from candidates for honours since the abolition of the order of merit. The ten-minute conundrum has now practically disappeared, and its place taken by more practical and straightforward questions. With the exception of some electricity and optics, there is practically nothing that the capable specialist would not be able to do on leaving school, and the course, therefore, suits not only those who are intending to take up research work, but also those who will afterwards turn to mechanical science, engineering, or physics.

(4) The use of a trolley and inclined plane has done much to smooth away the difficulties from the path of those who attempt an experimental introduction to dynamics. Most teachers now agree that it is unsatisfactory to allow the ordinary student to confine himself to a theoretical treatment. Mr. Ashford quotes from Thomson and Tait's standard treatise a remark that "Nothing can be more fatal to progress than a too confident reliance on mathematical symbols, for the student is only too apt to consider the *formula*, and not the *fact*, as the physical reality." And he has set

himself the task of devising a course which should guard the student against this danger. Illustrations are drawn from practical engineering, steamships, aëroplanes, motor-bicycles, turbines, &c., which should convince the reader of the real utility of mechanics, and arouse and preserve his interest. Text-books such as this do much to advance the cause of elementary mathematical education by enlarging the mental horizon of the student, and giving him a sound knowledge of the fundamental ideas, such as mass, force, energy, momentum, &c., without which any substantial progress is impossible.

(5) This course of practical arithmetic, geometry, and mechanics is written for first-year students taking a technical course, and is intended to occupy rather more than a hundred hours. The first forty pages deal with fractions, decimals, ratio, percentagé, and graphs; the next sixty with the mensuration of the triangle, circle, and simple solids; and the remainder with the principle of the lever, centre of gravity, and the measurement of work. The examples are numerous, simple, and practical.

(6) This small pamphlet gives an account of a graphical method for facilitating numerical calculations required in connection with comparatively complicated formulæ occurring in scientific and engineering work. Although disclaiming any originality for the methods he gives, the author points out that as yet they have received little or no attention from English writers. The theory is not difficult, but those whose mathematical knowledge is small will find it easy to master the practical procedure if they study the examples which are worked out in great detail, although they may consider the nomenclature rather alarming.

(7) There are few subjects which depend so much on the personality of the teacher for their success, and the interest they arouse in the student, as geometry. And this applies even more to its higher branches than to the elements. A carefully-chosen course on projection and homography not only stimulates the mind of the pupil by the power and generality of its root ideas, but also induces an enthusiasm which ensures a remarkable rapidity of progress. There are two distinct methods of procedure open to the teacher. On one hand, he may base his work on an analytical foundation, thus making use from the start of imaginary and ideal elements, and so establishing the validity of general projection and the principle of continuity. Properties of homography and involution, and the idea of a one-to-one correspondence, also admit of valuable illustrations from analysis. Or, on the other hand, he may restrict himself to the methods of pure geometry, and exclude imaginary elements until, at an advanced stage, they emerge from the consideration of an overlapping involution. In the treatise before us the author has adopted the latter method, which we are inclined to think is rather more difficult for the ordinary student. Its contents form a very comprehensive account of the projective geometry of lines and conics up to the standard of a university honours degree. The author writes clearly, and has brought together an extremely interesting collection of properties; the excellence of the diagrams calls for special notice. We do not hesitate to say that those who use this book will gain a sound knowledge and appreciation of the principles of higher pure geometry.

OUR BOOKSHELF.

The Climate and Weather of San Diego, California. By F. A. Carpenter. Pp. xii+118+plates. (San Diego: Chamber of Commerce, 1913.)

An excellent little book on the climate and weather of San Diego, South California, has been prepared by the local officer of the weather bureau, and published by the local chamber of commerce. The book contains twenty-seven short chapters dealing partly with San Diego town and bay, partly with San Diego county, and partly with general factors in weather and climate.

The characteristic feature of the climate is the "velo" cloud, to which the place owes its comparatively low summer temperature, in spite of its proximity to the tropics. (The latitude and longitude might with advantage have found a place at the beginning of the book.) The "velo" cloud is a cloud of a low stratus type, which "veils" the sun in the morning, and usually disappears with the coming of the sea breeze in the afternoon.

On the average the sun shines on 356 days of the year at San Diego, and the total rainfall is under 10 inches; at times, therefore, rain is earnestly desired, but we are told in illustration of the importance of local signs in weather-forecasting that San Diego's best-loved priest used to refuse to offer prayers for rain unless the wind had been in the south for three days. The book is eminently readable, and the statistical tables have been infused with a human interest. E. G.

Petrographische Untersuchungen an Gesteinen des Polzengebietes in Nord-Böhmen. By K. H. Scheumann. Pp. vi+607–776. (Leipzig: B. G. Teubner, 1913.) Price 8 marks.

The latest number of the *Abhandlungen* of the *Königl. Sächsischen Gesellschaft der Wissenschaften* contains a memoir by K. H. Scheumann on the Tertiary igneous rocks of the Polzen district, in northern Bohemia. These rocks are of the same age as those of the better-known Mittelgebirge, farther west, and have the same alkaline affinities, though there is not the same great preponderance of basic types. In the neighbourhood of Leipa occur numerous volcanic plugs and necks, composed of various alkaline basalts and trachydolerites, with tuffs of corresponding nature. In addition, dykes with a N.E.–S.W. direction are met with throughout the whole district. These have a wider petrographical range, and are discussed at length by the author. The most basic rocks of this series contain 50 per cent. of olivine, with melilite, biotite, haüyne, nepheline, &c. To this type the author gives the name *polzenite*, but it does not seem to differ essentially from alnöite. From this extreme the rocks range through melilite- and nepheline-basalts, haüyne-basalts, and various trachydolerites to phonolites, the most acid term being a trachytoid phonolite very rich in sanidine. The silica percentage ranges from less than 30 to 58. The whole assemblage of dyke-rocks is regarded as a single series, derived from a common magma by differentiation along definite lines. This conclusion is enforced by chemical analyses, fourteen in number, which yield smooth curves when plotted on a diagram. The author connects the differentiation with progressive crystallisation in the original magma, of trachydoleritic composition; and for a series of rock-types so related he proposes the term *pexitropic*.

Elements of Water Bacteriology with Special Reference to Sanitary Water Analysis. By S. C. Prescott and C. E. A. Winslow. Pp. xiv+318. Third edition. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 7*s*. 6*d*. net.

Attention has been directed in these columns to the previous editions of this work; to the first on July 7, 1904 (vol. lxx., p. 221), and to the second on November 5, 1908 (vol. lxxix., p. 6). In view of the important progress made during the last five years in sanitary bacteriology, the authors have thoroughly revised their work. Newer ideas on the effect of temperature upon the viability of bacteria in water are included; the recent recommendations of the committee on standard methods are discussed; the description of the isolation of specific pathogenes from water has been largely rewritten and much extended; and a new chapter on the application of bacteriology to the sanitary study of shellfish has been introduced.

Metallography. By Dr. Cecil H. Desch. Pp. xi+431. Second edition. (London: Longmans, Green and Co., 1913.) Price 9*s*.

The first edition of this book was reviewed in the issue of Nature for January 5, 1911 (vol. lxxxv., p. 301). In the present work the general plan and arrangement of the first edition remain unchanged, but the text has been revised, and the most important results of recent investigations have been incorporated. Important changes have been made in the treatment of the physical properties of alloys, and of the metallography of iron and steel.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Piltdown Skull and Brain Cast.

The discovery of the fragments of the Piltdown skull has given rise to a problem of a new kind. In all former discoveries of the remains of ancient man the part of the skull actually found was intact, or, if broken, a sufficient number of pieces were recovered to render reconstruction an easy task. In the case of the Piltdown skull, although the greater part of the bony walls of the cranial cavity were found, a large area of the forehead and along the middle line of the roof of the skull are still missing. The problem that has to be solved is: How much is missing? The solution of the problem, as Dr. Smith Woodward realised when he commenced his work of

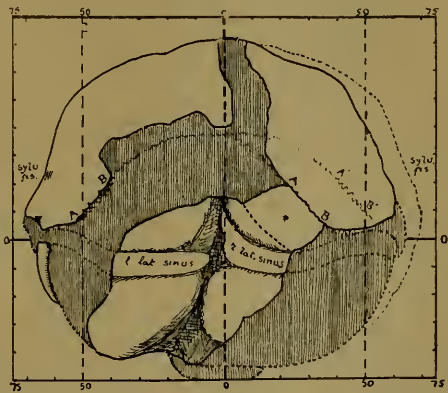

Fig. 1.—Occipital aspect of the brain-cast of the Piltdown skull as reconstructed by Dr. Smith Woodward. The parts missing in the skull are represented by vertical shading.

restoration, lies in the hinder or occipital wall of the skull. The fragment which Dr. Smith Woodward himself discovered gives a definite index to the width of the right half of the occipital bone, and also to the width of the hinder or occipital part of the head.

It is clear, then, that the first step in the reconstruction of the Piltdown skull must be an accurate adjustment of the parts which enter into the formation of the occipital wall. If a mistake is made in this initial step, then the error may become proportionately greater as one proceeds towards the region of the forehead. In my opinion, Dr. Smith Woodward has made a grave mistake in his restoration of the occipital region, and therefore the brain cast which he obtained from his reconstruction—the basis of Prof. Elliot Smith's preliminary note to the Geological Society—does not give an accurate representation of either the size or general form of the brain of Piltdown Man.

The nature of the problem and the manner of its solution will be made clear by the three accompanying figures. Fig. 1 represents the occipital aspect of the brain cast obtained in Dr. Smith Woodward's reconstruction; Fig. 2, the same view in a reconstruction of the skull made by the writer: Fig. 3, the same view of a brain cast from the skull of an Australian native, with a cubic capacity of 1460 cubic centimetres—rather a large skull for an Australian native. All three brain casts have been arranged on the same horizontal plane and drawn to the same scale. To facilitate comparison, they have been placed within squares of the same size. Three vertical lines are represented—the middle and two lateral lines. The lateral lines are 50 mm. apart from the middle line.

Fig. 2.—The same aspect from the reconstruction of the skull by the writer.

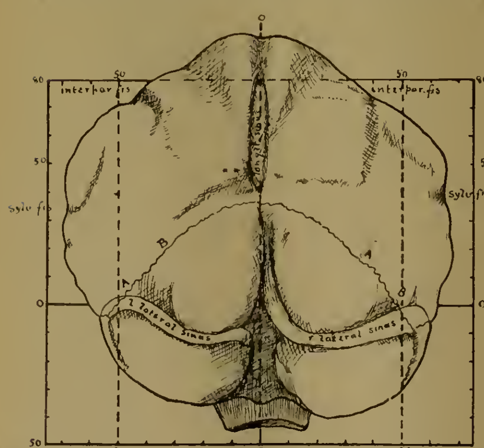

Fig. 3.—The same aspect of the brain cast from the skull of an Australian native—for comparison with figs. 1 and 2.

The leading principle which guides the task of reconstruction is symmetry—the right and left halves of the mammalian head and skull are approximately alike. When the test of symmetry is applied to the occipital region of the brain cast from Dr. Smith Woodward's reconstruction of the skull, it is at once seen that there is a great degree of discrepancy between the right and left halves; the amount which has to be added to the right half to make it approximately equal to the left is shown by the stippled line in Fig. 1. The discrepancy between the two halves is even more marked when the right and left halves of the lambdoid suture—the joint between the posterior margin of the two parietal bones and the occipital—are investigated.

The situation of corresponding parts of this suture are represented on the right and left halves of the recovered parts of the Piltdown skull; Dr. Smith Woodward has already recognised the presence of those two parts of the lambdoid suture. They are indicated on the three accompanying figures as A, B. Now on the left side of the skull the lambdoid suture cuts the lateral line 50 mm. from the mid-line; on the right side it falls 20 mm. short of the lateral line; to make the two sides approximately symmetrical, the right lambdoid suture has to be moved outwards until it occupies the position A′ B′, shown in Fig. 1. That degree of error exceeds even the amount found in human skulls deformed artificially or deformed by disease, and points to an error in reconstruction. It will be also seen that the right and left halves of the suture, as indicated on the brain cast—the discrepancy is even more marked on the reconstruction of the skull—have a different inclination to the mid-line of the reconstruction. It may be thought that all that is necessary to obtain symmetry is to move the parts of the right half outwards until the right and left halves of the brain cast are approximately equal in size; when this is done, it will be found that marked asymmetry of another kind is introduced. In moving one part, all the other parts of the skull are thrown out of place; the task has to be recommenced from the first initial step.

In Fig. 2 I give a drawing of the brain cast obtained when the parts of the skull are placed together according to their structural markings. There can be no doubt as to the middle line of the occipital bone; on its outer surface is clearly seen the ridge which indicates the division between the right and left halves of the neck. We may presume in this primitive man that the neck was symmetrical. The next point which has to be fixed definitely is the middle line on the roof of the skull. At first I accepted the middle line as fixed by Dr. Smith Woodward—an elevation on the outer aspect of the left parietal bone—near its hinder upper angle—corresponding to a wide depression which is to be seen on the inner aspect of that part of the bone. I found it impossible to obtain even an approximate symmetry of the right and left halves of the skull in all my attempts at reconstruction when I proceeded on this basis.

On comparing the corresponding regions of the Piltdown and Neanderthal brain casts, it became quite apparent that the markings of the middle line—which I had accepted from Dr. Smith Woodward—did not represent the middle line, but a region well to the left of that line. The excavation or groove which we had regarded as caused by the longitudinal blood sinus—a channel passing along the roof of the skull under the middle line—was not due to that structure, but to the well-marked elevations of the brain on each side of the longitudinal sinus. These cerebral elevations are clearly marked in the brain casts of Neanderthal man. In the skulls of all the higher primates, the longitudinal sinus, near the hinder end of the adjacent margins of the right and left parietal bones, is marked by a narrow deep groove with distinct edges; on the margin of the upper angle of the Piltdown fragment the edge or margin of this groove can be clearly recognised.

In Dr. Smith Woodward's reconstruction, therefore, it is not only necessary to move the fragments of the right side outwards; the left parietal bone has also to be moved outwards, or rather tilted upwards and outwards until it assumes a more vertical position, with the marking of the sinus in the middle line. When that is done, and the other parts correctly adjusted, the brain cast assumes the form and size represented in Fig. 2. I made many experiments to test other possible suppositions, but only when the fragments were placed as in Fig. 2 could I secure symmetry, and at the same time obtain all the anatomical markings in their normal situations. The brain cast obtained from this reconstruction displaces just over 1500 cubic centimetres of water. Dr. Smith Woodward estimated his brain cast provisionally at 1070 c.c.; the replicas of the brain cast which were distributed displace 1200 c.c. of water; even if the reconstruction carried out by Dr. Smith Woodward is accepted, and the right half is made approximately symmetrical with the left, the brain of Piltdown man will be about 200 c.c. above his original estimate.

In my reconstruction two other peculiar features of the original brain cast have disappeared. One is the sharp bending inwards or kinking of the temporal lobe of the brain; the other is the position of the foramen magnum—the opening in the base of the skull for the exit of the spinal cord. In the original reconstruction the lower margin of the occipital bone was brought forwards so far in the base of the skull that when a palate was articulated there was no room left for the soft palate and pharynx. The corresponding basal parts of the brain cast are, of course, also abbreviated.

I do not attach any high importance to actual brain mass; it is merely a rough indication of mental power when applied to human brains. So far as concerns the description of the actual markings of the Piltdown brain cast given by my friend Prof. Elliot Smith, I am in complete agreement, but so far as concerns general mass and conformation, it is clear, from his letter in Nature, October 2, p. 131, that I am at complete variance. How far I am right—to what extent I have made an error—remains to be seen; but the publication of these drawings and observations will show that I have made every endeavour to arrive as near the truth as is possible for me.

A. Keith.

The Theory of Radiation.

In his letter published in Nature of October 9, Prof. Maclaren has referred to my use of the concept of a natural unit of angular momentum, and perhaps a few explanatory remarks may be useful, as the work has not been published in a journal devoted to physics. The concept first appeared in my paper on the constitution of the solar corona, published in the Monthly Notices of the Royal Astronomical Society in June of last year. It was found that the energy frequency ratios of the atomic systems, which were held to be the origin of the main lines in the coronal spectrum, were always simple multiples of the quantity $h/2\pi$, where h is Planck's constant. As these ratios were nothing more or less than the angular momenta of the atoms, the conclusion was forced upon me that Planck's h could only be an angular momentum.

As was stated at the time, such an interpretation removes much of the difficulty otherwise pertaining to the quanta theory, when expressed in the usual way in terms of energy. It does not, of course, explain that theory, but merely renders it more intelligible as a possibility, for it is not difficult to obtain fair mechanical models of atoms the angular momentum of which can only have a discrete set of values. Prof. Maclaren, in his letter has, in fact, indicated a very beautiful one by the help of the magneton, which has a definite unit of angular momentum. It is evidently possible to construct a system containing multiples of that unit.

The more recent work of Dr. Bohr (*Phil. Mag.*, July and September of this year) applies the same concept to series spectra, but is different in that it postulates the angular momentum of an electron in the normal state of the atom as *exactly* $h/2\pi$. For example, the whole angular momentum of a neutral atom with five electrons is, on Bohr's theory, $5h/2\pi$. But I had found it necessary in the paper cited above that the value should be $25h/2\pi$. There is in this respect a discrepancy between the two theories, which is probably not serious, as Dr. Bohr has only calculated the series lines in hydrogen and in helium with a single electron, and therefore charged. (The number of electrons and its square are then identical.) The real test of his theory will lie in its capacity to account for the *usual* spectrum of helium—a test which does not appear difficult. For Dr. Bohr has concluded that helium will not take a negative charge. The ordinary spectrum must therefore come from the uncharged atom in its passage between stationary states, which are of a limited number, as there are only two electrons. It does not appear that the helium spectrum can be obtained in this way, but perhaps further investigation will modify this conclusion. Until this is done, the point raised by Prof. Fowler in a recent discussion in Nature, as to the apparent need for keeping the Balmer and Pickering spectra of "hydrogen" as two *distinct* series, has not been answered.

But as Prof. Maclaren states, whatever be the fate of this theory, the natural unit of angular momentum seems necessary. It is inevitably suggested by any atomic theory which now attempts to rest on a foundation of electrons and a positive nucleus; for its use is not restricted to the applications already mentioned. It is apparently the only ready means of explaining a type of spectral series which the writer has found recently to be of importance—a series in which the cube roots of the wave-lengths have constant differences.

Science and the Lay Press.

Many "lay" journalists will have welcomed the comments in Nature of October 9 (p. 172) on the "sensational paragraphs to the effect that Sir Frederick Treves had announced at the Radium Institute 'a complete revolution in the future of radium.'" For the undue enthusiasm shown, the Radium Institute is partly to blame. Sir Frederick claimed credit on behalf of it for the discovery that emanation was as valuable as radium in the treatment of cancer, and when Mr. Pinch was describing the good results obtained with emanation water in the treatment of arthritis deformans he interpolated the remark that this was something new in medicine. Undoubtedly, too, the impression was created in the minds of many of those present that by utilising emanation a gram of radium could be made to do the work of several grams. While in the matter of comment several newspapers fell into gross errors, they did little more than translate into popular language the sense of what was said.

Unfortunately in compressing what he had to say

Sir Frederick Treves did not find it possible to show clearly in what exact respects the institute claimed to have made an advance. I imagine his remarks were intended to serve a double purpose—to explain the part that radium can play in disease and to show on what lines the institute had new information to publish.

The conditions of lay journalism are such that the reporter is usually forced to estimate the value of claims put forward by considering the way in which they are presented, coupled with the standing of the speaker and of the institution that has given him a platform. Several papers have made the experiment of employing an expert in such matters, but on the whole the results have been disappointing. It is to be hoped that the episode, and your comments on it, will act as a warning for future occasions, and that in communications to the lay Press men of science will be more careful to preserve a proper perspective and to differentiate clearly between new and already well-known facts.

ONE OF THE REPORTERS PRESENT.

THE GLASGOW MEMORIAL TO LORD KELVIN.

IN May, 1908, in response to a widely expressed opinion that a memorial should be erected to Lord Kelvin, a meeting was called by the Lord Provost of Glasgow to consider the matter. This gathering, representative of the city and west of Scotland, resolved to mark in a fitting and permanent form its sense of the manifold benefits which Lord Kelvin's researches and discoveries in physical science, and his patient application of the same to the common uses of man by sea and land, have conferred upon the world, by establishing a worthy memorial of him in the city where he lived and laboured.

The desire thus expressed was amply accomplished on Wednesday, October 8, in the presence of a large and distinguished assemblage, including many veterans of science trained under Lord Kelvin, and leaders in other departments of life, when the unveiling of the memorial statue was performed by the Rt. Hon. Augustine Birrell, K.C., M.P., Lord Rector of Glasgow University. The statue stands in Kelvingrove Park, at the base of the hill on which the University is built, facing S.E. towards the river Kelvin and the city. It represents Lord Kelvin seated with his familiar green book and pencil in hand, in a characteristic attitude as when at work on some problem. Behind the figure are placed his binnacle and mirror galvanometer, with other emblems of his services to industry and science. The memorial is the work of Mr. A. McFarlane Shannan, Glasgow, and, in the words of Prof. Perry, as a faithful likeness and, what is more, as a work of art, it does all that art could do in awakening the emotions of reverence and love felt by all who came closely in touch with the great master.

At the unveiling ceremony, which took place at 11 a.m., a letter from Lady Kelvin was read expressing her regret at being unable to attend, and after a short introductory speech by the Lord Provost, Mr. Birrell began his address. He referred to William Thomson's early life and training in Glasgow, and traced his close and

Clay Model of Statue of Lord Kelvin in Kelvingrove Park, Glasgow. Sculptor, Mr. A. McF. Shannan.

life-long connection with the University, beginning as student, and ending its first stage as the author of original memoirs at the age of eighteen. Then came the eventful interlude at Cambridge, and Mr. Birrell genially recalled how Thomson's originality proved his undoing in the competition for the Senior Wranglership, and how "the ancient and eternal wrongs of the examination room" were mitigated later when Parkinson, despite his pace, was second Smith's Prizeman. Cambridge over, he returned to Glasgow to the professorship of natural philosophy, "a chair which he occupied and illuminated for half a century." In closing the review of Lord Kelvin's work in Glasgow as student, as investigator, and teacher, the Lord Rector added that he had said enough, and far more than was necessary, to prove that before all other cities, and above all other places, Glasgow is the city and the place for a statue of Lord Kelvin. Men like Lord Kelvin were seldom solitary voyagers, but rather leaders of a great company of thinkers and experimenters labouring to lighten the burden of suffering humanity. As a practical inventor as well as a thinker his claims appealed to all, and would continue to do so. It was therefore with pride and joy and confidence that he asked the City of Glasgow, for all time to come, to take good care of a beautiful memorial of a truly memorable man.

Principal Sir Donald MacAlister, in moving a vote of thanks to Mr. Birrell, said that the Lord Rector had performed the ceremony with his accustomed felicity, and had worthily expressed the homage of the city and University to one of its brightest ornaments. In the name of the subscribers, Prof. S. P. Thompson moved a vote of thanks to the sculptor; this was seconded by Prof. Perry, and Mr. Shannan replied.

At the luncheon following on the unveiling of the statue to Lord Kelvin the toast, "The Memory of Lord Kelvin," was proposed by the Rt. Hon. Arthur James Balfour, M.P.

Mr. Balfour dwelt upon Lord Kelvin's happy combination of great gifts, making him at once the greatest master of theory and a leading spirit in every department of practical affairs. His services to mankind, as man of business, inventor, teacher, investigator of the great problems of the universe, in order more and more to raise the material condition of mankind, rank him as greatest of the great group of physicists who have paved the way for the scientific revolution in the midst of which we are living. Lord Kelvin's want of sympathy with those latter-day speculations to which his own labours led up was not the imperviousness to ideas which comes of mental inertia. But what he would accept from other men depended at the moment upon the intense inner life that he led, which concentrated his attention upon certain lines of investigation, and made him almost oblivious of what was going on outside the current of his own thought. Great in knowledge, great in achievement, yet in himself the most modest, the most eager, the most childlike—in the good sense of the word—of men, his record had never been surpassed in the whole annals of physical science.

THE PREHISTORIC SOCIETY OF EAST ANGLIA.

The members of the Prehistoric Society of East Anglia are to be congratulated on the systematic manner in which they are studying the properties of flint, with special reference to the identification of human workmanship. In the latest part of their proceedings[1] Dr. W. Allen Sturge discussess the patina of flint implements, and concludes that it is produced entirely by exposure on the surface. Permanent burial appears not only to retard, but even to prevent, patination. Mr. J. Reid Moir describes some experiments on the chipping of flints, and attempts to show that the flaking of a margin by natural causes is comparatively irregular, while the blows directed by man to produce such flaking are at definite angles with much regularity. He also demonstrates that flakes produced by natural pressure often exhibit a bulb at each end. Mr. F. N. Haward follows with additional notes on the chipping of flints by natural agencies, and concludes that much can be accounted for by movements in the ground. He instances particularly the chipping due to the creeping motion of gravel at the top of pipes in the chalk.

[1] Proceedings of the Prehistoric Society of East Anglia, 1910–11, 1911–12, vol. i., pt. ii. (London: H. K. Lewis, 1912.)

Among descriptive papers may be specially mentioned that by Mr. J. Reid Moir on the much-discussed human skeleton discovered by him in a glacial deposit at Ipswich. Though interesting, it is by no means convincing in its argument that the skeleton lay in undisturbed ground; and the difficulty in believing that the human being in question lived before the deposition of the boulder clay is further enhanced by the report of Prof. A. Keith, who finds that there is no essential difference between this skeleton and that of a modern civilised man.

There may also be differences of opinion about the supposed flint implements, described by Mr. W. G. Clarke, from the basement bed of the Norwich Crag, in Norfolk; but Dr. Sturge's elaborate paper on Mousterian and other late Palæolithic flint implements from superficial deposits in East Anglia will be accepted without hesitation, and is all the more welcome from the abundance of French specimens which the author is able to select for comparison from his own cabinet. All the papers are well illustrated, but this one by Dr. Sturge especially so; and the only fault we have to find with them is their frequent diffuseness. A more concise and systematic mode of expression might be adopted in future with advantage.

NOTES.

An extra meeting of the Chemical Society will be held at Burlington House, Piccadilly, W., on Thursday, October 23, at 8.30 p.m., when the Ladenburg Memorial Lecture will be delivered by Prof. F. Stanley Kipping, F.R.S.

A lecture will be given under the auspices of the Swedenborg Society at the rooms of the Society of British Artists, Suffolk Street, on the evening of November 19, by Prof. W. B. Bottomley, of King's College, London, on Swedenborg's doctrine of the origin of life. Sir W. F. Barrett, F.R.S., will occupy the chair.

The High Commissioner of the Federated Malay States has notified that, in consideration of the importance of the London School of Tropical Medicine to the Government, a sum of 5000*l.* has been voted as a contribution to Mr. Austen Chamberlain's appeal for 100,000*l.* for the endowment of the school. The grant was made by the Legislative Council on the representation of unofficial members. Mr. Chamberlain's fund now amounts to 70,000*l*.

A discovery of arctic land, which, when further investigated, will add an important feature to even a small-scale map of the north polar region, is reported by *The Times* correspondent in St. Petersburg. It appears that Capt. Wilkitsky, in command of two Russian surveying ships off the north Siberian coast, has been working northward and westward from Vladivostok and Cape Dezhnev, and was brought to a stop by ice off Cape Chelyuskin. Proceeding northward in an attempt to turn the barrier, he came upon land—an eastward-facing coast—extending in a direction roughly north-north-west from 78° to 81° N., over a distance of 200 nautical miles. He was forced to return, and has sent his message from Fort St. Michael, in Alaska. The existence of land of such extent as is indicated at once suggests an interruption in the polar circulation, goes far to account for the habitually ice-bound condition of the Kara Sea to the south-west, and of the waters off Cape Chelyuskin itself (which must apparently be separated from the new land by a strait only some forty miles wide), and may be taken to bear upon the distinct northerly trend of the drift of Nansen's ship, the *Fram*, which appears in the charts between lats. 110° and 90° E. If the new land really terminates in 81° N., it may be added that the *Fram* easily missed it, being fully three degrees more northerly.

Mr. Truman H. Aldrich, of Birmingham, Alabama, has presented his entire collection of recent shells, about 20,000 named species, to the museum of the Geological Survey of Alabama. The series includes not only Mr. Aldrich's gatherings and the results of exchanges during more than fifty years, but several large private accumulations which were purchased entire, notably the Pike Mauritius series, the Jones Bermuda and Nova Scotia shells, and the Parker cabinet of about 5500 listed species. The Aldrich collection is particularly rich in operculate land shells and includes many types. About 1500 books, conchological and other scientific works, accompanied the gift. Mr. Aldrich has already proved himself a generous friend of the museum. Three years ago he gave all his duplicate shells, some 250,000, fine specimens; and the very rich set of Tertiary invertebrate fossils is largely due to him. His cabinet set of these fossils, one of the finest in the world, was acquired by the Johns Hopkins University of Baltimore.

A striking and impressive instance of the benefits conferred upon the human race by developments of modern science was provided by the occurrences in connection with the disastrous fire which destroyed the British steamship *Volturno* in mid-Atlantic last week during a heavy gale. The passengers and crew numbered 657, and it is known that 521 have been saved. All the survivors on board the ship when the vessels arrived which responded to the *Volturno's* wireless telegraphic call for help were saved. The Cunard liner *Carmania* received the first news of the fire, and immediately use was made of her wireless installation to send the cry for help far and wide, with the result that ten steamships were able to render aid. The 521 survivors thus owe their lives primarily to wireless telegraphy. Among the rescuing vessels was an oil-tank steamer, the *Narragansett*, which by discharging two large streams of oil, moderated the troubled waters and assisted in the work of rescue by enabling small boats to approach the burning vessel with less danger. A passenger on board the *Carmania* says, in *The Daily Mail*, that within five minutes after the commencement of the discharge of the oil, the sea for a hundred yards away from the *Narragansett* and towards the *Volturno* became absolutely calm, apart from a slight roll.

The death is announced, in his seventy-eighth year, of a distinguished American astronomer, Rear-Admiral John R. Eastman. In his boyhood he lived on a farm in New Hampshire, and attended only a public elementary school, afterward supporting himself by teaching until he entered Dartmouth College, where he graduated in 1862. After serving for a few years as an assistant at the U.S. Naval Observatory, he was appointed in 1865 professor of mathematics in the U.S. Navy. He retired in 1898 with the rank of captain, and was promoted in 1906 to that of rear-admiral. He was engaged for many years in astronomical observation and research, the bulk of his published work appearing in the annual volumes of the Government Observatory. He prepared and edited the Second Washington Star Catalogue, containing the results of nearly 80,000 observations at the Naval Observatory. He was the author of "Transit Circle Observations of the Sun, Moon, Planets, and Comets," published in 1903. Rear-Admiral Eastman was the first president of the Washington Academy of Sciences.

The death is announced of Sir John Batty Tuke, formerly M.P. for Edinburgh and St. Andrews Universities, at seventy-eight years of age. From an obituary notice in Tuesday's *Times* we learn that Sir John Tuke was educated at Edinburgh Academy and University. On taking the degree of M.D. he went out to New Zealand, where he was civil practitioner in medical charge of a wing of the 65th Regiment. On returning to Scotland in 1863 he began practice in Edinburgh. For some time he was assistant physician at the Royal Edinburgh Lunatic Asylum, and in 1867 was appointed medical superintendent of the Fife and Kinross District Lunatic Asylum. He returned to Edinburgh in 1873, and was associated with the late Dr. Smith and Dr. Lowe in the management of Saughton Hall Asylum, which he continued to direct until a few years ago. He was president of the Medico-Chirurgical Society and of the Neurological Society of the United Kingdom. He held the honorary degrees of D.Sc. (Dublin), LL.D. (Edinburgh), and LL.D. (St. Andrews). In 1895 Tuke was elected president of the Royal College of Physicians, Edinburgh, and in 1898, his last year of office, received the honour of knighthood. Two years later he succeeded the late Sir William Priestley as member of Parliament for Edinburgh and St. Andrews Universities. He retired from Parliament in 1910, and was succeeded by Sir Robert B. Finlay. Sir

John Batty Tuke will long be remembered as a great authority on the care and treatment of the insane. He gave himself to work hard at the problems which these cases present; and he deserved, and attained, a very high place in his profession, not only by his practice, but by his writings.

The Right Hon. James Stuart, formerly professor of mechanism and applied mechanics in the University of Cambridge, died on Sunday, October 12, in his seventy-first year. Mr. Stuart's early education was partly private and partly at the Madras College, St. Andrews. Thence he proceeded to the University of that city, where he graduated in 1861, and in the following year he won a minor scholarship at Trinity College, Cambridge. In 1864 he was elected to a foundation scholarship at Trinity, where in 1866 he graduated as Third Wrangler. He was elected a fellow of his college in 1867. The University Extension movement sprang from Mr. Stuart's interest in the education of women. He undertook in 1867 to deliver a course of lectures on astronomy to women teachers. The result was a number of invitations to lecture to working-men. By 1871 he had worked out a scheme of extension lectures, and the University of Cambridge was induced to give definite shape to his proposals. To-day something like a thousand courses of lectures are organised annually, and more than a hundred thousand persons benefit by the teaching. In 1875 Stuart was elected the first professor of mechanism and applied mechanics at Cambridge, and was chosen a member of the University Council. During the next ten years his energies were largely devoted to the founding of the mechanical workshops in which his teaching was carried on, and to the establishment of the mechanical science tripos in the University. Prof. Stuart entered the House of Commons in 1885, and was a member of the London County Council for many years. In 1889 his absorption in party politics in London led him to resign his professorial chair at Cambridge, after a successful tenure of fourteen years. In 1909 he was sworn a member of the Privy Council; and in 1898–1901 he was rector of St. Andrews University.

Mr. Percival Marshall is to be congratulated on the success of the fourth biennial *Model Engineer* Exhibition at the Royal Horticultural Hall. Here are collected together not only models of all kinds of professional make, together with their parts and tools suitable for their construction—good and not unduly expensive—but the work of a large band of amateur workers is exhibited also. No better evidence could be afforded of the stimulus which has been given to latent talent by *The Model Engineer*, now issued weekly, which Mr. Marshall was enterprising enough to found fifteen years ago, and also by the numerous societies and clubs which have come into existence, with this newspaper as a medium of communication. The admirable working drawings of models for which *The Model Engineer* has been so well known have had a valuable educational effect; and whether the immediate stimulus has been the desire to make a kite, a hydroplane, some kind of engine, or a wireless set, for the mere enjoyment of the thing or with the hope of obtaining one of the prizes for model work which the paper or the societies or clubs offer is a small matter, the educative process is carried out on attractive lines, and more serious study is encouraged. It is not possible in the available space to refer to individual exhibits of the amateur class, but reference may be made to the "horophone" or wireless receiving set designed for receiving the time signals from the Eiffel Tower or from Norddeich, mainly with the object of commenting on the fact that Greenwich time, now the time-basis of practically the whole civilised world, is sent out daily by Germany and France to Europe and the North Atlantic, while this country sits idly by accepting for its shipping the invaluable aid given freely by its two neighbours.

In connection with the Fourth International Botanical Congress to be held in London in 1915, a preliminary circular has been issued on behalf of the organising committee. The previous congress, held at Brussels in May, 1910, decided, on the invitation of the Royal Society of London, that the next meeting, in 1915, should be held in London. At a general meeting of British botanists, held in London in March, 1912, an organising committee was elected, and subsequently an executive committee. A number of distinguished patrons of botany were also invited to lend their support to the congress. The organising committee consists of three presidents—Sir David Prain, Prof. F. O. Bower, and Prof. A. C. Seward—the following vice-presidents: Prof. I. Bayley Balfour, Mr. W. Bateson, Dr. F. F. Blackman, Sir Francis Darwin, Prof. H. H. Dixon, Mr. G. C. Druce, Prof. J. B. Farmer, Mr. A. D. Hall, Dr. W. B. Hemsley, Dr. R. Kidston, Prof. F. W. Oliver, Mr. R. L. Praeger, Miss E. Sargant, Dr. D. H. Scott, Mr. A. G. Tansley, Prof. S. H. Vines, and Mr. H. W. Wager; and a list of members which is fully representative of British botany. Sir Frank Crisp is treasurer, Dr. A. B. Rendle general secretary, and Dr. Otto Stapf foreign secretary. The congress will meet from May 22 to May 29, 1915, and its work will include the various branches of botanical science, together with certain matters connected with nomenclature and bibliography left over from the previous meeting. The official language of the congress will be English, but any language may be used in the discussions. Member's subscription is fifteen shillings, and ladies accompanying members may attend the meeting and excursions on payment of ten shillings each. Particulars of meetings, discussions, excursions, &c., will be issued later. As it is estimated that the sum of 1000*l.* will be required to defray the expenses of the congress, the executive committee have decided to raise a fund for the purpose, and an appeal has been issued to British botanists and those interested in the science in Great Britain.

The Hull Municipal Museum, under its curator, Mr. T. Sheppard, continues to increase its collections. Recent additions include a fine bronze palstave lately found at Kirkella, the outfit of a Yorkshire clog-sole maker, a curious ancient wooden nut-cracker representing a human head, Saxon bronze brooches discovered at Hornsea, a fine collection of early jewellery and old firearms, while a large series of ethnographical objects from Nigeria, acquired by Mr. M. S. Cockin, has been deposited. The excellent and well-illustrated progress reports issued by the curator might with advantage be studied by other museum authorities as a means of popularising their collections.

The most important contribution to the October issue of *Man* is a paper by Prof. Flinders Petrie describing a series of the earliest perfect tombs discovered at the great cemetery of Tarkhan, forty miles south of Cairo. Two of them date from the time of King Zet, in the middle of the first dynasty. This series of interments was found absolutely undisturbed, and contained burials of the contracted form, the head lying north, the face east, on the left side, and accompanied by some small pottery and gazelle bones. In the tomb walls are two slits, through which it was believed that the food offerings reached the dead. Some 600 skeletons have been unearthed, those of the females being homogeneous, while the males fall into two groups, indicating that from prehistoric times there had been a slow intermixture of the dynastic race with the indigenous peoples.

Since 1911 the Cambrian Archæological Society has been engaged on the excavation of a Roman fortress in Mid Wales—Castell Collen, "the fortress of the hazel trees," close to Llandrindrod Wells. So far, a granary, the principia or headquarters building, and the house of the commandant have been unearthed. The place, from the evidence of coins and pottery, seems to have been occupied from the end of the first century to the close of the third century A.D. Among the discoveries are a bronze scabbard-scape of late Celtic work, a dolphin-shaped scabbard attachment of bronze, a silver ring with the motto "Amor Dvlcis," and an intaglio with a Roman horseman riding down a barbarian. Much work remains to be done, and contributions are invited by Mr. C. Venables Llewelyn, Llysdinain Hall, Newbridge-on-Wye.

The first report of the Eugenics Record Office of Cold Spring Harbour, Long Island, New York, was issued in June last by the superintendent, Mr. H. H. Laughlin. It contains an interesting account of the way in which the work of the office is organised, and of the elaborate card system which has been adopted for indexing the extensive collection of data in process of accumulation. The practical work of the office has three aims: (1) to collect and analyse family records for the purpose of studying heredity; (2) to organise courses for the training of the "field workers" to be employed in the collection of data; (3) to advise concerning the eugenical fitness of proposed marriages. For funds the office is principally indebted to Mrs. E. H. Harriman, but Mr. J. D. Rockefeller has also made generous contributions in providing for the salaries of five "field workers" and for the publication of memoirs and half the cost of the training class.

Major Greig gives an account of the present incidence of enteric or typhoid fever in India in a paper contributed to the All-India Sanitary Conference in Madras, 1912. The disease has greatly declined, as the following figures show:—Average admission per 1000 in 1895–1904, 22·3, in 1910, 4·1; constantly sick per 1000 in 1895–1904, 3·31, in 1910, 0·91; deaths per 1000 in 1895–1904, 5·62, in 1910, 0·62. The factors concerned in this decline are (*a*) segregation of the convalescent enteric patient until he is proved to be free from infection, (*b*) the elimination of the chronic carrier, (*c*) inoculation, (*d*) general sanitary improvement.

The curator's report of the Otago University Museum for 1912 records the definite transfer to the university of the Hocken library—consisting, it may be remembered, of a valuable collection of books, pamphlets, manuscripts, plans, and pictures relating to the history of New Zealand and the Maoris. Some idea of the size of the library may be gleaned from the statement that the printed catalogue of the bound books runs to several volumes.

A discovery of special importance in connection with the problem of the homology of the mammalian auditory ossicles is recorded by Mr. R. W. Palmer, University College, Reading. In dissecting the auditory region of a fœtal Australian bandicoot (Perameles) it was found that the ossicles and cartilages lie freely in a hollow of the thin dentary bone of the lower jaw, and comparison of their position, form, and relations with the corresponding region of the skull in certain Triassic anomodont reptiles renders it practically certain that the mammalian malleus represents the articular bone of the reptilian lower jaw, while the incus of the mammal corresponds to the quadrate of the reptile and the tympanic to the angular element of the jaw. The paper is published in the *Anatomischer Anzeiger*, vol. xliii., p. 512.

We have received from the publishers (Herren R. Friedländer und Sohn, Berlin) five parts, 34–38, of "Das Tierreich," edited by Dr. F. E. Schulze. These parts deal respectively with the butterflies of the family Amathusiidæ, the rhabdocelid turbellarian worms, the pteropod molluscs, the cæcilian amphibians, and the molluscs of the group Solenogastres; and the mere fact that the second of these (No. 35) comprises no fewer than 484 pages of text, coupled with the large number of parts already issued, gives some indication of the voluminous nature of the work. To how many parts it is expected to run we have no clue, but it may be mentioned that mammals and fishes are not touched in any of those already issued. Each part being separately paged, the entire work can be arranged in such order as may be best suited to the needs of individual students. So far as we can judge, the parts before us, which, like the rest, are by specialists in their respective subjects, maintain the high standard of their predecessors. As might have been expected in a work by different authors, the style of treatment is by no means uniform; the diagnoses of the species and groups being in some instances models of conciseness, while in others they tend to undue prolixity. The attention of "zoological recorders" may be directed to the fact that a new generic name is proposed on p. 17 of the part on Solenogastres, which may be an indication that others occur elsewhere in this invaluable work.

The report of the Meteorological Committee for the year ended March 31 differs from its predecessors in at least one important respect, viz. the omission of most of the usual appendices. These interesting documents are to be issued subsequently. The detailed reports of the work of the several divisions of the office, based to some extent upon such appendices, appear as heretofore. We are pleased to see that H.M. the King has shown his interest in the work by commanding that a copy of the useful daily weather report be regularly addressed to him. At the request of the Treasury, the committee is negotiating with the Scottish Meteorological Society with the object, *inter alia*, of securing closer cooperation with this body in respect of the supply of meteorological information to the public. It is stated that the committee has been much interested in a proposal for the more general use of the centimetre-gramme-second system of units in meteorological publications, and, for reasons given, they have decided to use the centibar or millibar instead of the inch, as far as possible, for all barometric measurements. Specimens of the daily and weekly weather reports are given with isobars shown for centibars (100=29·52 in.), and temperatures shown on the absolute temperature scale (273° A.=32° F.). Another important change refers to the modification of the code of signals hitherto used for storm warnings. All classes of weather forecasts issued during the year 1912 were very successful; many valuable wireless reports were received from H.M. ships, and a very large number from Atlantic liners, but only about one-twentieth of the latter reached the office in time to be included in "to-day's" map in the daily weather report, although nearly half of them could be utilised in one of the two smaller maps for "yesterday" shown in that report.

On October 3, Sir Joseph Thomson formally opened the new works of Messrs. W. G. Pye and Co. at Chesterton, near Cambridge, and in the course of his speech gave an account of his own connection with the establishment of Cambridge as an instrument-making centre. A laboratory in which any considerable amount of physical research is carried out requires an instrument maker of its own, and twenty-two years ago Sir Joseph appointed Mr. Pye to the post at the Cavendish laboratory. Under his management the laboratory workshops were greatly improved, and many exceedingly effective instruments turned out. In the meantime, a small business started by Mr. Pye developed and soon demanded his whole attention. This led to his resignation of the laboratory post eleven years ago. Since that time the business has grown so rapidly as to necessitate removal to a site admitting of further extensions in the future.

In the *Verhandlungen* of the German Physical Society for September 15, Drs. Gehlhoff and Neumeier, of the Danzig-Langfuhr Technical School, give the results of their measurements of the thermal and electrical properties of a series of alloys of bismuth and antimony at temperatures between −190° and 100° C. The principal results relate to the thermal and electrical conductivities which were determined by a modification of the method used by Lees. They show that the quotient of the thermal by the electrical conductivity and by the absolute temperature is not a constant as it should be according to the electronic theories of conduction, by decreases by 40 to 70 per cent. as the temperature rises from −190° to 100° C. The authors point out that this behaviour is analogous to that found by Lees for steel, nickel, and several alloys, and that it confirms the belief that the conduction of heat in many metallic conductors cannot be satisfactorily explained by the motion of free electrons.

Hitherto the laws of thermodynamics have been applied to gases, and also to investigations of the radiation pressure in a black body-cavity, but little has been done to combine gaseous pressure and radiation pressure in a single investigation. In the Bulletin of the Cracow Academy for May, Mr. T. Bialobjeski works out the conditions of equilibrium of a self-gravitating spherical mass of gas when radiation pressure is taken into account. The solution is essentially mathematical, namely, a deduction of conclusions from previously stated hypothesis; thus, to simplify matters, the author assumes the ordinary formulæ for a perfect gas and Stefan's formula for radiation pressure. The investigation has an important application to astrophysics, as it is shown that the equilibrium of the sun and stars may be affected by radiation pressure in a marked degree.

The revised London County Council reinforced concrete regulations governing the erection of reinforced concrete buildings in the London area have been amended by the Local Government Board, and have been submitted to the professional societies for further revision. These regulations have been the subject of much criticism, and additional comment on them is made by Mr. E. S. Andrews in *The Engineer* for October 3. Mr. Andrews points out that, to render the regulations reasonable and to remove some of the absurdities which arise in their application in some instances, further amendment is required, especially in questions of working stresses and modular ratios. The clauses governing these values penalise rich mixtures of concrete in the case of all rectangular beams, and also in many cases of beams of **T** section. The decrease in modular ratio suggested by the Local Government Board is reasonable, but the working stresses in the concrete do not increase for the richer mixtures in anything like the same ratio as obtains in actual experiment. Applied to columns, the regulations as to working stresses do not lead to obviously absurd results, but they do have the effect of discouraging the use of richer mixtures.

Messrs. George Routledge and Sons, Ltd., have in the press, and will shortly publish, "A Handbook of Photomicrography," by H. Lloyd Hind and W. Brough Randles. The new work will contain an account of the modern methods employed in photomicrography, with a description of the apparatus and processes, treated both from a microscopic and photographic point of view.

OUR ASTRONOMICAL COLUMN.

BRILLIANT METEOR OF OCTOBER 7.—A very fine meteor, which illuminated the heavens like a flash of lightning, was observed at various places in the west of England on October 7 at 10.35 p.m. It was seen by Mr. F. T. Naish at Bishopston, Bristol, and he recorded the position of the streak, which endured for nearly half a minute, as from $337^{\circ}+8^{\circ}$ to $327^{\circ}-2^{\circ}$. As observed by Miss Eleonora Armitage at Swainswick, near Bath, the meteor is described as coming rapidly from overhead and disappearing in Aquila. It left a luminous trail about 10° long, lasting for a few seconds.

Mr. F. C. Carey, of H.M.S. *Illustrious*, Devonport, noticed a lightning-like flash, and on looking upwards saw in due east, altitude 60°, a luminous train which was brighter in the upper portion and remained visible for several seconds.

The meteor was also visible from Keynsham, near Bristol, and by several other observers at Bristol.

From the data collected by Mr. Denning, he finds that the meteor had a probable radiant in Gemini, and that its height was from about seventy-four to fifty-two miles. The position of the flight was from over Wiltshire to the English Channel, about ten miles east of Paignton, Devonshire. Further observations are needed of a more exact character to determine its real path accurately. The meteor was a very swift one of the Leonid type, and it appeared on a very unsettled, showery evening, when, unfortunately, the sky was cloudy at many places.

COMETARY OBSERVATIONS IN 1909 TO 1912.—The principal contents of No. 12 of the *Mitteilungen der Hamburger Sternwarte* relate to the observations made of comets which appeared in the interval included in the years 1909 to 1912. The observations there recorded are both visual and photographic, the former being made with an equatorial of 256 mm. aperture and 3·02 m. focal length, and the latter with a 158 mm. Petzval objective of 760 mm. focal length, and a 5-in. Cooke triplet of 600 mm. focal length. Dr. K. Graff gives an account of the physical observations made with the large equatorial, and accompanies his remarks with an excellent series of drawings of the detailed structures in the heads of the various comets observed. Prof. A. Schwassmann limits his account to Brooks's comet (1911*c*), and describes in detail the chief points which are noticeable on the fine series of photographs which accompany the text. This publication also includes the observations made for the determinations of the positions of the comets and numerous minor planets, all made with the large equatorial by the observers, Dr. K. F. Bottlinger, Dr. K. Graff, and Herr H. Thiele.

NORMAL SYSTEM OF WAVE-LENGTHS IN THE SPECTRUM OF THE IRON ARC.—In this column for October 2 reference was made under the heading "The Wave-lengths of Certain Iron Lines" to the work of Dr. F. Goos. The current number of *The Astrophysical Journal* (vol. xxxviii., No. 2, p. 141) contains a further contribution by him towards "the establishment of a normal system of wave-lengths in the arc spectrum of iron." The main object of the communication is to show that it is not sufficient to prescribe a current of 5 to 10 amperes for the arc, as was adopted by the International Solar Union, but that it is absolutely necessary to define the manner of burning and the part of the arc used. Dr. Goos recommends the following procedure, based on many experiments:—

For the normal spectrum of iron he proposes an arc 5 mm. long (separation of the rounded ends from each other) between iron rods 6 mm. in diameter and with a current of 4 amperes. It should be used on a 220-volt circuit; the potential difference at the arc then falls to between 45 and 49 volts. It should be used with a pole changer, and the arc so projected on the slit of the spectrograph with the condensing lens that only a portion of the arc at the middle is used extending 1·5 mm. vertically at most. In order to show the importance of specifying exactly the arc conditions to be used, he directs attention to the difference in the values of the three observers of the normals of the second order. Thus he compares the wave-lengths of the iron arc as published by Kayser and himself with the measurements of St. John and Ware. He also includes measurements of the widths of some selected iron lines. The main cause of all the differences is due to pressure changes, and the whole investigation shows that the iron arc is far from homogeneous. Dr. Goos finally questions whether the measurements of the normals of the third order form a really homogeneous system, and he proposes that an entirely new series of observations should be made with more uniform light-sources.

MICROSCOPICAL EXAMINATION OF SKIN AND LEATHER.

IN the May number of the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, M. Georges Abt, of the Pasteur Institute, contributes an interesting and valuable paper on the microscopical examination of skin and leather, with special reference to salt stains and their effect.

The author first describes in detail the methods used for cutting and staining sections of skin. These are the general methods familiar to microscopists, but are varied slightly in order to differentiate the important histological elements of the skin for the particular purpose in view. The author endeavours to classify the different changes taking place in the skin during the various processes of manufacture into leather, and even goes so far as to suggest that the microscopical examination of the skin or hide in the various stages might be used to control the various processes.

In connection with his special investigation, the effect of salt stains, the author has prepared sections of the grain, flesh, and interior of the raw skin, the pelt, and of the finished leather, showing the characteristics of salt stains and their effect.

The work is supplementary, and supports the hypothesis deduced by the same writer from a chemical investigation of these stains ("Collegium," 1912, pp. 388–408). M. Abt differentiates between two types of salt stains. Stains of the first class are distinguished by the presence of calcium phosphate in places where grains of calcium sulphate have been deposited from the salt. In the section through these stains the nuclei of the connective tissue are very prominent. The author has proved them to contain iron and excess of tannin in the sections of stained leather. He assumes that these nuclei have been protected from the destructive action of micro-organisms in the preliminary processes by an envelope of an organic iron salt and of iron and calcium phosphate, and he goes on to show that as the salt stain progresses the nuclei ultimately disappear, the connective tissues being disintegrated, but not completely decomposed, as they would be by the action of bacteria, as claimed by Becker.

The second kind of stain investigated only applied to horse hides and to leather made therefrom. These are characterised by the presence of strongly pigmented epithelial tissues and the complete absence of calcium phosphate. The writer assum s, therefore, that these special stains proceed from the brown pigment in the cells of the Malpighi layer and internal epithelial hair sheath in the original skin. This pigment becomes fixed by mineral matter so that decomposition in the limes is resisted.

The author finds that the common factor in the stains examined is the presence of traces of iron. The persistence of the connective elements, especially the nuclei and epithelial tissues, is proved, and the very slight changes that take place in the connective tissue lead the writer to conclude that bacteria play a very small part in the production of the stains he examined.

In this paper M. Abt, for the stains he has examined, takes up practically the opposite view to that enunciated by Becker, who claims that many of the salt stains are largely caused by bacterial action.

The experiments carried out by M. Abt have been carefully performed, and the hypothesis he draws from the results obtained on the stains he has examined appear to be conclusive. The paper is extremely well illustrated by coloured photographs of prepared sections of normal and salt-stained skin and leather which are very clear, and are much more defined than the illustrations usually given in this type of work; in fact, these microphotographs are from magnificent sections, and are beautifully reproduced in the article. They are the finest reproductions of the structure of the hide and skin that have been published in recent times.

M. Abt's work on this subject is of great importance to leather technologists, and, while the author does not claim to have solved all the various kinds of salt stains, he has certainly solved a portion of the difficult problem, and appears to have definitely proved that what the tanner and leather-dresser call salt stains may originate from more than one cause, and may under different conditions vary in appearance and effect upon the skin.

The paper shows that M. Abt has carried out a very careful and systematic investigation, and it is a most valuable contribution to the elucidation of this problem, but in spite of this the subject is still by no means exhausted, and we venture to hope that M. Abt will investigate some other forms of salt stains which he has not yet dealt with. Although the author has undoubtedly clearly proved the cause, traced the history, and shown the effect of certain forms of salt stains, he has not yet described any practical method of avoiding this economic waste which is so vital to the tanners of calf and other similar leathers, but the paper brings us one step nearer this goal.

J. G. P.

THE BRITISH ASSOCIATION AT BIRMINGHAM.

SECTION H.

ANTHROPOLOGY.

Opening Address by Sir Richard C. Temple, Bart., C.I.E., President of the Section.

Administrative Value of Anthropology.

The title of the body of which those present at this meeting form a section is, as all my hearers will know, the British Association for the Advancement of Science, and it seems to me therefore that the primary duty of a sectional President is to do what in him lies, for the time being, to forward the work of his section. This may be done in more than one way: by a survey of the work done up to date and an appreciation of its existing position and future prospects, by an address directly forwarding it in some particular point or aspect, by considering its applicability to what is called the practical side of human life. The choice of method seems to me to depend on the circumstances of each meeting, and I am about to choose the last of those above mentioned, and to confine my address to a consideration of the administrative value of anthropology because the locality in which we are met together and the spirit of the present moment seem to indicate that I shall best serve the interests of the anthropological section of the British Association by a dissertation on the importance of this particular science to those who are or may hereafter be called upon to administer the public affairs of the lands in which they may reside.

I have to approach the practical aspect of the general subject of anthropology under the difficulty of finding myself once more riding an old hobby, and being consequently confronted with views and remarks already expressed in much detail. But I am not greatly disturbed by this fact, as experience teaches that the most effective way of impressing ideas, in which one believes, on one's fellow man is to miss no opportunity of putting them forward, even at the risk of repeating what may not yet have been forgotten. And as I am convinced that the teachings of anthropologists are of practical value to those engaged in guiding the administration of their own or another country, I am prepared to take that risk.

Anthropology is, of course, in its baldest sense the study of mankind in all its possible ramifications, a subject far too wide for any one science to cover, and therefore the real point for consideration on such an occasion as this is not so much what the students of mankind and its environments might study if they chose, but what the scope of their studies now actually is, and whither it is tending. I propose, therefore, to discuss the subject in this limited sense.

What, then, is the anthropology of to-day that claims to be of practical value to the administrator? In what directions has it developed?

Perhaps the best answer to these questions is to be procured from our own volume of "Notes and Queries on Anthropology," a volume published under the arrangements of the Royal Anthropological Institute for the British Association. This volume of "Notes and Queries" has been before the public for about forty years, and is now in the fourth edition, which shows a great advance on its predecessors and conforms to the stage of development to which the science has reached up to the present time.

The object of the "Notes and Queries" is stated to be "to promote accurate anthropological observation on the part of travellers including all local observers) and to enable those who are not anthropologists themselves to supply information which is wanted for the scientific study of anthropology at home." So, in the heads under which the subject is considered in this book, we have exhibited to us the entire scope of the science as it now exists. These heads are (1) physical anthropology, (2) technology, (3) sociology, (4) arts and sciences. It is usual, however, nowadays to divide the subject into two main divisions—physical and cultural anthropology.

Physical anthropology aims at obtaining "as exact a record as possible of the structure and functions of the human body, with a view to determining how far these are dependent on inherited and racial factors, and how far they vary with environment." This record is based on two separate classes of physical observation: firstly on descriptive characters, such as types of hair, colour of the eyes and skin, and so on, and actual measurement; and secondly on attitudes, movements, and customary actions. By the combined study of observations on these points physical heredity is ascertained, and a fair attribution of the race or races to which individuals or groups belong can be arrived at.

But anthropology, as now studied, goes very much further than inquiry into the physical structure of the human races. Man, "unlike other animals, habitually reinforces and enhances his natural qualities and force by artificial means." He does, or gets done for him, all sorts of things to his body to improve its capacities or appearance, or to protect it. He thus supplies himself with sanitary appliances and surroundings, with bodily ornamentation and ornaments, with protective clothing, with habitations and furniture, with protection against climate and enemies, with works for the supply of water and fire, with food and drink, drugs and medicine. And for these purposes he hunts, fishes, domesticates animals, and tills the soil, and provides himself with implements for all these, and also for defence and offence, and for the transport of goods, involving working in wood, earth, stones, bones, shells, metals and other hard materials, and in leather, strings, nets, basketry, matting and weaving, leading him to what are known as textile industries. Some of this work has brought him to mine and quarry, and to employ mechanical aids in the shape of machinery, however rude and simple. The transport of himself and his belongings by land and water has led him to a separate set of industries and habits: to the use of paths, roads, bridges, and halting places, of trailers, sledges, and wheeled vehicles; to the use of rafts, floats, canoes, coracles, boats, and ships, and the means of propelling them, poles, paddles, oars, sails, and rigging. The whole of these subjects is grouped by anthropologists under the term technology, which thus becomes a very wide subject, covering all the means by which a people supplies itself with the necessaries of its mode of livelihood.

In order to carry on successfully what may be termed the necessary industries or even to be in a position to cope with them, bodies of men have to act in concert, and this forces mankind to be gregarious, a condition of life that involves the creation of social relations. To understand, therefore, any group of mankind, it is essential to study sociology side by side with technology. The subjects for inquiry here are the observances at crucial points in the life-history of the individual—birth, puberty, marriage, death, daily life, nomenclature, and so on; the social organisation and the relationship of individuals. On these follow the economics of the social group, pastoral, agricultural, industrial, and commercial, together with conceptions as to property and inheritance (including slavery), as to government, law and order, politics and morals; and finally the ideas as to war and the external relations between communities.

We are still, however, very far from being able to understand in all their fulness of development even the crudest of human communities without a further inquiry into the products of their purely mental activities, which in the "Notes and Queries" are grouped under the term "Arts and Sciences." Under this head are to be examined, in the first place, the expression of the emotions to the eye by physical movements and conditions, and then by gestures, signs and signals, before we come to language, which is primarily expressed by the voice to the ear, and secondarily to the eye in a more elaborate form by the graphic arts—pictures, marks and writing. Man further tries to express his emotions by what are known as the fine arts; that is by modifying the material articles which he contrives for his livelihood in a manner that makes them represent to him something beyond their economic use—makes them pleasant, representative or symbolical—leading him on to draw, paint, enamel, engrave, carve and mould. In purely mental efforts this striving to satisfy the artistic or æsthetic sense takes the form of stories, proverbs, riddles, songs, and music. Dancing, drama, games, tricks and amusements are other manifestations of the same effort, combining in these cases the movements of the body with those of the mind in expressing the emotions.

The mental processes necessary for the expression of his emotions have induced man to extend his powers of mind in directions now included in the term "abstract reasoning." This has led him to express the results of his reasoning by such terms as reckoning and measurement, and to fix standards for comparison in such immaterial but all essential matters as enumeration, distance, surface, capacity, weight, time, value, and exchange. These last enable him to reach the idea of money, which is the measurement of value by means of tokens, and represents perhaps the highest economic development of the reasoning powers common to nearly all mankind.

The mental capacities of man have so far been considered only in relation to the expression of the emotions and of the results of abstract reasoning; but they have served him also to develop other results and expressions equally important, which have arisen out of observation of his surroundings, and have given birth to the natural sciences: astronomy, meteorology, geography, topography, and natural history. And further they have enabled him to memorise all these things by means of records, which in their highest form have brought about what is known to all of us as history, the bugbear of impulsive and shallow thinkers, but the very backbone of all solid opinion.

The last and most complex development of the mental processes, dependent upon all the others according to the degree to which they themselves have been developed in any given variety of mankind, is, and has always been, present in every race or group on record from the remotest to the most recent time in some form or other and in a high degree. Groups of men observe the phenomena exhibited by themselves or their environment, and account for them according to their mental capacity as modified by their heredity. Man's bare abstract reasoning, following on his observation of such phenomena, is his philosophy, but his inherited emotions influence his reasoning to an almost controlling extent and induce his religion, which is thus his philosophy or explanation of natural phenomena as effected by his hereditary emotions, producing that most wonderful of all human phenomena, his belief. In the conditions, belief, faith, and religion must and do vary with race, period, and environment.

Consequent on the belief, present or past of any given variety of mankind, there follow religious practices (customs as they are usually called) based thereon, and described commonly in terms that are familiar to all, but are nevertheless by no means even yet clearly defined: theology, heathenism, fetishism, animism, totemism, magic, superstition, with soul, ghost, and spirit, and so on, as regards mental concepts; worship, ritual, prayer, sanctity, sacrifice, taboo, &c., as regards custom and practice.

Thus have the anthropologists, as I understand them, shown that they desire to answer the question as to what their science is, and to explain the main points in the subject of which they strive to obtain and impart accurate knowledge based on scientific inquiry: that is, on an inquiry methodically conducted on lines which experience has shown them will lead to the minimum of error in observation and record.

I trust I have been clear in my explanation of the anthropologists' case, though in the time at my disposal I have been unable to do more than indicate the subjects they study, and have been obliged to exercise restraint and to employ condensation of statement to the utmost extent that even a long experience in exposition enables one to achieve. Briefly, the science of anthropology aims at such a presentation and explanation of the physical and mental facts about any given species or even group of mankind as may correctly instruct those to whom the acquisition of such knowledge may be of use. In this instance, as in the case of the other sciences, the man of science endeavours to acquire and pass on abstract knowledge, which the man of affairs can confidently apply in the daily business of practical life.

It will have been observed that an accurate presentation of the physical and mental characteristics of any species of mankind which it is desired to study is wholly dependent on accurate inquiry and report. Let no one suppose that such inquiry is a matter of instinct or intuition, or that it can be usefully conducted empirically or without due reference to the experiences of others; in other words, without sufficient preliminary study. So likely indeed are the uneducated in such matters to observe and record facts about human beings inaccurately, or even wrongly, that about a fourth part of the "Notes and Queries" is taken up with showing the inquirer how to proceed, and in exposing the pitfalls into which he may unconsciously fall. The mainspring of error in anthropological observation is that the inquirer is himself the product of heredity and environment. This induces him to read himself, his own unconscious prejudices and inherited outlook on life, into the statements made to him by those who view life from perhaps a totally different and incompatible standpoint. To the extent that the inquirer does this, to that extent are his observations and report likely to be inaccurate and misleading. To avoid error in this respect, previous training and study are essential, and so the "Notes and Queries on Anthropology," a guide compiled in cooperation by persons long familiar with the subject, is as strong and explicit on the point of how to inquire as on that of what to inquire about.

Let me explain that these statements are not intended to be taken as made *ex cathedrâ*, but rather as the outcome of actual experience of mistakes made in the past. Time does not permit me to go far into this point, and I must limit myself to the subject of sociology for my illustration. If a man undertakes to inquire into the social life of a people or tribe as a subject apart, he is committing an error, and his report will almost certainly be misleading. Such an investigator will find that religion and technology are inextricably mixed up with the sociology of any given tribe, that religion intervenes at every point not only of sociology but also of language and technology. In fact, just as in the case of all other scientific research, the phenomenon observable by the anthropologist are not the result of development along any single line alone, but of a progression in a main general direction, as influenced, and it may be even deflected, by contact and environment.

If again the inquirer neglects the simple but essential practice of taking notes, not only fully, but also immediately or as nearly so as practicable, he will find that his memory of facts, even after a short time, has become vague, inexact, and incomplete, which means that reports made from memory are more likely to be useless than to be of any scientific value. If voluntary information or indirect and accidental corrobation are ignored, if questions are asked and answers accepted without discretion, if exceptions are mistaken for rules, then the records of an inquiry may well mislead and thus become worse than useless. If leading or direct questions are put without due caution, and if the answers are recorded without reference to the natives' and not the inquirer's mode of classifying things, crucial errors may easily arise. Thus, in many parts of the world, the term "mother" includes all female relatives of the past or passing generation, and the term "brother" the entire brotherhood. Such expressions as "brother" and "sister" may and do constantly connote relationships which are not recognised at all amongst us. The word "marriage" may include "irrevocable betrothal," and so on; and it is very easy to fall into the trap of the mistranslation of terms of essential import, especially in the use of words expressing religious conceptions. The conception of godhead has for so long been our inheritance that it may be classed almost as instinctive. It is nevertheless still foreign to the instincts of a large portion of mankind.

If also, when working among the uncultured, the inquirer attempts to ascertain abstract ideas, except through concrete instances, he will not succeed in his purpose for want of representative terms. And lastly, if he fails to project himself sufficiently into the minds of the subjects of inquiry, or to respect their prejudices, or to regard seriously what they hold to be sacred, or to keep his countenance while practices are being described which to him may be disgusting or ridiculous—if indeed he fails in any way in communicating to his informants, who are often super-sensitively suspicious in such matters, the fact that his sympathy is not feigned—he will also fail in obtaining the anthropological knowledge he is seeking. In the words of the "Notes and Queries" on this point, "Nothing is easier than to do anthropological work of a certain sort, but to get to the bottom of native customs and modes of thought, and to record the results of inquiry in such a manner that they carry conviction, is work which can be only carried out properly by careful attention."

The foregoing considerations explain the scope of our studies and the requirements of the preliminary inquiries necessary to give those studies value. The further question is the use to which the results can be put. The point that at once arises here for the immediate purpose is that of the conditions under which the British Empire is administered. We are here met together to talk scientifically, that is, as precisely as we can: and so it is necessary to give a definition to the expression "Imperial Administration," especially as it is constantly used for the government of an empire, whereas in reality it is the government that directs the administration. In this address I use the term "administration" as the disinterested management of the details of public affairs. This excludes politics from our purview, defining that term as the conduct of the government of a country according to the opinions or in the interests of a particular group or party.

Now in this matter of administration the position of the inhabitants of the British Isles is unique. It falls to their lot to govern, directly or indirectly, the lives of members of nearly every variety of the human race. Themselves Europeans by descent and intimate connection, they have a large direct interest in every other general geographical division of the world and its inhabitants. It is worth while to pause here for a moment to think, and to try and realise, however dimly, something of the task before the people of this country in the government and control of what are known as the subject races.

For this purpose it is necessary to throw our glance over the physical extent of the British Empire. In the first place, there are the ten self-governing components of the Dominion of Canada and that of Newfoundland in North America, the six colonial States in the Commonwealth of Australia, with the Dominion of New Zealand in Australasia, and the four divisions of the Union of South Africa. All these may be looked upon as indirectly administered portions of the British Empire. Then there is the mediatised government of Egypt, with its appanage, the directly British administered Sudan, which alone covers about a million square miles of territory in thirteen provinces, in northern Africa. These two areas occupy, as it were, a position between the self-governing and the directly-governed areas. Of these, there are in Europe Malta and Gibraltar, Cyprus being officially included in Asia. In Asia itself is the mighty Indian Empire, which includes Aden and the Arabian coast on the west and Burma on the east, and many islands in the intervening seas, with its fifteen provinces and some twenty categories of native states "in subordinate alliance," that is, under general Imperial control. To these are added Ceylon, the Straits Settlements, and the Malay States, federated or other, North Borneo and Sarawak, and in the China Seas Hong Kong and Wei-hai-wei. In South Africa we find Basutoland, Bechuanaland, and Rhodesia; in British West Africa, Gambia, the Gold Coast, Sierra Leone, and Nigeria; in eastern and Central Africa, Somaliland, the East Africa Protectorate, Uganda, Zanzibar, and Nyassaland; while attached to Africa are the Mauritius, Seychelles, Ascension, and St. Helena. In Central and South America are Honduras and British Guiana, and attached to that continent the Falkland Islands, and also Bermuda and the six colonies of British West Indies. In the Pacific Ocean are Fiji, Papua, and many of the Pacific Islands.

I am afraid that once more during the course of this exposition I have been obliged to resort to a concentration of statement that is almost bewildering. But let that be. If one is to grapple successfully with a large and complex subject, it is necessary to try and keep before the mind, so far as possible, not only its magnitude, but the extent of its complexity. This is the reason for bringing before you, however briefly and generally, the main geographical details of the British Empire. The first point to realise on such a survey is that the mere extent of such an Empire makes the subject of its administration an immensely important one for the British people.

The next point for consideration and realisation is that an empire, situated in so many widely separated parts of the world, must contain within its boundaries groups of every variety of mankind, in such numerical strength as to render it necessary to control them as individual entities. They do not consist of small bodies lost in a general population, and therefore negligible from the administrator's point of view, but of whole races and tribes or of large detachments thereof.

These tribes of mankind profess every variety of religion known. They are Christians, Jews, Mahommedans, Hindus, Buddhists, Jains, Animists, and, to use a very modern expression, Animatists, adherents of main religions followed by an immense variety of sects, governed, however loosely, by every species of philosophy that is or has been in fashion among groups of mankind, and current in every stage of development, from the simplest and most primitive to the most historical and complex. One has to bear in mind that we have within our borders the Andamanese, the Papuan, and the Polynesian, as well as the highly civilised Hindu and Chinese, and that not one of these, nor indeed of many other peoples, has any tradition of philosophy or religion in common with our own; their very instincts of faith and belief following other lines than ours, the prejudices with which their minds are saturated being altogether alien to those with which we ourselves are deeply imbued.

The subjects of the British King-Emperor speak between them most of the languages of the world, and certainly every structural variety of human speech has its example somewhere in the British Empire. A number of these languages is still only in the process of becoming understood by our officials and other residents among their speakers, and let there be no mistake as to the magnitude of the question involved in the point of language alone in British Imperial regions. A man may be what is called a linguist. He may have a working knowledge of the main European languages and of the great Oriental tongues —Arabic, Persian, and Hindustani—which will carry him very far indeed among the people—in a sense, in fact, from London to Calcutta—and then, without leaving that compact portion of the British possessions known as the Indian Empire, with all its immense variety of often incompatible subordinate languages and dialects, he has only to step across the border into Burma and the Further East to find himself in a totally different atmosphere of speech, where not one of the sounds, not one of the forms, not one of the methods, with which he has become familiarised is of any service to him whatever. The same observation will again be forced on him if he transfers himself thence to southern Africa or to the Pacific Ocean. Let him wander amongst the North American Indians and he will find the linguistic climate once more altogether changed.

Greater Britain may be said to exhibit all the many varieties of internal social relations that have been set up by tribes and groups of mankind—all the different forms of family and general social organisation, of reckoning kinship, of inheritance and control of the possession of property, of dealing with the birth of children and their education and training, physical, mental, moral, and professional, in many cases by methods entirely foreign to British ideas and habits. For instance, infanticide as a custom has many different sources of origin.

Our fellow-subjects of the King follow, somewhere or other, all the different notions and habits that have been formed by mankind as to the relations between the sexes, both permanent and temporary, as to marriage and to what have been aptly termed supplementary unions. And finally, their methods of dealing with death and bringing it about, of disposing of the dead and worshipping them, give expression to ideas, which it requires study for an inhabitant of Great Britain to appreciate or understand. I may quote here, as an example, that of all the forms of human head-hunting and other ceremonial murder that have come within my cognisance, either as an administrator or investigator, not one has originated in callousness or cruelty of character. Indeed, from the point of view of the perpetrators, they are invariably resorted to for the temporal or spiritual benefit of themselves or their tribe. In making this remark, I must not be understood as proposing that they should not be put down, wherever that is practicable. I am merely trying now to give an anthropological explanation of human phenomena.

In very many parts of the British Empire, the routine of daily life and the notions that govern it often find no counterparts of any kind in those of the British Isles, in such matters as personal habits and etiquette on occasions of social intercourse. And yet, perhaps, nothing estranges the administrator from his people more than mistakes on these points. It is small matters—such as the mode of salutation, forms of address and politeness, as rules of precedence, hospitality, and decency, as recognition of superstitions, however apparently unreasonable—which largely govern social relations, which no stranger can afford to ignore, and which at the same time cannot be ascertained and observed correctly without due study.

The considerations so far urged to-day have carried us through the points of the nature and scope of the science of anthropology, the mental equipment necessary for the useful pursuit of it, the methods by which it can be successfully studied, the extent and nature of the British Empire, the kind of knowledge of the alien populations within its boundaries required by persons of British origin who would administer the Empire with benefit to the people dwelling in it, and the importance to such persons of acquiring that knowledge.

I now turn to the present situation as to this last point and its possible improvement, though in doing so I have to cover ground that some of those present may think I have already trodden bare. The main proposition here is simple enough. The Empire is governed from the British Isles, and therefore year by year a large number of young men are sent out to its various component parts, and to them must inevitably be entrusted in due course the administrative, commercial, and social control over many alien races. If their relations with the foreign peoples with whom they come in contact are to be successful, they must acquire a working knowledge of the habits, customs, and ideas that govern the conduct of those peoples, and of the conditions in which they pass their lives. All those who succeed find these things out for themselves, and discern that success in administration and commerce is intimately affected by success in social relations, and that that in its turn is dependent on the knowledge they may attain of those with whom they have to deal. They set about learning what they can, but of necessity empirically, trusting to keenness of observation, because such self-tuition is, as it were, a side issue in the immediate and imperative business of their lives. But, as I have already said elsewhere, the man who is obliged to obtain the requisite knowledge empirically, and without any previous training in observation, is heavily handicapped indeed in comparison with him who has already acquired the habit of right observation, and, what is of much more importance, has been put in the way of correctly interpreting his observations in his youth.

To put the proposition in its briefest form: in order to succeed in administration a man must use tact. Tact is the social expression of discernment and insight, qualities born of intuitive anthropological knowledge, and that is what it is necessary to induce in those sent abroad to become eventually the controllers of other kinds of men. What is required, therefore, is that in youth they should have imbibed the anthropological habit, so that as a result of having been taught how to study mankind, they may learn what it is necessary to know of those about them correctly, and in the shortest practicable time. The years of active life now unavoidably wasted in securing this knowledge, often inadequately and incorrectly even in the case of the ablest, can thus be saved, to the incalculable benefit of both the governors and the governed.

The situation has, for some years past, been appreciated by those who have occupied themselves with the science we are assembled here to promote, and several efforts have been made by the Royal Anthropological Institute and the Universities of Oxford, Cambridge, and London, at any rate to bring the public benefits accruing from the establishment of anthropological schools before the Government and the people of this country.

In 1902 the Royal Anthropological Institute sent a deputation to the Government with a view to the establishment of an official Anthropometric Survey of the United Kingdom, in order to test the foundation for fears, then widely expressed, as to the physical deterioration of the population. In 1909 the institute sent a second deputation to the present Government, to urge the need for the official training in anthropology of candidates for the Consular Service and of the Indian and Colonial Civil Services. There is happily every reason to hope that the Public Services Commission may act on the recommendations then made. This year (1913) the institute returned to the charge and approached the Secretary of State for India, with a view to making anthropology an integral feature of the studies of the Oriental Research Institute, to the establishment of which the Government of India had officially proposed to give special attention. The institute has also lately arranged to deal with all questions of scientific import that may come before the newly constituted Bureau of Ethnology at the Royal Colonial Institute, in the hope with its cooperation of eventually establishing a great *desideratum*—an Imperial Bureau of Ethnology. It has further had in hand a scheme for the systematic and thorough distribution of local correspondents throughout the world.

At Oxford, anthropology as a serious study was recognised by the appointment, in 1884, of a reader, who was afterwards given the status of a professor. In 1885, it was admitted as a special subject in the final honours school of natural science. In 1904, a memorandum was drawn up by those interested in the study at the University, advocating a method of systematic training in it, which resulted in the formation of the committee of anthropology in the following year. This committee has established a series of lectures and examinations for a diploma, which can be taken as part of the degree course, but is open to all officers of the public services as well. By these means a school of anthropology has been created at Oxford, which has already registered many students, among whom officers engaged in the administration of the British Colonies in Africa and members of the Indian Civil Service have been included. The whole question has been systematically taken up in all its aspects, the instruction, formal and informal, comprising physical anthropology, psychology, geographical distribution, prehistoric archæology, technology, sociology, and philology.

At Cambridge, in 1893, there was a recognised lecturer in physical anthropology, an informal office now represented by a lecturer in physical anthropology and a reader in ethnology, regularly appointed by the University. In 1904, as a result of an expedition to Torres Straits, a board of anthropological studies was formed, and a diploma in anthropology instituted, to be granted, not for success in examinations, but in recognition of meritorious personal research. At the same time, in order to help students, among whom were included officials of the African and Indian Civil Services, the Board established lectures on the same subjects as those taught at Oxford. This year, 1913, the University has instituted an anthropological tripos for its degrees on lines similar to the others. The distinguishing feature of the Cambridge system is the prominence given to field work, and this is attracting foreign students of all sorts.

In 1909, joint representations were made by a deputation from the Universities of Oxford and Cambridge to both the India and Colonial Offices, advocating the training of Civil Service candidates and probationers in ethnology and primitive religion.

In 1904, the generosity of a private individual established a lectureship in ethnology in connection with the University of London, which has since developed into a professorship of ethnology with a lectureship in physical anthropology. In the same year the same benefactor instituted a chair of sociology. In 1909 the University established a board of anthropology, and the subject is now included in the curricula for the degrees of the University. In and after 1914, anthropology will be a branch of the science honours degree. The degree course of the future covers both physical and cultural anthropology in regard to zoology, palæontology, physiology, psychology, archæology, technology, sociology, linguistics, and ethnology. There will also be courses in ethnology with special attention to field work for officials and missionaries, and it is interesting to note that students of Egyptology are already taking a course of lectures in ethnology and physical anthropology.

Though the universities have thus been definite enough in their action where the authority is vested in them, it is needless to say that their representations to Governments have met with varying success, and so far they have not produced much practical result. But it is as well to note here that a precedent for the preliminary anthropological training of probationers in the Colonial Civil Service has been already set up, as the Government of the Sudan has directed that every candidate for its services shall go through a course of anthropology at Oxford or Cambridge. In addition to this, the Sudan Government has given a grant to enable a competent anthropologist from London to run a small scientific survey of the peoples under its administration. The Assam Government has arranged its ethnographical monographs on the lines of the British Association's "Notes and Queries" with much benefit to itself, and it is believed that the Burma Government will do likewise. The Colonial Office has appointed a lecturer in anthropology for East and West Africa, and the Government of India is distributing copies of the anthropological articles in its Imperial Gazetteer to successful candidates for its civil services.

Speaking in this place to such an audience as that before me, and encouraged by what has already been done elsewhere, I cannot think that I can be mistaken in venturing to recommend the encouragement of the study of anthropology to the University of such a city as Birmingham, which has almost unlimited interests throughout the British Empire. For it should be remembered that anthropological knowledge is as useful to merchants *in partibus* in dealing with aliens as to administrators so situated. Should this suggestion bear fruit, and should it be thought advisable some day to establish a school of anthropology in Birmingham, I would also venture to point out that there are two requirements preliminary to the successful formation of almost any school of study. These are a library and a museum *ad hoc*. At Oxford there is a well-known and well-conducted anthropological museum in the Pitt-Rivers collection, and the museum of archæology and ethnology at Cambridge contains collections of the greatest service to the anthropologist. Liverpool is also interesting itself in such matters. The Royal Anthropological Institute is forming a special library, and both that institute and the University of London have the benefit of the splendid collections of the British Museum and of the Horniman Museum readily accessible. The libraries at Oxford and Cambridge are, I need scarcely say, of world-wide fame. At all these places of learning, then, these requisites for this department of knowledge are forthcoming.

It were almost superfluous to state why they are requisites. Every student requires, not only competent teachers to guide him in his particular branch of study, but also a library and a museum close at hand, where he can find the information he wants and the illustration of it. Where these exist, thither it will be found that students will flock. Birmingham possesses peculiar facilities for the formation of both, as the city has all over the Empire its commercial representatives, who can collect the required museum specimens on the spot. The financial labours also of those who distribute these men over Greater Britain, and indeed all over the world, produce the means to create the library and the school, and their universal interests provide the incentive for securing for those in their employ the best method of acquiring a knowledge of men that can be turned to useful commercial purpose. Beyond these suggestions I will not pursue this point now, except to express a hope that this discourse may lead to a discussion thereon before this meeting breaks up.

Before I quit my subject I would like to be somewhat insistent on the fact that, though I have been dwelling so far exclusively on the business side, as it were, of the study of anthropology, it has a personal side as well. I would like to impress once more on the student, as I have often had occasion to do already, that whether he is studying of his own free will or at the behest of circumstances, there is scarcely any better hobby in existence than this, or one that can be ridden with greater pleasure. It cannot, of course, be mastered in a day. At first the lessons will be a grind. Then, until they are well learnt, they are irksome, but when fullness of knowledge and maturity of judgment are attained, there is, perhaps, no keener sense of satisfaction which human beings can experience than that which is afforded by this study. Its range is so wide, its phases so very many, the interests involved in it so various, that it cannot fail to pleasantly occupy the leisure hours from youth to full manhood, and to be a solace, in some aspect or other, in advanced life and old age.

The processes of discovery in the course of this study are of such interest in themselves that I should wish to give many instances, but I must confine myself now to one or two. The student will find on investigation, for instance, that however childish the reasoning of savages may appear to be on abstract subjects, and however silly some of their customs may seem, they are neither childish nor silly in reality. They are almost always the result of "correct argument from a false premiss"—a mental process not unknown to civilised races. The student will also surely find that savages are not fools where their concrete interests are concerned, as they conceive those interests to be. For example, in commerce, beads do not appeal to savages merely because they are pretty things, except for purposes of adornment. They will only part with articles they value for particular sorts of beads which are to them money, in that they can procure in exchange for them, in their own country, something they much desire. They have no other reason for accepting any kind of bead in payment for goods. On few anthropological points can mistakes be made more readily than on this, and when they are made by merchants, financial disaster can well follow, so that what I have already said elsewhere as to this may bear repetition in part here. Savages in their bargains with civilised man never make one that does not, for reasons of their own, satisfy themselves. Each side, in such a case, views the bargain according to its own interest. On his side, the trader buys something of great value to him, when he has taken it elsewhere, with something of little value to him, which he has brought from elsewhere, and then, and only then, can he make what is to him a magnificent bargain. On the other hand, the savage is more than satisfied, because with what he has got from the trader he can procure from among his own people something he very much covets, which the article he parted with could not have procured for him. Both sides profit by the bargain from their respective points of view, and traders cannot, as a matter of fact, take undue advantage of savages, who, as a body, part with products of little or no value to themselves for others of vital importance, though these last may be of little or none to the civilised trader. The more one dives into recorded bargains, the more clearly one sees the truth of this view.

I have always advocated personal inquiry into the native currency and money, even of pre-British days, of the people amongst whom a Britisher's lot is cast, for the reason that the study of the mental processes that lead up to commercial relations, internal and external, the customs concerned with daily buying and selling, take one more deeply into aliens' habits of mind and their outlook on practical life than any other branch of research. The student will find himself involuntarily acquiring a knowledge of the whole life of a people, even of superstitions and local politics, matters that commercial men, as well as administrators, cannot, if they only knew it, ever afford to ignore. The study has also a great intellectual interest, and neither the man of commerce nor the man of affairs should disregard this side of it if he would attain success in every sense of that term.

Just let me give one instance from personal experience. A few years back a number of ingots of tin, in the form of birds and animals and imitations thereof, hollow tokens of tin ingots, together with a number of rough notes taken on the spot, were handed over to me for investigation and report. They came from the Federated Malay States, and were variously said to have been used as toys and as money in some form. A long and careful investigation unearthed the whole story. They turned out to be surviving specimens of an obsolete and forgotten Malay currency. Bit by bit, by researches into travellers' stories and old records, European and vernacular, it was ascertained that some of the specimens were currency and some money, and that they belonged to two separate series. Their relations to each other were ascertained, and also to the currencies of the European and Oriental nations with whom the Malays of the Peninsula had come in contact. The mint profit in some instances, and in other instances the actual profit European Governments and mercantile authorities, and even native traders, had made in recorded transactions of the past, was found out. The origin of the British, Dutch, and Portuguese money, evolved for trading with the Malays, was disclosed, and several interesting historical discoveries were made; as, for instance, the explanation of the coins still remaining in museums and issued in 1510 by the great Portuguese conqueror, Albuquerque, for the then new Malay possessions of his country, and the meaning of the numismatic plates of the great French traveller Tavernier in the next century. Perhaps the most interesting, and anthropologically the most important, discovery was the relation of the ideas that led up to the animal currency of the Malays to similar ideas in India, Central Asia, China, and Europe itself throughout all historical times. One wonders how many people in these isles grasp the fact that our own monetary scale of 960 farthings to the sovereign, and the native Malay scale of 1,280 cash to the dollar, are representatives of one and the same universal scale, with more than probably one and the same origin out of a simple method of counting seeds, peas, beans, shells, or other small natural constant weights. But the point for the present purpose is that not only will the student find that long practice in anthropological inquiry, and the learning resulting therefrom, will enable him to make similar discoveries, but also that the process of discovery is intensely interesting. Such discoveries, too, are of practical value. In this instance they have taught us much of native habits of thought and views of life in newly acquired possessions which no administrator there, mercantile or governmental, can set aside with safety.

I must not dwell too long on this aspect of my subject, and will only add the following remark. If any of my hearers will go to the Pitt-Rivers Museum at Oxford he will find many small collections recording the historical evolution of various common objects. Among them is a series showing the history of the tobacco pipe, commonly known to literary students in this country as the nargileh and to Orientalists as the hukka. At one end of the series will be found a hollow coconut with an artificial hole in it, and then every step in evolution between that and an elaborate hukka with its long, flexible, drawing-tube at the other end. I give this instance as I contributed the series, and I well remember the eagerness of the hunt in the Indian bazaars and the satisfaction on proving every step in the evolution.

There is one aspect of life where the anthropological instinct would be more than useful, but to which, alas, it cannot be extended in practice. Politics, government, and administration are so interdependent throughout the world that it has always seemed to me to be a pity that the value to himself of following the principles of anthropology cannot be impressed on the average politician of any nationality. I fear it is hopeless to expect it. Were it only possible the extent of the consequent benefit to mankind is at present beyond human forecast, as then the politician could approach his work without that arrogance of ignorance of his fellow-countrymen on all points except their credulity that is the bane of the ordinary types of his kind wherever found, with which they have always poisoned and are still poisoning their minds, mistaking the satisfaction of the immediate temporary interests and prejudices of themselves and comrades for the permanent advantage of the whole people, whom, in consequence, they incontinently misgovern whenever and for so long as their country is so undiscerning as to place them in power.

Permit me, in conclusion, to enforce the main argument of this address by a personal note. It was my fortune to have been partly trained in youth at a university college, where the tendency was to produce men of affairs rather than men of the schools, and only the other day it was my privilege to hear the present master of the college, my own contemporary and fellow-undergraduate, expound the system of training still carried out there. "In the government of young men," he said, "intellect is all very well, but sympathy counts for very much more." Here we have the root principle of applied anthropology. Here we have in a nutshell the full import of its teaching. The sound administration of the affairs of men can only be based on cultured sympathy, that sympathy on sure knowledge, that knowledge on competent study, that study on accurate inquiry, that inquiry on right method, and that method on continuous experience.

SECTION I.

PHYSIOLOGY.

Opening Address by F. Gowland Hopkins, F.R.S., President of the Section.

The Dynamic Side of Biochemistry.

In the year 1837 Justus Liebig, whom we may rightly name the father of modern animal chemistry, presented a report to the Chemical Section of the British Association, then assembled at Liverpool. The technical side of this report dealt with the products of the decomposition of uric acid, with which I am not at the moment concerned, but it concluded with remarks which, to judge from other contemporary writings of Liebig, would have been more emphatic had the nature of his brief communication permitted. Liebig had a profound belief that in the then new science of organic chemistry, biology was to find its greatest aid to progress, and his enthusiastic mind was fretted by the cooler attitude of others. In the report I have mentioned he called upon the chemists of this country to take note of what was in the wind, and while complimenting British physiologists and biologists upon their own work, urged upon them the immediate need of combining with the chemists. Ten years later, Liebig had still to write with reference to chemical studies: "Der Mann welcher in der Thierphysiologie wie Saussure in der Pflanzenphysiologie die ersten und wichtigsten Fragen zur Aufgabe seines Lebens macht, fehlt noch in dieser Wissenschaft" (Ann. Chem. Pharm., lxii., 257, 1847). Much later still, he was still making the same complaint. As a matter of fact, the combination of chemistry with biology, in the full and abundant sense that Liebig's earlier enthusiasm had pictured as so desirable, never happened in any country within the limits of his own century, while in this country, up to the end of that century, it can scarcely be said to have happened at all. But the regrettable divorce between these two aspects of science has been so often dwelt upon that you will feel no wish to hear it treated historically, and perhaps even any emphasis given to it now may seem out of place, since on the Continent, and notably in America, the subject of biochemistry (with its new and not very attractive name) has come with great suddenness into its kingdom. Even in this country the recent successful formation of a Biochemical Society gives sure evidence of a greatly increased interest in this borderland of science. Yet I am going to ask you to listen to some remarks which are a reiteration of Liebig's appeal, as heard by this association three-quarters of a century ago.

For one can, I think, honestly say that it is yet a rare thing in this country to meet a professed biologist, even among those unburdened either with years or traditions, who has taken the trouble so to equip himself in organic chemistry as to understand fully an important fact of metabolism stated in terms of structural formulæ. The newer science of physical chemistry has made a more direct appeal to the biological mind. Its results are expressed in more general terms and the bearing of its applications are perhaps more obvious, especially at the present moment. This fact increases the danger of a further neglect in biology of the organic structural side of chemistry, upon which, nevertheless, the whole modern science of intermediary metabolism depends. On the other hand, I think one may say that there are only a few among the present leaders of chemical thought in our midst who have set themselves to appraise with sympathy the drift of biological processes or the nature of the problems that biologists have before them. Anyone wishing to see the number of biochemical workers increased might therefore with equal justice appeal to the teachers of biology or to the teachers of chemistry for greater sympathy with the borderland. It is a moot point indeed as to which is the better side for that borderland to recruit its workers from.

But on the whole it is easier for the intelligent adult mind to grasp new problems than to learn a new technique. It is better that youth should be spent in acquiring the latter. That is why, though I admit that it would have been more obviously to the point if made some ten years ago, I feel justified in repeating to-day the appeal of Liebig to the leading chemists of this country, in the hope that they may see their way to direct the steps of more of their able students into the path of biochemistry. I have been specially tempted to do this, rather than to speak upon some of many subjects which would have interested this section more, for a very practical reason. I have been in a position to review the current demand of various institutions, home and Colonial, for the services of trained biochemists, and can say, I think with authority, that the demand will rapidly prove to be in excess of the supply. It will be a pity if the generation of trained chemists now growing up in this country should not share in the restoration of this balance. You certainly have the right to tell me that I ought, in the circumstances, to be addressing another section; but it may be long before any member of my cloth will have the opportunity of appealing to that section from the position of advantage that I occupy here. I believe you will forgive the particular trajectory of my remarks, because I am sure you will sympathise with their aim. Moreover, I have some hope that the considerations upon which I shall chiefly base my appeal will have some interest for members of this section as well as for the chemist. My main thesis will be that in the study of the intermediate processes of metabolism we have to deal, not with complex substances which elude ordinary chemical methods, but with simple substances undergoing comprehensible reactions. By simple substances I mean such as are of easily ascertainable structure and of a molecular weight within a range to which the organic chemist is well accustomed. I intend also to emphasise the fact that it is not alone with the separation and identification of products from the animal that our present studies deal; but with their reactions in the body; with the dynamic side of biochemical phenomena.

I have made it my business during the last year or two to learn, by means of indirect and most diplomatic inquiries, the views held by a number of our leading organic chemists with respect to the claims of animal chemistry. I do not find any more the rather pitying patronage for an inferior discipline, and certainly not that actual antagonism, which fretted my own youth; but I do find still very widely spread a distrust of the present methods of the biochemist, a belief that much of the work done by him is amateurish and inexact. What is much more important, and what one should be much more concerned to deny (though but a very small modicum of truth is, or ever was, in the above indictment), is the view that such faults are due to something inherent in the subject.

My desire is to point out that continuous progress, yielding facts which, by whomsoever appraised, belong to exact science, has gone on in the domain of animal chemistry from the days of Liebig until now, and that if this progress was until recently slow, it was, in the main, due to a continuance of the circumstance which so troubled Liebig himself—the shortage of workers.

But we must also remember that the small band of investigators who concerned themselves with the chemistry of the animal in the latter half of the nineteenth century suffered very obviously from the fact that the channels in which chemistry as a whole was fated to progress left high and dry certain regions of the utmost importance to their subject. In three regions particularly the needs of biochemistry were insistent. The colloid state of matter dominates the milieu in which vital processes progress, but, notwithstanding the stimulating work of Graham, the pure chemist of the last century consistently left colloids on one side with a shudder of distaste. Again, we have come to recognise that the insidious influence of catalysts is responsible for all chemical change as it occurs in living matter, but for many years after Berzelius the organic chemist gave to the subject of catalysis very cursory attention, fundamental though it be. Lastly, every physiological chemist has to realise that among his basal needs is that of accurate methods for the estimation of organic substances when they are present in complex mixtures. But the organic chemist of the nineteenth century did not develop the art of analysis on these lines. Of the myriad substances, natural or artificial, known to him at the most a few score could be separated quantitatively from mixtures, or estimated with any accuracy. It was a professional or commercial call rather than scientific need which evolved such processes as were available, so that this side of chemical activity developed only on limited and special lines.

All these circumstances were, of course, inevitable. Organic chemistry in Liebig's later years was concerned with laying its own foundations as a pure science, and for the rest of the century with building a giant, self-contained edifice upon them. The great business of developing the concepts of molecular structure and the wonderful art of synthesis were so absorbing as to leave neither leisure nor inclination for extraneous labours. But it is easy to recognise that, near the beginning of the present century, a sense of satiety had arisen in connection with synthetic studies carried out for their own sake. Workers came to feel that, so far as the fundamental theoretical aspects of chemistry were concerned, that particular side of organic work had played its part. In numerous centres, instead of only in a few, quite other aspects of the science were taken up: in particular, the study of the dynamic side of its phenomena. The historian will come to recognise that a considerable revolution in the chemical mind coincided roughly with the beginning of this century. Among the branches which are fated to benefit by this revolution—it is to be hoped in this country as well as others—is the chemistry of the animal.

But I would like to say that I do not find, on reading the contributions to science of those who, as professed physiological chemists, ploughed lonely furrows in the last century, any justification for the belief that the work done by them was amateurish or inexact; no suggestion that anything inherent in the subject is prone to lead to faults of the kind. Truly these workers had to share ignorance which was universal, and sometimes, compelled by the urgency of certain problems, had perforce to do their best in regions that were dark. But they knew their limitations here as well as their critics did, and relied for their justification upon the application of their results, which was often not understood at all by their critics.

There is little doubt, for instance, that it was the earlier attempts of various workers to fractionate complex colloid mixtures that led to the cynical statement that "*Thierchemie* is *Schmierchemie*." But the work thus done, even such work as Kühne's upon the albumoses and peptones, had important bearings, and led indirectly to the acquirement of facts of great importance to physiology and pathology.

In connection with enzyme catalysis the work done at this time by physiological chemists was in the main of a pioneer character, but it was urgently called for and had most useful applications. By the end of the century, indeed, it had become of great importance. I recall an incident which illustrates the need of suspended judgment before work done in new regions is assumed to be inexact. In 1885 E. Schütz published a study of the hydrolysis of protein by pepsin which showed that the rate of action of the ferment is proportionate to the square root of its concentration. When this paper was dealt with in Maly's "Jahresbericht" the abstractor (who from internal evidence, I believe, was Richard Maly himself) believed so little in such an apparent departure from the laws of mass action that he saw fit to deal with the paper in a ribald spirit, and to add, as a footnote to his abstract, the lines:—

> "Musst mir meine Erde
> Doch lassen steh'n
> Und meine Hütte die du nicht gebaut!"

Yet it is now known that the relation brought to light by Schütz does hold for certain relative concentrations of ferment and substrate. That it had limitations was shown by Schütz himself. The fact, however, involves no such shaking of the foundations as the abstractor thought. We quite understand now how such relations may obtain in enzyme-substrate systems.

As for analytical work involving a separation of complex organic mixtures, the biochemist of the last century was in this ahead of the pure organic chemist, as the development of urinary analysis if considered alone will show.

In countless directions the acquirement of exact knowledge concerning animal chemistry has been, as I have already claimed, continuous from Liebig's days until now. I would like in a brief way to illustrate this, and if I choose for the purpose one aspect of things rather than another, it is because it will help me in a later discussion. I propose to remind you of certain of the steps by which we acquired knowledge concerning the synthetic powers of the animal body, apologising for the great familiarity of many of the facts which I shall put before you.

It seems that the well-known Glasgow chemist and physician, Andrew Ure, was the first actually to prove, from observations made upon a patient, that an increased excretion of hippuric acid follows upon the administration of benzoic acid. Wöhler had earlier fed a dog upon the latter substance, and decided at the time that it was excreted unchanged; but when, later, Liebig had made clear the distinction between the two acids, Wöhler recalled the properties of the substance excreted by his dog, and decided that it must have been hippuric acid and not benzoic acid itself. Excited by the novel idea that a substance thus extraneously introduced might be caught up in the machinery of metabolism, Wöhler, immediately after the publication of Dr. Ure's statement, initiated fresh experiments in his laboratory at Göttingen, where Keller, by observations made upon himself, showed unequivocally that benzoic acid is, and can be on a large scale, converted into hippuric acid in the body. Thus was established a fact which is now among the most familiar, but which at that time stirred the imagination of chemists and physiologists not a little. The discovery immediately led to a large number of observations dealing with various conditions which affect the synthesis, but we may pass to the acute observations of Bertagnini. This investigator wished to earmark, as it were, the benzoic acid administered to the animal, in order to make sure that it was the same molecule which reappeared in combination. He so marked it with a nitro-group, giving nitro-benzoic acid and observing the excretion of nitro-hippuric acid. Later on he continued this interesting line of research by giving other substituted benzoic acids, and showed that in each case a corresponding substituted hippuric acid was formed. Even so far back as the earlier 'fifties a clear understanding was thus established that the body was possessed of a special mechanism capable of bringing a particular class of substances into contact with the amino-acid glycine, and of converting them, by means of a synthetical condensation (which had not then been induced by any laboratory method), into conjugates which, as later experiments have shown, are invariably less noxious for the tissues than the substances introduced. Great is the number of compounds which are now known to suffer this fate. To the story begun by Ure and Wöhler, chapter after chapter has been added continuously up to the present day. In 1876 came the classical experiments of Bunge and Schmiedeberg. After laborious but successful efforts to obtain a good method for the estimation of hippuric acid in animal fluids, these authors proved, by a method of exclusion, that, in the dog at least, the kidney is the seat of the hippuric synthesis. When, in their carefully controlled experiments, blood containing benzoic acid and glycine was circulated through that organ, after its isolation from the body, the production of hippuric acid followed. Schmiedeberg, a little later, convinced himself that the reaction in the kidney was a balanced one; the organ can not only synthesise hippuric acid, it can also hydrolise it. As with reactions elsewhere, so in the kidney cell, the equilibrium of the reaction depends on the relative concentration of the products concerned. Schmiedeberg then separated from the tissues of the kidney what he believed to be an enzyme capable of inducing the hydrolysis. Mutch, with improved methods, has recently shown that a preparation from the kidney, wholly free from intact cells, can, beyond all doubt, hydrolise hippuric acid under rigidly aseptic conditions, the reaction being one which comes to an equilibrium point when some 97 per cent. of the substance is broken down. The occurrence of this equilibrium, and the form of the reaction-velocity curve as obtained by Mutch, suggested that synthesis under the influence of the enzyme was to be expected, and, on submitting the mixture of benzoic acid and glycine to its influence, Mutch obtained a product which, though too small in amount for analysis, was almost certainly hippuric acid. I have myself obtained evidence which shows that the synthesis does certainly occur under these conditions.

The significance of this earliest known synthesis in the body is no limited one. The amide linkage established by it is one with which the body deals widely, and is, of course, of the type which is dominant in tissue complexes, since it is one which unites the amino-acids in the protein molecule.

Seeing, from the nature of the material supplied for the synthesis by the body itself, that the foreign substances administered must intrude themselves into the machinery of protein metabolism, it is not surprising that many have turned their minds to consider how far a detailed study of the phenomena might throw light upon this machinery. How far can the body extend its supply of glycine when stimulated by increasing doses of benzoic acid? What effects follow when administration is pushed to its limits? How is the fate in metabolism of the whole molecule of protein affected when one particular amino-acid is inharmoniously removed? Can the amino-acid be itself synthesised *de novo* in response to the call for it? These and similar questions clearly arise. I can only stop to remind you that there is evidence that, in connection with this particular chemical synthesis, the carnivore reacts differently to the herbivore. If the body of the former be flooded with benzoic acid, only a proportion undergoes condensation. Only so much glycine is supplied as would correspond, roughly, at any rate, with that rendered available by the normal contemporary breakdown of protein, whereas, in the herbivorous animal, pushing the administration of benzoic acid may lead to the excretion of so much conjugated glycine that it may contain more than half of the whole nitrogen excreted. This is, of course, much more than could come from the protein of the body, and it would seem that the amino-acid is prepared *de novo* for an express purpose, a significant thing. But I must not stop to consider questions which are still in course of study. Before the hippuric synthesis was first observed synthetic powers were thought to be absent from the animal. Since then we have been continuously learning of fresh instances of synthesis in the body, not only in connection with its treatment of foreign substances, with which I am just now concerned, but in connection with all its normal processes.

Another most interesting group of syntheses in which substances are so dealt with in the body as to reappear in conjugation with protein derivatives are those in which the sulphur group plays its part. In 1876 Baumann first introduced us to the ethereal sulphates of the urine, and, from much subsequent work, we know how great a group of substances, chiefly those of phenolic character, are, after administration, excreted linked to sulphuric acid. We have evidence to show that, in all probability, the original condensation is not with sulphuric acid itself, but that oxidation of a previously formed sulphur containing conjugate has preceded excretion, and we know that another group of substances leave the body combined with unoxidised sulphur. Certain cyanides—the aliphatic nitriles, for example—reappear as sulphocyanides; but, above all in interest, is the case described by Baumann, in which the intact cystein complex of protein, after suffering acetylation of its amino group, is excreted as a conjugate. The administration of halogen-benzene compounds is followed by the appearance of the so-called mercapturic acids in which the cystein is linked by its sulphur atom to the ring of chlor-, bromo-, or iodi-benzene. That large amounts of these conjugates can be formed during the twenty-four hours is certain, but it would be interesting to know what limit is set to this loss of cystin from the body.

I will now recall to you syntheses in which the substance supplied by the body is derived, not from protein, but from carbohydrate. The study of the fate of camphor in the body, carried out by Schmiedeberg and Hans Meyer in 1878, if it stood by itself, would abundantly illustrate the significance of this type of experiment. As you are aware, these workers proved that, after the administration of camphor, the urine contains a conjugate formed between an oxidation product of the camphor and an oxidation product of glucose. Both substances were then new to chemistry, and the latter—glycuronic acid—has since proved itself of great physiological interest. After Schmiedeberg's and Hans Meyer's experiments it was realised for the first time that the sugar molecule might play a part in metabolism quite distinct from its function as fuel, a fact that has much of cogency at the present time. We have good reason to believe that though, as a matter of fact, glycuronic acid is a normal metabolite, the actual synthesis concerns sugar itself, the oxidation of the glucose molecule occurring later. The compound formed is of the glucoside type, and the analogy with the formation of glucosides in the plant is unmistakable. Already the number of substances known to suffer this particular synthesis is legion. Almost every organic group yields an example.

Lastly, in illustration of a quite different type of synthesis (I can only deal with a few of the many known cases) we may recall the methylation which certain compounds undergo. The mechanism of this process, as it occurs in the body, is obscure, and its explanation would be of the greatest chemical interest. I must mention only one particular instance investigated by Ackermann. When nicotinic acid is fed to animals, it is excreted as trigonellin, a known vegetable base. This conversion involves methylation, and is of striking character as an instance of the artificially induced production of a plant alkaloid in the animal body.

The full significance of all such happenings will not be understood unless it be remembered that a nice adjustment of molecular structure is in many cases necessary to prepare the foreign substance for synthesis. Preliminary regulated oxidations or reductions may occur so as to secure, for example, the production of an alcoholic or phenolic hydroxyl group, which then gives the opportunity for condensation which was otherwise absent.

I have touched only on the fringes of this domain. The body of knowledge available concerning it has not been won systematically, and the fate of a multitude of other types of organic substances remains for investigation. The known facts have, one feels, an academic character in the view of the physiologist, and even in that of the pharmacologist, to whom we owe most of our knowledge about them. But, in my opinion, the chemical response of the tissues to the chemical stimulus of foreign substances of simple constitution is of profound biological significance. Apart from its biological bearings as the simplest type of immunity reaction, it throws vivid light, and its further study must throw fresh light on the potentialities of the tissue laboratories.

In a brilliant address delivered before the faculty of medicine of the University of Leeds, Lord Moulton likened the process of recovery in the tissues after bacterial invasion to the generation of forces which establish what is known to the naval architect as the "righting couple." This grows greater the greater the displacement of a ship, and finally may become sufficient to overpower the forces tending to make her heel over. It is surely striking to realise that the establishment of the "righting couple" which brings the tissue cell back to equilibrium after the disturbances due to the intrusion of simple molecules calls for such a complex of chemical events, events which ultimately result in the modification of the disturbing substance and its extrusion from the tissues concerned in a form less noxious to the body as a whole.

Oxidation, reduction, desaturation, alkylation, acylation, condensation; any or all of these processes may be brought *de novo* into play as the result of the intrusion of a new molecule into reactions which were in dynamic equilibrium. It is clear that chemical systems capable of so responding to what may be termed specific chemical stimuli must not be neglected by any student of chemical dynamics. The physiologist has for many years been engaged upon careful analyses of the mechanical and electric responses to stimulation. In the phenomena before us we find "responses" which are equally fundamental. If we do not study them exhaustively we shall miss an important opportunity for throwing light upon the nature of animal tissues as chemical systems.

One reason which has led the organic chemist to avert his mind from the problems of biochemistry is the obsession that the really significant happenings in the animal body are concerned in the main with substances of such high molecular weight and consequent vagueness of molecular structure as to make their reactions impossible of study by his available and accurate methods. There remains, I find, pretty widely spread, the feeling—due to earlier biological teaching—that, apart from substances which are obviously excreta, all the simpler products which can be found in cells or tissues are as a class mere dejecta, already too remote from the fundamental biochemical events to have much significance. So far from this being the case, recent progress points in the clearest way to the fact that the molecules with which a most important and significant part of the chemical dynamics of living tissues is concerned, are of a comparatively simple character. The synthetic reactions which we have already considered surely prepare us for this view; but it may be felt that, however important, they represent abnormal events, while the study of them has been largely confined to determining the end-products of change. Let me now turn to normal metabolic processes and to intermediary reactions.

We know first of all that the raw material of metabolism is so prepared as to secure that it shall be in the form of substances of small molecular weight; that the chief significance of digestion, indeed, lies in the fact that it protects the body from complexes foreign to itself. Abderhalden has ably summarised the evidence for this and has shown us also that, so far as the known constituents of our dietaries are concerned, the body is able to maintain itself when these are supplied to it wholly broken down into simple *bausteine,* any one of which could be artificially synthesised with the aid of our present knowledge. Dealing especially with the proteins, we have good reason to believe that the individual constituent amino-acids, and not elaborate complexes of these, leave the digestive tract, while Folin, Van Slyke, and Abel have recently supplied us with suggestive evidence for the fact that the individual amino-acids reach the tissues as such and there undergo change.

But still more important, when things are viewed from my present point of view, is the fact that recent work gives clear promise that we shall ultimately be able to follow, on definite chemical lines, the fate in metabolism of each amino-acid individually; to trace each phase in the series of reactions which are concerned in the gradual breakdown and oxidation of its molecule. Apart from the success to which it has already attained, the mere fact that the effort to do this has been made is significant. To those at least who are familiar with the average physiological thought of thirty years ago, it will appear significant enough. So long as there were any remains of the instinctive belief that the carbonic acid and urea which leave the body originate from oxidations occurring wholly in the vague complex of protoplasm, or at least that any intermediate products between the complex and the final excreta could only be looked for in the few substances that accumulate in considerable amount in the tissues (for instance, the creatin of muscle), the idea of seriously trying to trace within the body a series of processes which *begin* with such simple substances as tryosin or leucin was as foreign to thought as was any conception that such processes could be of fundamental importance in metabolism. However vaguely held, such beliefs lasted long after there was justification for them; their belated survival was due, it seems to me, to a certain laziness exhibited by physiological thought when it trenched on matters chemical; they disappeared only when those accustomed to think in terms of molecular structure turned their attention to the subject. But it should be clearly understood that the progress made in these matters could only have come through the work and thought of those who combined with chemical knowledge trained instinct and feeling for biological possibilities. Our present knowledge of the fate of amino-acids, as of that of other substances in the body, has only been arrived at by the combination of many ingenious methods of study.

It is easy in the animal, as in the laboratory, to determine the end-products of change; but, when the end result is reached in stages, it is by no means easy to determine what are the stages, since the intermediate products may elude us. And yet the whole significance of the processes concerned is to be sought in the succession of these stages. In animal experiments directed to the end under consideration, investigators have relied first of all upon the fact that the body, though the seat of a myriad reactions, and capable perhaps of learning, to a limited extent and under stress of circumstances, new chemical accomplishments, is in general able to deal only with what is customary to it. This circumstance has yielded two methods of determining the nature of intermediate products in metabolism. Considerations of molecular structure will, for instance, suggest several possible lines along which a given physiological substance may be expected to undergo change. We may test these possibilities by administering various derivatives of the substance in question. Only those which prove on experiment to be fully metabolised, or to yield derivatives in the body identical with those yielded by the parent substance, can be the normal intermediate products of its metabolism. All others may be rejected as not physiological. In a second method dependent upon this eclecticism of the body, substances are administered which so far differ from the normal that, instead of suffering a complete breakdown, they yield some residual derivative which can be identified in the excreta, and the nature of which will throw light upon the chemical mechanism which has produced it. For instance, a substance with a resistant (because abnormal) ring structure, but possessing a normal side chain, may be used to demonstrate how the side chain breaks down. Again, we may sometimes obtain useful information by administering a normal substance in excessive amounts, when certain intermediate products may appear in the excreta. Another most profitable method of experiment is that in which the substance to be studied is submitted to the influence of isolated organs instead of to that of the whole animal. Under these conditions, a series of normal reactions may go on, but with altered relative velocities, so that intermediate products accumulate; or again when, as may happen, the successive changes wrought upon a substance by metabolism occur in different organs of the body, this use of isolated organs enables us to dissect, as it were, the chain of events. Extraordinarily profitable have been the observations made upon individuals suffering from those errors of metabolism which Dr. Garrod calls "metabolic sports, the chemical analogues of structural malformations." In these individuals, nature has taken the first essential step in an experiment by omitting from their chemical structure a special catalyst which at one point in the procession of metabolic chemical events is essential to its continuance. At this point there is arrest, and intermediate products come to light.

As you know, most ingenious use of this ready-made experimental material has added greatly to our knowledge of intermediate metabolism. Admirable use, too, has been made of the somewhat similar conditions presented by diabetes, clinical and experimental. Every day our knowledge of the dynamics of the body grows upon these lines.

I know that the history of all these efforts is familiar to you, but I am concerned to advertise the fact that our problems call for ingenuity of a special sort, and to point out that an equipment in chemical technique alone would not have sufficed for the successful attack which has been made upon them. But I am even more concerned to point out that the direct method of attack has been too much neglected, or has been in the hands of too few; I mean the endeavour to separate from the tissues further examples of the simpler products of metabolic change, no matter how small the amount in which they may be present; an endeavour which ought not to stop at the separation and identification of such substances, but to continue until it has related each one of them to the dynamic series of reactions in which each one is surely playing a part. The earliest attempts at tracing the intermediate processes of metabolism looked for information to the products which accumulate in the tissues, but it seemed to be always tacitly assumed that only those few which are quantitatively prominent could be of importance to the main issues of metabolism. It is obvious, however, upon consideration, that the degree to which a substance accumulates is by itself no measure of its metabolic importance; no proof as to whether it is on some main line of change, or a stage in a quantitatively unimportant chemical by-path. For, if one substance be changing into another through a series of intermediate products, then, as soon as dynamical equilibrium has been established in the series, and to such equilibrium tissue processes always tend, the rate of production of any one intermediate product must be equal to the rate at which it changes into the next, and so throughout the series. Else individual intermediate products would accumulate or disappear, and the equilibrium be upset. Now the rate of chemical change in a substance is the product of its efficient concentration and the velocity constant of the particular reaction it is undergoing. Thus the relative concentration of each intermediate substance sharing in the dynamic equilibrium, or, in other words, the amount in which we shall find it at any moment in the tissue, will be inversely proportional to the velocity of the reaction which alters it. But the successive velocity constants in a series of reactions may vary greatly, and the relative accumulation of the different intermediate products must vary in the same degree. It is certain that in the tissues very few of such products accumulate in any save very small amount, but the amount of a product found is only really of significance if we are concerned with any function[1] which it may possibly possess. It is of no significance as a measure of the quantitative importance of the dynamical events which give rise to it.

To take an instance. The substance creatin has always asserted itself in our conceptions concerning nitrogenous metabolism because of the large amount in which it is found in the muscle. It may be of importance *per se*, and abnormalities in its fate are certainly important as an indication of abnormalities in metabolism, but we must remember that the work of Gulewitsch, Krimberg, Kutscher, and others has shown us that a great number of nitrogenous basic bodies exist in muscle in minute amounts. Maybe we shall need to know about each of these all that we now know, or are laboriously trying to know, about creatin, before the dynamics of basic nitrogen in muscle become clear. Fortunately for the experimenter, most of the raw materials required for tissue analysis are easily obtainable; there is no reason save that of the labour involved why we should not work upon a ton of muscle or a ton of gland tissue.

I am certain that the search for tissue products of simple constitution has important rewards awaiting it in the future, so long as physiologists are alive to the dynamical significance of all of them. Such work is laborious and calls for special instincts in the choice of analytical method, but, as I mentioned in an earlier part of this address, I am sure that high qualifications as an analyst should be part of the equipment of a biological chemist.

I should like now to say a few words concerning the actual results of this modern work upon intermediate metabolism, and will return to the amino-acids. It is clear that what I can say must be very brief.

We know that the first change suffered by an α-amino-acid when it enters the metabolic laboratories is the loss of its amino group, and, thanks to the labours of Knoop, Neubauer, Embden, Dakin, and others, we have substantial information concerning the mechanism of this change. The process involved

[1] A product of metabolism can only be said to have a "function" in a cell or in the body when, being the end-product of one reaction, it initiates or modifies reactions in another milieu.

in the removal of the amino group is not a simple reduction, which would yield a fatty acid, or substituted fatty acid, nor a hydrolytic removal which would leave an α-hydroxy-acid; but the much less to be expected process of an oxidative removal, which results in the production of a keto-acid.[2] If the direct evidence for this chemically most interesting primary change were to be held insufficient (though there is no insufficiency about it), its physiological reality is strongly supported by the proof given us by Knoop and Embden that the liver can resynthesise the original amino-acid from ammonia and the corresponding keto-acid. This profoundly significant observation is part of the evidence which is continually accumulating to show that all normal chemical processes of the body can suffer reversal. The next step in the breakdown involves the oxidation of the keto-acid, with the production of a fatty acid containing one carbon less than the original amino-acid. This in turn is oxidised to its final products along the lines of the β-oxidation of Knoop, two carbon atoms being removed at each stage of the breakdown. All this is true of the aliphatic α-amino-acids, and, with limitations, of the side chains of their aromatic congeners. In the case of certain amino-acids the course of breakdown passes through the stage of aceto-acetic acid. This happens to those of which the molecule contains the benzene ring, and Dakin has enabled us to picture clearly the path of change which involves the opening of the ring. This particular stage does not seem to occur in the breakdown of the aliphatic amino-acids, save in the case of leucin; the rule and the exception here being alike easy of explanation by considerations of molecular structure.

But direct breakdown on the lines mentioned is far from being the only fate of individual amino-acids in the body. The work of Lusk, completed by that of Dakin, has shown us that of seventeen amino-acids derived from protein no less than nine may individually yield glucose in the diabetic organism, and there are excellent grounds for believing (indeed, there is no doubt) that they do the same to a duly regulated extent in the normal organism. The remaining seven have been shown not to yield sugar, and there is therefore a most interesting contrast in the fate of two groups of the protein *Bausteine*. Those which yield sugar do not yield aceto-acetic-acid, and those which yield the latter are not glycogenic. One set, after undergoing significant preliminary changes, seems to join the carbohydrate path of metabolism, the other set ultimately joins a penultimate stage in the path which is traversed by fats.

I will here venture to leave for one moment the firm ground of facts experimentally ascertained. Unexplored experimentally, but quite certain so far as their existence is concerned, are yet other metabolic paths of prime importance, along which individual amino-acids must travel and suffer change. We know now from the results of prolonged feeding experiments upon young growing animals, which I myself, as well as many others, have carried out, that all the nitrogenous tissue complexes, as well as the tissue proteins, can be duly constructed when the diet contains no other source of nitrogen beside the amino-acids of protein. The purin and pyrimidin bases, for instance, present in the nuclear material of cells certainly take origin from particular amino-acids, though we have no right to assume that groups derived from carbohydrates or fats play no part in the necessary syntheses. While recent years have given us a wonderfully clear picture as to how the nucleic acids and the purin bases contained in them break down during metabolism, we have as yet no knowledge of stages in their synthesis. But it is clear that to discover these is a task fully open to modern experimental methods, and though a difficult problem, it is one ready to hand. Again, in specialised organs substances are made which are of great importance, not to the structure, but to the dynamics of the body. These have become familiar to us under the name of Hormones. We know the constitution of one of these only, adrenaline. The molecule of this exemplar has a simple structure of a kind which makes it almost certain to be derived from one of the aromatic amino-acids. It is clearly open to us to discover on what lines it takes origin. Facts of this kind, we may be sure, will form a special chapter of biochemistry in the future. I would like to make a point here quite important to my main contention that metabolism deals with simple molecules. As a pure assumption it is often taught, explicitly or implicitly, that although the bowel prepares free amino-acids for metabolism, only those which are individually in excess of the contemporary needs of the body for protein are directly diverted to specialised paths of metabolism, and these to the paths of destructive change. All others—all those which are to play a part in the intimacies of metabolism—are supposed to be first reconstructed into protein, and must therefore again be liberated from a complex before entering upon their special paths of change. But there is much more reason (and some experimental grounds) for the belief that the special paths (of which only one leads to the repair or formation of tissue protein) may be entered upon straightway. Mrs. Stanley Gardiner (then Miss Willcock) carried out some feeding experiments a few years ago, and in discussing these I pointed out that they offered evidence of the direct employment for special purposes of individual amino-acids derived as such from the bowel. It seemed at the time that the argument was misunderstood or felt to carry little weight, but later Prof. Kossel (*Johns Hopkins Hospital Bulletin*, March, 1912) quoted my remarks with approval and expressed agreement with the view that the *Bausteine* of the food protein must, in certain cases, be used individually and directly.

I wish I had time to illustrate my theme by some of the abundant facts available from quite other departments of metabolism; but I must pass on.

The chief thing to realise is that as a result of modern research the conception of metabolism in block is, as Garrod puts it, giving place to that of metabolism in compartments. It is from the behaviour of simple molecules we are learning our most significant lessons.

Now interest in the chemical events such as those we have been dealing with may still be damped by the feeling that, after all, when we go to the centre of things, to the bioplasm, where these processes are initiated and controlled, we shall find a milieu so complex that the happenings there, although they comprise the most significant links in the chain of events, must be wholly obscure when seen from the point of view of structural organic chemistry. I would like you to consider how far this is necessarily the case.

The highly complex substances which form the most obvious part of the material of the living cell are relatively stable. Their special characters, and in particular the colloidal condition in which they exist, determine, of course, many of the most fundamental characteristics of the cell: its definite yet mobile structure, its mechanical qualities, including the contractility of the protoplasm, and those other colloidal characters which the modern physical chemist is

[2] Dakin's recent work is giving us an insight into the mechanism of the keto-acid formation. Amino-acids in aqueous solution dissociate into ammonia and the corresponding keto-aldehyde. The oxidation involved is therefore concerned with the conversion of the aldehyde into the acid.

studying so closely. For the dynamic chemical events which happen within the cell, these colloid complexes yield a special milieu, providing, as it were, special apparatus, and an organised laboratory. But in the cell itself, I believe, simple molecules undergo reactions of the kind we have been considering. These reactions, being catalysed by colloidal enzymes, do not occur in a strictly homogeneous medium, but they occur, I would argue, in the aqueous fluids of the cell under just such conditions of solution as obtain when they progress under the influence of enzymes *in vitro*.

There is, I know, a view which, if old, is in one modification or another still current in many quarters. This conceives of the unit of living matter as a definite, if very large and very labile molecule, and conceives of a mass of living matter as consisting of a congregation of such molecules in that definite sense in which a mass of, say, sugar is a congregation of molecules, all like to one another. In my opinion, such a view is as inhibitory to productive thought as it is lacking in basis. It matters little whether in this connection we speak of a "molecule" or, in order to avoid the fairly obvious misuse of a word, we use the term "biogen," or any similar expression with the same connotation. Especially, I believe, is such a view unfortunate when, as sometimes, it is made to carry the corollary that simple molecules, such as those provided by foodstuffs, only suffer change after they have become in a vague sense a part of such a giant molecule or biogen. Such assumptions became unnecessary as soon as we learnt that a stable substance may exhibit instability after it enters the living cell, not because it loses its chemical identity, and the chemical properties inherent in its own molecular structure, by being built into an unstable complex, but because in the cell it meets with agents (the intracellular enzymes) which catalyse certain reactions of which its molecule is normally capable.

Exactly what sort of material might, in the course of cosmic evolution, have first come to exhibit the elementary characters of living stuff, a question raised in the presidential address which so stirred us last year, we do not, of course, know. But it is clear that the living cell as we now know it is not a mass of matter composed of a congregation of like molecules, but a highly differentiated system; the cell, in the modern phraseology of physical chemistry, is a system of coexisting phases of different constitutions.[3] Corresponding to the difference in their constitution, different chemical events may go on contemporaneously in the different phases, though every change in any phase affects the chemical and physico-chemical equilibrium of the whole system. Among these phases are to be reckoned not only the differentiated parts of the bioplasm strictly defined (if we can define it strictly) the macro- and micro-nuclei, nerve fibres, muscle fibres, &c., but the material which supports the cell structure, and what have been termed the "metaplasmic" constituents of the cell. These last comprise not only the fat droplets, glycogen, starch grains, aleurone grains, and the like, but other deposits not to be demonstrated histologically. They must be held, too—a point which has not been sufficiently insisted upon—to comprise the diverse substances of smaller molecular weight and greater solubility, which are present in the more fluid phases of the system—namely, in the cell juices. It is important to remember that change in any one of these constituent phases, including the metaplasmic phases, must affect the equilibrium of the whole cell system, and because of this necessary equilibrium-relation it is difficult to say that any one of the constituent phases, such as we find *permanently* present in a living cell, even a metaplasmic phase, is less essential than any other to the "life" of the cell, at least when we view it from the point of view of metabolism. It is extremely difficult and probably impossible by any treatment of the animal completely to deprive the liver of its glycogen deposits, so long as the liver cells remain alive. Even an extreme variation in the quantity is in the present connection without significance because, as we know, the equilibrium of a polyphasic system is independent of the mass of any one of the phases; but I am inclined to the bold statement that the integrity of metabolic life of a liver cell is as much dependent on the coexistence of metaplasmic glycogen, however small in amount, as upon the coexistence of the nuclear material itself; so in other cells, if not upon glycogen, at least upon other metaplasmic constituents.

Now we should refuse to speak of the membrane of a cell, or of its glycogen store, as living material. We should not apply the term to the substances dissolved in the cell juice, and, indeed, would scarcely apply it to the highly differentiated parts of the bioplasm if we thought of each detail separately. We are probably no more justified in applying it, when we consider it by itself, to what, as the result of microscopic studies, we recognise as "undifferentiated" bioplasm. On ultimate analysis we can scarcely speak at all of living matter in the cell; at any rate, we cannot, without gross misuse of terms, speak of the cell life as being associated with any one particular type of molecule. Its life is the expression of a particular dynamic equilibrium which obtains in a polyphasic system. Certain of the phases may be separated, mechanically or otherwise, as when we squeeze out the cell juices, and find that chemical processes still go on in them; but "life," as we instinctively define it, is a property of the cell as a whole, because it depends upon the organisation of processes, upon the equilibrium displayed by the totality of the coexisting phases

I return to my main point. The view I wish to impress upon you is that some of the most important phenomena in the cell, those involving simple reactions of the type which we have been discussing, occur in ordinary crystalloid solution. We are entitled to distinguish fluid (or more fluid) phases in the cell. I always think it helpful in this connection to think of the least differentiated of animal cells—to consider, for instance, the amœba. In this creature a fluid phase comes definitely into view with the appearance of the food vacuole. In this vacuole digestion goes on, and there can be no doubt, from the suggestive experimental evidence available, that a digestive enzyme, and possibly two successive enzymes (a pepsin followed by a trypsin) appear in it. It is now generally admitted that digestion in the amœba, though intracellular, is metaplasmic. The digestion products appear first of all in simple aqueous solution. Is it not unjustifiable to assume that the next step is a total "assimilation" of the products, a direct building up of all that is produced in the vacuole into the complexes of the cell? If there be any basis for our views concerning the specificity of, say, the tissue proteins, they must apply to the amœba no less than to the higher animal, and we must picture the building-up of its specific complexes as a selective process. The mixture of amino-acids derived from the proteins of the bacteria or other food eaten by it may be inharmonious with their balance in the amœba. Some have to be more directly dealt with, by oxidation or otherwise. If the digestive hydrolysis occur outside the complexes, we may most justifiably assume that other prepara-

[3] See in this connection the very able exposition of the views developed by Zwaardemaker and others, by Botazzi in Winterstein's "Handbuch," vol. i.

tive processes also occur outside them. We need not think of a visible vacuole as the only seat of such changes. Similar fluid phases in the cell may elude the microscope, and the phenomena would be just as significant if reactions occur in the water imbibed by the colloids of the cell or present in the intra-micellar spaces of the bioplasm. It is always important to remember that 75 per cent. of the cell substance consists of water.

All of these considerations we may apply to the tissue cells of the higher animal. To my mind, at least, the following considerations appeal. It is noteworthy that all the known complexes of the cell—the proteins, the phosphorous complexes, the nucleic acids, &c.—are susceptible to hydrolysis by catalytic agents, which are always present, or potentially present. If the available experimental evidence be honestly appraised, it points to the conclusion that only to hydrolytic processes are the complexes unstable. Under the conditions of the body they are, while intact, resistant to other types of change, their hydrolytic products being much more susceptible. Since hydroclastic agents are present in the cell we must suppose that there is, at any moment, equilibrium between the complexes and their water-soluble hydrolytic products, though the amount of the latter present at any moment may be very small. Now, I think we are entitled to look upon assimilation and dissimilation, while very strictly defined, as being dependent upon changes in this equilibrium alone. They are processes of condensation and hydrolysis respectively. Substances which are foreign to the normal constitution of the complexes—and these comprise not only strictly extraneous substances, but material for assimilation not yet ready for direct condensation, or metabolites which are no longer simple hydrolytic products—do not enter or re-enter the complexes. They suffer change within the cell, but not as part of the complexes. When, for instance, a supply of amino-acids transferred from the gut reaches the tissue cell, they may be in excess of the contemporary limits of assimilation; or, once more, individual acids may not be present in the harmonious proportion required to form the specific proteins in the cell. Are we to suppose that all nevertheless become an integral part of the complexes before the harmony is by some mysterious means adjusted? I think rather that the normality of the cell proteins is maintained by processes which precede actual condensation or assimilation. Conversely, when the cell balance sets towards dissimilation, the amino-acids liberated by hydrolysis suffer further changes outside the complexes. So when a foreign substance, say benzoic acid, enters the cell, we have no evidence, experimental or other, to suggest that such a body ever becomes an integral part of the complexes. Rather does it suffer its conjugation with glycine in the fluids of the cell. So also with cases of specific chemical manufacture in organs. When, for instance, adrenaline—a simple, definite crystalline body—appears in the cells of the gland which prepares it, are we to suppose that its molecule emerges in some way ready-made from the protein complexes of the gland, rather than that a precursor derived from a normal hydrolytic product of these proteins or from the food supply is converted into adrenaline by reactions of a comprehensible kind, occurring in aqueous solution, and involving simple molecules throughout? While referring to adrenaline, I may comment upon the fact that the extraordinarily wide influence now attributed to that substance is a striking illustration of the importance of simple molecules in the dynamics of the body.

It should be, of course, understood, though the consideration does not affect the essential significance of the views I am advancing, that the isolation of reactions in particular phases of the cell is only relative. I have before emphasised the point that the equilibrium of the whole system must, to a greater or less degree, be affected by a change in any one phase. A happening of any kind in the fluid phases must affect the chemical equilibrium and, no less, the physico-chemical equilibrium, between them and the complexes or less fluid phases. A drug may have an "action" on a cell, even though it remain in solution, and it may have a specific action because its molecular constitution leads it to intrude into, and modify the course of, some one, rather than any other, of the numerous simple chemical reactions proceeding in the cells of different tissues.

But I must now turn from consideration of the reactions themselves to that of their direction and control. It is clear that a special feature of the living cell is the organisation of chemical events within it. So long as we are content to conceive of all happenings as occurring within a biogen or living molecule all directive power can be attributed in some vague sense to its quite special properties.

But the last fifteen years have seen grow up a doctrine of a quite different sort which, while it has difficulties of its own, has the supreme merit of possessing an experimental basis and of encouraging by its very nature further experimental work. I mean the conception that each chemical reaction within the cell is directed and controlled by a specific catalyst. I have already more than once implicitly assumed the existence of intracellular enzymes. I must now consider them more fully.

Considering the preparation made for it by the early teaching of individual biologists, prominent among whom was Moritz Traube, it is remarkable that belief in the endo-enzyme as a universal agent of the cell was so slow to establish itself, though in the absence of abundant experimental proof scepticism was doubtless justified. So long as the ferments demonstrated as being normally attached to the cell were only those with hydroclastic properties, such as were already familiar in the case of secreted digestive ferments, the imagination was not stirred. Only with Buchner's discovery of zymase and cell-free alcoholic fermentation did the faith begin to grow. Yet, a quarter of a century before, Hoppe-Seyler had written (when discussing the then vexed question of nomenclature, as between organised and unorganised "ferments"): "The only question to be determined is whether that hypothesis is too bold which assumes that in the organism of yeasts there is a *substance* [the italics are mine] that decomposes sugar into alcohol and CO_2 . . . I hold the hypothesis to be *necessary* because fermentations are chemical events and must have chemical causes. . . ." If in the last sentence of this quotation we substitute for the word "fermentations" the words "the molecular reactions which occur within the cell," Hoppe-Seyler would, I think, have been equally justified.

Remembering, however, the great multiplicity of the reactions which occur in the animal body, and remembering the narrow specificity in the range of action of an individual enzyme, we may be tempted to pause on contemplating the myriad nature of the army of enzymes that seems called for. But before judging upon the matter the mind should be prepared by a full perusal of the experimental evidence. We must call to mind the phenomena of autolysis and all the details into which they have been followed; the specificity of the proteolytic ferments concerned, and especially the evidence obtained by Abderhalden and others, that tissues contain numerous enzymes, of which some act upon only one type of polypeptide, and some specifically on other polypeptides. We must remember the intracellular enzymes that slit the phosphorous complexes of the cell; the lipases, the amylases, and the highly specific invert ferments, each adjusted to the hydrolysis of a particular sugar. We have also to think of a large group of enzymes acting specifically upon other substances of simple constitution, such as the arginase of Kossel and Dakin, the enzyme recently described by Dakin which acts with great potency in converting pyruvic aldehyde into lactic acid, and many others. Nothing could produce a firmer belief in the reality and importance of the specialised enzymes of the tissues than a personal repetition of the experiments of Walter Jones, Schittenhelm, Wiechowski, and others, upon the agents involved in the breakdown of nucleic acids; each step in the elaborate process involves a separate catalyst. In this region of metabolism alone a small army of independent enzymes is known to play a part, each individual being of proven specificity. The final stages of the process involve oxidations which stop short at the stage of uric acid in man, but proceed to that of allantoin in most animals. It is very instructive to observe the clean, complete oxidation of uric acid to allantoin, which can be induced *in vitro* under the influence of Wiechowski's preparations of the uric acid oxidase, especially if one recalls at the same time, in proof of its physiological significance, that this oxidase, though always present in the tissues of animals, which excrete allantoin, is absent from those of man, who does not.

I will not trouble you with further examples. We have arrived, indeed, at a stage when, with a huge array of examples before us, it is logical to conclude that all metabolic tissue reactions are catalysed by enzymes, and, knowing the general properties of these, we have every right to conclude that all reactions may be so catalysed in the synthetic as well as in the opposite sense. If we are astonished at the vast array of specific catalysts which must be present in the tissues, there are other facts which increase the complexity of things. Evidence continues to accumulate from the biological side to show that, as a matter of fact, the living cell can acquire *de novo* as the result of special stimulation new catalytic agents previously foreign to its organisation.

It is certain, from very numerous studies made upon the lower organisms, and especially upon bacteria, that the cell may acquire new chemical powers when made to depend upon an unaccustomed nutritive medium. I must be content to quote a single instance out of many. Twort has shown that certain bacteria of the Coli-typhosus group can be trained to split sugars and alcohols which originally they could not split at all. A strain of *B. typhosus* which after being grown upon a medium containing dulcite had acquired the power of splitting this substance, retained it permanently, even after passage through the body of the guinea-pig, and cultivation upon a dulcite-free medium. Similar observations have been made upon the Continent by Massini and Burri; the latter showed by ingenious experiments that all the individuals of a race which acquires such a new property have the same potency for acquiring it. No one, at the present time, will deny that the appearance of a new enzyme is involved in this adjustment of the cell to a new nutritive medium.

We have not, it is true, so much evidence for similar phenomena in the case of the higher animals. The milk-sugar splitting ferment may be absent from the gut epithelium before birth, and in some animals may disappear again after the period of suckling, but here we probably have to do with some simple alternation of latency and activisation. But among the "protective" ferments studied by Abderholden we have, perhaps, cases in which specific individuals appear *de novo* as the result of injecting foreign proteins, &c., into the circulation. Consider, moreover, the case of the reactions called out by simpler substances. We have seen that an enzyme separable from the kidney tissue can catalyse the synthesis no less than the breakdown of hippuric acid. Now the cells of the mammalian kidney have always had to deal with benzoic acid or chemical precursors of benzoic acid, and the presence of a specific enzyme related to it is not surprising. But living cells are not likely to have ever been in contact with, say, bromo-benzol, until the substance was administered to animals experimentally. Yet a definite reaction at once proceeds when that substance is introduced into the body. It is linked up, as we have seen, with cystein. Now, this reaction is not one which would proceed in the body uncatalysed; if it be catalysed by an enzyme, all that we know about the specificity of such agents would suggest that a new one must appear for the purpose. I have allowed myself to go beyond ascertained facts in dealing with this last point. But once we have granted that specific enzymes are real agents in the cell, controlling a great number of reactions, I can see no logical reason for supposing that a different class of mechanism can be concerned with any particular reaction.

If we are entitled to conceive of so large a part of the chemical dynamics of the cell as comprising simple metaplasmic reactions catalysed by independent specific enzymes, it is certain that our pure chemical studies of the happenings in tissue extracts, expressed cell juices, and the like, gain enormously in meaning and significance. We make a real step forward when we escape from the vagueness which attaches to the "bioplasmic molecule" considered as the seat of all change. But I am not so foolish as to urge that the step is one towards obvious simplicity in our views concerning the cell. For what indeed are we to think of a chemical system in which so great an array of distinct catalysing agents is present or potentially present; a system, I would add, which when disturbed by the entry of a foreign substance regains its equilibrium through the agency of new-born catalysts adjusted to entirely new reactions? Here seems justification enough for the vitalistic view that events in the living cell are determined by final as well as by proximate causes, that its constitution has reference to the future as well as the past. But how can we conceive that any event called forth in any system by the entry of a simple molecule, an event related qualitatively to the structure of that molecule, can be of other than a chemical nature? The very complexity, therefore, which is apparent in the catalytic phenomena of the cell to my mind indicates that we must have here a case of what Henri Poincaré has called *la simplicité cachée*. Underlying the extreme complexity we may discover a simplicity which now escapes us. If so, I have of course no idea along what lines we are to reach the discovery of that simplicity, but I am sure the subject should attract the contemplative chemist, and especially him who is interested and versed in the dynamical side of his subject. If he can arrive at any hypothesis sufficiently general to direct research he will have opened a new chapter of organic chemistry—almost will he have created a new chemistry.

It must not be supposed that I am blind to the fact that the phenomena of the cell present a side to which the considerations I have put before you do not apply. Paul Ehrlich, in his recent illuminating address to the International Congress of Medicine, remarked that if, in chemistry, it be true that *Corpora non agunt nisi liquida,* then, in chemiotherapy, it is no less true that *Corpora non agunt nisi fixata.* Whatever precisely may be involved in the important principle of "fixation" as applied to drug actions, it remains, I think, true that the older adage applies to the dynamic *reactions* which occur in the living cell. But there are doubtless dynamic phenomena in which the cell complexes play a prominent part. The whole of our doctrine concerning the reaction of the body to the toxins of disease is based upon the fact that when the cell is invaded by complexes other than those normal to it, its own complexes become involved. I must not attempt to deal with these phenomena, but rather proceed to my closing remarks. I would like, however, just to express the hope that the chemist will recognise their theoretical importance. He will not, indeed, be surprised at the oligo-dynamic aspects of the phenomena, startling as they are. When physico-chemical factors enter into a phenomenon the influence of an infinitely small amount of material may always be expected. It is a fact, for instance, as Dr. W. H. Mills reminds me, that when a substance crystallises in more than one form it may be quite impossible to obtain the less stable forms of its crystals in any laboratory which has been "infected" with the more stable form, even though this infection has been produced by quite ordinary manipulations dealing with the latter. Here, certainly, is a case in which the influence of the infinitesimal is before us. But what I feel should arrest the interest of the chemist is the remarkable mingling of the general with the particular which phenomena like those of immunity display. In the relations which obtain between toxin and anti-toxin, for example, we find that physico-chemical factors predominate, and yet they are associated to a high degree with the character of specificity. The colloid state of matter, as such, and the properties of surface determine many of the characteristics of such reactions, yet the chemical aspect is always to the front. Combinations are observed which do not seem to be chemical compounds, but rather associations by adsorption; yet the mutual relations between the interacting complexes are in the highest degree discriminative and specific. The chemical factor in adsorption phenomena has, of course, been recognised elsewhere; but in biology it is particularly striking. Theoretical chemistry must hasten to take account of it. The modern developments in the study of valency probably constitute a step in this direction.

It is clear to everyone that the physical chemist is playing, and will continue to play, a most important part in the investigation of biological phenomena. We need, I think, have no doubt that in this country he will turn to our problems, for the kind of work he has to do seems to suit our national tastes and talents, and the biologist just now is much alive to the value of his results. But I rather feel that the organic chemist needs more wooing and gets less, though I am sure that his aid is equally necessary. In connection with most biological problems, physical and organic chemists have clearly defined tasks. To take one instance. In muscle phenomena it is becoming every day clearer that the mechanico-motor properties of the tissue, its changes of tension, its contraction and relaxation, depend upon physico-chemical phenomena associated with its colloidal complexes and its intimate structure. Changes in hydrogen-ion concentration and in the concentration of electrolytes generally, by acting upon surfaces or by upsetting osmotic equilibria, seem to be the determining causes of muscular movement. Yet the energy of the muscle is continuously supplied by the progress of organic reactions, and for a full understanding of events we need to know every detail of their course. Here then, as everywhere else, is the need for the organic chemist.

But I would urge upon any young chemist who thinks of occupying himself with biological problems the necessity for submitting for a year or two to a second discipline. If he merely migrate to a biological institute, prepared to determine the constitution of new products from the animal and study their reactions *in vitro,* he will be a very useful and acceptable person, but he will not become a biochemist. We want to learn how reactions run in the organism, and there is abundant evidence to show how little a mere knowledge of the constitution of substances, and a consideration of laboratory possibilities, can help on such knowledge. The animal body usually does the unexpected.

But if the organic chemist will get into touch with the animal, it is sure that the possession of his special knowledge will serve him well. Difficulties and peculiarities in connection with technique may lead the professor of pure chemistry to call his work amateurish, and certainly his results, unlike those of the physical chemist, will not straightway lend themselves to mathematical treatment. He may himself, too, meet from time to time the spectre of Vitalism, and be led quite unjustifiably to wonder whether all his work may not be wide of the mark. But if he will first obtain for us a further supply of valuable qualitative facts concerning the reactions in the body, we may then say to him, as Tranio said to his master:

> "The mathematics and the metaphysics
> Fall to them as you find your stomach serves you."

All of us who are engaged in applying chemistry and physics to the study of living phenomena are apt to be posed with questions as to our goal, although we have but just set out on our journey. It seems to me that we should be content to believe that we shall ultimately be able at least to describe the living animal in the sense that the morphologist has described the dead; if such descriptions do not amount to final explanations, it is not our fault. If in "life" there be some final residuum fated always to elude our methods, there is always the comforting truth to which Robert Louis Stevenson gave perhaps the finest expression, when he wrote:

> "To travel hopefully is better than to arrive,
> And the true success is labour."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Leeds.—An anonymous donor has generously signified, through the Chancellor (the Duke of Devonshire), his intention of presenting to the University of Leeds the sum of 10,000*l.* for the erection of the much-needed building for the school of agriculture at the University. This gift will enable the University, in conjunction with the Yorkshire Council for Agricultural Education and with the help, it is hoped, of a grant from the Government, to provide without further delay the headquarters of agricultural education and research for the three Ridings of Yorkshire. The organisation of agricultural teaching in Yorkshire has been taken by the Board of Agriculture as the model for all other parts of England, and the rapid growth of the agricultural courses and the development of research in animal nutrition and other subjects have made it necessary to provide new buildings and laboratories on an extensive scale for the school of agriculture at the University of Leeds. The University Council has provided a site for the new building, and much of the experimental work will be done at the Manor Farm, Garforth.

Manchester.—Mr. A. R. Wardle, assistant demonstrator in zoology in the Royal College of Science, London, has been appointed lecturer in economic zoology in succession to Mr. J. Mangan, who resigned at the end of last session to take up the position of assistant to the professor of biology in the Government Medical College, Cairo.

Mr. W. McBretney, headmaster of the Storey Institute, Lancaster, has been appointed headmaster of the new Secondary School and Technical Institute at Wallsend.

Four Gresham Lectures on Harvey, Darwin, and Huxley will be delivered on October 28, 29, 30, and 31, by Dr. F. M. Sandwith, Gresham professor of physic. The lectures, which will be given at the City of London School, Victoria Embankment, E.C., are free to the public, and will begin each evening at six o'clock.

It is stated in *Science* that M. Ernest Solvay, the discoverer of the Solvay process for the manufacture of sodium carbonate, celebrated the fiftieth anniversary of that discovery on September 2 last at Brussels by giving more than 200,000*l.* to educational and charitable institutions and the employees of his firm. The Universities of Paris and Nancy each received 20,000*l.*

The new engineering laboratories at University College, Dundee, were opened on October 14, by Sir Alexander Kennedy, F.R.S. The chair of engineering was one of the first to be established at Dundee University College, and in 1882, Prof. (now Sir Alfred) Ewing, K.C.B., was elected as its first occupant. For some few years after the foundation of the college, the facilities for the experimental teaching of engineering were meagre, and it was not until 1887 that an engineering laboratory on an adequate scale was provided. In January, 1911, the University authorities decided to build and equip a new engineering block, utilising for the purpose a grant of 10,000*l.* made by the Carnegie Trust for the development of the Scottish Universities. This department has been erected at a cost, including equipment, of about 15,500*l.* Owing to the completion in 1910 of the Peters's Electrical Engineering Laboratory, the college is well equipped for the study of this branch of engineering, and the present laboratories are devoted to the investigation of problems involved in civil and mechanical engineering. The heat-engine equipment at present includes an experimental steam engine, a gas engine, and a petrol motor, while provision is made for the installation of a Diesel oil engine and a steam turbine in the near future. The heat engine-room also contains all the apparatus necessary for the measurement of the heat value of solid and gaseous fuels, for the analysis of flue, exhaust, and fuel gases, and for the measurement of the dryness of steam, &c. The equipment of the strength of materials laboratory consists of a 50-ton Buckton single-lever testing machine, fitted for tension, compression, and cross-breaking, and with autographic recorder, an alternating stress machine, and cement testing machine, along with apparatus for determining the moduli of elasticity and rigidity, and for investigating the strength of struts and the elastic vibrations and deformations of structures. The hydraulic equipment includes a 24-in. Pelton wheel, a 9-in. inward flow pressure turbine, an electrically-driven centrifugal pump, capable of discharging 450 gallons per minute, an Oddie-Barclay high-speed differential-ram reciprocating pump, a flume, 3 ft. broad and 45 ft. long, for the study of weir and channel flow, and apparatus for studying the friction of fluids in pipes, the impact of jets, &c.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 29.—M. C. Jordan in the chair.—J. **Guillaume**: Observation of the occultation of the Pleiades by the moon, made September 20, 1913, with the *coudé* equatorial at Lyons Observatory.—Léopold **Fejér**: Harmonic polynomials.—H. **Tietze**: Continuous representations of surfaces on themselves.—C. **Beau**: The relations between tuberisation of roots and the attack by endophytic fungi in the course of development of *Spiranthes autumnalis*.

October 6.—M. P. Appell in the chair.—H. **Deslandres**: Remarks on the general electric and magnetic fields of the sun. A full discussion of the work of Hale in comparison with that done at Meudon by the author.—A. **Chauveau**: A comparison of human and bovine tuberculosis from the point of view of innate or specific aptitude of receiving or cultivating the bacillus. A development of views put forward in an earlier paper. The author holds that no human being, whatever the state of health, is incapable of receiving the tubercle infection, and regards this as a necessary consequence of his experiments on cattle. In the case of human beings exposed to infection and escaping, it is not the stronger subjects alone who escape. The practical conclusion is drawn that in the battle against tuberculosis, it is the bacillus which must be attacked, and hence that concentration on strengthening the vitality of the possible patient is unscientific.—R. **Lépine** and M. **Boulud**: The origin of the sugar secreted in phlorizic glycosuria. The results of experiments are cited contradicting the hypothesis that the sugar eliminated in phlorizic glycosuria arises from the renal cells. The point of attack in the kidney appears to be especially the vascular endothelium.—Charles **Depéret**: The fluvial and glacial history of the Rhône valley in the neighbourhood of Lyons. The Rhône glacier reached the Lyons region at a later period than the Quaternary epoch.—J. **Bosler**: The spectrum of the Metcalf comet, 1913*b*. Photographs taken at Meudon show a feeble continuous spectrum with three condensations corresponding to hydrocarbons (Swan spectrum) and cyanogen. It is nearly identical with the spectrum of the Schaumasse comet.—Michel **Plancherel**: The convergence of series of orthogonal functions.—Georges **Rémoundos**: Families of multiform functions admitting exceptional values within a domain.—Emile **Jouguet**: Some properties of waves of shock and combustion.—Léon **Guillet** and Victor **Bernard**: The variation of the resilience of some commercial alloys of copper as a function of the temperature. The alloys examined included seven bronzes with tin, ranging from 3·5 per cent. to 20 per cent., four brasses, and one aluminium bronze. The results are given graphically in two diagrams.—Charles **Nicolle** and L. **Blaizot**: An atoxic antigonococcic vaccine. Its application to the treatment of blennorrhagia and its complications. The authors have obtained a stable, atoxic antigonococcic serum by a method not disclosed, and give details of its curative action in a considerable number of cases.—Ch. **Dhéré** and A. **Burdel**: The absorption of the visible rays by the oxyhæmocyanines. Three reproductions of photographs of spectra are given. There would appear to be one absorption band common to all the oxyhæmocyanines.—M. de Montessus de **Ballore**: An attempt at synthesis of seismic and volcanic phenomena.—Ph. **Flajolet**: Observation of a curious formation of cirrus.

New South Wales.

Linnean Society, August 27.—Mr. W. W. Froggatt, vice-president, in the chair.—A. M. **Lea**: Revision of the Australian Curculionidæ belonging to the subfamily Cryptorhynchides, Part xii. This paper deals with the balance of the genera, more particularly those allied to Poropterus, and species of this immense subfamily of weevils, and, with the exception of a concluding instalment dealing with the classification, distribution, &c., is the last of the series. Fifteen genera (one proposed as new) and twenty-three species (two proposed as new) are described.—W. N. **Benson**: The geology and petrology of the Great Serpentine Belt of New South Wales, Part i., Introductory. The area described stretches from Warialda to Tamworth, embracing about 2000 square miles, together with one hundred square miles in the Nundle district, S.S.E. of Tamworth. A general description of the palæozoic formations is given. A great extension of the radiolarian rocks has been proved, both laterally and in vertical range. The sequence in igneous rocks is sketched.

BOOKS RECEIVED.

Preliminary Geography. By E. G. Hodgkinson. Pp. xvi+225. (London: W. B. Clive.) 1*s*. 6*d*.

Memoirs of the Department of Agriculture in India. Botanical Series. Vol. vi., No. 3. Studies in Indian Tobaccos, No. 3. The Inheritance in Nicotiana of Characters Tabacum, L. By G. L. C. Howard. Pp. 25–115+plates. (Calcutta: Thacker, Spink and Co.; London: W. Thacker and Co.) 3 rupees.

Die Luftfahrt. Ihre Wissenschaftlichen Grundlagen und Technische Entwicklung. By Dr. R. Nimführ. Dritte Auflage. Pp. viii+132. (Leipzig and Berlin: B. G. Teubner.) 1.25 marks.

Experimental-Zoologie. By Dr. Hans Przibram. 4. Vitalität. (Lebenszustand.) Pp. viii+179+x plates. (Leipzig and Wien: F. Denticke.) 10 marks.

LARGE TRAVELLING MICROSCOPE

conforms in its dimensions and general design to Model D. It is fitted with the new form of fine adjustment, having continuous cam and worm screw movement with milled heads at the sides. This mechanism, after several years of practical test, has proved to be superior in action and more durable than the micrometer screw.

Price, complete in case, with Abbe condenser, iris diaphragm and worm focussing screw, triple nosepiece, objectives $\frac{3}{8}''$ and $\frac{1}{8}''$, eyepieces I. and II.	£12	5	0
Ditto and $\frac{1}{12}''$ oil immersion objective and eyepiece IV. ...	17	10	0
Ditto ditto and mechanical stage	21	0	0
Ditto ditto ditto and dark ground condenser...	23	1	0

WATSON'S MICROSCOPES

have a world-wide reputation for Class and Laboratory Work. They are unequalled for rapidity, accuracy, and durability.

British made at Barnet, Herts. **Guaranteed for 5 Years.**

THE "RESEARCH" MICROSCOPE

is of the size, design, and workmanship that give finest results with continuous working. Its many conveniences suit it for all classes of work with high or low powers, for original research or photography. It has :—Two inches of movement to the coarse adjustment for low-power work. Large top plate to stage. Mechanical stage with movements of 1⅜″ horizontally and 1″ vertically. Milled heads controlling movements of the stage work on the same axis. Vertical lever, side limb fine adjustment. All working parts are slotted and sprung so that the smoothness of movement which characterises WATSON MICROSCOPES may be maintained for a lifetime.

PRICES :—Research Microscope, as figured and described, Stand only	£12	0	0
Ditto with 2 Eyepieces, Objectives 2/3″ and 1/6″ N.A. 0.74, with 1 millimetre working distance, new aplanatised Abbe Illuminator with Iris Diaphragm, Double Nosepiece, complete in Mahogany Case ...	£17	17	6
WATSON'S 1/12″ Oil Immersion Objective, 1·30 N.A., gives a flat field and exquisite definition	£5	0	0

WATSON'S MICROSCOPE CATALOGUE ALSO GIVES DETAILS of Blood Counting Apparatus, Instruments for Bacteriology, &c. Copies will be sent gratis on request.

INDEX NUMBER.

No. 2295, Vol. 92] THURSDAY, OCTOBER 23, 1913 [Price One Shilling

Registered as a Newspaper at the General Post Office.]

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY,

SOUTH KENSINGTON, LONDON, S.W.

The following Special Courses of Advanced Lectures will be given, commencing in November next:—

ROYAL COLLEGE OF SCIENCE.

Subject.	*Conducted by*
Colour Vision	Sir William de W. Abney, K.C.B., D.Sc., D.C.L., F.R.S.
Mining Geology—Part A (of 3 courses on Economic Geology)	Professor Watts, LL.D., Sc.D., M.Sc., F.R.S., F.G.S., and Assistant Prof. Cullis, D.Sc., F.G.S.

For further particulars of these and other Courses to follow, application should be made to the Registrar.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY

SOUTH KENSINGTON, LONDON, S.W.

DEMONSTRATOR IN MINE-SURVEYING.

Applications are invited for the post of DEMONSTRATOR in MINE-SURVEYING. Salary £200 per annum. The successful candidate will be required to enter on his duties on November 3.

A candidate should have had good experience in Engineering surveying both on surface and underground, and should be a skilful draughtsman and quick computer.

Applications, accompanied by copies of not more than three testimonials, and, if possible, by examples of draughtsmanship, booking, &c., should be addressed to the Secretary, Imperial College of Science and Technology, South Kensington, S.W.

UNIVERSITY OF LONDON.

The following Advanced Lectures will be delivered:—

A Course of eight Lectures on "The Cytology and Affinities of the Higher Fungi," by Dr. H. C. I. Gwynne-Vaughan, at University College, Gower Street, W.C., on Thursdays, commencing on October 23, 1913, at 5 p.m.

A Course of four Lectures on "The Cerebro-spinal Fluid," by Professor W. D. Halliburton, F.R.S., and Professor W. E. Dixon, F.R.S., jointly, at King's College, Strand, W.C., on Mondays, November 3, 10, 17, and 24, 1913, at 4.30 p.m.

Admission free, without ticket.

P. J. HARTOG, Academic Registrar.

UNIVERSITY OF LONDON.

CHADWICK LECTURES.

A Course of three Lectures on "The Place of the Open-Air School in Preventive Medicine," will be delivered under the Chadwick Benefaction by Sir George Newman, M.D., Chief Medical Officer of the Board of Education, at the University of London, South Kensington, S.W., on Tuesdays, November 4, 11, and 18, 1913, at 5 p.m.

Admission free, without ticket.

P. J. HARTOG, Academic Registrar.

RUTHERFORD TECHNICAL COLLEGE NEWCASTLE-UPON-TYNE.

Principal—C. L. Eclair-Heath, Wh.Sc., A.M.I.M.E.

APPOINTMENT OF LECTURER IN ENGINEERING.

Salary £150, rising by £10 to £180.

The Council of the above College invite applications for the above appointment from gentlemen having good works and drawing office experience, first-class technical school training, training in engineering laboratory work, and some teaching experience in day or evening work.

The commencing salary will be increased by £7 10s. for every year's service in a similar capacity up to maximum of four years.

The appointment is a full time appointment (partly day and partly evening work). Applications should be made before Wednesday, November 5, on forms which, with further particulars, may be obtained from the undersigned.

Education Office,
Northumberland Road,
Newcastle-upon-Tyne,
October 15, 1913.

SPURLEY HEY,
Secretary.

BIRKBECK COLLEGE,

BREAMS BUILDINGS, CHANCERY LANE, E.C.

Principal: G. Armitage-Smith, M.A., D.Lit.

COURSES OF STUDY (Day and Evening) for the Degrees of the UNIVERSITY OF LONDON in the

FACULTIES OF SCIENCE & ARTS

(PASS AND HONOURS)

under RECOGNISED TEACHERS of the University.

SCIENCE.—Chemistry, Physics, Mathematics (Pure and Applied), Botany, Zoology, Geology and Mineralogy.

ARTS.—Latin, Greek, English, French, German, Italian, History, Geography, Logic, Economics, Mathematics (Pure and Applied).

Evening Courses for the Degrees in Economics and Law.

SESSIONAL FEES { *Day:* Science, £17 10s.; Arts, £10 10s. *Evening:* Science, Arts, or Economics, £5 5s.

POST-GRADUATE AND RESEARCH WORK.

Prospectuses post free, Calendar 3d. (by post 5d.) from the Secretary.

CITY OF LONDON COLLEGE.

ACTING IN CONJUNCTION WITH THE LONDON CHAMBER OF COMMERCE.

WHITE ST., and ROPEMAKER ST., MOORFIELDS, E.C.

(Near Moorgate and Liverpool Street Stations).

Principal: SIDNEY HUMPHRIES, B.A., LL.B. (Cantab.)

EVENING CLASSES IN SCIENCE.

Well-equipped **LABORATORIES** for Practical Work in **CHEMISTRY, BOTANY, GEOLOGY.**

Special Courses for Pharmaceutical and other examinations. Classes are also held in all Commercial Subjects, in Languages, and Literature. Art Studio. All Classes are open to both sexes.

DAY SCHOOL OF COMMERCE. Preparation for a COMMERCIAL or BUSINESS career.

Prospectuses, and all other information, gratis on application.

DAVID SAVAGE, *Secretary.*

SOUTH-WESTERN POLYTECHNIC INSTITUTE, CHELSEA.

SPECIAL EVENING COURSES.

Bacteriology and Fungus Culture—Hugh MacLean, D.Sc., Ch.B., M.D.; Biochemistry—Hugh MacLean, D.Sc., Ch.B., M.D.; Crystallography and Mineralogy—*A. J. Maslen, F.L.S., F.G.S.; Electricity and Magnetism—*L. Lownds, B.Sc., Ph.D.; Foods and Drugs Analysis—H. B. Stevens, F.I.C., Ph.C., F.C.S.; Heredity and Evolution—*J. T. Cunningham, M.A.; Human Physiology—F. O'B. Ellison, B.A., M.D.; Metallography & Pyrometry—W. A. Naish, A.R.S.M., A.I.M.M.; Optics—*F. W. Jordan, B.Sc., A.R.C.S.; Organic Chemistry—*J. C. Crocker, M.A., D.Sc.; Physical Chemistry—*J. C. Crocker, M.A., D.Sc.; Plant Ecology—F. Cavers, D.Sc., F.L.S.; Pure Mathematics, subsidiary subject for B.Sc. Honours—*T. G. Strain, M.A.; Recent Researches in Biochemistry—Hugh MacLean, D.Sc., Ch.B., M.D.; Stratigraphical Geology with special reference to foreign areas—T. C. Nicholas, B.A. (Camb.); Vector Analysis. Complex Quantities with applications to Physics—*J. Lister, A.R.C.S.

* Recognised Teachers of London University.

Evening Courses commenced for the Session 1913-14 on Monday, September 22, 1913, and the Day Courses on Monday, September 29, 1913. Further particulars on application to the Secretary.

Telephone: 899 Western.

SIDNEY SKINNER, M.A., Principal.

TO SCIENCE AND MATHEMATICAL MASTERS.

January (1914) Vacancies.

Graduates in Science and other well-qualified masters seeking posts in Public and other Schools should apply at once, giving full details as to qualifications, &c., and enclosing copies of testimonials, to:—

MESSRS. GRIFFITHS, POWELL, SMITH & FAWCETT,

Tutorial Agents (Estd. 1833),

34 Bedford Street, Strand, London.

Immediate notice of all the best vacancies will be sent.

UNIVERSITY COLLEGE OF WALES, ABERYSTWYTH.

The Council invite applications for the post of LIVE STOCK OFFICER, who will be attached to the staff of the Agricultural Department of the College. A knowledge of Welsh will be regarded as an additional qualification. Salary not to exceed £500 per annum. Applications should be sent to the undersigned, from whom further particulars may be obtained, not later than November 20 next.

J. H. DAVIES, M.A., Registrar.

THURSDAY, OCTOBER 23, 1913.

LORD RAYLEIGH'S SCIENTIFIC PAPERS.

Scientific Papers. By John William Strutt, Baron Rayleigh, O.M., F.R.S. Vol. v., 1902–1910. Pp. xiii+624. (Cambridge University Press, 1912.) Price 15*s*. net.

THE fifth volume of Lord Rayleigh's papers contains his researches from 1902 to 1910; it is a volume of nearly eighty papers on subjects of a very varied nature—no slight record for a man during the seventieth decade of his life.

The four earlier volumes of the work have already been noticed in NATURE, and there is little more to be said with regard to the volume now under review.

The thanks of all interested in the advance of physical science are due in the first place to the author for thus reissuing in collected form his work during his own lifetime, and in the second to the Cambridge University Press for publishing it in the present admirable form. The issue of the collected works of great mathematicians—Adams, Cayley, Maxwell, Stokes, Rayleigh, Tait, and Kelvin—which the Press has undertaken in recent years has been of the utmost value to students throughout the world; and of this series no volumes have been more eagerly looked for or met with a more welcome reception than those of Lord Rayleigh. The pages under review afford ample evidence of the author's special powers, clearness of vision, whether in regard to the mathematical theory of his subject or to the essential details of an experimental inquiry; a firm grasp of mathematics as an instrument to solve the problem he is attacking; readiness to use simple methods of experiment where these suffice; the power to see when it is necessary to call in the highest skill of the instrument-maker or the minute care of the observer—these are manifest throughout.

It must suffice for the present to refer to one or two of the papers which appear of most interest to the present writer; the volume must find a place on the shelves of every physical library, and be continually referred to by students and workers.

One of the earliest papers reprinted from the Phil. Trans. for 1902 deals with the isothermal relation between the pressure and volume of a gas at pressures of from 75 to 150 mm. of mercury. The conclusion reached is that to one part in 5000 at least air, hydrogen, oxygen, and argon obey Boyle's law at the pressures concerned and at ordinary temperatures ($10^\circ - 15^\circ$). For nitrous oxide the deviations are somewhat greater. The work was extended to higher pressures up to one atmosphere in a further paper (Phil. Trans., 1905).

In two interesting papers the question whether the earth's motion affects the rotatory polarisation or produces double refraction of light are both answered in the negative. Other papers, again, bear evidence as to Lord Rayleigh's activity as a member of the Explosives Committee, or as adviser to the Trinity House, while a large part of the volume deals with various problems of small vibrations either optical, acoustical, or electrical, *e.g.* on the bending of waves round a spherical obstacle; on the dynamical theory of gratings; on the application of Poisson's formula to discontinuous disturbances, together with a series of acoustical notes.

Reference should also be made to a series of papers dealing with the measurement of the wave-length of light, commencing with one in the *Philosophical Magazine* for 1906, on some measurements of wave-lengths with a modified apparatus, followed by another on further measurements of wave-lengths, *Phil. Mag.*, xv., 1908. Both these papers are admirable examples of Lord Rayleigh's method of dealing with experimental difficulties of a high order without any undue elaboration of apparatus, and of his success in securing results. The method employed was a modification of that of Fabry and Perot, and the observations recorded in the first paper verified to one part in a million the values found for the wave-lengths, in terms of that of the red cadmium line, of the more important lines of cadmium, mercury, zinc, and soda, by Michelson and Fabry and Perot.

In conclusion reference should be made to papers on skin friction on even surfaces, a note to a paper by Prof Zahm, *Phil. Mag.*, 1904, and on the application of the principle of dynamical similarity, Reports of the Advisory Committee for Aëronautics, 1909–10 and 1910–11.

These deal with the conditions to be observed when calculating the resistance on bodies moving through the air from experiments on models. On the assumption that the resistance depends on the velocity and viscosity of the air and on the size of the surface, and is approximately proportional to the square of the velocity, it is shown that the resistance R is given by the equation—

$$R = \rho V^2 f(\nu/Vl),$$

where ρ, V, and ν are the density, velocity, and viscosity of the fluid, and l a linear quantity defining the size of the body, f being an unknown function. It follows from this that if the resistances are to be treated as proportional to the squares of the velocities for the actual body and the model, the comparisons must be made at velocities for which Vl is constant—*i.e.* at velocities inversely proportional to the size of the body and model respectively.

Enough has probably been written to direct attention to the wide range and absorbing interest of the subjects discussed in this volume.

CONCERNING BIRDS.

(1) XI. *Jahresbericht* (1911) *der Vogelwarte Rossitten der Deutschen Ornithologischen Gesellschaft.* Teil II. By Prof. J. Thienemann. Pp. 1–75.

(2) *The Food of some British Wild Birds: a Study in Economic Ornithology.* By W. E. Collinge. Pp. vi+109. (London: Dulau and Co., Ltd., 1913.) Price 4*s.* net.

(3) *The Bodley Head Natural History.* By E. D. Cuming. With Illustrations by J. A. Shepherd. Vol. i., British Birds. Passeres. Pp. 120. (London: John Lane, 1913.) Price 2s. net.

(1) IN the second part of the eleventh annual report of the "Vogelwarte," or bird-watching station, at Rossitten in East Prussia, Dr. Thienemann sets forth the 1911 results of the migration inquiry. The method pursued is marking the birds with numbered and addressed rings, and it continues to yield very interesting results. We notice that more than one black-headed gull born near Rossitten has been recovered in England, and a starling marked in the nest in Livonia on June 10, 1911, was shot on December 26, 1911, near Buckfast Abbey, South Devon. Other black-headed gulls from Rossitten were reported from Hungary, Croatia, Switzerland, and Piedmont; and one marked at Munich was found again at Tunis. Best of all is the case of a Rossitten gull marked in the nest July 18, 1911, and shot in November in Barbadoes. We may recall the fact that a British marked gull has been reported from the Azores.

Some new records of German storks from Africa bring the total of such cases up to twenty-four. They include recoveries from the Mbomu-Ubangi basin (North Congo), German East Africa, and the Victoria East district of Cape Province (the southernmost locality, 32° 46′ S.). Interest also attaches to storks recovered in Europe, for while most of those from Germany (east and west), Denmark, and Holland have been found to migrate south-eastwards towards Asia Minor on their way to Egypt and further south, we have a second case of a West German stork migrating towards Spain.

It is difficult to pick and choose among the interesting records, such as three hooded crows recovered after intervals of more than six years; a lesser black-backed gull marked at Rossitten in autumn and reported from Servia after three weeks; a young woodcock marked near St. Petersburg, July 3, 1911, recovered in dept. Gers, S.W. France, December 12, 1911; a wood pigeon marked in the nest near Dresden and obtained five months later in dept. Lot-et-Garonne, S.W. France; a rough-legged buzzard marked in the nest in northern Swedish-Lapland in July, and shot near Vienna four and a-half months later; an eagle (*A. pomarina*) marked in the nest in Russian Kurland in July, and recovered two months afterwards in Southern Bulgaria. A discussion of certain rather puzzling movements of the red-legged falcon concludes this interesting paper. Dr. Thienemann is to be heartily congratulated on the success which has attended the inquiry which he so energetically pursues.

(2) Mr. Collinge has done a very useful piece of work in presenting in compact form the results of his *post-mortem* examination of 3048 adult birds and 312 nestlings, and in giving along with this an up-to-date summary of what is known in regard to the food of the commonest British birds. We do not speak without feeling when we say that it is no light task to examine the food-canals of 3000 birds, and to make sure, or as sure as one can, of the significance of their imperfectly preserved contents. Mr. Collinge has done his work carefully, and the results are proportionately valuable—helping us, none too soon, to get away from the practical mistakes engendered by prejudice and hearsay evidence. Mr. Collinge has also been careful in his presentation of the work done by other observers.

Attention may be directed to the interesting (but all too short) chapters on the food of nestlings, on the *rôle* of birds in destroying or distributing the seeds of weeds, and on the relation of birds to forestry. Of the twenty-nine species of birds which have been especially studied by the author, only five are regarded as distinctively injurious, viz., the house-sparrow, bullfinch, sparrow-hawk, wood pigeon, and stockdove; six are regarded as altogether too plentiful, and consequently injurious, viz., missel thrush, blackbird, greenfinch, chaffinch, starling, and rook; the blackcap is injurious, but not plentiful; the jay is held to be neutral; and the remaining sixteen are beneficial, most of them meriting protection, especially the owls, the wren, and the plover. It must be borne in mind, however, that these are average verdicts, and Mr. Collinge would doubtless agree that they require modification for different parts of the country. The book does not deal at all with fish-eating birds, in regard to some of which there is a warm difference of opinion—to be settled by gathering more facts

—between the champions of birds on one hand and angling associations on the other. We hope this book will pass through many editions, and gain in strength as it grows—incorporating new data and extending its scope.

(3) Of making books—big and little—about birds there is no end, and the more the merrier as long as each newcomer is accurate and sincere, with something fresh to reveal. There is no doubt of a welcome for the "Bodley Head" bird-book, for Mr. Shepherd's drawings are charming characterisations, quite unusually successful in revealing the ways and habits of the birds. There is a good deal of psychology in them. The text is pleasantly and clearly written, without waste of words, and with insight into what is most distinctive. We would suggest that the inclusion of rarities, such as the rose-coloured pastor, is uncalled for in a book of this kind.

NEW AMERICAN BOOKS ON AGRICULTURE.

(1) *Cooperation in Agriculture.* By G. H. Powell. Pp. xv+327+xvi plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 6*s*. 6*d*. net.

(2) *The Farmer of To-morrow.* By F. I. Anderson. Pp. viii+308. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 6*s*. 6*d*. net.

(3) *Animal Husbandry for Schools.* By Prof. M. W. Harper. Pp. xxii+409. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 6*s*. net.

(4) *Elementary Tropical Agriculture.* By W. H. Johnson. Pp. xi+150. (London: Crosby Lockwood and Son, 1913.) Price 3*s*. 6*d*. net.

(1) THE first book on the list contains a very interesting account of the cooperative movement in America, especially as applied to agriculture. The subject is a very difficult one, and the author shows in his opening pages that he is fully aware of the intricacies and pitfalls in which it abounds. In the first instance a cooperative movement is not necessarily organised for the sake of profit; it may also be—and is, indeed, primarily—run for the benefit of its members in other directions. Secondly, as the author brings out very vividly, the average farmer is not a specialist. He produces a variety of general crops, each of which has to be handled and marketed through different agencies. Moreover, the supplies he uses are secured from different sources. He is thus in an entirely different position from the specialist farmer, who devotes his main attention to some one crop, such as apples, potatoes, &c., and therefore has much in common with others who are in the same line of business. These men can easily combine; they have to face the same problems of production, transport, distribution, and sale. Everywhere it is found that cooperation is easier for them than for the ordinary farmer.

The author therefore considers it a fundamental principle that a successful industrial organisation among farmers must be founded on a special industry, such as cotton, tobacco, milk, &c. Further, that the unit must lie in a restricted area. It also seems necessary for success that the organisation must be born in times of adversity; if it springs up in times of prosperity it has less chance of surviving the competition of existing agencies. Having laid down these fundamental principles, the author proceeds to show what has been done in the various States to apply them to the case of the ordinary farmer producing various crops.

(2) In this book Mr. Anderson gives a vivid account of the problem of soil fertility as it is understood by the Bureau of Soils at Washington. It is written in the direct popular style that is being cultivated with marked success by some of the present American authors, and it gives a very lively picture of the work done by the Bureau and its bearing on present-day agricultural problems in America. The author does not attempt any discussion of the hypotheses, and his statement of the position of the other side is somewhat inaccurate; in a popular book, however, it is something if the other side is recognised at all, even though it is only set up to be knocked over.

Besides all this there is a very spirited account of the position of American agriculture to-day, the movement back to the land, the introduction of business methods, the rise in capital value of the land, and the question of soil treatment. All these matters are dealt with in a light and easy fashion which cannot fail to hold the reader's interest.

(3) The third book on the list is one of the Rural Text-book Series, and is designed for schools and for short-course students at the colleges. It is thoroughly worthy of its companions in the series. The descriptions of the animals are good, and the illustrations are both adequate and to the point. The general reader will be struck by the large part British live stock play in the animal husbandry of the United States. After an enumeration of the different breeds, the author passes on to the methods of judging. The animal's mouth affords useful guidance here, and some good illustrations are given showing the appearance of the teeth at different ages. Next follows a detailed description of the score card, an American invention of great value that has now found its way into English colleges.

The selection of animals to be fattened is no longer a haphazard matter. Farmers and graziers have learnt by experience that animals which fatten well possess certain points in common. Thus a good beef steer for fattening has a head with definite characteristics, which are thus set out by the author :—

"It should be broad and short, the face and cheeks should be full and deep with a broad, strong lower jaw. The nostrils should be large. The eyes should be large, prominent, and mild, indicating a quiet temperament. The forehead should be somewhat prominent, and covered with a mass of wavy hair. The ear should be of medium size, and covered inside and out with fine silky hair, and should be neatly attached to the head."

The other parts of the body have to be observed in similar detail. It would be interesting to inquire how far these "points" possess any real significance, and how far they are purely fanciful. Although the author does not help us in this matter, he has done good service by placing on record the points recognised in American practice.

(4) Mr. Johnson has gathered together in this little book—the only British book on the list—the main principles involved in tropical agriculture, with a view to the introduction of the subject into schools. He is convinced that West African youths must be encouraged to adopt agriculture as a profession if the immense potential agricultural wealth of the country is to be extensively developed; he considers that the unhealthiness of the climate must militate against the direct exploitation of the industry by Europeans. This being so, it is obviously necessary that the principles of agriculture should be introduced into West African schools, and the book is intended for this purpose. It begins with a chapter on soil, then with six chapters on the plant, dealing respectively with the seed, the root, the stem, leaves, the flower, and the fruit. Next follows an account of the food of plants, in which the author reverts once more to the soil. Two chapters on diseases and insect pests come next, and finally there is a section dealing with the school garden. The book is well got up, and is clearly written; it should serve very well the purpose for which it is intended.

THE POPULARISATION OF SCIENCE.

Harmsworth Popular Science. Edited by Arthur Mee. In 43 parts. (London: The Amalgamated Press, Ltd.)

THE days when Science was an intellectual preserve for the few are long since past, and popularisation has become an art—increasingly an art. For if we compare a work like that before us with the "Useful Information for the People," or the "Science for All," or the "Popular Educator" of half a century ago, we cannot but admit that popularisation has made strides. The scope is more ambitious, bigger and deeper subjects are tackled; the mode of presentation is more interesting, which implies greater psychological skill; the style tends to be clearer, more vivid, less wordy; the illustrations are often extraordinarily educative; and the whole thing is more vertebrated. Sometimes it is the evolution-idea that gives unity to the treatment; sometimes it is an enthusiastic conviction that Science is for Man—to aid him to enter into his kingdom; more rarely the unifying aim is to work out a course of intellectual gymnastics—"a brain-stretching discipline."

Those who have listened to fine examples of popular lectures, such as some of the Evening Discourses at the British Association or at the Royal Institution, or who have read Huxley's or Tyndall's, must admit that sound popularisation is possible. If the lecturer has a deep first-hand knowledge of what he is talking about, if he has lucidity, vividness, the teacher's instinct, and a few more gifts and graces, what may he not achieve—as we have seen and heard—in the way of making even a difficult subject luminous to an average intelligence, and that without any lowering of the scientific standard? And if sound popularisation is possible, it is also for many reasons desirable. Knowledge is power: *savoir pour prévoir, et prévoir pour pourvoir*; its increase is an increase not of sorrow to well-constituted minds, but of interest and zest, alleviating what Shakespeare calls "life-harming heaviness"; and thirdly, no one can doubt that one of the most pressing social needs of the age is the better education of the wage-earners, and, of course, of the leisured class as well. Therefore we heartily welcome the extraordinary work before us, because it is sound popularisation, and sometimes reaches a very high level of success.

The book runs to more than 5000 pages, and it has twelve main themes. It tells of other worlds in space, of the making of the earth, of early forms of life, of the pedigree of plants, of the evolution of animals, of the ascent of man, of the laws of health, of the mastery of natural forces, of the rise of industry, of the development of commerce, of the history of society, and of the possible improvement of the race. It is, of course, sketchy, selective, and sometimes a little sensational, but it keeps to the facts, it is written with great skill, and it seems to us a big educational success. There is vitality and earnestness throughout, and the illustrations are exceptionally vivid and arresting. The numerous portraits of scientific workers give a personal touch to the text. We have tried it on a boy of ten and a somewhat *blasé* reader of fifty, and both give the same verdict—that it is extraordinarily interesting. We should like to have seen the authors' names, and we should like to cut the parts and bring, let us say, all the Hygiene together; but these are minor matters. We wish this popularisation all success, because it is sound; and what are the factors in this soundness?

It appears to us that the chief desiderata in an educational enterprise of this sort are the following:—Getting contributors with the gifts and graces already alluded to, plus the crowning humility of taking pains and obeying the editor (to whom our compliments); the good sense not to pretend that everything is easy, since nothing thorough is; the critical faculty of discerning what can be presented accurately, and at the same time intelligibly, for while most true ideas are clear there is a clarity that only dazzles the man in the street; and, last, the restraint which forbids "giving to the ignorant, as a gospel, in the name of Science, the rough guesses of yesterday that to-morrow should forget." We do not mean to suggest that this huge work has all these virtues in perfection, but it has striven after them, and therefore we wish it well.

OUR BOOKSHELF.

Arabische Gnomonik. No. 1. By Dr. Carl Schoy. Pp. 40+2 plates. Aus dem Archiv der Deutschen Seewarte.) (Hamburg, 1913.)

This mathematical account of Moslem dialling, by a writer already known for his studies of Arabic astronomy, forms one of the publications of the Deutsche Seewarte.

The author first touches on the bibliography. There is food for thought in the fact that but two references are given to English writers. The Arabic sun-dial differs from that of the Greeks in having a single point, at the apex of a spike, for index, in place of the gnomon. The horizontal dial is first treated, and rules are given for laying off "temporary hour-lines." These hours, duodecimal subdivisions of the daylight interval, vary in length; nevertheless, their inconvenience did not prevent their universal adoption until the time of Abu'l Hassan, who introduced equal hours about 1200 A.D. They are specially dealt with in the third chapter. The analysis of the clepsydra in this chapter gives unequal hours, since it assumes—erroneously—a constant rate of discharge.

Next follow two chapters on the determination of the Kibla and the times of prayer—sunset, nightfall, dawn, noon, and afternoon (asr). The last, with its various definitions, is discussed in some detail. The closing chapters concern vertical, cylindrical, and conical dials.

Though leaning towards the academic in places (the author employs declinations of 36°, −69°, −45°, and 63° on p. 21), the work is of high interest and much utility to all who have to do with Moslem chronometry. A few typographical errors apart, it is well printed, but an index would have been a useful addition.

J. I. C.

Cotton Spinning. By W. S. Taggart. Vol. I. Including all Processes up to the End of Carding. Pp. xxxvi+262. Fourth edition. Vol. II. Including the Processes up to the End of Fly-frames. Pp. xiv+245. Fifth edition. (London: Macmillan and Co., Ltd., 1913.) Price 4*s*. net each.

These books have been brought up to date, and much new matter and many illustrations have been added. In all essential respects they resemble the previous editions, which have gained a wide circulation among students and practical cotton-spinners.

Modern Problems in Psychiatry. By Prof. Ernesto Lugaro. Translated by Drs. D. Orr and R. G. Rows. With a Foreword by Sir T. S. Clouston. Pp. vii+305. Second edition. (Manchester University Press, 1913.) Price 7*s*. 6*d*. net.

The first English edition of Prof. Lugaro's book was reviewed in the issue of Nature for January 6, 1910 (vol. lxxxii., p. 273). The present issue differs in no important respect from the former; a large number of minor changes, including the correction of several errors, have been made.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Spectra of Helium and Hydrogen.

Recently Prof. Fowler (Month. Not. Roy. Astr. Soc., December, 1912) has observed a number of new lines by passing a condensed discharge through mixtures of hydrogen and helium. Some of these lines coincide closely with lines of the series observed by Pickering in the spectrum of the star ζ Puppis, and attributed to hydrogen in consequence of its simple numerical relation to the ordinary Balmer series. Other lines coincide closely with the series predicted by Rydberg and denoted as the principal series of the hydrogen spectrum. The rest of the new lines show a very simple relation to those of the latter series, but apparently have no place in Rydberg's theory.

From a theory of spectra (*Phil. Mag.*, July, 1913) based on Rutherford's theory of the structure of atoms and Planck's theory of black-radiation, I have been led to the assumption that the new lines observed by Fowler are not due to hydrogen, but that all the lines are due to helium and form a secondary helium spectrum exactly analogous to the ordinary hydrogen spectrum. This view is supported by recent experiments of Mr. Evans (Nature, September 4, p. 5), who observed the line 4686 in a helium tube not showing the ordinary hydrogen lines. Prof. Fowler (Nature, September 25, p. 95), on the other hand, brings forward some objections against the assumption that the lines are due to helium. In his communication Fowler states that the two series of lines, denoted by him as the first and the second principal series of the hydrogen spectrum, in his opinion cannot be united within the limits of error of observation in a single series, such as my theory claims. However, I believe that it is possible on the theory to account for the lines in satisfactory agreement with the measurements.

The first and the second columns of the table below contain the wave-lengths given by Fowler for the new lines and the corresponding limits of error of observation. The lines are marked by P_1, P_2, and S. according as they belong to the first or the second principal series or the Sharp series respectively. The figures in the third column are the products of the wave-lengths and the quantity $\frac{1}{n_1^2} - \frac{1}{n_2^2}$, where n_1 and n_2 are given in the bracket.

	$\lambda \cdot 10^8$	Limit of error	$\lambda\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right)\cdot 10^{10}$	
P_1	4685·98	0·01	22779·1	(3 : 4)
P_2	3203·30	0·05	22779·0	(3 : 5)
P_1	2733·34	0·05	22777·8	(3 : 6)
P_2	2511·31	0·05	22778·3	(3 : 7)
P_1	2385·47	0·05	22777·9	(3 : 8)
P_2	2306·20	0·10	22777·3	(3 : 9)
P_1	2252·88	0·10	22779·1	(3 : 10)
S	5410·5	1·0	22774	(4 : 7)
S	4541·3	0·25	22777	(4 : 9)
S	4200·3	0·5	22781	(4 : 11)

The figures in the third column are very nearly equal, and apparently there is no indication of a systematic difference in the figures corresponding to the lines denoted by P_1 and P_2.

The corresponding figures for the first lines in the ordinary spectrum of hydrogen (Ames, *Phil. Mag.*, xxx., p. 48, 1890) are:—

$\lambda \cdot 10^8$	$\lambda\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right)\cdot 10^{10}$	
6563·04	91153·3	(2 : 3)
4861·49	91152·9	(2 : 4)
4340·66	91153·9	(2 : 5)
4101·85	91152·2	(2 : 6)
3970·25	91153·7	(2 : 7)

According to the theory in question we have

$$K=\lambda\left(\frac{1}{n_1^2}-\frac{1}{n_2^2}\right)=\frac{ch^3(M+m)}{2\pi^2E^2e^2Mm},$$

where c is the velocity of light, h Planck's constant, e and m the charge and mass of an electron, and E and M the charge and mass of the central positive nucleus in the atom. This formula is deduced exactly as that given in the *Phil. Mag.*, where, however, in order to obtain a first approximation the mass of the electron is neglected in comparison with that of the nucleus.

The above tables give for hydrogen and for helium respectively

$$K_H=91153.10^{-10}, \quad K_{He}=22779.10^{-10}.$$

The ratio between these values is:—

$$\frac{K_H}{K_{He}}=4·0016.$$

From the theoretical formula we get for hydrogen, putting $E=e$ and $M=1835m$, and using recent determinations of h, e, and m:—

$$K=92.10^{-7}.$$

The agreement with the experimental value is within the uncertainty due to experimental errors in h, c, and m.

The theoretical value for the ratio between K for hydrogen and for helium can be deduced with great accuracy, as it is independent of the absolute values of h, e, and m. Putting $E_{He}=2E_H$ and $M_H=4M_H$, we get from the formula:

$$\frac{K_H}{K_{He}}=4·00163$$

in exact agreement with the experimental value.

It may be remarked that according to the theory helium must be expected to emit a series of lines closely, but not exactly, coinciding with the lines of the ordinary hydrogen spectrum. These lines, hitherto not observed, correspond to $n_1=4$ and $n_2=6$, 8, 10 . . ., and have the wave-lengths 6560·3, 4859·5, 4338·9 . . . The lines are expected to appear together with the lines of the Sharp series observed by Fowler and to have intensities of the same order as the latter lines.

N. BOHR.

The University, Copenhagen, October 8.

I AM glad to have elicited this interesting communication from Dr. Bohr, and I readily admit that the more exact form of his equation given above is in close accordance with the observations of the lines in question. It will be seen that the equation now introduces a modified value for the Rydberg series "constant," 109675, in addition to its multiplication by 4 for the particular series under consideration. The constant 22779, which is deduced from the wave-lengths of the lines is the reciprocal of this modified number, and in the usual numerical form, for oscillation frequencies corrected to vacuum, the equation for the lines would be:—

$$n=(4\times 109{,}720)\left\{\frac{1}{3^2}-\frac{1}{m^2}\right\}$$

where m takes the values 4, 5, 6 . . . .

With this modification, the agreement with the observations is very close; in only two cases do the calculated values differ from those observed by amounts greater than the estimated limits of error, and I should not like to insist that such errors in the measurements are inadmissible. It may therefore be possible to unite the P_1 and P_2 series in a single equation, as Dr. Bohr's theory requires, but it should be noted that the combination demands the recognition of a type of series differing from those previously known. The result of this combination is to give what may be called a "half-step" series, such as would be obtained by combining ordinary first and second subordinate series, in the special case where the fractional parts of the terms $(m+\mu)$ in Rydberg's equations for the two series differed by exactly 0·5. Consideration of the relative intensities of the two sets of lines would in general prohibit this procedure, but this objection cannot be made in the case of the lines under discussion. It is possible that the magnesium spark lines, which I have recently described, form another series of the same kind, but I know of no others.

The corrected formula given by Dr. Bohr leads to the further important result that alternate members of the ζ Puppis series cannot be superposed on the Balmer hydrogen lines, as at first appeared, but should be slightly displaced with respect to them. Dr. Bohr, however, appears to have inadvertently interchanged the last two figures of the constant 22779 in working out the wave-lengths, and the lines should be expected, within very narrow limits, at 6560·37, 4859·53, 4338·86, 4100·22 . . . . This should provide a valuable test of the theory, as the lines near Hβ and Hγ, at least, should not be very difficult to detect, if present, in stars of the ζ Puppis type. The tables published by Lockyer and Pickering give no indications of lines in the positions calculated, but further examination of the photographs is highly desirable.

It should be noted in conclusion that Dr. Bohr's theory has not yet been shown to be capable of explaining the ordinary series of helium lines.

A. Fowler.

Imperial College, South Kensington, October 14.

Azolla in Norfolk.

A very interesting case of the rapid spread of an introduced species is afforded by *Azolla caroliniana*, a North American species. So far as the Norfolk Broads are concerned, this free-floating water-fern has hitherto been confined to a single ditch or "dyke" near Horning Ferry, on the river Bure. Here the plant flourished greatly, covering the entire surface, but owing to the isolation of the "dyke" was prevented from spreading. According to an inhabitant of the neighbouring village of Ranworth, the plant has been observed in this one spot for the past fifteen years. I have no evidence as to its original introduction. The disastrous floods of August, 1912, carried some of the plant into the Bure, and its increase during the past twelve months has been extraordinary. Distributed by the tide it is now abundant in several of the Broads, and is carried by the tide in large quantities along the Bure and its tributaries, the Thurne and the Ant. It has found the still waters of South Walsham and Ranworth Broads particularly suited to its needs. It is most partial to the reed swamps of *Typha angustifolia*, so characteristic of the borders of our fen-lakes, and with this protection it is seen in large crowded expanses. More and more of the marsh and fen "dykes" are being invaded. It seems probable that the spread of the species to the other rivers of the Norfolk system, the Yare and the Waveney, will be prevented by the brackish nature of the water below Acle Bridge. I understand that a hard winter would probably kill the plant off, but its abundant sporocarps would carry it over to the succeeding spring.

Undoubtedly ecologists will soon find it necessary to include *Azolla caroliniana* in the local open reed-swamp association as a subdominant. It is a highly ornamental plant, being pale green in spring, and exhibiting a hundred shades of brown and red in autumn.

It would be interesting to know the result of competition between Azolla and members of the Lemnaceæ, and I am at present carrying out experiments to test this point.

W. E. Palmer.

Great Yarmouth.

The Theory of Radiation.

I owe Prof. Nicholson an apology. His work is, of course, earlier than Dr. Bohr's, and is actually cited by the latter. The wording of my letter (Nature, October 9) implies the reverse.

S. B. McLaren.

University College, Reading, October 18.

RESEARCH IN AERODYNAMICS.

The fourth volume of researches from the Institut Aerodynamique de Koutchino covers the period 1910–1912, and deals mainly with determinations of the air-resistance of various bodies and with comparisons between the results obtained at Koutchino with those of observers elsewhere. A change in the standard temperature corresponding to the published results has been made since the publication of the three earlier volumes, the later determinations being referred to 15° C. instead of 0° C. to bring the results to a form more easily comparable with those of other experimental establishments.

An examination into the velocity standard of the institution has been carried out, the ultimate standard being the movement of the end of a whirling arm 16 ft. in radius. Three independent methods of estimating and correcting for the motion of the air in the room were used prior to the calibration of various anemometers on the whirling arm. The anemometers were divided into two groups, the first containing "vane instruments" and the second "pressure tubes."

It was found, when the anemometers were transferred to the wind-channel of the laboratory, that the vane type of anemometer gave somewhat lower results than the pressure tubes, and it was concluded that the latter were more trustworthy, since the centrifugal effect of whirling on the vane instruments might easily account for the differences found.

Using the new calibration of the air-channel resulting from these experiments, a series of determinations of the resistance of square plates normal to the air-current was made. The plates were 12·5, 25, and 50 millimetres side, and the values of the absolute coefficient of resistance are given as 0·58, 0·57, and 0·57 respectively. This is somewhat higher than the value hitherto accepted for plates of this size, and is more nearly equal to that previously given for plates of from 300 to 500 millimetres.

The same plates were also tested at inclinations to the air-current, the curves obtained for the normal force showing the well-known maximum at an inclination of about 35°.

Amongst the theoretical investigations is one entitled, "Méthode des variables de dimension zéro et son application en Aerodynamique." Reference is made to papers by Lord Rayleigh and others, but, curiously enough, there does not seem to be any indication throughout the paper that the author considers the method to have any further importance than that of convenience. Approached from another point of view, the method of no-dimensional variables arises directly from the principles of dynamical similarity, and is only one of the many uses of the laws governing similar motions. The importance of the physical meaning behind the mathematics appears to have been overlooked.

In the articles in this volume which deal with comparisons with other observatories it is concluded that the type of channel having enclosing walls is preferable to that of Eiffel, and that the channel used at Göttingen is more steady than that at Koutchino.

An attempt was made to repeat an experiment by Rateau on a discontinuity in the centre of pressure variations of an inclined plate. Between inclinations of 25° and 50° Rateau found a sudden change, whilst at Koutchino a continuous and well-defined curve was obtained over the same range, the curve linking up the ranges 0 to 25° and 50° to 90°. It is definitely stated that, although difficult to measure, the position of the centre of pressure for any inclination was always unique.

THREE BOOKS OF TRAVEL.[1]

(1) THE type of travel-narrative to which Sir Edward Thorpe's volume belongs is one of the commonest among books, but his manner of treating his subject is by no means common. The book bears upon it the stamp of a labour of love; to any reader who is attached to France, attracted by river navigation, or even generally was made in a steam yacht across the Channel, up the Seine to Paris, and back. It was made, it would appear, leisurely, and gave ample opportunity for the travellers to become well acquainted with the many beautiful places on the river, and for one of them, Miss Olive Branson, to prepare the admirable series of sketches with which the book is mainly illustrated, though some of the pictures are drawn from another source, and there is also a series of large-scale maps (1 : 125,000) of the rivers; these last will be found of real service to those who follow Sir Edward Thorpe on this fine river, as will the directions he gives in regard to its navigation and the official arrangements connected therewith.

Fig. 1.—Ba'albek, temple of Jupiter and Anti-Libanus. From "The Fringe of the East."

interested in the picturesque in scenery or architecture, it will make exquisitely pleasant reading; the personal element in the narrative, which introduces the companions who made the voyage, is never (as it often is in such books) given an exaggerated prominence, and withal there appears here and there indications of the scientific authority of the writer which suffice to give the book a further peculiar value. The journey with which the book deals

(2) Mr. Lukach, in the sub-title of his book, describes his journey as lying "through past and present provinces of Turkey." He has visited Mount Athos and other Levantine monasteries, and the islands of Rhodes and Cyprus, to each of which he devotes chapters. With the Holy Land, and especially Jerusalem, he deals at greater length, and his travels, which are dealt with in this volume, extended along the Syrian coast, inland along the north-and-south line from Jerusalem and the Dead Sea through Damascus, Hama and Aleppo, and as far as the Euphrates at Tell Ahmar, a village-name famous in association with Hittite and Assyrian remains. Much of the book consists merely of the

[1] (1) "The Seine from Havre to Paris." By Sir Edward Thorpe. Pp. xxi+493. (London: Macmillan and Co., Ltd., 1913.) Price 12s. 6d. net.
(2) "The Fringe of the East. A Journey through Past and Present Provinces of Turkey." By H. C. Lukach. Pp. xiii+273+plates. (London: Macmillan and Co., Ltd., 1913.) Price 12s. net.
(3) "A Naturalist in Cannibal Land." By A. S. Meek. Pp. xviii+238+plates. (London: T. Fisher Unwin, n.d.) Price 10s. 6d. net.

narrative of travel, but this is very well told, and many experiences which are likely to be of value to other wanderers in the somewhat intricate paths of the Nearer East are given prominence. Mr. Lukach has already written on Cyprus, and perhaps his chapter on that island in the present volume may be indicated as of special value, including as it does a brief historical review, but throughout the book, a medley as it must necessarily be, there is found a laudable tendency to avoid assuming for the reader a foreknowledge of the complex lines of Levantine history. For example, the note and "genealogical" table of the Eastern Churches on pp. 113, 114, will be welcome to those who have striven to comprehend the religious divisions of Eastern Christendom. The book is illustrated with many good photographs, mostly the author's own, and there is a small route-map.

(3) Mr. A. S. Meek has made extensive zoological collections for the Tring Museum, and in the present volume he narrates his adventures while doing so, and also, at the outset, gives some account of his preparation for a collector's career. We follow him, in his narrative, to New Guinea and to various island-groups in the region of that great island—the Trobriands, the Louisiades, the Solomons, &c. In New Guinea itself he has travelled widely, and not in British territory only; his two last chapters deal with expeditions into the heart of the Dutch area. Mr. Meek asserts that he can claim to be neither a man of science nor a descriptive writer; his colleagues at the museum, on the one hand, and his readers, on the other, may be willing to find undue modesty in the statement. Certainly he has provided the museum with much new material; an introduction to his book by the Hon. Walter Rothschild makes that clear, while so far as the literary claims of the work are concerned, the book has had the benefit of editorship at the hands of Mr. Frank Fox, who is well qualified for the task by his authoritative knowledge of Australasia. Mr. Meek's text unquestionably increases in interest as it progresses, and in addition to his personal adventures (from which, quietly narrated as they are, his own spirit of intrepidity emerges clearly enough) and his successes as a collector, a tribute is certainly due to his ability in dealing with the natives, on whose friendly aid—of the winning of which there is but one method and that the right one—he has often needed, and been able, to rely.

Fig. 2.—Scene, Trobriand Islands. From "A Naturalist in Cannibal Land."

NOTES.

The council of the Royal Meteorological Society has awarded the Symons gold medal to Mr. W. H. Dines, F.R.S., in recognition of the valuable work which he has done in connection with meteorological science. The medal will be presented at the annual meeting of the society on January 21, 1914.

The annual Huxley Memorial Lecture of the Royal Anthropological Institute will be delivered on Friday, November 14, by Prof. W. J. Sollas, F.R.S., who will take as his subject "Paviland Cave." Prof. A. Keith, F.R.S., president of the institute, will occupy the chair.

THE death is announced, at sixty-two years of age, of Mr. H. Herbert Smith, vice-president of the Surveyors' Institution, a member of the council of the Royal Agricultural Society, and Gilbey lecturer on the history and the economics of agriculture, Cambridge University, 1900–03.

THE Paris *Temps* has just instituted an inquiry in scientific, industrial and medical circles as to directions in which developments of research are most desired. The object is to suggest the most useful discoveries which it is possible to make in the present state of scientific knowledge, and to indicate those awaited eagerly by workers in such various branches of science as electricity, mechanics, chemistry, physics, bacteriology, astronomy, &c. The result of the inquiry will show the point of view from which, at the close of this year, men of science are looking toward the future.

THE council of the Yorkshire Naturalists' Union has elected Mr. T. Sheppard, of Hull, the president for next year. The Yorkshire Naturalists' Union is one of the most successful associations of its kind in Great Britain, and has published many important monographs on the flora and fauna of the county, and also issues *The Naturalist*, which is one of the oldest scientific monthly magazines in the country. The union has a membership of nearly four thousand, and about forty important natural history societies are affiliated with it.

THE Harveian oration was delivered before the president and fellows of the Royal College of Physicians, on October 18, by Dr. J. Mitchell Bruce, who took for his subject "The Origin and Nature of Fever." The president of the college, Sir Thomas Barlow, presented the Baly gold medal to Dr. J. S. Haldane, F.R.S. The award of this medal is made every alternate year, on the recommendation of the president and council, to the person who shall be deemed to have most distinguished himself in the science of physiology, especially during the two years immediately preceding the award.

THE report of the council of the Cardiff Naturalists' Society adopted at the recent annual meeting shows that the membership is now 505, of whom twenty are life members. We notice that the council in May, 1913, adopted a suggestion made by Principal Griffiths that steps should be taken towards securing an early visit to Cardiff of the British Association. At the subsequent meeting of the City Council the suggestion was approved. An invitation has been forwarded to the council of the British Association, but the earliest practicable date now vacant is 1919. The programme for the present session deals with a diversity of topics, among which various aspects of animal and plant life are prominent.

THE council of the Institution of Civil Engineers has made the following awards for papers published in the Proceedings without discussion during the session 1912–13:—A Telford gold medal to Mr. James Mackenzie (Johannesburg); Telford premiums to Messrs. H. Hawgood (Los Angeles), J. K. Robertson (Bombay), G. S. Perry (Sydney, N.S.W.), and Gervaise Purcell (Los Angeles); and the Crampton prize to Mr. William Mason (Liverpool). The council has made the following awards in respect of students' papers read before provincial associations of students during the past session:—The James Forrest medal and a Miller prize to Mr. P. M. Chadwick (Birmingham); and Miller prizes to Messrs. A. J. S. Pippard (Bristol), T. P. Geen (Bristol), C. E. Holloway (Bristol), J. W. Burns (Glasgow), and B. A. E. Heilig (Birmingham).

THE Faraday Society has arranged for a general discussion on the passivity of metals to be held on Wednesday, November 12, in the rooms of the Chemical Society, Burlington House. The president-elect, Sir Robert Hadfield, F.R.S., will preside, and the following provisional programme has been arranged: Dr. G. Senter will open the discussion with a general introduction to the subject, and there will be papers by Dr. G. Grube (Dresden) on some anodic and kathodic retardation phenomena and their bearing upon the theory of passivity; Dr. D. Reichinstein (Zürich) on interpretation of recent experiments bearing on the problem of the passivity of metals; Dr. H. S. Allen on photo-electric activity of active and passive irons. Communications will also be read from Profs. G. Schmidt (Münster), Max LeBlanc (Dresden), E. Shoch (Texas), and Günther Schulze (Reichsanstalt, Charlottenburg).

A PARIS telegram announces the death, in a state of destitution, of M. Charles Tellier, the inventor of the cold storage system, at eighty-six years of age. Appreciative accounts of M. Tellier's work appear in *The Times* of October 21, and are here summarised. Born at Amiens, he devoted himself to scientific research, and his experiments found a practical outcome in 1876, when the first experimental cargo of frozen meat left France for Buenos Aires in *Le Frigorifique*, which had been built under his direction with cold storage compartments. His invention met at first with little appreciation, but at the present day cold storage has not only changed completely the set of the world's food trade, but has deeply affected the economic development of many important nations. Although *Le Frigorifique* was M. Tellier's finest achievement, he did not cease from the early 'sixties on to his death to apply all his forces to the advancement of that scientific knowledge on which practical refrigeration depends. His two books, written in very early days, "Le Froid appliqué à la Bière," and "La Conservation de la Viande par le Froid," laid the foundation of our knowledge of cold storage, and they have been followed by numerous other publications and papers, setting forth, as he made them, the results of his researches.

IT is announced in the October number of *The Museums Journal* that the next meeting of the Museums Association will be held at Swansea, the special object of meeting at that town being to offer advice with regard to the work of a newly established museum and art institute. In a later paragraph of the same issue reference is made to the question of the future of the museums established and furnished by the late Sir Jonathan Hutchinson at Haslemere, Selby, and Charles Street, London. Although the founder is believed to have spent something like 30,000*l*. on these institutions, no provision for their future maintainance is made in his will, the executors being empowered to dispose of them in such manner as they think best. At a meeting held at Haslemere last week it was announced that Mr. Jonathan Hutchinson, writing on behalf of the trustees of Sir Jonathan Hutchinson's estate, had stated that if it were found possible to raise the necessary endowment fund, the trustees were willing to hand over by deed the freehold site and the museum with all its contents to a suitable trust committee. It was also intimated that other members of the Hutchinson family were prepared to give substantial monetary help to any fund which it might be proposed to raise. The value of the site at Haslemere is estimated by the trustees at about 4000*l*.

The inaugural lecture for the newly founded lectureship in palæobotany at University College, University of London, was delivered on Friday, October 17, by Dr. Marie Stopes. Dr. Teall, F.R.S., the director of the Geological Survey, was in the chair. In the course of her lecture Dr. Stopes communicated the view that palæobotany is an independent science, though its main results are of particular service to botany, geology, or in practical mining. The first part of the lecture was devoted to a historical account of the subject, and a number of quotations were made from old books not generally known to palæobotanists. Historically the science has passed through three phases: the first when fossil plants were looked on as wanton ornaments, even at a time when animal fossils were recognised as being of organic origin; the second when plant impressions were drawn accurately and described, but without true understanding; the third when a scientific study of plant fossils revealed their importance in the conceptions of evolution and morphology of living plants, their value as "thermometers of extinct continents," and their importance to the stratigraphical geologist and coal miner. Dr. Teall said that he had been recently much impressed by the results of fossil botany, and expressed a hope that more students would give it careful attention. Prof. F. W. Oliver, F.R.S., in thanking Dr. Teall and the lecturer, said that he realised that the botanical side of palæobotany was not its only one; he agreed with the lecturer that palæobotany was an independent science, and he hoped before long to see a department of palæontology in the University.

On Wednesday, October 15, a conversazione was held at King's College, by the Royal Microscopical Society, when nearly five hundred fellows and their friends were received by the president, Prof. G. Sims Woodhead. The object was to bring together, so far as practicable, a series of exhibits which would demonstrate the many uses to which microscopes may be put at the present time, both in science and commerce, and to enable those interested or engaged in microscopic work to demonstrate the methods they employed and the results they had obtained. The centre tables in the Great Hall of the college were occupied by pond-life exhibits, and more than forty microscopes were arranged under the direction of D. J. Scourfield. These were the centre of interest to a large number of visitors throughout the evening, many of the living objects being beautifully shown. Among the exhibits which also engaged the attention of visitors, that by F. W. Watson Baker, a demonstration of the actual grinding of a lens for a microscope objective, holds a high place. The subjects of other interesting exhibits were:—A beautiful series of slides showing wild flowers under opaque illumination, Conrad Beck; preparation of rock sections, C. H. Caffyn; an experiment with the Abbe diffraction microscope to illustrate the effect of altering the phase of one of the spectra forming on image of a grating, J. E. Barnard; transparencies in colour, E. Cuzner and T. E. Freshwater; colour stereoscopic slides of water mites, H. Taverner; an eyepiece micrometer with diffraction grating—an ingenious method of avoiding the errors common to most micrometers, J. W. Gordon; foraminifera, E. Heron-Allen and A. Earland; apparatus for stereo-photomicrography and also for high-power binocular observation, J. W. Ogilvy; fluorescent objects illuminated by ultra-violet light, Max Poser; and exhibits to illustrate differential colour illumination, J. Rheinberg. Two lectures were delivered during the evening, one by Dr. E. J. Spitta on diatom structure and a demonstration of the microscopic structure of rocks, by C. H. Caffyn.

Some "Notes on the Struggle for Existence in Tropical Africa" are contributed to the current number of *Bedrock* by Mr. G. D. H. Carpenter, who spent nearly three years on the equatorial islands of Lake Victoria in studying the tsetse-fly on behalf of the Royal Society's Sleeping Sickness Commission. He emphasises the importance of studying mimicry under natural conditions rather than in the cabinet, and advances it as a strong argument in favour of the truth of the mimetic theory that the resemblance of one insect to another is explicable in exactly the same way as the resemblance of an insect to a dead leaf. On the theory of natural selection through minute variations, mimetic resemblances are simply a special case of coloration analogous to other special cases.

The October number of *The Fortnightly Review* contains an article by Henri Fabre, the veteran naturalist of Sérignan, on his relations with Charles Darwin. The article illustrates in an interesting way some of the leading characteristics of these two remarkable men—the combined fertility and caution in speculation shown by Darwin, with his determination to bring every hypothesis to the test of experiment; and the unrivalled powers of observation possessed by Fabre, his enthusiasm in the pursuit of his favourite study, and the charm of his literary style. Darwin, being interested in the homing instincts of the mason-bees, suggested to Fabre the making of experiments to determine, if possible, whether this instinct was at all dependent on a perception by the insects of the direction in which they were first carried away from their nests. A whole series of trials was carried out by Fabre, the essential feature in which was the enclosure of marked bees in a dark box, the carrying of the box with its inmates in a direction opposite to that from which the release was to take place, and the repeated rotation of the box at different points of the route, in order to ensure that the captive bees should lose their bearings during the journey. The experiment was repeated, with variations, many times over, the almost uniform result being that from 30 to 40 per cent. of the liberated bees found their way home without difficulty. This was contrary to the expectation of both inquirers, and Darwin next proposed to try the effect of placing the insects within an induction coil, "a curious notion," as Fabre observes. The experiment was performed, with amusing results. But in the end the experimenter was fain to confess that the homing instinct of his bees remained a mystery.

The Gypsy Lore Journal (vol. vi., Part 4) is largely devoted to an account by Mr. E. O. Winstedt of "The Gypsy Coppersmiths' Invasion of 1911–13." Owing to the reticence displayed by these people, the origin of the party which visited England is uncertain. Some claimed to be Caucasians, others Russians, and many seem to have forgotten the place whence they started. Galicia seems to be the probable home of many of the immigrants. They appear to be genuine gypsies, their skin colour being practically identical with that of the Russian peasantry. In their metal work there are remarkable coincidences with Indian art products. This monograph contains a very complete account of their religious beliefs, organisation, dress, manners, and customs. The excellent work being carried out, with very limited resources, by the Gypsy Lore Society, which has its headquarters at 21A Alfred Street, Liverpool, should invite support from all who are interested in this remarkable race and from students of anthropology.

RECENTLY the Prehistoric Society of East Anglia formed a committee to investigate the "Red Crag shell portrait" at present in the possession of Dr. Marie C. Stopes. The report of the committee has now appeared in the excellent Proceedings of that society (Part 3, vol. i.). The shell represents a typical Red Crag species, and bears the crude carving of a human face. The committee reported that "the weight of evidence was in favour of the Pliocene age of the human work on the shell . . . it was impossible to speak with absolute certainty on the point." One has only to glance at the other articles included in this volume to see how much and varied is the prehistoric research which is being carried out at present in East Anglia. Dr. Allen Sturge has applied Drayson's theory to explain the occurrence of periods of glaciation; a description is given by Mr. J. Reid Moir of worked flints from the mid-glacial gravel and chalky boulder clay of Suffolk; an account is written by Col. Underwood of Pleistocene bones and flint implements from a gravel pit at Dovercourt, Essex. The description of a Palæolithic site on Wretham Heath, near Thetford, by Dr. J. E. Marr, of Cambridge, is particularly interesting. Mr. W. G. Clarke contributes a paper on Norfolk implements of Palæolithic "cave" type. The Proceedings of the East Anglia Prehistoric Society contain matter which archæologists and anthropologists cannot afford to overlook.

A PARAGRAPH in NATURE of October 9 (p. 175) upon a pamphlet recently issued by the National Equine Defence League, referred to a Bill to prohibit the docking of horses, printed at the end of the pamphlet, as having become law. The honorary secretary of the league writes to say that the Bill was abandoned last session in order to be amended, and will again be introduced next session. A clear statement to this effect might with advantage have been printed upon the same page of the pamphlet to prevent a mistaken conclusion such as was arrived at by our contributor. The honorary secretary will be pleased to forward any information upon the subject to anyone applying to him at Beaconsfield Road, New Southgate, London, N.

IN No. 2014 of the Proceedings of the U.S. National Museum (vol. xlvi., pp. 93–102) Mr. C. W. Gidley gives a preliminary account of mammalian remains from a Pleistocene cave-deposit near Cumberland, Maryland. Lower jaws of a bear and a dog are described as new species—*Ursus vitabilis* and *Canis ambrusteri*. As the former differs from the American black bear (*U. americanus*) merely by the larger lower canines, it might well have been regarded as a race of that species. The latter is of the size of a wolf, but has the lower carnassial tooth approximating to that of a coyote or a jackal. In the legend to the figures on p. 100 and the first paragraph on the opposite page, no fewer than eight misprints are noticeable, one of which, namely *Hyscius*, for *Lyciscus*, is distinctly puzzling.

THE size of litters and the number of nipples in swine forms the subject of an interesting paper by Messrs. G. H. Parker and C. Bullard in the Proceedings of the American Academy of Arts and Sciences, vol. xlix., No. 7. The authors have prepared a record of 1000 litters of unborn pigs of various breeds, and by means of tables arranged in order of the number of pigs in the litter are shown the relative position of the pig in the uterus, its sex, and the number and arrangement of its nipples. Of the total number of pigs examined 3024 were males and 2946 females, and in the whole population it was found that the nipples ranged from 8–18, with a mean of 12·2 and a mode of 12. In the majority (3559) the arrangement of the nipples was regular in character. No obvious relation would appear to exist between the size of the litter and the number of nipples in the females; though there may be as few nipples as eight and as large litters as fifteen, disadvantageous combinations of large litters borne by females with few nipples cannot be of frequent occurrence. Commonly there are about twice as many nipples, twelve, as young, six.

In the course of an article, "The Transmutation of the Elements," in the October number of *Bedrock*, Dr. Norman Campbell deals with the apparent synthesis of neon out of helium and oxygen by Messrs. Collie and Patterson, which was described last February, as well as with Sir J. J. Thomson's observation that helium, hydrogen, and neon can be obtained from many solids by kathode-ray bombardment. Dr. Campbell takes the view that to apply the word "transmutation" to these processes is rather an unfortunate step, although it might be described as mere quibbling to say that the kathode rays do not produce transmutation when the results of transmutation can only be made evident by means of kathode rays. If gold could be "liberated" from lead by such bombardment, the amount so liberated would only be the amount accumulated by long ages of spontaneous disintegration, and would utterly fail to materialise the traditional idea of "transmutation."

Vols. ix. and x. of the Collected Researches of the National Physical Laboratory maintain the high standard of excellence we have come to look on as natural in the work which issues from that institution. The present volumes cover the twenty-three papers published in the scientific or technical Press or in the proceedings of learned societies during the year 1912. One of the most important of the papers dealing with engineering problems is that on the properties of welded joints in iron and steel. It is found that acetylene welded joints are not so good as hand or electrical welded, and that while hand welded are somewhat better than electrical for alternations of stress, they are not so uniform in the results they give. Another important contribution to engineering knowledge is made in the report on the properties of alloys of aluminium and zinc. An extended series of tests leads to the general conclusion that the alloy containing 20 per cent. of zinc is the most promising. In electrical engineering the valuable papers on the properties of insulating materials and the circumstances which affect them supply much trustworthy information in a field in which uncertainty has reigned for too long a period. Other important facts are brought out in papers on the visibility of faint lights like those of vessels at sea, on photographic lenses and shutters, on the electricity emitted by carbon at high temperatures, and, lastly, that on a determination of the ohm by alternating-current methods, which has led to a result slightly less than the value at present accepted.

Messrs. C. A. Parsons and Co., Ltd., have despatched from their Heaton Works at Newcastle-on-Tyne the largest turbo-generator yet completed. An illustrated account of this machine appears in *Engineering* for October 17. The machine has been built to the order of the Commonwealth Edison Company of Chicago, a Corporation owning probably the greatest collective power-station in the world, and has been designed for a continuous load, at 750 revolutions per minute, of 25,000 kw., at a power factor of 0·95, the periodicity being 25 complete cycles per second. The steam consumption guaranteed is notable, and marks an epoch in steam plant. With steam at 200 lb. per sq. in., superheated to an extent of 200° F., and an absolute pressure in the condenser equivalent to 1 in., the guaranteed steam consumption at 20,000 kw. is 11·25 lb. per kw. output from the alternator; at 25 per cent. over or under the normal load, 11·65 lb. per kw. output; and at half-load, 12·5 lb. per kw. output. The steam consumption guaranteed for this turbine set—the largest ever fitted to a single shaft—is equal to 8·1 lb. per shaft-horse-power per hour, a result not hitherto attained in marine practice. Were oil fuel used in the boiler furnaces of a marine plant having this steam consumption, the fuel used would amount to 0·6 lb. per shaft-horse-power per hour, a result nearly comparable, from the point of view of radius of action in warships, with that attained by internal-combustion engines.

The ninth half-yearly volume of the Journal of the Institute of Metals contains the presidential address of Prof. Huntington and some half-dozen papers of considerable scientific and technical interest, read at the spring meeting of the institute. These include a paper by Mr. Alexander Siemens on metal filament lamps, papers on corrosion by Mr. Arnold Philip and by Dr. G. H. Bailey, a paper on the microstructure of German silver, by Mr. O. F. Hudson, and papers on the heat treatment of alloys by Mr. G. H. Gulliver and by Messrs. H. S. and J. S. G. Primrose. The excellent photomicrographs which illustrate the presidential address and three of the papers are a noteworthy feature of the present volume.

Messrs. Newton and Co., 72 Wigmore Street, London, W., have issued new catalogues giving full particulars of the optical lanterns, kinematographs, and projection apparatus which they able to supply. The sectional catalogues now published separately by this firm will prove a great convenience, as it will be possible easily to keep each up to date. Among these catalogues those describing the new science lanterns and the arc lamps deserve special mention. These instruments are the result of many experiments, and deserve the careful attention of lecturers and science teachers.

The October issue of Mr. C. Baker's list of second-hand scientific instruments contains particulars of more than two thousand pieces of scientific apparatus. Each instrument is guaranteed to be in working order, and the majority are in new condition. Especial attention may be directed to section 1 of the catalogue devoted to microscopes and accessories, of which a fine collection is available for selection.

At the head of the review of "The British Parasitic Copepoda" in Nature of October 16 (p. 193) the price of the work was erroneously given as 15*s*. The secretary of the Ray Society writes to point out that this is the price of vol. i. only; and that the price of vol. ii. is 25*s*. The price of the complete work is, therefore, 40*s*. net.

OUR ASTRONOMICAL COLUMN.

COMET NEWS.—*Astronomische Nachrichten* (No. 4686) gives improved elements for comet 1913*b* (Metcalf), and also an ephemeris, including the current week, from which the following positions are taken :—

12h. M.T. Berlin.

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Oct. 23	20 51 54	+15 7·8	
24	50 52	13 18·9	
25	49 57	11 36·2	9·1
26	49 9	9 59·7	
27	48 26	8 28·6	
28	47 50	7 2·9	
29	47 19	5 42·0	9·4
30	20 46 53	+4 25·8	

The comet is rapidly reducing its northern declination, and as its magnitude is also decreasing it will become an object only for larger apertures.

Westphal's comet is becoming an interesting object, and will for some time be in a good observing position. It is moving into the constellation of Vulpecula, and during the first week of November will pass into Cygnus and become involved in the Milky Way. A photograph taken on September 28 showed a broad tail 3·5° long, a round nucleus of 20 min. in diameter, and a distinct nucleus. It has been glimpsed with the naked eye, and is an easy object for binoculars. The following is an approximate ephemeris :—

	R.A. h. m.	Dec. ° ′
Oct. 24	20 48	+19 46
28	43	22 23
Nov. 1	39	24 50
5	20 36	+27 16

It is worthy of note to mention that both Westphal's and Metcalf's comets are in about the same region of the sky, being less than two degrees apart on October 22.

The following are three positions for comet 1913*c* (Neujmin), now a faint object, published in *Astronomische Nachrichten* (No. 4685) :—

	R.A. (true) h. m. s.	Dec. (true) ° ′
Oct. 22	23 34 0	+13 55·7
26	35 29	14 33·3
30	37 29	15 7·4

The same journal (No. 4686) publishes the information received by Banachiewicz to the effect that the brightness of Neujmin's comet appears to be fluctuating. Its magnitude is fainter than 11.

ORBITS OF EIGHTY-SEVEN ECLIPSING BINARIES.—Dr. Harlow Shapley contributes to *The Astrophysical Journal* for September (vol. xxxviii., No. 2) a summary of an important though laborious piece of work on the orbits of eighty-seven eclipsing binaries. In the present publication he restricts himself to a few of the general results, leaving the complete statistical discussion for a future Princetown University Observatory publication. Some of the conclusions here briefly summarised show that the better the observations of an eclipsing binary are, the more satisfactory is the theoretical representation of the light variations. Further irregularities in the shape of the light-curves disappear with increased photometric accuracy. The existence of darkening towards the limb of the stellar disc is clearly indicated, and actually demonstrated in a few cases. There is a positive indication that the fainter star is self-luminous, and no case arises where it is necessary to assume one component completely dark. In discussing the distribution of densities relative to spectra the first-type stars (spectra B and A) show a marked preference for an intermediate density. The second-type stars fall into two groups, one preceding and the other following in order of density the first-type stars. Dr. Shapley points out that these two groups are obviously identical with the two classes of second-type stars of very greatly different luminosity discussed by Hertzsprung and Russell, and the facts collected afford direct support of Russell's theory that the differences in brightness of the two groups are to be ascribed in the main to great differences in the mean density.

VARIATIONS IN THE EARTH'S MAGNETIC FIELD.—In a short article in *Science* (August 29, 1913) Prof. Francis E. Nipher states that a series of open-air observations has fully verified the conclusions he has published regarding local magnetic storms. It appears that clouds prevent the solar ionisation of the air in their shadows, just as does the earth. When the molecules of air are ionised they become little magnets, and arranging themselves along the lines of force add their effect to that of the earth's magnetic field. In the absence of the solar radiation, wind or falling rain destroys this arrangement. It is hence suggested that local, daily, and annual variations are due to local variation in the weather. In a previous article in *Science* (May 30) Prof. Nipher describes a model with which a somewhat similar magnetic storm can be produced experimentally. In the model iron filings take the place of the ionised molecules of air.

THE LIGHT CURVE OF *o* CETI.—In the *Memorie della Società degli Spettroscopisti Italiani*, September, 1913, Sig. G. B. Lacchini publishes the results of his observations of this variable made during the period July 12, 1912–March 11, 1913. He used a telescope of 6 cm. aperture, 80 cm. focal length, with powers of 20 and 40, the comparison stars employed being those of the variable star section of the B.A.A. The epoch of minimum found was December 10, 1912, a result differing by only one day from that found by Dr. E. Guerrieri (December 9, 1912). The star lost one magnitude per twenty-seven days, and gained one magnitude per eleven days, according to Sig. Lacchini, which figures compare with 29·6 days and nine days respectively as determined by Dr. Guerrieri. The actual faintest magnitude recorded was 9·09 on December 3, 1912.

THE FRAUENFELD MEETING OF THE SWISS SOCIETY FOR THE ADVANCEMENT OF SCIENCE.

THE ninety-sixth annual meeting of the Société Helvétique des Sciences Naturelles was held, as already announced, at Frauenfeld in September. The set discourses were largely attended, and were listened to with considerable interest. Prof. Grubemann, in his lecture on the most recent methods employed in petrography, referred especially to the evolution of rocks, and the bearing of metallography and the chemistry of colloids on his subject. Prof. Maillefer gave an account of his researches on the geotropism of plants, partly from an experimental and partly from a mathematical point of view. He claimed to have proved that gravity has an effect on the curvature of a plant which requires time to take effect, and may be expressed by saying that the curvature possesses a velocity proportional to the sine of the angle made by the plant with the vertical and an acceleration proportional to the time of exposure. The effect is, he said, felt by the plant from the outset, though the time measurements seem to depend on the instruments used in the observations. His results were in a subsequent communication partly corroborated by Dr. Tröndle, who, however, does not admit the presence of an acceleration.

We pass over the remaining lectures, interesting as they were, remarking only on those of Profs. Keller and Dutoit. Prof. Keller dwelt on the points of resemblance between life in the Caucasus and that of the lake-dwellers in Switzerland in prehistoric times. Prof. Dutoit gave a brilliant exposition of the assimilation which is going on of the methods of analytical chemistry to those of physical chemistry and biology. The new processes employed which are, in point of fact, due in great measure to Prof. Dutoit himself, and have already rendered considerable services both to manufactures and science—are indirect, and have the advantage of great precision and extreme rapidity.

Turning to the separate sections, we commence with botany. Prof. Chodat, whose unique collection of cultures of algæ now numbers more than half a hundred, spoke of the bearing of his experiments on the systematic classification of these plants. Dr. Baumann, who has been studying the vegetation of the Lake of Constance, described how the small shells of gasteropods in these regions become coated with tufa, deposited by the algæ In this interesting way immense sandbanks of coarse sand, called after the little snails whose débris form it, "Schneckerlisand," are deposited in the lake. Prof. Ernst discussed parthenogenesis and apogamy among the Angiospermæ, and showed that, contrary to Treub and Lotsy, the embryo of the Balanophoraceæ is formed normally. The asexual reproduction of garlic from the point of view of heredity and natural selection was treated by Dr. Vogler. Prof. Edouard Fischer, who has been engaged in experiments on corn-rust, showed the connection between the appearance of this plague and the position of the leaf attacked with respect to the horizontal. Mr. Jaccard discussed the influence of a mechanical force on the production and constitution of wood and woody plants.

The section of geology occupied itself with the fossils, the stratification, and the relief of Switzerland. Prof. Albrecht Heine communicated his latest observations of glacial deposits as corroborating his somewhat controverted explanation of the formation of alpine lakes by a subsidence of the earth's crust in these regions during the diluvial epoch. Dr. F. Mühlberg showed by an interesting collection of lantern-slides the fallacious nature of the interpretation of the formation of part of the Jura given by the Bonn school. Prof. H. Schardt spoke on a subject which belongs properly to the borderland of geology, the typical phenomena of injection. He pointed out how, during the gradual cooling of a mass of magma, sudden pressures of a tectonic nature must sometimes occur, squeezing the molten material into the interstices of the neighbouring rocks and causing the phenomena in question.

In the chemical section the school of Geneva was strongly represented. Dr. Reverdin's determination of the constitution of certain anisidines, in particular of the two still doubtful trinitro-*p*-anisidines, is of a more advancedly technical character than Prof. A. Pictet's interesting discovery by the process of distillation *in vacuo* of a new kind of tar smelling of petroleum, and Messrs. Briner and Kühne's reinvestigation of the still obscure mechanism of the chamber process for the production of sulphuric acid. The opinion arrived at by these latter investigators is that SO_4H_2 is obtained by direct oxydisation of SO_2 into SO_3, the nitrous anhydride serving only as a catalytic. Of quite a different nature were Dr. Piccard of Munich's account of his experiments on certain dyes, and Dr. W. Baragiola's report on the physical, chemical, and physico-chemical experiments which have been made on wine and grape-juice.

In the physical section there were several communications deserving of mention; we content ourselves with signalising that of Prof. Perrier and H. Kamerlingh Onnes on the magnetisation of mixtures of liquid oxygen and nitrogen. These mixtures are found simpler to deal with than pure oxygen, the specific magnetisation coefficient of which had been already shown to differ materially from what would be expected by the law of Curie-Langevin. Experiments made at a temperature between $-195°$ and $-210°$ show that the deviation from the law in question depends on the mutual approach of the molecules caused by the fall of temperature.

In the mathematical section Prof. Fueter gave some instructive examples of algebraic equations possessing a prescribed group; Prof. Crelier read a paper, conceived in the order of ideas of Sturm, on correspondences in synthetic geometry, with special reference to the curve of the third order and third class; while Dr. Speiser and Prof. Bieberbach dealt with factorisation of algebraic forms and conformal representation respectively. Dr. Mirimanoff communicated a new and elegant proof of the theorem of Cantor-Bendixon, which, as he pointed out, falls into the same category as the first proof of that theorem without Cantor's transfinite numbers, that given by W. H. Young in "Sets of Intervals on the Straight Line" (Proc. L.M.S., 1, xxxv., pp. 245–268). Prof. W. H. Young gave a paper on "The Integral of Stieltjes and its Generalisation," showing how the theory of the integration of any function with respect to a function of bounded variation could be built up by the method of monotone sequences alone, and giving examples of new theorems, into the enunciation of which the new concept does not enter, and which he had obtained by means of its use.

Communications were also made to the sections for zoology, and for geophysics, cosmical physics, and meteorology, among them one by Dr. P. Mercanton, who added some details to Dr. de Quervain's account of the Swiss expedition across Greenland last year and the meteorology of that country. The rate of motion of the Greenland glaciers, which are mostly riddled with crevasses, was found, he said, to vary from one to two metres a day. At the base the grains of dust were not very large, the mean size not exceeding that of those in the alpine glaciers. Observations on some of the ancient glacial terraces showed that part of the dust was of cosmic origin.

PLANKTON DISTRIBUTION.[1]

In the University of California Publications in Zoology (vol. ix., No. 6), Mr. C. O. Esterly discusses the vertical distribution of certain Copepoda as shown by a large number of hauls made in the region of San Diego, between the years 1905 and 1911. Dividing the twenty-four hours into a "day" period from 6 a.m. to 6 p.m., and a "night" period of the remainder, the author finds in the results obtained a distinct night migration towards the surface, with a corresponding downward movement during the day. For nine out of ten species specially considered the time of this maximum occurrence at the surface is found to vary between 6–8 p.m. and 10–12 p.m., *Calanus finmarchicus* attaining its maximum in the latter period. The depth shown for the day plurimum is more obscure, ranging between 50 and 200 fathoms.

[1] "The Occurrence and Vertical Distribution of the Copepoda of the San Diego Region, with particular Reference to Nineteen Species." By Calvin O. Esterly. (Berkeley: University of California Press.)

The paper contains a large collection of data especially important as all relating to the same area and extending over a long period, but a marked want of care is shown both in the handling of the records and in the conclusions drawn from them. Numerous errors left uncorrected in the tables are very confusing though not, it would seem, seriously affecting the main results. Greater importance attaches to conclusions formed often quite out of proportion to the evidence available. As regards the question of nocturnal migration to the surface, while the records show the strongest evidence of a surface maximum during the night hours, they are far too incomplete to be relied on as indicating any definite period of optimum conditions. The maximum obtained for *Calanus finmarchicus*, for example, between 10 and 12 p.m., rests on the slender evidence of a single haul of 2·8 hours in duration, in which between three and four thousand specimens occurred. If this were indeed an optimum period, a higher average than fifty-eight specimens per hour might be expected between midnight and 2 a.m. The occurrence of a species in exceptionally large numbers suggests the presence of exceptional conditions, it may be, a combination of several factors at the time, to account for it. In estimating averages such a haul may, if unsupported by other evidence, give results that are quite misleading, and where it is used, as in the present case, for time-frequency alone, it is unsafe to place narrow limits to the period in which it happens to fall. In the two-hour period preceding this, viz. 8–10 p.m., an average of 973 specimens per hour is obtained from eight hauls made during that time. Had no other data been available than the four hauls covering this period in Table 2, the average given would be no more than nineteen specimens per hour in place of the 973. The example serves to emphasise the need of repeated observations before any safe estimate of such averages can be formed, or any deductions made from the latter.

The same remarks are applicable to the averages for Eucalanus and Metridia especially. For the former three maxima are shown, for the afternoon, evening, and morning severally, and the suggestion is even put forward that these are probably of normal occurrence, and should be considered so. The maximum for Metridia, placed at 10–12 p.m., rests, like that of Calanus, on the unsafe basis of a single haul of 31,900 specimens, the same haul as that from which the maximum for Calanus was obtained. The second highest aggregate for this species, namely 3401 specimens, was obtained from three hauls made between midnight and 2 a.m., and is apparently likewise dependant almost entirely on one haul of 3200 specimens, leaving an average of 100 specimens for the other two. In the case of *Labidocera trispinosa* the disproportion is greater still. Here the maximum, falling between 6 and 8 p.m., shows an aggregate of 2630 specimens obtained during this period in five successful hauls out of thirty, one haul containing 2425. The second highest aggregate, falling between 4 and 6 a.m., with a total of 527 specimens obtained in seven hauls, includes one haul with 500 specimens.

It cannot be lost sight of that all of these higher figures occur between the late evening and early morning hours, and, as a matter of general observation, the night preponderance of Copepod plankton near the surface will not perhaps be questioned by many. But data such as these are manifestly too incomplete alone to bear any interpretation more restricted than this, and though regarded by the author as implying different optimum periods characterising the different species, seem rather to express collectively particular instances of more or less abundant occurrence, in which any one or other of the species considered might equally well have been encountered on another occasion. It is indeed difficult to understand how, reasoning on such frail evidence, the discussion is carried even to the point of recognising in these different maxima obtained hidden characters distinguishing the species which are supplementary to those of structural features, such as to indicate, it may be, with more extended knowledge the apparent rather than real nature of the latter.

In estimating the hourly averages for the surface hauls the time occupied is made to include, rightly it would seem, that of hauls from which a species was absent. Thus is obtained the average number of animals occurring per hour of hauling. In calculating the depths for the day plurima, as shown by the self-closing nets, the averages based on the number of animals per fathom passed through are not treated in the same manner, but merely express the depth of the layer of water as a fixed quantity regardless of the number of hauls made through it. Thus, for *C. finmarchicus*, the region of the day maximum shown between 50 and 77 fathoms is estimated by all the animals in all the hauls (seventeen) made through that section of water being treated as though occurring in one haul through 25 fathoms. The average found at this depth, namely, 15·7 per fathom, therefore denotes no more than the distribution over the layer concerned of an aggregate of animals captured between 50 and 75 fathoms, and cannot be considered as on the same plane with that found between 75 and 100 fathoms, where six hauls made through a similar depth of water show an average of 5·7 animals per fathom. If the repetition of hauls through a given column of water be not given a true value, the averages are incomparable with one another, and important evidence afforded will be lost in the results obtained.

Considerable distortion of the latter averages is liable to have arisen through no allowance having been made for differences in the size of the nets used, amounting to as much as one-half the mouth opening. The impression that such allowances are of no practical value, if intended to be understood literally, might have been removed had the author tested the different-sized nets against one another.

L. R. C.

THE BRITISH ASSOCIATION AT BIRMINGHAM.

SECTION K.

BOTANY.

OPENING ADDRESS BY MISS ETHEL SARGANT, PRESIDENT OF THE SECTION.

WE were welcomed to Birmingham last night, and now—made free of the city—we assemble this morning to justify our position as its guests. But before entering on the work of the section, your president is authorised, and even required by custom, to glance at the events of the past year in the botanical world.

My predecessor in this chair had a great loss to record in the death of Sir Joseph Hooker, the *doyen* of British botanists, and a familiar figure at so many meetings of this Association, where we were proud to feel that he belonged to our section. This year we have no peculiar grief, but we join with the whole Association in lamenting the death of Lord Avebury. We have some right to offer a special tribute to his memory, since several of his published works were on botanical subjects. His book on the "Fertilisation of Flowers" in the "Nature Series" opened a new world to many non-botanical readers, and there are probably others here besides myself who have reason to be grateful to him for that charming introduction to field botany, and for the companion volume on "Flowers, Fruits, and Leaves." The great mass of first-hand information on the external characters of seedlings, contained in two massive volumes under the modest title of "A Contribution to our Knowledge of Seedlings," was collected under his direction and put together by himself. It is not only a book of reference to students of vegetable embryology, but no doubt played its part in reviving interest in that important subject. The work which he published was, however, the least part of Lord Avebury's contribution to natural history. He represented a small but most distinguished class of naturalists, amateurs in the best sense of the word, since they work for pure love of the subject. Whether they happen to be men of affairs in great positions, like Lord Avebury, or artisans devoting their Saturday afternoons to original research in natural history, they are the salt of the subject, preserving it from the worst effects of a purely professional and academic standard.

There is one more event of the past year to be mentioned before entering on the professional portion of this address. Section K has made a great innovation in choosing a woman for its president this year, and I will not refrain from thanking you in the name of my sex because I happen to be the woman chosen. And though I must and do feel very keenly the honour you have done me as a botanist in electing me to this position, yet that feeling is less prominent than gratitude for the generosity shown to all women in that choice. Speaking in their name, I may venture to say that the highest form of generosity is that which dares to do an act of justice in the face of custom and prejudice.

The main subject of my address this morning is the development of botanical embryology since 1870.

Botanists, as well as zoologists, have used the term embryology in two senses. Balfour's remarks apply to both sciences:—

"Strictly interpreted according to the meaning of the word, it ought to deal with the growth and structure of organisms during their development within the egg-membranes, before they are capable of leading an independent existence. Modern investigators have, however, shown that such a limitation of science would have a purely artificial character, and the term embryology is now employed to cover the anatomy and physiology of the organism during the whole period included between its first coming into being and its attainment of the adult state."

The older botanists used the term in the narrower sense. They included the study of the embryo-sac and the structures contained in it before the formation of the unfertilised egg-cell, as well as the fertilisation of the latter and its subsequent divisions. But they did not proceed beyond the resting-stage of the embryo within the ripe seed. Here, as in zoology, this division is arbitrary and inconvenient. Accordingly, in the following remarks on the embryology of Angiosperms, I include every stage in the development of the plant, from the first division of the fertilised egg-cell to maturity.

Systematists, from Cæsalpino onwards, have paid much attention to the structure of the seed, and their observations are the earliest we possess on botanical embryology. They were, indeed, forced to study the embryo because its characters are often of systematic importance. The number of cotyledons, for instance, is the most constant character which separates the two great classes of Angiosperms. Again, the endosperm is not part of the embryo, but its presence or absence in the ripe seed—so important systematically—determines the functions of the cotyledons after germination, and thus influences their structure profoundly. In this way botanists became familiar with the structure of the embryo in the ripe seed before they had traced its origin from the fertilised egg-cell or followed its development after germination.

The early history of the embryo was a sealed book to observers without the help of the compound microscope. Accordingly we find that work on the external morphology of seedlings preceded that on the formation of an embryo. For the description of seedlings we must go back to the middle of last century. The greatest name in this school is that of Thilo Irmisch (1815–79). His work, like that of earlier observers in the same field, was neglected by the succeeding generation owing to the rapid development of microscopic botany. For a time the study of anatomy eclipsed that of external morphology.

The earliest observers to study the embryo-sac of Angiosperms with the help of the compound microscope were naturally attracted by the history of the ovum and the process of fertilisation. Little progress was made in this direction, however, owing to the imperfect technique of the day. The divisions of the fertilised egg-cell are more easily followed, as Hanstein showed in 1870. His classical paper is the foundation of botanical embryology in the narrower sense—that is, of the study of the embryo from origin to germination.

This period in the plant's history would seem, indeed, very well defined. It begins with the first division of the fertilised egg-cell—undoubtedly a natural epoch, for a new generation dates from it. It ends with the formation of the ripe seed, which is a true physiological epoch, since it corresponds with a complete change in the conditions of life. We have seen also that the morphologists who have dealt with the immature plant have fallen naturally into two groups, one ending and the other beginning their work at this very point.

Experience, however, has shown here, as in zoology, that embryologists lose more than they gain by this division of their subject. It is, indeed, neither so simple nor so natural as it appears at first sight.

It is not simple because the embryo is not always completely dormant during the interval between the formation of the ripe seed and the first steps in germination. On the contrary, in a large proportion of Monocotyledons, and in a smaller but still considerable proportion of Dicotyledons, the embryo is an almost undifferentiated mass of meristem when the seed first ripens. It becomes differentiated internally and externally by degrees during the long interval before germination. This is sometimes called the maturation of the seed, and it is quite distinct from its ripening. Maturation is a process characteristic of the seeds of geophilous plants, which commonly lie in the ground for a year at least before germination.

In such cases the period of rest occurs immediately after the seed is ripe, and while the embryo is still undifferentiated. But the embryo is not comparable morphologically to that in the seed of an annual, for example, which may have ripened at the same time. The embryo of an annual has root, stem, and leaves, besides its cotyledons, and is ready to germinate immediately on the return of spring.

The morphologist, then, must continue the study of his geophilous embryo throughout the period of maturation if he is to compare it with that of the annual. Even then he will find it less advanced than the annual embryo, though both be examined as they break out of the seed. For the geophyte may perhaps be four or five years before it flowers, while the annual has to complete its whole life-cycle in a single season.

Nor is the division of the subject into two parts, the first ending with the embryo in the ripe seed, a natural one, even if the time of maturation be included in that first period. The structure of the embryo cannot be completely grasped by reference to its past only. The observer must expect adaptive characters of three kinds: first, those imposed upon the embryo in the past by its development within the embryo-sac while it is still parasitic on the parent plant; secondly, certain adaptations to the process of germination itself; and, finally, characters which will be useful after germination. Before the utility of the characters included in this third class can be fully understood, the development of the seedling must be followed for some time. In short, the structure of the embryo is dependent on its future, as well as on its past; and a division of the subject which excludes that future is, as Balfour says, purely artificial. Thus the work done of late years on the anatomy of the seedling has not only completed Irmisch's work on its external morphology, but has also thrown light on the problems of early embryology attacked by Hanstein and his immediate followers.

These problems are of two kinds, relating to the internal anatomy or the external morphology of the embryo. Hanstein himself was chiefly interested in the former. It is curious to realise when reading his paper that up to the date of its publication botanists were prepared to find an apical cell in the embryo of Angiosperms. They acknowledged, indeed, that no such cell existed in the growing-points of the mature plant.[1] There each new portion of tissue was formed by the activity of a group of similar and equivalent cells. But it still seemed possible that the embryo might possess an apical cell in the earlier stages of its growth—a reminiscence of its Cryptogamic ancestors. Hanstein's work disposed once for all of this possibility. It was conclusive even against the great authority of Hofmeister, who had described an apical cell in the embryo of orchids.

One general result of the work on the embryo since Hanstein's time has been to discredit phylogenetic theories based on its early history. Indeed, it was scarcely to be expected that a small mass of meristem, developing within a confined space and feeding parasitically on the tissues of the mother-plant, should preserve ancestral features, and one is surprised to find a morphologist with the experience and the wide grasp of Hanstein attaching so much importance to the succession of divisions within such a body. The conscientious student finds it a laborious task to follow the work done in plant embryology during the period which succeeded the publication of Hanstein's great paper. No wonder that when the end is seen to discredit rather than crown much of that work, when he realises how little has been gained as a result of so much patient toil, he is apt to renounce the whole subject in disgust. Yet in science we dare not rule out the unexpected, perhaps even less in morphology than elsewhere. Hanstein and his successors did good service when they described the growth of the pro-embryo from the fertilised egg-cell, its division into suspensor and embryo, the general development of both, and the appearance of external and internal differentiation in the embryo before germination.

Some of Hanstein's general conclusions as to internal anatomy have become the common property of text-books; for instance, the early differentiation of dermatogen in the embryo, and its subsequent development into the epidermal system. He was less successful in demonstrating the initial independence of plerome and periblem and their relation to the vascular cylinder of the mature stem.

[1] Korschelt in 1884 revived the hypothesis that the growing points of some Angiosperms at any rate increased by means of an apical cell. He worked chiefly on aquatic plants. His views have not been accepted.

The early differentiation of plerome and periblem from the internal tissues of the embryonic axis, and their continued formation at the growing points of stem and root respectively, are processes which demand the most careful investigation, on account of their bearing on the stelar hypothesis.

Dr. Schoute's work on the exact relationship of plerome and periblem at the growing-point to the central cylinder and cortex as differentiated in the older regions of the same axes, whether stem or root, is very important. He accepts Prof. Van Tieghem's definition of the stele as the solid cylinder of root or stem enclosed within the endodermis. The endodermis itself, of course, is considered as belonging to the cortex, because in the root its cells are opposite the radial files of the inner cortex, and, indeed, form the inmost rank of those files This is assumed to indicate a common origin by repeated tangential division. The cells of the pericycle—the outermost layer of the stele—alternate with those of the endodermis. As a rule, there is no corresponding radial arrangement in the cortical tissue of the stem, but where such exists—as in the stem of Hippuris—the endodermis is again included in it and terminates it.

Using the microtome as an instrument of precision, Dr. Schoute in 1903 published the most careful observations on the growing-points of roots. His aim was to determine whether the limit between plerome and periblem (Hanstein) corresponded with that between stele and cortex (Van Tieghem). For this purpose Dr. Schoute was, of course, obliged to choose roots in which the plerome is clearly distinguished from the periblem at the growing-point. In the end he obtained precise results in three species: *Hyacinthus orientalis*, *Helianthus annuus*, and *Linum usitatissimum*. In each of these the periblem passed into the cortex, its inner layer becoming the endodermis, and the plerome gave rise to the stele only.

Owing to difficulties of observation, arising chiefly from the insertion of leaves close up to the growing-point and displacements in the original stem-structure consequent on this habit, Dr. Schoute was not equally successful in his work on stems. *Hippuris vulgaris* was the only species to give definite results. In this species he found that the plerome gave rise not only to the stele, but also to the endodermis, and to the two or three layers of cortex immediately beyond it. If these results are well founded the limit between plerome and periblem does not correspond with that between stele and cortex in the stem of Hippuris. Moreover, doubt is thrown on the assumption made by all previous observers that rows of cortical cells arranged in radial files must be of common origin.

Observations on a single species, however well attested, form a slender basis for conclusions regarding stems in general. Nor have Dr. Schoute's observations escaped criticism. Dr. Kniep has since examined the growing-point of Hippuris, and believes that he can identify plerome with central cylinder, and periblem with cortex, even in this test case. However this may be, no one denies the obscurity of stem anatomy in this respect compared to that of the root, nor the cause of that obscurity. The continuity of the stem stele is perpetually interrupted by the insertion of the leaf-traces, just as the symmetry of the stem growing-point is destroyed by the formation of leaf rudiments close up to its apex.

The stelar hypothesis is essentially an assertion of the real homology between the vascular systems of stem and root throughout all vascular plants. This was pointed out to me more than twenty years ago by Dr. D. H. Scott, and it has been the sheet anchor to which I have since clung through much stress of morphological weather. No difficulty arises so long as we are dealing with roots only, or with the stems of those vascular Cryptogams in which the vascular system is a closed cylinder, without gaps at the insertion of the leaf-traces. In such stems the vascular cylinder is as well-defined as in all roots, and can be described in the same terms. But the case is quite different in the stems of Phanerogams, where to all appearance the primary vascular cylinder is a system built up of leaf-traces, embedded in a parenchymatous matrix. And the early anatomists were faced at once by this problem in its crudest form. Beginning with the anatomy of Phanerogams, they first became acquainted with the primary structure of the Dicotyledonous stem. That of the root was not clearly understood until many years later; perhaps because anatomists attempted to interpret it by reference to the skeleton of the stem, and in the same terms. But there is nothing in the vascular anatomy of the root to correspond with the leaf-trace, and the leaf-trace is the vascular unit of stem-structure in all Phanerogams. Here, as elsewhere, confusion of nomenclature went hand in hand with confusion of thought, and it is difficult to say which was cause and which effect.

Even when the facts of root-structure were accurately known, the conception of the leaf-trace bundle as the structural unit continued to be a stumbling-block. In 1877 De Bary published his monumental work on plant anatomy, and though it still keeps its place as the great book of reference on that subject, his descriptions of root anatomy appear to the modern botanist to be written in a dead language. When he calls the vascular axis of the root a "radial bundle" it is quite clear that he regards this as a purely formal term, not implying any true homology between the leaf-trace bundle of the stem and the axial core of the root. He does not, indeed, consider a bundle as a unit: he defines it as a compound structure "formed of tracheids and sieve-tubes definitely grouped."[2] But the word "bundle" was already impressed with another superscription. However defined originally, it had connoted the unit of stem-structure to a generation of botanists. With that connotation, De Bary's use of the term is in hopeless conflict. Moreover, the conception underlying that use was already out of date in 1877. Modern anatomy dates from 1871, when Prof. Van Tieghem published the first of his great series of memoirs on the subject. In these the axial core of the root was treated as equivalent to the whole system of leaf-trace bundles in the stem, though the word "stele" was not yet invented. This conception gained ground from the first; it was popularised by the happy choice of a name in 1886. From that date the stelar hypothesis has replaced all other schemes of vascular anatomy. The advance then made on all previous generalisations has been shown by the new impulse given to research, and the comparative simplicity introduced into text-book anatomy.

We cannot claim equal simplicity, I fear, for the technical language of research in this subject, and this alone should inspire caution, for obscurity of language rarely persists where there is no corresponding obscurity of thought.

No one now doubts that the central cylinder of the root in Phanerogams is far more closely comparable to the leaf-trace cylinder of the stem than to any one of the traces within it. Yet when the comparison becomes detailed, difficulties are constantly arising. Where, for example, there is a medulla in the root it certainly forms part of the stele, which is a solid cylinder sharply defined by the specialised endodermis surrounding it. But the leaf-traces in the young stem surround a massive cylinder of parenchyma, precisely resembling the parenchyma of the cortex, with which it is in apparent connection through the gaps between the leaf-traces. Even the secondary formations do not completely divide one system from the other. When a specialised endodermis is present it is not so clearly defined as in the root: in many cases it is not present—in other words, there is no cell-layer outside the leaf-trace cylinder which is differentiated in any way from the surrounding tissues. In a few instances—most baffling of all—an endodermis surrounds each leaf-trace.

The stele in the stem of Phanerogams is not of necessity a morphological fiction, because in many stems its precise limits cannot be determined. If, indeed, the word be used as a descriptive term, its value is seriously impaired by every instance in which it fails to describe stem-structure with precision. But morphology is not merely descriptive. If we suppose that the stem-stele in remote ancestors of the Phanerogams was as well defined as that of the root and clearly comparable to it, we may attach a real morphological meaning to the term when applied to modern Phanerogams, provided we can show cause to believe that what we call the stele in their stems represents the ancestral stele. Its tissues will then have a history distinct from those of the cortex, though not clearly separated from them. The burden of proof, however, certainly lies with those who assert that an apparently continuous and uniform tissue can be separated into two parts of distinct origin.

The evidence advanced is of two kinds—one founded on the comparative anatomy of stems, and the other on the history of the tissues in the individual plant. Dr. Schoute has argued the case with great skill from the first point of view in his "Stelärtheorie." Depending to a large extent on his own researches, he has collected a great body of evidence to show that in the stems of Angiosperms a specialised layer is commonly distinguished from adjacent tissues either by the peculiar thickening characteristic of the endodermis in the root, or by the presence of starch in its cells. He shows that such a sheath surrounds the vascular cylinder in a very large proportion of the Dicotyledons examined, and in a majority of the Monocotyledons. Among Gymnosperms it occurs but rarely. Observing that the Angiosperms in which this bundle-sheath is obscure or wanting are commonly closely related to species in which it is perfectly well defined, Dr. Schoute concludes that its absence in such cases must be attributed to reduction.

Allowing that such a layer is as general among Angiosperms as Dr. Schoute believes, grave doubts may still exist as to its homology with the endodermis of the root. The latter is defined not only by its thickened walls, but also by the position of its cells. They form the inmost rank of the series of radial files which distinguish the inner cortex, and the morphological endodermis—the phlæoterma, as Strasburger calls it—can usually be distinguished by this purely morphological character, even when its walls are unthickened. In the stem, however, the cells of the inner cortex are not radially arranged, except in rare cases, such as Hippuris. Thus there is no morphological criterion to distinguish the phlæoterma, or inmost cortical layer of the stem, from adjacent tissues. The bundle-sheaths distinguished by their

[2] "Comparative Anatomy of Phanerogams and Ferns." 1st Eng. ed., 1884, p. 400.

thickened walls or by the presence of starch in their cells are physiologically similar; they play a definite part in the economy of the stem, but the presence of either character must depend mainly on the demands of the conducting or assimilating system, and need not imply the morphological identity of such layers with each other, or with the layer performing a similar function in the root.

Turning now to the second class of evidence—that drawn from the history of the tissues in the individual plant—we have already seen that the differentiation of plerome from periblem is far less definite at the growing point of the stem than at the root. Doubts have even been thrown on the identity of plerome and periblem with stele and cortex respectively. But we have not yet followed the development of the tissues of the embryo into those of the seedling.

The normal seedling[3] of all Phanerogams consists at first of cotyledons, hypocotyl, and root, the plumular bud being still rudimentary. The primary root lies as a rule in a straight line with the primary stem, or hypocotyl. The hypocotyl is commonly the first part of the embryo to lengthen, and then its xylem is lignified a little earlier than that of the root or even that of the cotyledon. But when—as in many Monocotyledons—the base of the cotyledon lengthens first, lignification begins in that region and advances through the hypocotyl to the primary root.

The anatomy of the seedling at this epoch has lately been investigated by many independent observers. They constitute, indeed, the third school of embryology to which I have referred as completing the work of two earlier schools—namely, morphologists of the type of Irmisch, and students of early embryology like Hanstein and his school. But though the subject is limited to a short period in the history of the plant, and to one in which its vascular structure is comparatively simple, yet it has been attacked from different sides, and the attempt to give a concise account of the results attained is beset with difficulties. For the present, however, I propose to consider only their bearing on the stelar hypothesis.

Indeed, seedling anatomy becomes extremely important when the vascular system of the root is compared with that of the stem. For in the seedling we have a complete and simple vascular skeleton, which at one end belongs to the primary root of the plant, and at the other to its primary stem. There must be an intermediate region in which stem-structure passes into root-structure, and the method of transition should at least suggest, if it does not precisely determine, the relation in which they stand to each other. For this reason great value has been attached by anatomists to the transitional region of the main axis. It was not completely investigated, however, until the microtome was introduced into botanical practice, for the change of structure is often very abrupt, and cannot be studied in detail unless all possible sections are present in their proper order.

In this, as in other branches of modern anatomy, Prof. Van Tieghem was first in the field. In his memoir of 1872, "Sur les Canaux Secréteurs des Plantes," he described the course of the bundles of the hypocotyl of *Tagetes patula*, an example of the second type of transition given in his textbook (1886). The three types were, indeed, already identified in 1872, for the first and third are defined in a footnote appended to the description of Tagetes.

Tagetes patula was, of course, examined in 1872 with the aid of hand-sections only. Two traces enter the hypocotyl from either cotyledon, and form in the end a diarch root. The plane passing through its xylem poles is the median plane of the cotyledons. In the upper part of the hypocotyl this plane bisects the space which separates the two bundles entering each cotyledon. So far the description of Tagetes given in 1872 is identical with the generalised account of type 2 in the text-book (1886). But a detail of some importance is mentioned in the description of Tagetes which does not reappear in the definition of type 2. In each of the spaces just mentioned—called, for convenience, xylem spaces, because they lie above the xylem poles of the root—lies an isolated xylem element, the direct continuation of the most external element in one of the root poles, and this element comes to an abrupt end higher up.

Thus Prof. Van Tieghem has tacitly assumed that Tagetes is exceptional in this respect, and this view was also adopted by Prof. Gérard in his laborious and accurate paper of 1881. He describes the transitional phenomena of a number of Dicotyledons, among them *Tagetes erecta*. Not only is the transition in this species exactly the same as that in *T. patula*, but the author records a similar isolation of primitive xylem elements in *Raphanus niger*, *Ipomaea versicolor*, and *Datura Stramonium*, still treating the arrangement as exceptional.

These details are important, because if certain protoxylem elements belonging to the root are not continued upwards in regular succession into the cotyledonary or plumular bundles, but end abruptly in hypocotyl or base of cotyledon, there is not that complete correspondence between stem- and root-structure which is assumed in Van Tieghem's three types. In all of them the xylem and phloem bundles of the root are continued into the cotyledons or plumule. On their way through the hypocotyl they may divide or be displaced, and the xylem bundles "rotate"—that is, they turn on their own axes until the protoxylem is internal. But all the elements present in the root are continued upwards in regular succession, and are simply rearranged in the upper part of the seedling. This is one of the main arguments advanced by Prof. Van Tieghem to support his view that the steles of root and stem are identical.

According to most later observers, however, such temporary prolongation of the root-poles upwards as that described by Profs. Van Tieghem and Gérard in a few instances, and considered by them as exceptional, is really of general occurrence. The protoxylem elements, indeed, are not commonly isolated from the main xylem of the cotyledonary traces as in Tagetes, but are in more or less complete contact with them on either side. Such contact is approached in *Raphanus niger*, where it is very clearly suggested in Prof. Gérard's figures.

There is then a real difference of opinion on a question of fact between Prof. Van Tieghem and his school, on the one hand, and certain modern embryologists on the other. Three distinct views are now held as to the interpretation of the isolated xylem elements in the hypocotyl of Tagetes. I shall try to state them as fairly and concisely as possible.

Profs. Van Tieghem and Gérard treat Tagetes and the genera which resemble it as exceptional, because part of the external xylem of the root is continued upwards between the cotyledonary traces, and dies out in the base of the cotyledon. They consider that the remainder of the external xylem turns on itself and becomes internal in the usual way.

Prof. Gravis and his pupils think that a similar prolongation of the xylem poles of the root into the hypocotyl or cotyledon is the rule, and that they terminate there abruptly. But in most cases this vestigal root-xylem is not isolated; it is in contact on either side with the early xylem of the cotyledonary

[3] By this qualification I mean to exclude cases in which the young seedling is very greatly reduced.

traces, and is therefore apt to be confused with it. The characteristic shape of so many cotyledonary traces arises in this way. They are often called double bundles, but according to Prof. Gravis they are more than double, for each really consists of two traces in close contact with the last vestige of root-xylem. The latter always disappears higher up in the cotyledon, and the two traces may then unite into a midrib, with or without lateral branches. As a consequence of this view, Prof. Gravis considers that there is no morphological continuity in the hypocotyl between the vascular systems of root, stem, and leaf.[4] Their traces are merely in contact sufficiently intimate for physiological purposes. There can, therefore, be no true homology between the central cylinder of the stem and that of the root.

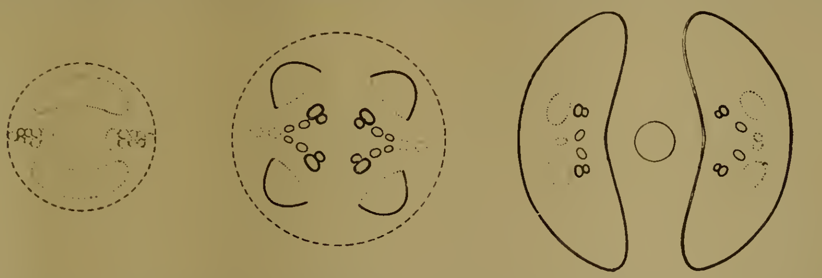
The third view is that of M. Chauveaud, who has been engaged for upwards of twenty years in following the development of the vascular elements in the hypocotylar region and its neighbourhood. He agrees with Prof. Gravis that the presence of external xylem is the rule in the hypocotyl and in the base of the cotyledon. But he considers that this external xylem belongs to the primitive structure of hypocotyl and cotyledon as well as to that of the root. We have already said that the vascular system of seedlings is first differentiated in the hypocotyl, base of cotyledon, and base of primary root. In all these regions M. Chauveaud thinks the primitive stele to be root-like—in his own phrase it belongs to the "disposition alterne." The xylem alternates with the phlöem, and its development is centripetal. This primitive formation, however, is permanent only in the root, and commonly in the lower part of the hypocotyl also. In the upper part of the hypocotyl and in the base of the cotyledons the first xylem elements are fugitive. They disappear so early that, as a rule, they are missed completely by the anatomist, who is apt to prefer well-differentiated tissues, and therefore to choose seedlings which are past their first youth.

In considering the theory of stelar evolution in which M. Chauveaud has correlated his own long series of observations with the results of other embryologists, I shall confine myself strictly to the question now under discussion—namely, the extent to which the stele of the young stem in Phanerogams can be considered to represent that of the root. Prof. Van Tieghem, as we have seen, considers them completely homologous, while Prof. Gravis denies that they are homologous at all.

M. Chauveaud occupies a middle position. If I understand his views rightly, he considers that there is an early phase in the development of the seedling in which the stele of the hypocotyl—at that time the only representative of the stem—is developing on exactly the same lines as the stele of the primary root, and is, in fact, continuous with it. At that epoch each cotyledonary trace is also developing on the same plan. It belongs to the same phase of evolution, and in many species of Dicotyledons the insertion of the cotyledons is the simplest imaginable. The original stele of the hypocotyl divides below the cotyledonary node, and one-half goes to each cotyledon.[5]

In species where this formation is clearly developed there cannot be said to be any transition between stem- and root-structure. Stem-stele and root-stele are continuous: their steles are developing in the same way. Even the leaf-traces of the first two leaves are on similar lines, and their insertion, therefore, does not modify the structure of the stele.

How, then, does the structure we associate with the stem of Phanerogams appear. In the transitonal region of the hypocotyl the first xylem elements—perhaps only two or three at each pole—alternate with the phlöem groups. The elements next differentiated lie within them, for development is still centripetal, but in two diverging groups. The xylem-ray is then shaped like an inverted V. Each arm of the V approaches the adjacent phlöem group as it travels inwards, until the last-formed elements lie on the same radius as the centre of the phlöem group, but well within it. The next elements are differentiated on that radius, but are directed towards the phlöem: development has become centrifugal. These successive xylem formations are called by M. Chauveaud the *alternate*, the *intermediate*, and the *superposed*. They are distinguished in the diagram by dotted lines for the alternate elements, thin lines for the intermediate, and thick lines for the superposed.



The alternate elements are fugitive in this transitional region; they commonly disappear as the superposed elements become conspicuous. The intermediate xylem persists. But higher up in the hypocotyl the intermediate elements, too, disappear as the seedling grows older. They vanish in the traces of the cotyledons also, and in the cotyledons themselves. Thus in seedlings of a certain age we have endarch bundles at the top of the hypocotyl, forming a stele of the stem type, and an exarch stele lower down, which passes unchanged into the root. The connection between the two is maintained by the intermediate xylem of the transitional region.

Although M. Chauveaud has been publishing his researches since 1891, yet he has only lately (1911) put his results into a connected form, and they are therefore less familiar than might otherwise be expected to anatomists who are not also embryologists. They clearly have a direct bearing on the theory of

the stele. Before, however, entering on this subject, I ought to say something on the question of fact. In my opinion M. Chauveaud's figures and descriptions represent the vascular development in the hypocotyl and cotyledons of Angiosperms more accurately than any others with which I am acquainted. He has dealt more fully with Dicotyledons than Monocotyledons, but I have been able to verify his account of the latter to some extent by reference to my own preparations, which include a number of species closely allied to those which he has cut. Among Dicotyledons I have had the great advantage of consulting the preparations of Miss Thomas and of Mr. R. H. Compton. Neither of these botanists made their preparations to illustrate M. Chauveaud's theory; indeed, they attacked the subject, as I did, with aims distinct from his. There has therefore, been nothing like complete verification in any single species, but so remarkable a correspondence with his figures in similar stages of the material, that I am satisfied of M. Chauveaud's fidelity.

Assuming, then, that his account of the vascular development in a young seedling is substantially correct, what are we to conclude as to the homology of the central cylinder of the stem with that of the root?

M. Chauveaud himself believes the stem cylinder in the upper hypocotyl of a fairly old seedling to be a true stele, but one belonging to a later phase of evolution than that of the root, and not, therefore, strictly homologous with it in the sense in which the earliest vascular formations in cotyledon and hypocotyl respectively were homologous with each other. He considers the successive vascular formations which we have just followed in these regions—formations marked by the appearance of alternate, intermediate, and superposed xylem in turn—to represent three successive phases of stelar development. The root-stele corresponds to the first of these phases only.

But questions of phylogeny are strictly historical, and the only precise meaning that can be attached to the expression "successive phases of stelar development" in the seedling of an Angiosperm is that at some past period a group of plants in the direct line of descent of Angiosperms possessed a stele resembling that which is now a mere stage in the life of the individual. Thus the alternate formation found throughout the very young seedling implies an ancestral group with an exarch stele in stem as well as root, and a leaf-trace of corresponding structure.

There is nothing at all improbable in this hypothesis, since groups with exarch steles in stem as well as root are found among living and extinct plants. But if adopted several important consequences would follow. The seedling while it consists of cotyledons, hypocotyl, and primary root only—the plumule present as a mere bud—must represent a past period in race-history when its ancestors possessed an exarch stele in stem and root alike; when the stem-stele belonged to the stem only, and the insertion of leaf-traces hardly modified its structure; when it entered the root without change, and therefore no transitional region occupied and puzzled the anatomist of the period.

This early stage in the development of the seedling is succeeded by that in which the epicotyl begins to grow, and as a rule the epicotyl is quite undoubtedly modern.[6] Its vascular skeleton is built up of leaf-traces, which are endarch from the first. At the cotyledonary node they are inserted on the vascular cylinder of the hypocotyl, which has become endarch at the top. This transition has been effected lower down in the hypocotyl, as described already, by the formation first of intermediate, and then of superposed xylem, together with the gradual disappearance of the original alternate xylem.

Thus the cotyledonary node may be considered to mark the interval between two acts in the drama of evolution—an interval the length of which cannot yet be estimated, but is clearly to be reckoned in geological epochs.

The race-history of the Phanerogamic stem-cylinder is at present unknown. How did the ancestral stele lose its exarch character, and what intermediate stages led up to its present construction from endarch leaf-traces? Possibly the development of the hypocotyl may give a clue as suggested by M. Chauveaud, and the change have been effected by the development of intermediate xylem. Or Prof. Jeffrey may be right in deriving the leaf-traces from a siphonostele which has been gradually more and more broken up by the appearance of foliar gaps. This process is said to be exhibited in the young epicotyl.[7] Until this point is cleared up the exact relationship of the vascular cylinder of the stem to that of the root will remain obscure. As a matter of convenience the stem-cylinder will, no doubt, be called a stele, even though anatomists should acknowledge that it cannot be considered as strictly homologous with the stele of the root. Much confusion of thought would, however, be avoided if the two structures were not treated as strictly comparable.

There can be very little doubt that the insertion of leaves has brought about the change, and I might suggest here that the insertion of leaves on an exarch stem-stele would be an interesting subject for research. The literature of the subject is scattered, and its treatment seems to me very incomplete. An exarch axis bearing leaves is, of course, exceptional, but more common among extinct plants than among recent species. So far as my very cursory examination of the literature has gone, it seems a general rule that the leaf-traces are inserted on the xylem poles of the stele.[8]

Hitherto I have considered modern embryology in relation to a single problem of internal anatomy—namely, the comparison of the vascular system of the stem to that of the root. But the evidence of embryology is also of great weight in questions of internal morphology and phylogeny.

Several questions of this kind are discussed by Hanstein, from whose classical paper I continue to date. For example, his account of the embryo of Monocotyledons suggests two distinct problems. One belongs to formal morphology—namely, the question whether a terminal member can be considered as a leaf. The other is a question of phylogeny: whether Dicotyledons are derived from a monocotylous ancestor or Monocotyledons from a dicotylus form. Both these questions I have discussed elsewhere,[9] and only refer to them now as examples of the way in which seedling anatomy has proved complementary to that of the older embryologists.

The most obvious interpretation of Hanstein's observations is that the single cotyledon of Monocotyledons is equivalent to the pair found in Dicotyledons. This would imply that Dicotyledons were

[6] The epicotyl in the *Viciea* has been described as containing centripetal xylem. The facts are given by Mlle. Goldschmid (1876), Prof. Gérard (1881), M. Chauveaud (1911) and Mr. Compton (1912). The theoretical interpretation is discussed by M. Chauveaud (*l.c.*, p. 348) and Mr. Compton (*l.c.*, pp. 93–95). There seems every reason to think, as Mr. Compton suggests, that the character is adaptive, depending on the twining habit. He points out that *Vicia Faba*, which does not twine, has a normal epicotyl.

derived from an ancestor with one cotyledon, apparently terminal, which gave rise to the existing pair by a process of fission. But other interpretations were always possible, and the terminal hypothesis received a shock when Count Sohms-Laubach discovered that in certain Monocotyledons the single cotyledon is lateral from the first.

The comparative antiquity of Monocotyledons and Dicotyledons has been one of the first questions raised by the study of seedling anatomy. It is remarkable that both the hypotheses founded on work of this kind assert the greater antiquity of the dicotylous form. But if the cotyledonary member of Monocotyledons is derived from one or both cotyledons of an ancestral pair, it cannot be considered as terminal. Thus the evidence of seedling anatomy bids fair to settle both these questions, as I think it will settle others of the same kind mentioned by Hanstein.

The descriptive work of Irmisch and the school he represents has been carried on of late years by an American naturalist, Mr. Theo. Holm, with all the technical advantages given by modern instruments of research. His papers are commonly written with systematic intention, but the external characters of the species he describes are correlated with their internal anatomy, and the structure of the adult form is traced from its origin in the seedling. His monograph on *Podophyllum peltatum* is an example of this method, and illustrates its advantages in a very striking way. But it is becoming much more usual to compare the seedling with the adult form, as may be seen in two monumental works now being published in parts: "Das Pflanzenreich," edited by Engler, and "Lebensgeschichte der Blütenpflanzen Mitteleuropas," edited by Kirchner, Loew, and Schröter.

In a very useful paper on modern developments of seedling anatomy Mr. Compton has pointed out that the subject has been attacked from several divergent points of view. I have already referred to the work of M. Chauveaud and Prof. Gravis, and have now come to that of a number of English botanists, whose aim—as Mr. Compton observes—is mainly phylogenetic. They are even more clearly distinguished by their methods, which are those of comparative anatomy. Instead of following the development of the seedling of a single species from germination to the age at which its cotyledons begin to decay, as M. Chauveaud has done in a number of carefully selected instances, they have compared the seedlings of different species and different genera at about the same age, generally choosing the epoch at which the tissues of cotyledon, hypocotyl, and primary root are most completely differentiated. There is nothing new in this treatment of the subject. It was employed in 1872 by Prof. Van Tieghem [10] in his paper on the anatomy of grass seedlings, in which he compares them with other Monocotyledons of the same age. Much greater precision is possible, however, now that the microtome has come into general use.

The literature of this subject has increased rapidly of late years. The list of references in the footnote [11] appended to this paragraph is, I fear, far from complete. But it is not part of my plan to review this work critically. The time is, perhaps, not ripe for such a review, and certainly the time at my disposal to-day is quite insufficient for it. Perhaps I may be allowed to offer some general remarks, first on the method itself, and then on the criticisms it has encountered.

To compare the structure of organisms with each other is, of course, the recognised method of comparative anatomy, of systematic botany, and, in fact, of all branches of morphology. The great difficulty in all such work is to distinguish between adaptive characters of comparatively recent origin and the characters inherited from remote ancestors. The history of systematic botany is very instructive in this respect. Systematists discovered by degrees, and by means of repeated failures, that characters could not be picked out as important for purposes of classification on *à priori* grounds. No character is of uniform importance throughout vascular plants, for example. On the contrary, it may be of great value in the classification of one group and worthless in another, though closely allied. Generations of botanists have laboured to build up the natural system in its present form, and it is constructed from the ruins of abandoned systems. We all agree now that the guiding principle in all morphology is that our classification should represent relationships founded on descent only. But the natural system was complete in its main features before that principle was understood. It represented the feeling for real affinity developed in botanists by the study of plant form, independently of any theory as to the cause of such affinity.

This, of course, is the commonplace of botanical history, but we do not always realise that all morphological work is done under similar conditions. The only valid appeal from criticism is to the future: a new method is approved by its results. Therefore, to embark on a new branch of morphology is a real adventure. The morphologist risks much time and much labour. He knows that the evidence which he proposes to gather painfully, to test critically, to present logically, may, after all, prove of little consequence, and he has to depend on his own instinct to lead him in the right course. In his degree he resembles Columbus, to whom a few sea-borne seeds and nuts meant a new continent.

Hence the difficulty of criticising recent work. When once a conclusion of some importance has been formulated it may be tested by evidence drawn from other branches of research. Until that time criticism from outside is of little value. Those who are working at the subject must, of course, form their own opinion on its possibilities, for each has to decide for himself whether he shall continue on those lines.

The subject of seedling anatomy is no longer very new. It is too late now to debate on the *à priori* probability of ancestral characters surviving in the young seedling. No one doubts that a vascular stump sometimes persists after the organ it originally supplied has disappeared.[12] Therefore there is no glaring improbability in the suggestion that the vascular skeleton of the young seedling may afford a clue to the structure of a remote ancestor. But this is only saying in other words that botanists are justified in giving the subject a fair trial. That trial is now proceeding. Some general conclusions have been formulated already, but they have not yet stood the test of time. In all probability the final judgment on this subject will be given by a future generation of botanists on evidence not as yet before us. In the meantime we shall all form our own opinion as to the prospects of the method. Speaking for myself, I think that it has already thrown much light on embryological problems, and is likely to throw more.

At the end of this very short and imperfect sketch of the progress of botanical embryology in recent years, it is natural to look back and attempt to estimate the importance of the whole subject and its relation to other branches of botanical science. I have treated it from the morphological side only, but clearly every department of botany must deal with the immature plant as well as with the adult form. For example, the struggle for existence between two species in any particular locality must be profoundly affected by the characters of their seedlings. If one species should gain a decided advantage over the other early in life, the vanquished species may never live to form seed, and may thus disappear from that neighbourhood in the first generation. This is an extreme case to show the importance of considering seedling structure in problems of ecology and distribution.

The internal structure of seedlings is certainly a department of vegetable anatomy, just as their adaptation to the conditions of life is a department of vegetable physiology. That the connection between embryology and systematic botany must be equally close seems at first sight to be beyond dispute, but the exact nature of that connection is as yet undetermined. In systematic botany we have the net result of an enormous mass of experience. Generations of botanists have examined and described the external characters of plants; they have arranged and rearranged them in groups until at last the instinct for affinity has been satisfied. In this continual sifting of characters some have been separated out as generally of systematic importance—the floral characters, for examples, and those of the seed. Certain features of the embryo are included among those characters, as already mentioned, but, on the whole, systematists have dealt exclusively with the adult plant. The embryo itself has been treated rather as a portion of the seed than as an individual.

It would be rash to assume that seedling characters have been disregarded by systematists because they were too busy with the fully-developed plant to pay proper attention to the young forms. In all probability some of the earlier botanists examined the external characters of seedlings and rejected them when they proved of little systematic value. But embryology, like the other branches of botany, entered on a new phase when the compound microscope came into general use. It was commonly denied that the anatomical characters of mature plants had systematic value until the test case of fossil botany was decided in favour of anatomy. We need not be surprised that conclusions drawn from the new embryology—that is, the embryology which includes internal characters as well as external—sometimes appear to conflict with the results of systematic botany, and it does not necessarily follow that embryological evidence is of no systematic value. The fault may lie with the embryologists, who, being human, do occasionally misinterpret their facts, or possibly the natural system may need some modification in the light of new knowledge. When both explanations have failed to account for the discrepancy in a number of cases we may be forced to give up looking for phylogenetic results from embryology.

And so in the end the appeal is again to Time, who as Milton says—devours

"No more than what is false and vain,
And merely mortal dross.
So little is our loss.
So little is thy gain."

[12] *Cf.* the discussion of the homology of the Orchis-flower in Ch. Darwin's "Fertilisation of Orchids," chap. xiii., p. 2?5 in second ed., 1888.

SECTION L.

EDUCATIONAL SCIENCE.

FROM THE OPENING ADDRESS BY PRINCIPAL E. H. GRIFFITHS, LL.D., F.R.S., PRESIDENT OF THE SECTION.

We have now had forty years' experience of compulsory education, and more than ten years' experience of the working of the Education Act of 1902. We are spending at the present time out of the rates and taxes about thirty-four millions per annum upon education. It seems reasonable, as a nation of shopkeepers, that we should ask if we are getting value for our money, and the reply will, of course, depend on what we mean by value, for the man in the counting-house, the man in the street, and the man in the schoolroom all have different standards of valuation.

Some of us are old enough to contrast the position of to-day with that of forty years ago. Do we observe any definite advance in knowledge, intelligence, character, or manners, as compared with the pre-compulsory days? We must all be aware of the tendency to magnify the past at the expense of the present, but, after making due allowance for the fact that "the past seems best, things present ever worst," it appears difficult to find distinct evidence of improvement in any way commensurate with the sacrifices which have been made.

I have taken every opportunity of ascertaining the views of men of varied occupations and differing social positions upon this matter, and I confess that the impression received is one of universal discontent. The complaints are not only of want of knowledge, but also, which is far more serious, of want of intelligence. Consider a trivial example drawn from my own experience. I am a motorist in a small way. My ambition has been restricted in the matter of chauffeurs to lads fresh from our elementary schools, whom I have employed for what I may summarise as washing and greasing purposes. Some six or seven of such lads have passed through my hands during the past nine years, and all of them have been at a primary school for some seven or eight years. They came with good characters, and all had passed up to the fifth or sixth standard. None of them could spell correctly, keep simple accounts, or appear to derive any enjoyment from reading.

Nevertheless, two of them, at all events, gave evidence of a real liking for mechanics, and within a year or so could be trusted to take the engines to pieces, clean them, and replace them with but little supervision. It might be argued that although they had imperfectly acquired the rudiments of "the three R's," the aptitude of these lads was the result of their training. Of this, however, I could find no evidence. It is difficult to understand how these boys could have profited so little by their many years of school life. If such an example is in any way typical, it is time to consider what the country is obtaining in return for the thirty millions annually expended on elementary education alone.

It may be thought that I have been unfortunate in my experience. I do not, however, believe that my case *is* singular. In *The Contemporary Review* for July, 1909, Prof. Stanley Jevons contributed an article on "The Causes of Unemployment." He referred therein to the opportunities afforded him by University Settlement Boys' Clubs in London and Cardiff of forming a judgment concerning the products of our primary schools. He described the following experiment:—

"I arranged to test a few members of the Boys' Club. They were gathered in a room with pens and papers and were asked to write down the following short sentence, which was spoken to them distinctly twice, as an example of the kind of message which they might be expected to have to write occasionally for an employer: "I have not been able to find the book which you sent me to fetch." The test was one both of memory and spelling, and most of the boys failed in one or both respects."

Prof. Jevons gave facsimiles of the results, which I am unable to reproduce; but I can indicate the nature of the spelling. It will be noticed that there are no words of two syllables. The following is the best of the batch:—

Boy aged nearly sixteen: "I cannot (fetch) find the book which you sent me to fetch."

The following are from boys aged fourteen and fifteen respectively:—

"I have not been *abele* to find the *boock whi witch* I sent you (for) to *fitch*."

"I have Not *bend* able to find the book *With* I sent you to *fath*."

All these boys have been through one of our large primary schools.

Prof. Jevons added: "In contemplating the question of unemployment one is at once led to the conclusion to which so many other economic problems ultimately lead—that the only certain means of abating the evil is the improvement of the individual."

Passing from such limited experiences to the views of those who are brought into contact with the products in bulk, a sense of dissatisfaction and uneasiness is no less evident. Consider the following extracts from the presidential address of Mr. Walter Dixon, to the West of Scotland Iron and Steel Institute in October last:—

"I have, over a somewhat extended period and a wide area, made inquiries amongst those who have the control of about 200,000 men in our own allied industries, with the following results:

"It is the unanimous opinion that any book-learning outside the rudiments of 'the three R's' is considered a matter outside the requirements of the education of more than 90 per cent. of the usual manual workers. In other words, the work that these men are called upon to do, the labour which they have to perform in their daily avocation, would be as efficient, as successful, and as expeditiously performed if the men had no school education whatever outside 'the three R's.'"

If there is any truth in this severe indictment there is small cause for wonder if a general sense of uneasiness exists amongst those who consider that the future prosperity and safety of this country are dependent on the manner in which we train the rising generation.

In justice to Mr. Dixon I must give a further extract from his address:—

"During the recent meeting of the British Association in Dundee I spent some time amongst educational authorities, not only those belonging to our own country, but delegates from other nations, and I find that they themselves are beginning to see the futility of the present methods and to realise that they are ploughing the sands. Amongst other matters, it was of interest to note that they are at present promulgating a scheme for what they call vocational education. In other words, I gather that they are now attempting in a modified way to replace the old 'prentice system by teaching trades in their schools, so that children may enter the trades as skilled workers—a system which, to my mind, would render the present confusion more confounded. . . . We must recognise that the mechanical developments of the last half-century have done away in a large measure with the possibility of the interest which man could once take in his daily work, inasmuch that few men now make anything, but only a *small portion of something*. A statement was made at Dundee that 135 different persons were employed in the making of a boot. It is not to be expected that any of these 135 workers can get enthusiastic about their particular bit. We must recognise that as long as we live under the reign of industrial competition the hours of labour are likely to be hours of stress, and that when a man has finished his labour it is only right, it is only human, that he should have hours of reasonable recreation. It is with a view of making these hours of recreation worthy of the nation to which we belong that I feel that our educational methods might, and ultimately will, be altered and rendered valuable."

If I may venture to summarise Mr. Dixon's address as a whole, it appears to me that the argument is somewhat as follows: It is admitted that "the three R's" are necessary for all workers, of whatever grade, almost as necessary for the mental as are sight and hearing for the physical equipment. A large majority of manual labourers, however, are not rendered any more efficient in the discharge of their tasks by further instruction of an academic character, and therefore we should aim at providing them with some form of education which would so quicken their intelligence as to enable them to find an interest in matters external to their employment and thus lead them to utilise their hours of creation in a sane and healthy manner. It should be our object not so much to train all our soldiers as if they were to be generals, as to give them that education which would make them good soldiers, and to spare no expenditure of time or money in the further education and development of the small percentage who have shown those qualities which lead, under proper guidance, to high achievement.

The assumption that all children are fitted to profit by more than the rudiments of academic education is, I believe, responsible for many of our present difficulties. In physical matters we seem to be wiser. We take account of bodily disabilities; we do not train lame men for racing, or enter carthorses for the Derby; we do not accept the short-sighted or the colour-blind as sailors; but those who talk of compulsory further education appear to think that all men are on an equality as regards mental equipment. Democracy in its control of education counts noses rather than brains, I observe, for example, that the education committees, on which I have, or have had, the honour of serving, are unwilling to continue those higher technical classes in science in which the numbers are necessarily small. A class of four in higher mathematics will probably be discontinued, whereas a class of one hundred in shorthand will be regarded as a highly successful achievement.

Such education committees, however, are only carrying out what is apparently the policy of those sitting in the seats of authority. A nation which expends but four millions for the encouragement of higher education and research and thirty millions on the rudiments cannot be said to lend that recognition, assistance, and encouragement to the best brains of the country which is the one form of educational outlay which is certain to bring, as Mr. Wells has truly indicated, not only the best return industrially, but also an immunity from invasion otherwise unobtainable.

It is possible that the views taken by Mr. Dixon and the employers and business men whose opinions I have attempted to gather are unduly pessimistic. I have, therefore, turned naturally to the teachers, with many of whom I am brought into contact.

I find, on the whole, much the same spirit of pessimism prevailing. I can only recollect one gentleman—a teacher of long experience and high standing—who takes a brighter view of the position. According to him, the children leave our schools better instructed, more intelligent, and better mannered than was the case some twenty years ago.

It is true that teachers as a body agree that there has been one real advance—viz., the abolition of the system of payment by results—but many of them admit that during the past ten years progress, if any, has been slight. They plead in extenuation that the large size of the classes is in itself a barrier to real efficiency, and that the teacher is so fettered by regulations, so bothered by the fads of individual inspectors, that we ought to be gratified, rather than disappointed, by the results achieved. It is a significant fact that the supply of teachers for our primary schools is diminishing, and that, as a necessary consequence, the proportion of fully trained and qualified teachers, although increasing, is unduly small. The attractions of the profession are undoubtedly insufficient. When we consider the meagre salaries, the slow, very slow, promotion, the few prizes and the slight social recognition, it is a surprising fact that so many able men and women are prepared to accept the lot of teachers in our primary schools.

The teaching profession, if profession it can rightly be termed, compares unfavourably with the so-called learned professions. It is noticeable that but few of our primary school teachers are prominent in civic affairs. Their representation on education committees, for example, is quite inadequate; during the discharge of their duties they are unable to mix with their fellow-citizens, and thus gain experience in the same manner as the clergyman, the doctor, or the solicitor. The regulations practically forbid participation in public life, and the teachers' activities are regarded as bounded by the walls of the schoolroom.

If the results of our educational system are disappointing, it is not for us to throw the blame on the teachers. Until we learn that satisfactory results can be obtained only when the life and emoluments of the schoolmaster are such as to offer avenues to distinction comparable with those of the learned professions, we cannot hope to attract into what should be, after all, the most important of all professions, the best brains and energies of the community.[1]

Undoubtedly, however, we *have* made advances within the last generation. Our outlook is different, but we are expecting higher achievement without affording that inducement which entitles us to demand it. Our industrial needs have impressed upon us the necessity of a wider view of the meaning of the word "education." We are slowly learning that we should aim at the awakening of the intelligence, rather than at the mere imparting of knowledge by what I might term force-pump methods. Forcible feeding is not proving a success either physically or mentally.

Some fifty years ago a leading name in the educational world was that of Todhunter—a name which I admit was regarded with terror rather than affection by many of us in our school days. As a correction to pessimism I venture to inflict upon you the following extract from Todhunter's "Conflict of Studies," published in 1873:—

"It may be said that the fact makes a stronger impression on the boy through the medium of his sight, that he believes it more confidently. I say that this ought not to be the case. If he does not believe the statement of his teacher—probably a clergyman of mature knowledge, recognised ability, and blameless character—his suspicion is irrational and manifests a want of the power of appreciating evidence, a want fatal to his success in that branch of science he is supposed to be cultivating."

I take a singular pleasure in this extract. In times of depression it serves as a tonic and drives one to the conclusion that, after all, our progress, however slow, is real, although I have an impression that the Todhunter school is not entirely extinct.

So far, the only result of my inquiries has been the discovery, if discovery it was, that dissatisfaction with our present system was the prevailing sentiment. I decided, therefore, to take the somewhat bold step of endeavouring to ascertain the attitude of those who have most to do with the administration thereof. I ventured to send to all the directors of education in England and Wales a series of questions, the answers to which I hoped might throw light on the matter. In order to elicit, if possible, free expression of opinion I stated that their replies would in general be used only for statistical purposes, and in no case would indication be given of the authority with which the writer was concerned.

I take this opportunity of most sincerely thanking the many directors who have been so good as to assist me in this inquiry. No fewer than 121 of these gentlemen have undertaken the task of returning replies, and when I reflect upon the extent to which their energies are employed in compiling returns for their various authorities and for the Board of Education, I realise my temerity in thus adding to their labours.

In analysing the replies it has been necessary to divide them into the following classes, viz.: (1) Counties, (2) county boroughs, and (3) boroughs and urban districts, as the conditions in these areas, under the Act of 1902, differ considerably.

We must remember that as the directors of education have to work the machinery, they are perhaps in a better position than any others to form a judgment as to excellences and defects. True, they look on the matter through official spectacles, which are always more or less tinted, and they may, like many owners of motor-cars, have a tendency to hide imperfections.

[1] It appears that our average expenditure per child per working week (including interest on buildings, &c.) is about 1s. 8d. Perhaps we are getting in return as much as we deserve at the price.

In Class 1 (counties) I received replies from thirty-six directors; in Class 2 (county boroughs) from forty; and in Class 3 (boroughs and urban districts) from forty-five.

The authorities concerned are fairly representative of all portions of England and Wales, and both of rural and urban districts. In order to render comparisons possible, I express the nature of the replies in percentages of the whole of the class. I believe, however, that the effect of reading out, in circumstances of this kind, a large number of tables containing numerical data would be to occupy a considerable portion of your time, and yet leave but little definite impression. I have, therefore, given these tables as an appendix to this address, and will now only trouble you with a reference to the results and some examples of the interesting remarks included in the replies.

My first question was :—

I. "Do you consider that the centralisation of authority in the hands of county councils has caused any decay of interest in education in your district?"

Reference to Table 1 will show that while in large areas the effect of the Act has been to stimulate interest in educational matters, in small boroughs and urban districts the reverse has been the case. It is difficult, however, to classify strictly many of the replies, as will be seen from the following examples.[2]

As a natural sequence to this interrogation I made the following inquiry, namely :—

II. "Would you prefer the educational authority to be one elected *ad hoc*, as in the days of the school boards, rather than the system as at present established?"

As might be expected, those directors who considered that the present system has caused a decay in local interest are, with some few exceptions, in favour of a return to an authority elected *ad hoc*. Replies in the affirmative form a large proportion of the whole, no less than 72 per cent. of the boroughs and urban districts being in favour of a return to the old system. In considering the answers to both these questions it should be remembered that previous to the Act of 1902 counties, as such, had no experience as regards primary education.

The Act of 1902 gave to the county councils, as regards the constitution of their education committees, considerable powers of cooption. I was anxious to find to what extent this power had been utilised, and, therefore, my third question was :—

III. "To what extent has cooption of members of the education committee been adopted in your area—*i.e.* what proportion do the coopted members bear to the whole committee, and what is the proportion of coopted women members?"

The average percentage of coopted members is curiously equal in all three classes—viz. thirty-one, thirty-three, thirty. The highest percentage is forty-eight, and the lowest three. It is noticeable that the percentage of coopted members is less in Wales than in England. A reference to the tables will show that a considerable number of directors are desirous that the principle of cooption should be extended.

My fourth question was :—

IV. "Have your local committees, or bodies of school managers, the right of appointing (*a*) head teachers, (*b*) assistant teachers?"

I find that, as regards head teachers, more than one-half of the counties, one-third of the boroughs, but only a small proportion of the county boroughs, have delegated all powers; the right of appointing assistant teachers being delegated to a slightly greater extent.[3]

The general result of the replies indicates that the power of appointment is unsatisfactorily exercised by local bodies of managers.

V. "Has the authority established a college for the training of elementary teachers, under its own management, or in conjunction with others?"

I find that as large a proportion as one-seventh of the authorities (counties and county boroughs) whose directors have returned replies have established training colleges. It does not appear, therefore, as if the present dearth of teachers was due to lack of training facilities.

I was anxious to ascertain if the effect of such local training colleges was to restrict the freedom of teachers, and the sixth question was as follows :—

VI. "Is the general effect of the present system to restrict the freedom of choice of teachers to those from your own locality?"

In about half the counties the answer is in the affirmative, and in the county boroughs about four-fifths.

It would appear that, on the whole, the opinion of directors is that the effect of the establishment of local training colleges has been to encourage the evil of what I may term "inbreeding."

VII. "Do you consider the curricula of (*a*) primary, (*b*) secondary, schools under your authority as overcrowded? If so, can you indicate the directions in which you consider there could be a reduction?"

Rather more than half of the authorities consulted considered that the curricula of the elementary schools are overcrowded, and rather more than a third are of the same opinion as regards the curricula of the secondary schools.

VIII. "Are you in favour of an increase in the number of vocational schools? Or do you consider that the effect of such increase would be detrimental to the standard of general education throughout the country?"

One-third of the county directors consulted, and almost half of those of the county boroughs and boroughs, answer in the affirmative, whereas rather more than one-fifth state their inability to arrive at a conclusion. A number of those who answer in the affirmative qualify their replies by stating: "For children over fourteen," or "General education must be first considered," "Provided general education is continued."

As a whole, the weight of opinion is strongly against any increase in vocational schools for children who have not completed their primary education.

IX. "What is the average size of the classes in your primary schools?"

I find that the average size of the classes in the counties is thirty-four, and in the boroughs forty-two, and they vary from over sixty-three down to ten. The smaller average in the counties is evidently due to the large proportion of rural schools.

My next question concerned the counties only. I was anxious to ascertain the effect of the clause of the Act which places on the locality the task of finding the greater portion of the money for additional buildings, viz. :—

X. "Do you consider Par. 18, 1 (*a*), (*c*), (*d*) of the 1902 Act to work harshly or to the disadvantage of educational progress?"

It appears that some 40 per cent. of the directors are of opinion that the effect of the clause is unsatisfactory. It must be remembered that it is not probable

[2] The examples referred to will be found in the address as printed in full and issued by the British Association.

[3] As regards non-provided schools, in all cases (by the Act) the power of appointing head teachers is in the hands of the managers.

that the officials of county councils would regard this matter from an impartial point of view, for, no doubt, the existing conditions lighten the burden of the county rates. It is somewhat surprising that in such circumstances the percentage of those answering in the affirmative is so large.

XI. "Has your council delegated to your education committee all the powers permitted by the Act? If not, are you in favour of such delegation?"

I find that while over 90 per cent. of the county authorities have delegated all powers, less than one-half of the county boroughs and three-fifths of the boroughs and urban districts have adopted the same course. An overwhelming majority (85 per cent.) of the directors of all classes are in favour of full delegation.

XII. "Please add any special criticisms of, or suggestions for, improvements in the Act."

It was very evident that most of my correspondents were anxious to avoid an expression of their views in this matter. The nature of many of the replies may be indicated by that of one of the directors—namely, "No, thank you." On the other hand, several have been so good as to write me short treatises on the subject, containing very valuable expressions of opinion. It is difficult, however, to quote from many of these without betraying the condition on which I invited confidence—namely, that I would give no indication as to the localities concerned. On one matter all who have expressed their opinions are in accord, viz.: "The greatest difficulty of the Act is the dual control for non-provided schools, more especially with regard to staffing."

It is stated that "the transfer and promotion of teachers is almost impossible under the present system." I feel, however, that the less I touch on this aspect of the matter the better for the peace of mind of this section. Again, all directors urge the necessity of relieving the increasing burden of the rates. One states that the proportion of Treasury grants has dropped from 66 per cent. in 1906 to 48 per cent. in the past year, while the local rate has been nearly trebled. Again: "Some means should be obtained to enable authorities with a large number of rural schools to provide adequate education without increasing the overwhelming burden now imposed upon them."

I may sum up as follows the impression left on my mind by the study of all the replies, of which I have given only a few examples.

1. The Act appears to give greater satisfaction in the counties than in the county boroughs and boroughs and urban districts, although even in the counties the position of the smaller rural schools is a cause of dissatisfaction.

2. That in the boroughs there is, on the whole, a preponderance of opinion in favour either of an authority elected *ad hoc*, or a more liberal exercise of the power of cooption.

3. That there is a preponderance of opinion that the appointments of school teachers should in all cases rest in the hands of the L.E.A.

4. That there is a tendency under the present system, except in centres of large population, to restrict the choice of teachers to those who have received their education locally, and that the effect of such restriction is detrimental.

5. That greater freedom in educational matters is advisable. The effect of the present system is to produce a dull uniformity, although it is doubtful whether the head teachers themselves or the Board of Education are most to blame.

6. That an increase in the number of vocational schools is not desirable, unless great care is taken that only those scholars are admitted who have received a sound general education.

7. That one of the greatest hindrances to progress is the large size of the classes.

8. That there should be a greater delegation of powers to the education committees, and that the L.E.A. should have complete control over all forms of education within its own area.

9. That a Redistribution Bill in the matter of areas is desirable, especially in the relation of urban areas to the rural districts connected with them.

10. That the dearth of fully qualified teachers cannot be remedied until the profession is made sufficiently attractive by increased emoluments and more rapid promotion. Mere increase in the number of training colleges is no remedy.

11. And, lastly, there is a consensus of opinion that a greater proportion of the cost of education should be borne by the Treasury, and that the danger to education arising from the rapid rate of increase in the education rate is a very real one. If education in this country is to be successful it must be made popular. This is impossible when every step in advance means an addition to the local burdens.

I am afraid that the tenor of this correspondence does little to modify the pessimistic views to which I have previously directed attention. Regarded in bulk it conveys the idea that the writers are endeavouring to make the best of a bad case. As shown by the last reply quoted (*supra*), the race of Mark Tapleys does not appear to be entirely extinct.

I wish it had been possible to obtain the confidential opinion of H.M.I.s, but I, at all events, am not one who would dare to question the gods, the distinguishing characteristic of those admirable officials being a cold infallibility which renders approach inadvisable. It must be remembered, however, that veiled hints of the need of drastic reforms have emanated from the highest quarters, and one of the most hopeful signs of the situation is that such information as has been vouchsafed to us appears to indicate that those who are moving in the matter actually acknowledge that there is an educational as well as a sectarian and a political aspect of the question. Nevertheless, so far as I am personally concerned I still find my chief consolation in the quotation from Todhunter which I have already inflicted upon you.

I am now going to take a bold step—namely, to express my own opinion on this matter of primary education. I consider that we are proceeding in the wrong order, in that we give greater prominence to the acquisition of knowledge than to the development of character.

There is truth in Emerson's dictum that "the best education is that which remains when everything learnt at school is forgotten." We appear to think that the learning of "the three R's" *is* education. We must remember that in imparting these we are only supplying the child with *means* of education, and that even when he has acquired them the mere addition of further knowledge is again not education. If we impart the *desire* for knowledge and train the necessary mental appetite, the knowledge which will come by the bucketful in after life will be absorbed and utilised.

It is, I know, easy to talk platitudes of this kind. We have, in justice to the teacher, to remember that character depends on home life, as well as on school life; but, nevertheless, if we could educate public opinion on this matter progress might be possible. We want to introduce the spirit of our much-abused public schools into all schools, namely, a sense of responsibility—and, as a necessary sequence, a sense of discipline—a standard of truthfulness and consideration. In this connection I have been greatly impressed by a report issued by the Warwickshire County Council on the effect of the establishment of the prefect system in the elementary schools of that county, and I wish it was possible to place this report in the hands of every teacher in the country. It is stated in the introduction that "the fundamental idea of the prefect system is the formation and development of character and the utilising for this purpose of the efforts and activities of our pupils themselves."

The pamphlet contains a description of the system as established, and the different methods adopted in the schools of the county in carrying it into effect.

A summary of the head teachers' remarks, compiled by the Director of Education, is given as an appendix, and I cannot resist the temptation to quote largely from his report:—

"In the autumn of 1911 a conference of head teachers was held on prefect systems in elementary schools. It was then decided that all the head teachers present should try the system for a year, each one on his or her own lines, and then report as to its working.

"Nearly all have now made reports, one only having failed without good cause. Reports have come in from six large or middling boys' schools, three large girls' schools, two large mixed schools, mostly in villages, and one infants' school—twenty-three in all, embracing schools of practically every type.

"The record, with one exception, is a story of success, in most cases of extraordinary success, so much so as to put the possibility and value of the system beyond a doubt. Whether in developing the prefect's own character, or in creating a sense of school honour among the other children, or in smoothing the whole working of the school, the result is equally striking. And the more ambitious the scheme of a school, the more it approximates to the public school tradition, the bigger the faith in boy and girl nature, the greater has been the success. The few evidences of comparative disappointment come from schools where the system has been tried haltingly and with distrust. Where there has been courageous faith in the children they have risen to it to a degree that must surprise even those who were readiest to believe in school self-government. Nor is the success confined to large schools or boys' schools. Boys' and girls' and mixed schools, town schools and village schools, all have the same tale to tell. A supply teacher who has served in seven schools since the conference has found that 'from all classes of children, town and country, a ready response is made to an appeal for added responsibility and trust on their part.' . . .

"The prefect, being in authority himself, comes to see the necessity and value of discipline. He is as keen as is his head for the school's honour; he worries the unpunctual, he takes charge of the playground. He is proud at being asked and able to help in matters of school routine, most of all when the teacher is called out of the class-room and he is himself responsible for order. And woe then to the disorderly or slack! . . .

"In its way one of the most remarkable applications of the system is its appearance in a miniature form in an infants' school. Children of six and seven, happy in the possession of the monitor's bow of ribbon, take care of the younger children and remove dust which has escaped the caretaker's eye. . . .

"It is a moot point whether a written constitution helps or not. Some teachers deprecate rules, as limiting a prefect's sense of responsibility and his freedom to follow out his own ideas. That rules, however, meet some want seems to be proved by the fact that at a school where the head master had purposely made none the boys themselves drew up their code, and, the head master adds: 'I could not have got out any better rules.'"

The origin of the movement the results of which are thus described is due to the man whom I regard as the greatest educator of our time—namely, Sir Robert Baden-Powell. I believe that the Boy Scout movement is rendering greater service than our complicated State machinery in preparing those who are brought within its influence for the struggles of life. It is a matter for regret that so small a fraction of the children in our schools is able to share its benefits. I only wish it were possible for our political system to admit the appointment of Baden-Powell as Minister of Education, with plenary powers, for the next ten years!

He states that when visiting a great agricultural school in Australia he asked the principal to inform him briefly what was the general trend of his training. The reply was: "Character first; then Agriculture."

If this, suitably modified, could be adopted as the motto for all our schools, the present attitude of the man in the street towards education would soon undergo modification.

There is truth in Dr. Moxon's statement that "A man has to be better than his knowledge, or he cannot make use of it," and our efforts should be mainly directed to making the character and the intelligence of the child so much better than his knowledge that increase in knowledge will follow as a matter of course. Let us devise some kind of universal junior scout system which may so brighten the intelligence that the boy will *want to know*. Let him also discover that the paths to knowledge are reading, writing, and arithmetic; he will then gladly follow his guides and gather more by the way than when he is pushed along those paths in a perambulator.

So long as we attach greater importance to the results of examination than to the judgment of the teacher our system stands self-condemned, for it places knowledge above character.

It is natural that the discontented amongst us should try to cast the blame on those in authority, and I confess that at times I feel as if I could join the militant section and relieve my feelings by throwing stones through the windows of the Board of Education; but in recent years I have been privileged to pass to the other side of those windows, and I have, to some extent, been led to realise how able and how devoted are the men to whom the guidance of our educational system is entrusted. All who are brought in contact with them must acknowledge their earnestness and their zeal in the cause in which they are enlisted, and it is remarkable how, in the discussion of educational questions, they can, in moments of partial *abandon*, cease to be strictly official and become almost human. It is evident, however, that the aim of such men must ever be the smooth working of the machine as a whole. The comforting words "coordination," "uniformity," "efficiency," are ever in their minds. A system planned on one great design and perfected in all its details is the ideal for which they are bound, consciously or unconsciously, to strive. The pity of it is that the more successful their efforts, the worse it is for education in this country.

Evolutionary progress is only possible where variety exists, and variety is necessarily abhorrent to the official mind. Freedom for local authorities to adopt their own methods, to experiment—and often to fail—is the system, if system it can be called, by which alone advance is possible. The curse of uniformity, perhaps the greatest curse of all, is a necessary consequence of over-centralised control.

I have trespassed so greatly upon your forbearance in discussing matters connected with primary education that I must give but brief expression to any views concerning the secondary and higher branches.

As I have previously indicated, State aid should be restricted to those who are able to profit thereby. The 25 per cent. free-place regulation has, it is generally admitted, brought into the secondary schools many really able students. On the other hand, there is no doubt that a certain proportion thereof would be more profitably employed in serving their apprenticeship in the business in which they are to earn their bread-and-butter. It is, of course, understood that those whose parents can afford to pay for the further education of their children and who are ready to do so are not here referred to, but, careful selection assured, generous assistance to those in need of help suggests itself as the best policy.

Another subject for consideration is the disproportion between the assistance given by the State to the training of primary and of secondary teachers. I understand that to the latter object, so far as England and Wales are concerned, the not impressive sum of 5000*l*. is delegated. After making due allowance for the difference in numbers under the respective headings, it is difficult to understand how it is necessary to expend a sum approaching 700,000*l*.[1] on the training of primary teachers, and only 1/140th of that amount on training those who are to guide our most able students in the pursuit of knowledge.

Had time permitted I should have liked to dwell on the evil effects of what I may term our conspiracy of silence regarding sexual instruction. If the proverbial visitor from Mars was engaged in a tour of inspection in our country, I think nothing would strike him as more extraordinary than that a subject which so closely concerns the progress of the race and the welfare of the individual should be entirely ignored in our system of education. By our action (or rather want of action) we tacitly admit that knowledge is harmful, and that we deliberately prefer such knowledge, which must necessarily be attained in one way or another, to arrive by subterranean channels and by agencies which will present facts of vital importance in their worst possible aspect.

We cannot be said to be really educating our children so long as we withhold from them all guidance in one of the most difficult problems which will be presented to them in later life, and when one reflects on the misery and wreckage consequent on our silence, it is difficult to speak with due moderation. I will therefore content myself with suggesting to those interested in this matter a study of the procedure adopted in the schools of Finland, in which systematic instruction is given by carefully selected teachers; it is stated with the happiest results.

I have referred, when speaking of primary education, to the curse of uniformity as one of the greatest evils of our educational system. So far, at all events, our provincial universities have escaped, although not entirely unscathed, from the cramping effects of departmental control. The situation, however, is not free from danger. It is necessary that these universities should be State-aided. It is also evident that, if we are to hold our own in competition with other nations, State assistance must be increased. There is danger, therefore, that the blight of uniformity and official control may descend upon them. The danger is not immediate, but it is nevertheless real. To some of us an ominous sign was the transference of the dispensation of the university grants from the Treasury to the Board of Education. It is true that we have evidence that no desire for undue control is manifest at the present time, and it is an encouraging sign that the Minister of Education, in a recent dispute connected with one of our youngest universities, intimated that he considered it beyond his province to interfere with its proceedings.

In this connection Mr. Austen Chamberlain has given me permission to read the following extract from a letter which I recently received from him:—

"I am in complete agreement with you as to the importance of preserving to the universities the greatest possible freedom and liberty. For this very reason I was at first strongly opposed to transferring the administration of the Treasury grants to the Board of Education; but I found that, for one reason and another, a considerable portion of their receipts were already received from the latter Board, and it was represented to me that this involved unnecessary complication and overlapping, and that the universities were likely to receive more generous consideration if the whole of the grants were placed in the hands of a single authority. At the same time I was assured that the Board of Education had no desire to claim a control different in character or extent from that which the Treasury had previously exercised. On receiving these assurances I withdrew my opposition to the transfer and sent word to the Chancellor of the Exchequer that I no longer held him bound by an undertaking which he had given me in the House of Commons that the transfer should not take place."

Another encouraging sign is the *personnel* of the Advisory Committee which the Board has established to guide it in matters connected with the University grants. We cannot, however, be certain that such wise views will always prevail, and I have already dwelt on the inevitable tendency of any department of State to influence and control the policy of all bodies receiving assistance from the Treasury.

The freedom of the universities is one of the highest educational assets of this country, and it is to the advantage of the community as a whole that each university should be left unfettered to develop its energies, promote research and advance learning in the manner best suited to its environment. It is conceivable that it might be better for our universities to struggle on in comparative poverty rather than yield to the temptation of affluence coupled with State control.

The State is at present devoting some 180,000*l*. to the support of university education in England and Wales. If, in addition, we include such institutions as the National Physical Laboratory and the grant of 4000*l*. to the Royal Society, we may say that this country is expending about 200,000*l*. per annum on the highest education and the promotion of research, a total but slightly exceeding that devoted to *one* of the universities of Germany. Comment appears needless.

When we reflect on the magnitude of the results

[1] Note I.—Grants for 1911–12:—

1. Grants from Board of Education:—		
(*a*) Maintenance grants to training colleges and hostels	£470,910	
(*b*) Building grants	93,406	
		£564,406
2. Grants from L.E.A.'s:—		
(*a*) To training colleges	21,682	
(*b*) To hostels	787	
(*c*) Scholarships (not possible to ascertain total)	?	
		22,469
Total		£586,875

Note II.—To the above must be added the grants in aid of bursars and pupil teachers, which amount to £101,802.

which would inevitably follow an adequate encouragement of research, the irony of the position becomes more evident. It was stated on authority that Pasteur during his lifetime saved for his country the whole cost of the Franco-Prussian War. It is computed that nearly one and three-quarter millions of our population are to-day dependent for their living upon industries connected with the mechanical generation of electricity—a population which may be said, without undue use of imagery, to be living on the brain of Faraday. We possess mathematicians who, granted encouragement, opportunity, and time, could establish laws of stability of aëroplanes. Suppose we spent some millions in discovering *the* man and enabling him to complete his task; the result might be an addition to our security greater than that of a fleet of super-Dreadnoughts. Unfortunately, there are no votes to be gained by the advocacy of opportunities for research!

Associations such as ours should spare no effort to bring home to the minds of the people the truth of the statement that the prosperity of this kingdom is dependent on its industries, and that those industries are founded on applied science.

Some years ago the *Petit Journal* invited its readers to answer the question, "Who were the twenty greatest Frenchmen of the nineteenth century?" No fewer than fifteen million votes were recorded. The resulting list included the names of nine scientific men, and Pasteur led by 100,000 votes over Victor Hugo, who came second, Napoleon securing the fourth place. It is obvious that a poll of such magnitude must have been representative of all classes. I ask you to reflect on the probable result, *mutatis mutandis,* if such a poll was taken in this country. I am afraid we should find the names of football and cricket heroes included, but I doubt if the name of a single man of science would appear amongst the immortals.

It should be our mission to make evident to the working man his indebtedness to the pioneers of science. Demonstrate to him the close connection between the price of his meat and the use of refrigerating processes founded on the investigations of Joule and Thomson; between the purity of his beer and the labours of Pasteur. Show the collier that his safety is to no small extent due to Humphry Davy; the driver of the electric tramcar that his wages were coined by Faraday. Make the worker in steel realise his obligation to Bessemer and Nasmyth; the telegraphist his indebtedness to Volta and Wheatstone, and the man at the "wireless" station that his employment is due to Hertz. Tell the soldier that the successful extraction of the bullet he received during the South African war was accomplished by the aid of Röntgen. Convince the sailor that his good "landfall" was achieved by the help of mathematicians and astronomers; that Tyndall had much to do with the brilliancy of the lights which warn him of danger, and that to Kelvin he owes the perfection of his compass and sounding line. Impress upon all wage-earners the probability that had it not been for the researches of Lister they, or some member of their family, would not be living to enjoy the fruits of their labours. If we can but bring some 5 per cent. of our voters to believe that their security, their comfort, their health, are the fruits of scientific investigation, then—but not until then—shall we see the attitude of those in authority towards this great question of the encouragement of research change from indifference to enthusiasm and from opposition to support.

When we have educated the man in the street it is possible that we may succeed in the hardest task of all, that of educating our legislators.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—A valuable addition to the equipment of the mining department of the University has been made in the form of an electrically-driven oil-boring derrick, which has been presented by the Oilwell Engineering Company, of Cheadle. The apparatus is capable of boring to a depth of 2000 ft., and by its means mining students will be able to acquire practical experience in the handling of oil-boring plant.

The following appointments have been made:—Mr. L. J. Wills, assistant lecturer in geology and geography; Mr. David Brunt, lecturer in mathematics (to succeed Mr. S. B. McLaren); Dr. C. L. Boulenger, reader in helminthology; Mr. H. G. Jackson, assistant lecturer in zoology.

By the will of the late Henry Follett Osler the University is to receive the sum of 10,000*l*., with a prospective share in the residuary estate.

LEEDS.—The following appointments have been made to the staff of the University:—Mr. S. H. Stelfox, assistant lecturer and demonstrator in engineering; Mr. F. Powis, demonstrator in chemistry; Mr. E. Lee, assistant lecturer in agricultural botany; Mr. N. M. Comber, assistant lecturer in agricultural chemistry; Mr. D. B. Morgans, assistant lecturer and demonstrator in mining.

THE Concrete Institute has arranged a course of six educational lectures on reinforced concrete: its commercial development and practical application, to be given by Mr. H. Kempton Dyson, on Wednesdays in November and December, beginning on November 12. The lectures will be given in the Lecture Hall of the institute, Westminster. There is no fee for the course; admission will be by ticket, obtainable on application from the secretary, the Concrete Institute, Denison House, 296 Vauxhall Bridge Road, Westminster, S.W.

AN examination of the prospectus of the East Ham Technical College, which was opened in 1905, and on which some 33,000*l*. was spent, shows that the boroughs round London are fully alive to the importance of providing a practical training in technology and science for those engaged in the industrial pursuits of the locality. The work of the college is done in some eight departments, and important among these are those for men engaged in building trades, engineers, chemists, commercial men, and for women workers. The more elementary evening classes are held in three preparatory evening schools in different parts of the borough, but in the college itself a preparatory industrial course has been provided designed to enable students later to follow intelligently the lectures and laboratory work in the different departments of technology.

PRESIDING at a recent meeting of the Senate of Calcutta University, Sir Ashutosh Mookerjee made an interesting speech on some of the work of the University. According to a report of the speech given in *The Pioneer Mail*, the University has arranged for lectures for M.A. and M.Sc. students in eleven different branches of study, including pure mathematics and botany. The University has made itself directly responsible for the instruction of 1005 students in Calcutta in these subjects for the M.A. and M.Sc. examinations. Post-graduate teaching on this scale has never before been attempted in any Indian university, and that there is a genuine demand for higher instruction is established by the readiness with which students in large numbers have eagerly joined the classes in such subjects as pure mathematics. The Government of India has made a liberal grant for the acquisition of a site, and plans have been nearly completed for further extension of the University buildings. When the new buildings are erected, there will be ample accommodation for the purposes of instruction, and, it will be possible to accommodate on the premises at least two hundred post-graduate students.

THE calendar for the session 1913-14 of the North of Scotland College of Agriculture has reached us. The classes of the college are held in the University of Aberdeen, except the class in agricultural engineering, which is held in Robert Gordon's Technical College, Aberdeen. The courses of instruction provided are arranged for the benefit of every section of the agricultural community. Persons who can attend the college only for four consecutive weeks in winter will find a short practical course extending over four weeks and including lectures on such subjects as feeding-stuffs, live-stock, diseases of animals, and so on. The full lectures on agriculture and agricultural chemistry extend over three years, but the complete course is modified in a variety of ways to meet particular needs and to enable students to secure the college diploma or the national diploma in agriculture. There is a special department of forestry, and for practical work, through the liberality of several landed proprietors, excellent facilities are afforded. The close proximity to Aberdeen of large wooded areas places it in an advantageous position for the teaching of forestry. Farmers residing within the college area are entitled to receive advice and assistance from members of the college staff free of charge. There is, also, a carefully arranged scheme of county extension work under the superintendence of a general county organiser.

THE calendar of the University of Sheffield for the session 1913-14, a copy of which has been received, provides striking evidence of the successful efforts which provincial universities are making to keep in close touch with the varied actvities of the districts they serve. Not only does the University of Sheffield train students who desire to follow the usual academic courses which culminate in degrees in arts, pure science, medicine, law, and so on, but it provides also graduated instruction in such applied sciences as engineering, metallurgy, and mining, and awards degrees in these branches of technology to students who at the end of the training comply with the reasonable regulations specified in the calendar. To meet the special needs of students whose circumstances make it impossible for them to devote the time necessary for complying with the conditions for degrees, associateship and diploma courses have been arranged. The mining department of the University carries out a system of extension lectures in technical science in the West Riding of Yorkshire; a works pupils' certificate course has been arranged by the University in consultation with the Sheffield Master Builders' Association to meet the requirements of students who are working with the object of becoming master builders; a diploma course in domestic science has been inaugurated; and in other ways the University is assisting the higher education of Sheffield workers.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 13.—M. F. Guyon in the chair.—Paul **Marchal**: The acclimatisation of *Novius cardinalis* in France. In 1912 *Icerya purchasi* was accidentally introduced into France, at Cap Ferrat, and caused great damage. This plant pest has been successfully fought in California and elsewhere by the introduction of its natural enemy, *Novius cardinalis*, and steps were taken to acclimatise this at Cap Ferrat. The results were completely successful, the Icerya being rapidly exterminated.—Charles **Depéret**: The fluvial and glacial history of the Rhône valley in the neighbourhood of Lyons. Evidence is given that there were three glacial invasions of this region and not two, as currently held, leading to the formation of three fluvio-glacial terraces.—Leopold **Fejér**: Trigonometric polynomials.—Michel **Fekete**: A property of the roots of the arithmetical means of a real integral series.—N. **Gunther**: The cononical form of algebraical equations.—M. **Tomassetti** and J. S. **Zarlatti**: The problem of two bodies of variable masses.—Thadée **Peczalski**: Relations between the coefficients of expansion and the thermodynamical coefficients.—France **Giraud**: Certain reactions depending on reply currents.—R. **Dongier** and C. E. **Brazier**: The sound effect produced at the contact of a metallic point and the surface of a crystal or a metal by the passage of an alternating current. A faint musical note was first noted in a galena detector at the Eiffel Tower. Means have been found to reinforce this note so that wireless signals can be heard at a distance of 22 metres from the apparatus.—Ch. **Gravier**: An automatic method of developing photographic plates. —B. A. **Dima**: The photo-electric effect of metallic compounds. The photo-electric effect of analogous compounds of the same metal depends on the valency of the metal in those compounds. The four oxides of manganese offer a clear example of this.—Yugi **Shibata** and G. **Urbain**: The spectrochemistry of the complex cobalt compounds. A study of the absorption bands in the visible and ultra-violet spectra of solutions of complex cobalt salts.—M. **Taffanel** and Le **Floch**: The combustion of gaseous mixtures. Mixtures of methane and air were heated to various temperatures between 535° C. and 640° C., and the rates of combustion measured. These results are extrapolated to evaluate the inflammation temperatures of these mixtures.—P. **Lemoult**: Leucobases and colouring matters of diphenylethylene. The first stage of oxidation of the *cyclo*hexylidenic leucobase,

$$E.H_{10}.=C.[EH_4N(CH_3)_2]_2.$$

Tetrahydro-malachite green.—C. **Gerber** and P. **Flourens**: The trypsin of *Calotropis procera* and the poison which accompanies it. The latex contains a proteolytic ferment very resistant to heat, and most active in alkaline or neutral media. It coagulates milk and digests casein and fibrin. Injected subcutaneously it is rapidly fatal to some animals (guinea-pig, pigeon), whilst in others it produces only local troubles (white rat, rabbit). Separation of the trypsin and the toxic substance has not been effected.—A. **Gouvel**: The genus Palinurus in Madagascar.—A. **Brachet**: The inhibiting action of the sperm of *Sabellaria alveolata* on the formation of the membrane of fertilisation of the egg of *Paracentrotus lividus*.—A. **Paillot**: Parasitic coccobacilli of insects.—Sabba **Stefanescu**: The structure of the crown of the elephant's molars.—Michel **Longchambon**: The breccia of the marmorean complex: conclusions which may be drawn concerning the age and the localisation of lherzolite.—François **Picavet**: The commemoration of Roger Bacon in 1914. It is proposed to publish a complete edition of Roger Bacon's works.

CAPE TOWN.

Royal Society of South Africa, September 17.—The president in the chair. W. A. **Jolly**: The interpretation of the electrocardiogram. The interpretation of the electrocardiogram has remained doubtful, notwithstanding the large amount of work that has been devoted to it in recent years, and very divergent views are entertained as to the significance of the various features of the curve without conclusive evidence having been adduced for them. The author gives an explanation arrived at from experiments on the isolated tortoise heart, and especially from cases of systolic alternation in auricles and ventricle.—Paul A. **Methuen** and John **Hewitt**: A contribution to our knowledge of the anatomy of the chameleon. After making a comparative examination of the lungs, sternum, and skull in various members of the family the authors conclude that the most generalised and probably most primitive forms are the genera Brookesia and Rhampholeon (the latter not actually examined by the authors), whilst the viviparous small chameleons of the pumilus group, so characteristic of South Africa, are the most primitive in the genus Chameleons: for these latter species, pumilus and allies, the authors revive the old generic name Lophosaura of Gray. It appears probable that the family, as we know it to-day, has spread from a centre of origin situated in that portion of the Ethiopian region of which there now remains two separated components, Madagascar and the Cape province of Sclater. There is no evidence in favour of a northern origin for this family.—R. **Marloth**: Note on the Pollination of *Encephalartos altensteinii* (Kaffir bread tree). The insect on which the transport of the pollen from the male cone to the female cone of *Encephalartos altensteinii* and *E. villosus* depends is not a Phlœophagus, as stated in a paper recently published in the Transactions of the Royal Society, S.A., but *Antliarrhinus zamiae*, that means the same insect which lives in the seeds of these plants until the cones disintegrate and enable the mature insect to escape from them. The female insect pollinates the ovules while moving about between them for the purpose of depositing its eggs. Although according to Dr. Rattray's observations, some or most, or even sometimes all, the seeds of a cone are thus destroyed by the grubs of the insect, the visits of the insect are nevertheless essential to the plant, for without them no seeds would be formed at all. The case is quite parallel to that of the Yucca moth (Pronuba), which, while depositing its eggs into the pistil of the Yucca, pollinates the flower.

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part 3 for 1913, contains the following memoirs communicated to the society:—

July 20, 1912.—A. **Ansel**: Seismic records at Göttingen during 1911 (with seven figures and a table, illustrating the graphical solution of spherical triangles).

March 8, 1913.—L. **Geiger**: Seismic records at Göttingen during 1909.

May 24.—G. **Pólya**: Approximation by means of polynomials, all the roots of which fall within an angular sector.—R. **Fueter**: A property of the *Klassenkörper* of complex multiplication.—G. **Tammann**: The melting point.—O. **Mügge**: Filiform crystals of green vitriol and silver.—L. **Godeaux**: Cyclic involutions of order 2α and genus 1 on a surface of genus 1.

July 5.—R. W. **Hoffmann**: The embryonic development of the Strepsiptera (preliminary communication, with figures).

July 19.—D. **Hilbert**: Remarks on the foundation of an elementary theory of radiation.—O. **Toeplitz**: A problem, connected with Dirichlet-series, in the theory of series of powers of an infinite number of variables.

The business communications (part 1 for 1913) include reports by H. **Wagner** on the Samoa Observatory for 1912–13, and by F. **Klein** on the progress of the publication of Gauss's works.

BOOKS RECEIVED.

Studies in Cancer and Allied Subjects. Vol. i., The Study of Experimental Cancer. A Review. By Dr. W. H. Woglom. Pp. xi+288+plates. Vol. iii., From the Department of Zoology, Surgery, Clinical Pathology, and Biological Chemistry. Pp. ix+308. (New York: Columbia University Press.) Each 5 dollars net.

A Geography of the British Empire. By W. L. Bunting and H. L. Collen. Pp. iv+159. (Cambridge University Press.) 3s. 6d.

Early Wars of Wessex. By A. F. Major. Edited by the late C. W. Whistler. Pp. xvi+238. (Cambridge University Press.) 10s. 6d. net.

Weeds: Simple Lessons for Children. By R. L. Praeger. Pp. x+108+iii plates. (Cambridge University Press.) 1s. 6d. net.

The Freezing-Point Lowering, Conductivity, and Viscosity of Solutions of certain Electrolytes in Water, Methyl Alcohol, Ethyl Alcohol, Acetone, and Glycerol, and in Mixtures of these Solvents with one another. By H. C. Jones and collaborators. Pp. vii+214. (Washington, D.C.: Carnegie Institution.) 2 dollars.

The Wonders of Wireless Telegraphy. By Prof. J. A. Fleming. Pp. xi+279. (London: S.P.C.K.) 3s. 6d. net.

A Text-book of General Embryology. By Prof. W. E. Kellicott. Pp. v+376. (New York: H. Holt and Co.) 2.50 dollars.

Industrial and Commercial Geography. By Prof. J. R. Smith. Pp. xi+914. (New York: H. Holt and Co.) 3.50 dollars.

Die Atomionen chemischer Elemente und ihre Kanalstrahlen-Spektra. By Dr. J. Stark. Pp. 43. (Berlin: J. Springer.) 1.60 marks.

Zur Krise der Lichtäther-Hypothese. By Prof. P. Ehrenfest. Pp. 23. (Berlin: J. Springer.) 60 pfennigs.

Die Europaeischen Schlangen. By Dr. F. Steinheil. Drittes Heft. Plates 11 to 15. (Jena: G. Fischer.) 3 marks.

RADIATION THEORIES.

Vorlesungen über die Theorie der Wärmestrahlung. By Dr. Max Planck. Zweite Auflage. Pp. xii+206. (Leipzig: J. A. Barth, 1913.) Price 7 marks.

THE first edition of this book, which appeared in 1906, was reviewed in NATURE (October 11, 1906, Supplement iii.). The many and varied contributions to our knowledge of radiation phenomena that have been published in the ensuing seven years have made it necessary for Dr. Planck to rewrite and modify the book to a considerable extent, so that it now contains many novel features. As before, the object of the book is to apply the statistical methods previously used in the kinetic theory of gases to the phenomena of radiation, and full use is made of Boltzmann's views on the interpretation of entropy in connection with the theory of probability. But the present treatment is largely based on the remarkable assumption which the author designates as the "quantum-hypothesis."

The property thus assumed for the elementary electrical oscillators under consideration may perhaps best be explained by comparing them to the cisterns, of which many have been invented and which are so arranged that when the water in them reaches a certain level they overturn and empty themselves, then returning to their original position to be refilled. In other words, absorption takes place continuously, while emission occurs intermittently when the energy of the oscillator attains one or other of certain discrete values. This "quantum hypothesis," as the author points out, is analogous to the electron theory, which assigns a definite magnitude to the electron or "elementary quantum" of electricity. It accounts for Nernst's observed phenomena, and, further, it is in accordance with the view that every different radiation corresponds to a certain definite temperature, and it is already beginning to form an important element in present-day physical researches.

It need scarcely be pointed out that the quantum hypothesis entails irreversibility and thus overcomes a difficulty of the kinetic theory of gases, namely, that even statistical methods apparently fail to account for irreversible phenomena when applied to a system the elements of which are subject to the equations of reversible dynamics, unless some further assumption is made ("Assumption A" of the late Mr. Burbury). It will thus be seen that the present method does not pretend to afford a so-called "dynamical proof" of the phenomena of radiation, and in the preface Dr. Planck distinctly expresses the view that a new principle cannot in general be represented by a model working according to old laws. It will also be evident that brief indications of the new method, such as those contained in this notice, cannot be regarded as adequate descriptions of the real substance of Dr. Planck's investigations.

It was natural that a theory fraught with such far-reaching consequences should attract considerable attention at the recent meeting of the British Association, and the occasion was the more suitable as the presidency of Sir Oliver Lodge had attracted to the meeting a number of physicists all keenly interested in radiation theories. It would be undesirable to refer in greater length to these discussions, as they will be dealt with elsewhere. A popular account of modern radiation theories, including special reference to Dr. Plancks quantum hypothesis, was given by Dr. Max Born, of Gottingen, in *Die Naturwissenschaften* 21, for May 28, p. 499.

It does not appear to the present reviewer that the quantum hypothesis is necessarily irreconcilable with dynamical principles. If we take the equations of motion of a dynamical system and write down the expressions for the second differential coefficients of the squares and products of its velocities, we obtain formulæ which may be said to determine the energy accelerations of the system in the same way that the ordinary equations of motion determine the accelerations of the masses. If we assume conditions of statistical equilibrium we find a definite amount of energy associated with a definite system, and we further find that certain conditions must hold in order that energy equilibrium may be possible. Such a method establishes a kind of principle of duality between the properties of matter and the properties of energy, and is distinctly favourable to an atomic theory of energy. But the attempt to reduce everything to dynamics would of course land us in the old difficulty over the irreversibility.

G. H. B.

CHEMICAL TEXT-BOOKS.

(1) *Osmotic Pressure.* By Prof. A. Findlay. Pp. vi+84. (London: Longmans, Green & Co., 1913.) Price 2s. 6d. net.

(2) *The Organometallic Compounds of Zinc and Magnesium.* By Dr. Henry Wren. Pp. viii+100. (London: Gurney and Jackson, 1913.) Price 1s. 6d. net.

(3) *The Chemistry of Dyeing.* By Dr. J. K. Wood. Pp. vii+80. (London: Gurney and Jackson, 1913.) Price 1s. 6d. net.

(4) *V. v. Richter's Chemie der Kohlenstoffverbindungen oder organische Chemie.* Elfte Auflage. Zweiter Band. Carbocyclische und heterocyclische Verbindungen. Neu bearbeitet von Dr. Richard Anschutz. In Gemeinschaft mit Dr. Hans Meerwein. Pp xxii+1048. (Bonn: Friedrich Cohen, 1913.) Price 26 marks.

(5) *Traité Complet d'Analyse Chimique Appliquée aux Essais Industriels.* By Prof. J. Post and Prof. B. Neumann. Deuxième Edition Française Entièrement Refondue par G. Chenu et M. Pellet. Tome Troisième. Second Fascicule. Pp. 465-903+v. (Paris: A. Hermann et Fils, 1913.) Price 15 francs.

(6) *Traité de Chimie Minérale.* By H. Erdmann. Ouvrage traduit sur la 5e édition allemande par Prof. A. Corvisy. Tome Premier. Introduction à la Chimie et Métalloïdes. Pp. iv+559. (Paris: A. Hermann et Fils, 1913.) Price 12 francs.

(7) *Laboratory Text-Book of Chemistry.* By V. Seymour Bryant. Part I. Pp. vi+246. (London: J. and A. Churchill, 1913.) Price 4*s.* net.

(1) THOSE who have read Dr. Findlay's book on the phase rule will have formed great expectations of his promised monograph on osmotic pressure, and we believe they will not be disappointed. The expression osmotic pressure of a solution has become a familiar one both to chemists and biologists, though, as Dr. Findlay is careful to point out, it is incorrect. A solution does not in itself have any osmotic pressure, the term being loosely used to denote the mechanical pressure *which would be produced* if the solution were separated from the pure solvent by a membrane which was permeable only to the solvent. The confusion of thought which has arisen in connection with the subject, especially amongst the biologists, is unfortunately very considerable, so that Dr. Findlay's clear treatise comes at an opportune moment and should be widely read. Although necessarily mathematical in parts, it is not unduly so, even for the biological reader.

The author shows himself to be no bigot in favour of the extreme views of the German physical-chemical school, and his chapter on the cause of osmosis and the action of the semipermeable membrane reaches a high standard. Regarded from the biological side, the subject of osmosis is one in which we are on the eve of important developments requiring interpretation in the broadest possible manner. In the past the tendency has been to give too little attention to the chemical meaning of the osmotic phenomena, but this error is avoided in the present work.

The work of Lord Berkeley in this country and that by Morse in America is described at length and its bearing on the general theory of ideal solutions discussed in a separate chapter. Emphasis is laid on the thermodynamic equation connecting the osmotic pressure with the vapour pressure of solutions.

(2), (3) Chemical monographs are evidently fashionable, and the success of the biochemical series edited by Dr. Plimmer and the inorganic series for which Dr. Findlay is responsible has inspired others to imitate them. The new series for which Dr. Cumming is sponsor are, however, of a different type and can scarcely lay claim to the title monograph—indeed, the use of the term is misleading. They are essentially summaries intended for advanced students with the examination bugbear in front of them, and though no doubt they will be very useful, they are in no way authoritative in the same sense as the other monographs to which reference has been made. However, they are well printed and convenient in size and price, and should prove very popular among students.

No. 1 in the series is Dr. Wren's essay on the organometallic compounds of zinc and magnesium. Though Grignard described the reaction which now bears his name so recently as 1900, the method has proved so fruitful in effecting organic syntheses that their number is already legion, and the subject forms, we fear, a very favourite examination question—hence, no doubt, the motive and form of the present summary. The mode of using the reagent is first described, but the bulk of the book is devoted to the description, with copious formulæ, of the products formed by its aid. A few pages are devoted to the theory of the reaction. The final section deals with Blaise's more recent applications of the organometallic derivatives of zinc, which afford reagents of less general activity and of greater ease of control.

Dr. Wood's summary of the chemistry of dyeing is simply and clearly written and devoid of technical terms, so that it should appeal to a wider public than the chemical student and, indeed, be in the hands of all practical dyers. The scheme followed is first to discuss the chemical composition and properties of the textile fibres, then to deal with the classification and properties of dyes, and lastly with the nature of the dyeing processes. A small bibliography and index is attached. The author is to be congratulated on the clear way in which he has dealt with the rival theories of dyeing within a short space.

(4) A new edition of Richter scarcely calls for criticism beyond the statement that the authors have maintained the standard of a work which has been indispensable to all students of organic

chemistry in the past and is likely to prove equally valuable to all in the future. No other text-book is so exhaustive and yet relatively still readable. We have taken the opportunity to test it somewhat severely and always found the desired information. The new edition does, however, afford an opportunity of noting the enormous increase in our knowledge of this part of organic chemistry—embracing the carbocyclic and heterocyclic compounds. Our former copy of the ninth edition, bearing the date 1901, is a modest little work of 809 pages, measuring 4 × 6 inches. The new edition requires 1048 pages, measuring $4\frac{1}{2} \times 7$ inches.

Even in 1900 the would-be chemist made some attempt to master the whole of Richter—to-day this is obviously impossible, and the student is forced to specialise at an early stage in his reading. Fortunately, chemical literature is now enriched by very many special monographs of a very readable character and free from too much elaboration of detail. When these are supplemented by Richter—the encyclopædia of chemistry—the student is indeed well armed. We have one suggestion only—namely, the author's name, as well as the journal reference, should be quoted in the references to the original literature. The omission of the author's name prevents reference to the abstracts of the original in the Journal of the Chemical Society or in the *Centralblatt* when the original paper itself is not available.

(5), (6) These translations of well-known standard German works testify to the rank taken by German science in other lands: they are already well known in this country. The second part of vol. iii. of Prof. Neumann's technical analysis contains Schultz's famous monograph on coal tar and artificial colouring matters, which already has a world-wide reputation and forms an appropriate complement to Germany's most famous chemical industry. This is the second French edition translated from the third German edition of the work.

Prof. Corvisy's book is a translation for the first time of the fifth German edition of the first volume of Erdmann's well-known work. The translator refers to the need of such a work in France, where no other book is available for students covering the ground in quite the same way.

(7) This book is intended to be actually used as a laboratory note-book in schools, the pupil having to write his answers in the spaces in the text left for the purpose. Precise instructions are given how to do everything and what to observe and infer, and in quantitative exercises only the actual figures have to be filled in by the schoolboy. The book is elaborately bound and somewhat expensive. We fear we do not agree with the author's interpretation of practical chemistry; indeed, we had hoped that books of this type had ceased to exist.

E. F. A.

PROBLEMS OF LIFE AND REALITY.

(1) *Essais de Synthèse Scientifique.* By E. Rignano. Pp. xxi + 294. (Paris: F. Alcan, 1912.) Price 5 francs.

(2) *Contre la Métaphysique.* By F. Le Dantec. Pp. 255. (Paris: F. Alcan, 1912.) Price 3 francs 75 centimes.

(3) *Modern Science and the Illusions of Prof. Bergson.* By H. S. R. Elliot. With a preface by Sir Ray Lankester, K.C.B., F.R.S. Pp. xix + 257. (London: Longmans, Green and Co., 1912.) Price 5*s.* net.

(4) *Wissenschaft und Wirklichkeit.* By Max Frischeisen-Köhler. Pp. viii + 478. (Berlin: B. G. Teubner, 1912.) Price 8 marks.

(5) *The Young Nietzsche.* By Frau Förster-Nietzsche. Translated by A. M. Ludovici. Pp. viii + 399. (London: W. Heinemann, 1912.) Price 15*s.* net.

THE first two of these volumes contain a curiously similar plea for the theorist in science. M. Rignano in his opening essay (1) maintains that there are a number of central problems in the biological sciences, in which there is almost a deadlock, due to the fact that they have been attacked exclusively by two opposite groups of specialists. One such problem, awaiting the synthetic view, is that of the nature of life and growth. Others are: the meaning of religion as viewed from the psychological and the sociological points of view; the economic and ideologic factors in history; the antithesis of socialism and liberal economics. These are dealt with in successive essays. In the first the various transformist theories are reviewed, in order to demonstrate how far-reaching may be the clarifying effects of a single piece of theorising. At the same time the *leit-motiv* of the whole volume is introduced—the mnemonic principle. The recapitulation of phylogenetic development in ontogenesis is essentially mnemonic, as is assimilation.

The same principle is next applied more in detail to the problem of growth, by means of a summary of the author's "centro-epigenetic" theory of development. This asserts that growth is determined by a nervous circulation, independent of a nervous system, consisting of discharges of specific nervous energy accumulated in the germ-plasm, each discharge depositing a substance apt in decomposing to regenerate the same specific nervous current. "Memory" in this wide sense is next applied to explain the affective tendencies (conations) which are regarded as strivings to regain physiological equilibrium. Thus one and the same explanation holds of all the finalism of life, namely, the mnemonic property of vital substance, that faculty of "specific accumulation" which belongs exclusively to nervous energy, itself the basis of life. The other essays reveal the same acuteness, fertility, and confidence in theorising.

(2) M. le Dantec, after a semi-serious demonstration that the philosopher is an artist, to be appreciated by those vibrating in harmony with him rather than understood by mankind at large, and a plea for more reasoning in natural science and less "kitchen-technique," proceeds also to consider the central problems of biology. All vital phenomena fall under the head of "functional assimilation." The organism assimilates *qua* organ of its function at the moment. Thus a mammal into whose peritoneum cow's milk is injected assimilates this, if it survives, *qua* organ of the struggle against cow's milk, but not absolutely, for it retains a trace or "memory" (cf. Rignano) in that its serum will henceforth give a precipitate with cow's milk. Thus it is impossible to separate "nature" and "nurture," though the part played by the latter must be relatively small "on pain of death." Like M. Rignano, a Neo-Lamarckian, M. le Dantec holds that among the transmissible acquisitions are the instincts, and logic, "the *résumé* of ancestral experience."

(3) Mr. Elliot's view of philosophy is, broadly, that it consists in making unfounded and untestable statements about the universe—mapping the back of the moon. Now this is surely a mistake; philosophy is not description, but explanation; and to explain is to bring unconnected or conflicting facts under one general law or notion. Sometimes it is merely a question of selecting the right familiar notion, but often a *new* "appropriate conception" has to be created, a process the difficulty and importance of which Mill so greatly underestimated; and philosophical explanation is evidently likely to be of this nature.

Thus while it is legitimate criticism of a philosophy to say that it is incomprehensible (a line pretty effectively worked by Schopenhauer) it is unreasonable to insist that it must be easily comprehensible, or use only everyday notions. Nor can one fairly complain if philosophers do not adduce specific facts for their theories. Negative evidence can disprove an explanatory hypothesis; positive evidence can only "verify" it cumulatively, and here the facts are broadly not in dispute. This, if correct, invalidates much that Mr. Elliot says about M. Bergson's "besetting fallacies," *e.g.*, the "mannikin fallacy." Again, his keen scent for "false analogy" often leads Mr. Elliot to take as demonstration what is clearly meant as "explication." While always acute and often touching on real difficulties, Mr. Elliot too often allows himself to be tempted, in sporting parlance, into smashes which find the net.

(4) Perhaps the least of the differences between the last work and Herr Frischeisen-Köhler's essay in critical realism is that in the latter M. Bergson is not so much as mentioned. The nineteenth century saw a movement of opposition to the intellectualism of the seventeenth and eighteenth centuries, and the book aims at helping to find a common point of view for the sciences typical of the two points of view—mathematics and history, the latter of which can never be based on pure thought. The method is a critical consideration of the conditions involved in consciousness, which themselves contain the bases of knowledge. Of the categories or modes of experiencing involved in consciousness, however, only that of reality is considered.

The closely-reasoned exposition is impossible to summarise here, but it involves the discussion of the two main modern attempts to derive all experience from the laws of pure thought—the logical idealism of the Marburg school and the philosophy of values developed by Windelband and Rickert. Finally, the empirical bases of our notion of reality are found, above all, in experiences of striving and resistance. Like fish in a glass bowl we are unable to go further in some directions, and since this experience always occurs in conjunction with certain sense-impressions, we recognise in these that which sets limits to our subjectivity. The real remains, indeed, always within the conditions of consciousness in general, but within consciousness the independence of the objective world from the self is assured. The book is a clearly-written, cautious, and eminently helpful discussion of the difficult problems with which it deals.

(5) Having nothing in common with the other works except that it deals with a philosopher, the life of Nietzsche by his sister is an interesting and pleasing account of the first happy portion of that tragic existence. Strangely unlike a morose apostle of hardness is the almost painfully well-behaved child in the country parsonage, the brilliant schoolboy with all the German idealism and *schwärmerei*, the student shocked by the coarseness of university conviviality, the youthful professor of classics, the heroic but too sensitive ambulance volunteer in the Franco-Prussian war. The book takes us to the end of the friendship

with the Wagners, and it is its main weakness that it fails to make clear the reason either for the intensity or for the abrupt end of this devotion. The translation is quite satisfactory, and some excellent portraits add much to the book's effectiveness.

TEXT-BOOKS ON HEAT AND THERMODYNAMICS.

(1) *An Introduction to the Mathematical Theory of Heat Conduction.* With engineering and geological applications. By Prof. L. R. Ingersoll and O. J. Zobel. Pp. vi+171. (London and Boston: Ginn and Co., n.d.) Price 7*s.* 6*d.*

(2) *The Laws of Thermodynamics.* By W. H. Macaulay. Pp. viii+71. (Cambridge: University Press, 1913.) Price 3*s.* net.

(3) *A Text-book of Thermodynamics (with special reference to Chemistry).* By J. R. Partington. Pp. viii+544. (London: Constable and Co., Ltd., 1913.) Price 14*s.* net.

(4) *Lehrbuch der Thermodynamik.* Nach Vorlesungen von Dr. J. D. v. d. Waals. Bearbeitet von Dr. Ph. Kohnstamm. Zweiter Teil. Pp. xvi+646. (Leipzig: J. A. Barth, 1912.) Price 12 marks.

(5) *Leçons de Thermodynamique.* By Dr. Max Planck. Avec une conference du même à la Société chimique de Berlin sur Le Théorème de Nernst et L'Hypothèse des Quante. Ouvrage traduit sur la troisième édition allemande (augmentée). By R. Chevassus. Pp. 310. (Paris: A. Hermann et Fils, 1913.) Price 12 francs.

(1) THIS book is the outcome of the authors' teaching experience, and as one might expect, covers the ground usually required for a university degree. The subject-matter includes the Fourier equation, the steady flow of heat in one and more than one dimension, periodic flow in one dimension, Fourier's series applied to the linear flow of heat in the case of an infinite as well as semi-infinite solid, heat sources, slab and radiating rod, and in addition radial flow, instantaneous heat source at a point, sphere with surface at constant temperature, sphere cooled by radiation, and the general case of heat flow in an infinite medium. The concluding chapter deals with the formation of ice. The appendix contains a list of values for the thermal conductivities and emissivity factors, as well as the more commonly occurring integrals and miscellaneous formulæ. The striking feature about the book is the prominence which is given to the experimental applications of the expressions derived. These belong mainly to engineering, though the student of pure physics will find many of them of considerable interest. At the end of each chapter there are a number of problems to be worked out. As the work covers a relatively large field the authors have had to restrict themselves to typical cases. Full references are given, however, on particular points to larger works and original papers. The authors have compiled a very useful text-book of moderate size, which should appeal to a fairly wide circle of readers.

(2) This monograph contains a succinct account of the fundamental principles of thermodynamics. The writer has been singularly happy in combining precision and accuracy of statement with remarkable lucidity and readableness. Although he warns us in the preface that the tract should be read "in conjunction with other information," it ought to be found by no means beyond the grasp of the beginner. The subject is presented, in the first instance, from the engineer's point of view, though the nature of the publication is such as to preclude any very detailed illustrations of an applied character. This has the advantage, however, of making the work more interesting to the general reader. The author commences by explaining perfect differentials, and then passes on to the first and second laws and the four thermodynamic relations. In addition to the perfect gas, considerable space is devoted to the treatment of wet and dry steam, and a short account of the lead accumulator. The monograph as a whole forms a very excellent introduction to engineering thermodynamics.

(3) The first sixteen chapters of Mr. Partington's "Thermodynamics" represent a very full and detailed account of the classical theory along the usual lines. The two final chapters of the book deal rather briefly—considering the growing importance of the subject—with Nernst's heat theorem and the theory of energy quanta. The reader is assumed to be fairly well equipped as far as mathematics is concerned, and for chemists, at any rate, the book will in places make fairly severe reading. All the thermodynamic potentials (Gibbs' μ included) are freely employed, as well as the cycle method. Perhaps the least satisfactory is the chapter on electrochemistry. An English book dealing with thermodynamics from the chemical point of view is rather badly wanted, however, and Mr. Partington's deserves to meet with a good reception.

(4) As anyone familiar with van der Waals' writings will anticipate, the present work is by no means a text-book of thermodynamics in the ordinary sense of the term. This second volume, like the first (which appeared in 1908), is based upon Prof. van der Waals' lectures, the material being edited for the Press by Prof. Kohnstamm. As the sub-title expressly states, this volume deals

with the application of thermodynamics to liquid-gaseous systems containing more than one component. Although the phase rule and the theory of dilute solutions (from the osmotic point of view) are discussed at some length, the greater part deals with the problems of phase equilibrium from the points of view and by the methods with which one associates the name of van der Waals himself. The book is divided into two main parts, first, the consideration of systems in the absence of external forces, chemical or capillary effects, and secondly, the behaviour of systems when exposed to such forces. The work requires no introduction to English readers. The fundamental nature of the subject itself, and the fact that it emanates from the greatest living authority upon this subject, ought to provide a sufficient reason for every physicist and physical chemist becoming acquainted with it.

(5) Planck's thermodynamics is already so well known to readers in every country that it is only necessary in this place to direct attention to the appearance of the (enlarged) French translation of the third German edition. It would be utterly futile to attempt any worthy review of this book in the space of a few lines. A very interesting feature of this edition is the incorporation by the French translator of the lecture on Nernst's theorem and the energy quanta hypothesis delivered by Prof. Planck in December, 1911, before the German Chemical Society, and also a list of the papers on thermodynamics published by Prof. Planck with cross-references to the paragraphs of the book in which the same subjects are treated. The work is divided into four parts: the first deals with fundamental experiments and definitions, the second and third with the first and second laws, whilst the concluding part takes up the application of those laws to special physical chemical cases. The last chapter of this part is devoted to the discussion of the absolute value of entropy (Nernst's theorem). As an illustration of the place which Planck's "Thermodynamics" occupies, it may be mentioned that a fourth German edition has already appeared this year. It is high time that the English translation was brought up to date.

W. C. McC. L.

OUR BOOKSHELF.

The Annual of the British School at Athens. No. xviii. Session 1911–1912. Pp. viii + 362 + 15 plates. (London: Macmillan and Co., Ltd., n.d.) Price 25*s.* net.

The eighteenth volume of the Annual of the British School at Athens for the session 1911–12 is fully up to the level of this excellent series. The chief archæological article gives an account by Messrs. A. J. B. Wace and M. S. Thompson of the excavations at Halos, one of the smaller and less-known cities in Thessaly. A group of tombs at the foot of the acropolis was opened. Such cist graves formed of slabs are common in Thessaly, both in the fourth prehistoric period and in the Early Iron Age, to which the Halos tombs belong. Here there is no sign of cremation, simple inhumation being the only process. On the other hand, the excavation of a neighbouring tumulus proved that here corpses were burned. Thus in these two cemeteries we find two different methods of disposal of the dead. From an examination of the pottery and fibulæ it seems clear that the cremation tumulus is of a date later than that of the cist graves, and it may be referred to the middle of the so-called Geometric period, about the ninth century B.C. No exact parallel to this type of cremation burial has yet been found in Greece or elsewhere, and it differs from that of Halstatt and the rites described in the Homeric poems in some important particulars. The tumulus is clearly post-Homeric, and may be an Achæan burial in a degenerate or modified form.

Mr. M. N. Tod's paper on Greek numerical notation is of special importance. By a review of the epigraphical evidence he seeks to determine the numerical systems employed in the various Greek cities, and to state afresh some of the conclusions which we are entitled to draw from it. This paper is devoted only to the so-called "acrophonic" or "initial" class of numerical notation, the consideration of the other main type, in which the letters are used in their alphabetical order as numerical signs, being reserved for later treatment. The earliest example of this type appears to belong to the fifth century B.C., and the diversity of the systems employed in the various cities seems to be due to the modifications introduced into the pure numbers to make them capable of expressing money, weights, and measures. The detailed epigraphic evidence thus presented deserves the attentive study of students of the early history of mathematics.

The New Encyclopaedia. Edited by H. C. O'Neill. Pp. vii + 1626. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 7*s.* 6*d.* net.

This encyclopædia is handy in shape and fairly light in weight, and considering the limits of size, it appears to be as complete and authoritative as can be expected. The expert in any branch of knowledge may note the omission of facts which he might think could have been included, but the general reader will find brief summaries on many topics. He will, therefore, find this volume useful, and will be able to continue his studies under the guidance of the bibliography which is appended to the more important articles. The information appears to be accurate and modern, but some of the less informative maps might have been omitted.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Reflection of γ Rays from Crystals.

In some recent investigations Prof. Rutherford and Mr. H. Richardson have analysed the γ radiations emitted by a number of radio-active products. They have shown, for example, that radium B emits three distinct types of γ radiation, which are absorbed exponentially by aluminium with absorption coefficients $\mu=230$, 40, and 0·51 (cm.)$^{-1}$ respectively. On the other hand, radium C appears to emit essentially only one type of γ radiation, the absorption coefficient of which is $\mu=0{\cdot}115$ in aluminium.

Recently we have undertaken an examination of these types of radiation by the methods developed for X-rays by W. H. and W. L. Bragg, and by Moseley and Darwin, which consist in determining, either by the photographic or electric method, the intensity of the X-rays reflected from a crystal at different angles of incidence. In our experiments the source of γ radiation was a thin α-ray tube containing about 100 millicuries of emanation, the γ rays arising from the products of the emanation, radium B and radium C. A diverging cone of rays fell on a crystal of rock-salt, and the distribution of the reflected radiation was examined by the photographic method. The source and photographic plate were each about 10 cm. from the centre of the crystal. Suitable precautions were taken to reduce to a minimum the effect on the photographic plate of the primary and secondary β rays and penetrating γ rays. The source was first arranged so that the radiation made an average angle of about 9° with the face of the crystal.

It was calculated from the known data of the crystal that the radiation $\mu=40$ from the radium B, if homogeneous, should be strongly reflected at about this angle. A group of fine lines comprised between the angles 8° and 10° have been observed on the photographic plate in a number of experiments. Similar results have been observed with a crystal of potassium ferrocyanide, kindly loaned to us by Mr. Moseley. On examining the reflection for an angle of 2° another series of fine lines was obtained on the plate, probably resulting from the reflection of the more penetrating radiations from radium B and radium C.

The experiments indicate that the γ radiation for which $\mu=40$ is complex, and consists of several groups of rays of well-defined wave-length. Experiments are in progress to examine carefully the character of this reflected radiation, both by the photographic and electric method. It is hoped that in this way definite evidence will be obtained on the constitution and wave-length of each of the types of γ radiation which are emitted from radium B and radium C.

The Piltdown Skull and Brain Cast.

Now that my friend Prof. Keith has explained (NATURE, October 16, pp. 197–99) so lucidly his reasons for making a big brain-case of the Piltdown fragments it is possible to define precisely the point at issue between us.

I should say at the outset that any anatomist, working with the plaster casts but without reference to the actual fragments from which they were moulded, might solve the extraordinarily difficult problem of reconstruction of the cranium in the way Prof. Keith has explained so plausibly. But the bones themselves present features which make such a solution altogether inadmissible. Anyone who examines the left parietal and temporal bones cannot fail to recognise that there is no room for any doubt as to the relative positions of these bones the one to the other, which is not that claimed for them by Prof. Keith.

The right parietal fragment and the occipital can be put into their proper positions and the symmetry of the two branches of the lambdoid suture be restored without producing "any marked asymmetry of another kind," such as troubled Prof. Keith, and without the necessity of making any such liberal additions to the capacity of the cranium as he demands (see his Fig. 2).

The "marked asymmetry of another kind" that he could overcome only by the adoption of the most drastic measures was created wholly by his refusal to admit the possibility that the middle line in the parietal region, as determined by Dr. Smith Woodward, was a close approximation to the truth.

The determination of the précise location of the middle line in the frontal and parietal regions is one of quite exceptional difficulty, but a number of facts and considerations make it certain that it is not where Prof. Keith would place it.

The crux of our difference, then, is the criteria which Prof. Keith uses for determining the middle line in the posterior parietal region. He writes (*op. cit.*, p. 198 *et seq.*):—"In the skulls of all the higher primates, the longitudinal sinus, near the hinder end of the adjacent margins of the right and left parietal bones, is marked by a narrow deep groove with distinct edges; on the margin of the upper angle of the Piltdown fragment the edge or margin of this groove can be clearly recognised."

It must be remembered that the area in question (the "upper angle" of the quotation) is immediately above the middle part of the lambdoid suture, which is preserved upon the larger parietal fragment. Prof. Keith does not seem to have realised this fact, for he represents the lambdoid suture (in his Fig. 2) as a large arch (A, B, A, B) crossing the middle line a short distance below the larger bone fragment. If a series of human and simian cranial casts be examined it will be found that, contrary to Prof. Keith's statement, in a considerable proportion of them there is no trace whatever (in the place just above the lambda corresponding to that preserved in the Piltdown specimen) of "the narrow deep groove with distinct edges" on which Prof. Keith relies as his guide for the determination of the middle line. This is especially the case in the casts of the more primitive human and the simian crania, as Profs. Boule and Anthony have pointed out in their discussion of the Chapelle-aux-Saints and La Quina brain-casts.

On these grounds Prof. Keith "moved the left parietal bone outwards or rather tilted [it] upwards and outwards until it assumes a more vertical position" (p. 199). But in order to do this he had to get rid of one of "the peculiar features of the original brain-cast—the sharp bending inwards or kinking of the temporal lobe of the brain" (p. 199). If Prof. Keith had not opened out the angle between the left temporal and parietal bones the aperture of the ear would have been made to look towards the neck, when he "tilted the left parietal upwards and outwards"! But the precise relationship of the left temporal and parietal bones is not a matter of argument but of fact; no one who examines the actual fragments and sees how precisely the edges of these bones fit one on to the other can refuse to admit that the parieto-temporal angle of Dr. Smith Woodward's restoration is a genuine peculiarity of this skull. If this is admitted it becomes impossible to tilt the upper margin of the parietal upwards and outwards. In other words, this peculiar articulation of the temporal bone affords confirmatory evidence of the proper location of the middle line.

It is a very interesting fact that the curious conformation of the temporal region of the brain, to the reality of which Prof. Keith objects, is quite analogous to that exhibited in the remarkable cranial cast of the Gibraltar skull, of which he is the custodian, and in some of the casts of primitive crania (negro, Australian, and Tasmanian) which he kindly obtained for me.

The greater part of Prof. Keith's letter deals with the lack of symmetry in the original reconstruction, which was due to a slight error in the positions assigned to the occipital and right parietal fragments. The need for this correction was realised before the meeting of the Geological Society last December; and this was taken into consideration when I was writing my preliminary note. G. Elliot Smith.

The University of Manchester.

"Aëroplanes in Gusts."

I shall esteem it a favour if you will spare a little space in which to refer to the unsigned review of the first edition of my book, "Aëroplanes in Gusts," printed in Nature of October 2.

It is not at all my intention to refer to or contest an adverse opinion standing alone, but there is associated with that opinion, in a way that might appear to justify it, a misstatement of fact that I can scarcely be expected to pass without an endeavour to correct.

Your readers are informed that I "measure the effect of a gust of wind by the accelerations of the air particles relative to the aëroplane." That I certainly do not do, and your reviewer has no excuse whatever, in anything I have written, for attributing to me so simple and foolish an error as the words imply. A most casual reading of my book, even in its first pages, shows, decisively, that I quite properly measure the gust—not "the effect of a gust," whatever that may mean—by the acceleration of headway, or acceleration of the velocity relative to the air, which, independently of that due to gravity and even of that due to the propeller, is being *impressed* upon the flying machine by the air.

The confusion made possible by not maintaining or exhibiting, as I have done in my book, the distinction between an actual acceleration and an impressed acceleration, and by not excluding the gravitational acceleration, scarcely needs enlarging upon or explaining in the columns of Nature.

S. L. Walkden.

Muswell Hill, N., October 4.

I have just received the second edition of "Aëroplanes in Gusts," and in reply to the author's criticism of my review, I cannot do better than quote the passage on p. 2 containing the definition:—

"Using therefore the term 'headway' in place of the cumbersome 'velocity relative to the air,' it will be taken for granted that the reader knows that:—

"(1) The instantaneous *strength* of gust at any point of the air as regards a given flying-machine flying at that point is measured by the acceleration of headway which any singularity of the air at that point is impressing upon the flying-machine, and the *direction* of the gust is opposite to the direction of the impressed acceleration.

"For example:—If the air is accelerating downwards at 40 ft. p.s. p.s., it is impressing upon the flying-machine an upward acceleration of headway of 40 ft. p.s. p.s., and this is the measure of the downward gust. In other words, the gust is of strength 40 ft. p.s. p.s., downwards. Simple velocity as distinguished from rate of change of velocity is, it will be noticed, completely ignored."

(The author then goes on to point out that accelerations may be represented by straight lines. Agreed.)

On p. 4 he says:—

"The general method of finding the impressed accelerations acting at a given instant upon a flying-machine consists in first answering the question:—

"If at any given instant the flying-machine could be suddenly transformed to a small smooth concentrated mass, how would it accelerate relative to the air?

"The acceleration answering the above question is the 'resultant relative gravity' of the following discussion, and when common gravity is subtracted *in vector sense* the result is the acceleration tendency or impressed acceleration due to the gusts. When from this result the impressed acceleration due to the absolute acceleration of the air at the place of the flying-machine is also subtracted *in vector sense* there will usually be found an impressed acceleration remaining. This is due to the air having what is called "velocity structure" at the point, and to the flying-machine in crossing that structure creating for itself a rate of change of headway."

If Mr. Walkden considers that he has received any injustice through the use of the term "effect of a gust" in substitution for his reference simply to "a gust," or the measure thereof, the reference to "effect" should certainly be withdrawn. But as regards his views on "impressed accelerations," the above quotations will probably appeal to readers of Nature far more effectively than any criticism, however adverse. Yet several journals have reviewed the book favourably, and it has run into a second edition.

The Reviewer.

Mass as a Measure of Inertia.

Can any of your readers enlighten me as to the authorship of the definition, "The mass of a body is the dynamical measure of its inertia"? I am under the impression that it is due to Clerk Maxwell, but have not been able to find where it occurs. I should be grateful for information as to where to look for it. W. C. Baker.

School of Mining, Queen's University, Kingston, Ont., October 13.

ENGINEERING RESEARCH AND ITS COORDINATION.

The questions of the coordination and encouragement of research in engineering have been brought forward in various ways recently. In April Sir Frederick Donaldson, chief superintendent of Woolwich Arsenal and president of the Institution of Mechanical Engineers, referred to them in his presidential address. At the recent summer meeting of the same institution held in Cambridge, Mr. G. H. Roberts, of Woolwich, read an interesting paper entitled "A Few Notes on Engineering Research and its Coordination," while the matter was also touched upon by the president of the Institution of Water Engineers in his presidential address.

"I have long thought," he says, "and indeed it must be obvious to all who reflect upon the subject, that a great mass of experimental work is lost to the community because the results in many cases are not properly recorded, and even when complete records are kept, the results remain with the investigator," and after referring to the advantages of combining for research the experience and opportunities of a number of people, he continues:—"It occurs to me therefore to ask whether it is possible to make this institution"—the Institution of Water Engineers—"a clearing house for the handling of some at least of the many problems to which we devote time and thought."

Again, Sir Frederick Donaldson writes:—

Research in the hands of firms and engineering undertakings has already been advocated, and no one would wish to see such efforts in any way hampered, but if it were possible to coordinate the work more than is done at present, and also to place the results at the disposal of the profession more readily than is now the case, great advantage may be expected to result. Is it not worth considering whether inquiries should not be made to see if an Engineering Research Committee, the bounds of which should be much wider than membership of this institution alone [the Institution of Mechanical Engineers] could be got together with a view to organising, coordinating, and assisting research, more especially for engineering purposes?

Mr. Roberts's paper commences with the statement that

Although engineering as an applied science has now reached a high state of development, and has in many of its branches become highly specialised, it is somewhat remarkable that no definite and generally recognised system has been formulated for making known for the benefit of the profession as a whole the results of the numerous private researches and experiments which are continually being carried on.

The paper describes a few of the researches of general interest carried on at Woolwich Arsenal

with the hope that it may induce others to come forward and add to the stock of general knowledge and it may thus form the nucleus of a clearing house of engineering information.

Sir Frederick Donaldson goes farther than the formation of such a clearing-house; he suggests, as we have seen, in addition the organisation, coordination, and assistance of research: we will return to this point later.

To many readers of Nature interested mainly in branches of science other than engineering, the need for a clearing-house may appear strange. A man after he has carried through a research in chemistry, physics, or one of the biological sciences, is not usually averse to giving his paper to the world. He communicates it to one of the scientific societies. In due time it appears in the journal, and is abstracted into one or more of the numerous and valuable periodicals which undertake such work for the great benefit of other investigators. But it is otherwise with much engineering or other technical research. The work is carried out for a special purpose: to determine the proper material to use in some structure; to see if some alloy which it would be convenient to employ for a certain machine will retain its properties under the conditions of temperature and stress to which it will be subject; to settle the form of bolt or screw-thread which for a given diameter offers the greatest resistance to shocks or impact and the like. Mr. Roberts's paper gives us examples. He records the results of tests on many specimens of timber used in the arsenal; of an investigation into the standard shapes and dimensions of tensile specimens; of numerous experiments on aluminium alloys. He describes a special instrument for indicating the yield-point of tensile specimens, and discusses the effect of the time-factor upon results of tensile testing and the unification of methods of reporting. Any of these investigations might have been carried out in some other works, and the result, when it had been utilised for the job in hand, forgotten and left to pass into oblivion.

Investigations of the kind, though of real value, may scarcely be of sufficient importance to be worked up as a paper for communication to one of the technical societies—always a somewhat elaborate business—and, indeed, results and methods sufficient for the purpose in view, and deserving of record, would be felt not unfrequently to be unsuitable for an evening's formal discussion. Again, there is the desire, sometimes the necessity, to keep the results private, and the disinclination to spend time in working them up for publication. Possibly some of these difficulties could be met by a committee guiding a staff of men whose business it would be to keep in intimate touch with works in which investigations of general interest were going on. The knowledge of these men would enable them to suggest to the committee what researches it was important should be secured for the public: they might assist the workers in preparing these for publication, or, where complete publication was not necessary or desired, in abstracting such parts as could usefully be placed on record. The committee, or the committee's records, would in time become a storehouse of information to be searched by a would-be investigator before he commenced his own experiments. Useful knowledge would be disseminated and overlapping prevented. The difficulties of the attempt are fairly obvious. Success, if it could be achieved on a sufficient scale, would be a real advantage to engineers.

But this is distinct from Sir Frederick Donaldson's suggestion of organising and advising as to research. To attempt this for the whole field of engineering science is a heavy task, and it may be questioned whether such work is not better done by a number of special committees, each working in a more limited field. Possibly a main committee like the main committee of the engineering standards committee is wanted to start the subordinate bodies and coordinate their work. Such special committees do exist at present. Prof. Hopkinson mentioned in the discussion on Mr.

Roberts's paper the gaseous explosions committee of the British Association. The alloys research committee of the Institute of Mechanical Engineers; the newly established research committee of the electrical engineers; the reinforced concrete committee of the civil engineers; or the Government Advisory Committee for Aëronautics, are all instances. For the success of such committees three things are needed—a man or men to carry out the research, a laboratory or works with proper equipment for the experiments, and funds to defray the expenses.

Prof. Hopkinson did well in the discussion at Cambridge to direct attention to the individuality of research. Much—everything—depends on the man, and he must have freedom. The committee may specify the objects of the inquiry, and indicate in general terms the methods to be followed, but no real result will ensue unless the investigator has ideas of his own, and, after the suggestions laid before the committee are approved, is free to carry them out.

The gaseous explosions committee owes its success to Dugald Clerk and Hopkinson; the alloys research committee to Roberts-Austin, Carpenter, and Rosenhain; while the work of the Advisory Committee for Aëronautics would lose nearly all its value were it not for the energy and devotion of the staff of the National Physical Laboratory.

Engineering research—technical research, indeed, of all kinds—differs, however, from much scientific research in that it can be organised. The problems proposed are usually fairly definite. What are the properties of a certain series of alloys? How are they modified by temperature, forging, annealing, and the like? Do the results of impact tests depend on the form and dimension of the specimen? What is the exact series of changes of temperature and pressure in the cylinder of a gas-engine? How are the forces and couples on an aëroplane related to its aspect to the wind? The problems may be difficult, the answers may elude inquiry; but, given the man, the laboratory, and the funds, a committee meeting at intervals to discuss the results of the experiments may reasonably hope in time to meet with success.

Sir Frederick Donaldson and his colleagues have raised questions of great interest and importance, well worth the careful consideration of those engaged in bringing the results of scientific inquiry to bear on the problems of manufacture and construction.

HIGHER EDUCATION AND THE STATE.

Lord Haldane had something important to say upon the subject of provision for higher education in the course of his speech at the opening of the new buildings of the department of applied science of the University of Sheffield on Saturday last. An account of his address will be found elsewhere in this issue, but we are more particularly interested in a summary of the main points, communicated by him to representatives of the Press. Lord Haldane explained that he desired it to be realised fully that he was announcing the considered decisions of the Cabinet upon the subject of university education, and was indicating the policy to be followed. The substance of his remarks was expressed as follows:—

The main features of the Board of Education's scheme are a recognition of the great strides being made in university education by the United States and Germany, and an intention to maintain closely the connection between pure science and applied science and to check any tendency on the part of any of the younger universities to cultivate the latter at the expense of the former. Theory and practice must keep together. Men of business must remember that much of what is distinctive in the inventive and industrial genius of this country comes from theoretical sources.

Unless we wake up fully about this matter of education, and particularly higher education, I am a little nervous as to what the state of things with regard to our industrial supremacy will be fifteen or twenty years hence.

The nation will have to make up its mind to give considerably more out of central funds. The plans for these advances are now fashioned. I hate any idea of increasing expenditure, whether out of local or national sources, if it can be avoided. But this cannot be avoided. It is salvage money, and unless you spend it you will go back as a nation, and your revenues by which you keep up your fleets and your armies will begin to shrink, because you will not be holding your own in that great industrial position from which your power and your wealth have come.

We have now, therefore, a definite statement of the position which university work is to take in the national scheme of education adumbrated by various Ministers since the beginning of this year. There is a clear acknowledgment of the fact that in the matter of State provision for higher education we have not kept pace with other progressive nations; that scientific work which has no industrial interest is as important as that of which the direct application can be seen; that national advancement can be secured best by increase of scientific knowledge; and that all these things involve contributions from the national exchequer greatly in excess of those hitherto given.

Readers of Nature scarcely need reminding that the policy thus broadly outlined has been urged consistently and persistently in these columns. Ten years ago, Sir Norman Lockyer, in his presidential address to the British Association at Southport, gave the evidence from which each one of the points mentioned by Lord Haldane could be justified; and since then, year by year, particulars have been given in the reports of the British Science Guild of the progress being made in the endowment of higher education and research abroad, in comparison with the position in this country. It was shown, for instance, in the last report of the Guild, that the total receipts of universities in the United States in the year 1910–1911 amounted to nearly nineteen million pounds, and the benefactions to four and a half millions. In the same year, the total receipts of those universities and university colleges in Great Britain in receipt of grants from the Board of Education was little more than 600,000*l.*, of which amount the total State grant was roughly one half. The State grants to universities in Prussia alone are more than twice as much as are contributed to our universities from the national exchequer.

Lord Haldane may therefore safely say that the United States and Germany have made far greater strides in university education than have been undertaken in this country. When he wrote the introduction to Sir Norman Lockyer's collection of addresses on education and national progress (1906), he suggested that the private donor should be encouraged, but that the motto of the Chancellor of the Exchequer as regards expenditure upon matters connected with higher education and research should be *Festina lente.* "I do not mean," he wrote, "that the Government ought not to spend public money generously upon the universities. I mean that it should not be spent unless and until a case for the necessity of such expenditure has been clearly made out."

We may be permitted to conclude from the address at Sheffield that Lord Haldane is now of the opinion that a case has been made out for increased national provision for our educational forces. He knows as well as anyone that the great advances being made in education in other countries constitute a formidable menace to ourselves, and that the State can wait no longer for like developments if it desires to maintain a leading position among progressive peoples. He has now stated authoritatively that the Cabinet realises our weakness, and accepts the only policy which will remedy it. We have read this pronouncement with lively satisfaction, and shall welcome any measure which will put the policy into effect.

DR. LUCAS-CHAMPIONNIERE.

THE sudden death of Dr. Just Lucas-Championnière has brought regret to many surgeons in this country, who knew the excellence of his character and of his work. He was seventy years old, surgeon to the Hôtel Dieu (the great hospital in Paris, founded by Saint Louis)—Commander of the Legion of Honour, and member of the French Academy. His father was the first editor of one of the chief medical journals of France; his grandfather had been a leader in the heroic war of La Vendée. From the Collége Rollin, Lucas-Championnière went to the Hôtel Dieu as a student, and was *interne* there in 1865. He became one of the most eminent of all French surgeons of his time, and received honours from many countries, including the Fellowship of the Royal Colleges of Surgeons of London and of Edinburgh. He was a great "all-round" surgeon; but he gave especial study to the operative treatment of hernia, and to the management of fractures. His best recreation—so far as he had time for it—he found in music.

To us over here—some of us may remember his genial presence in London during the 1881 International Medical Congress—he stands for the introduction into France of Lister's antiseptic method. He in France, and Saxtorph in Denmark, were the teachers of the new learning. He came to Glasgow in 1868, and Edinburgh in 1875, that he might learn for himself, watching Lister himself, every detail of the method. He so worshipped the work of Lister that, in the later years of his life, he resented the changes of method, the preference for things "aseptic" over things "antiseptic"; he hoped that surgery would return to "Lister's own method." There are few surgical books more pleasant to handle than his "Pratique de la Chirurgie Antiseptique"—with its portrait of Lister for a frontispiece, and the loyalty and devotion of the writing. It is pitiful to think how slow was the spread of the new learning; what misery was added, for want of the antiseptic method, to the misery of the Franco-German War; what unbelief, and worse than unbelief, delayed the universal recognition of Lister even in our own country.

NOTES.

A Royal Commission has been appointed to inquire into the subject of venereal diseases in the United Kingdom. The terms of reference are:—To inquire into the prevalence of venereal diseases in the United Kingdom, their effects upon the health of the community, and the means by which those effects can be alleviated or prevented, it being understood that no return to the policy or provisions of the Contagious Diseases Acts of 1864, 1866, 1869 is to be regarded as falling within the scope of the inquiry. The members of the Commission are:—Lord Sydenham of Combe, G.C.S.I., F.R.S. (chairman), the Right Hon. Sir David Brynmor Jones, K.C., M.P., Mr. Philip Snowden, Sir Kenelm E. Digby, G.C.B., K.C., Sir Almeric FitzRoy, K.C.B., Sir Malcolm Morris, K.C.V.O., Sir John Collie, Dr. A. Newsholme, Canon J. W. Horsley, the Rev. J. Scott Lidgett, Dr. F. W. Mott, Mr. J. E. Lane, Mrs. Scharlieb, Mrs. Creighton, and Mrs. Burgwin. The secretary to the Commission is Mr. E. R. Forber, of the Local Government Board, to whom any communications on the subject may be addressed.

By Order in Council dated October 14 new denominations of standards of the metric carat of 200 milligrams and its multiples and submultiples have been legalised for use in trade in the United Kingdom on and after April 1, 1914. The permissible abbreviation of the denomination "metric carat" is "C.M." The weights legalised range from 500 C.M. to 0·005 C.M., the series being 5, 2, 1 throughout. The legalisation of the metric carat has been undertaken by the Board of Trade after consulting representatives of the trade in diamonds and precious stones, and is the outcome of a resolution passed at the General Conference on Weights and Measures, held in Paris in 1907, advocating the adoption of an international standard carat. Diamond dealers in this country were at first opposed to any change, and it is only quite recently that they have found it necessary to reconsider their views on the subject, owing to the progress made on the Continent in enforcing the adoption of the metric carat. The new standards are intended to displace the old English carat weight, which has never had legal sanction, but has long been in use in this country, and is recognised by the trade as defined by the relation $151\frac{1}{2}$ carats = 1 oz. troy, so that it is equivalent to 3·1683 grains, or to 205·3 milligrams nearly.

By the death of Mr. William Hunting, on October 24, the veterinary profession has lost one of its most brilliant members, and the public in general one of its most strenuous workers in the cause of public health, especially in relation to the prevention of diseases transmissible from animals to man. Mr. William Hunting was born in 1844, receiving his early education at the Edinburgh Academy, and his professional training at the New Veterinary College, Edinburgh. He obtained his diploma of membership of the Royal College of Veterinary Surgeons in 1865, and became a fellow in 1877. His former teacher, Prof. Gamgee, established a veterinary college in London, and selected him to teach anatomy and physiology, and after a while Mr. Hunting was appointed professor of veterinary science at the Royal Agricultural College, Cirencester. He did not retain this chair for long, and eventually he settled in general practice in London, where he was brought into daily contact with glanders in horses, a disease with which his name will always be associated. He was later elected to the council of the Royal College of Veterinary Surgeons, and became its president, the highest honour his profession could bestow on him, in 1894–5. Mr. Hunting was acknowledged to be the greatest authority on clinical glanders, and it was mainly owing to his efforts that the London County Council instituted its campaign against this disease which was so easily communicable to man, and almost invariably fatal. For this purpose the L.C.C. appointed him as its chief inspector, from which post he retired under the age limit. He lived, however, to see the disease got well under control with every prospect of its being completely eradicated in a comparatively few years. He published an illustrated monograph on glanders in the horse and in man, the best work in existence on the disease, and he has also contributed the chapter on this affection in Hoare's "System of Veterinary Medicine." He had only recently been invited to provide a paper on the same subject for the International Veterinary Congress, which will meet in London in 1914. He founded and edited *The Veterinary Record*, and published a standard work on horse-shoeing, and was also a prolific writer to the veterinary Press. Amongst the many offices he held at the time of his death, Mr. Hunting was president of the National Veterinary Association, examiner for the membership and fellowship of the Royal College of Veterinary Surgeons, examiner for the membership of the Royal Agricultural College, and for the meat inspector's certificate of the Royal Sanitary Institute. He was also a member of the board of studies in veterinary science in the University of London, and a governor of the Royal Veterinary College.

Dr. F. H. Hatch has been elected president of the Institution of Mining and Metallurgy for the forthcoming year.

Mr. Stephen Reynolds, a member of the Departmental Committee inquiring into the condition of the inshore fisheries, has been appointed adviser on these fisheries to the Development Commission.

Dr. H. R. Mill, director of the British Rainfall Organisation, has been compelled to take a complete rest for a time on account of his eyes, which have been affected by the continual strain of his work. He will leave next month for a voyage to New Zealand, and is advised not to attempt to take up for at least a year any work which involves close attention. It is hoped that the rest and change will have a decidedly beneficial effect upon Dr. Mill's eyesight and general health.

The young Malay elephant at the Zoological Gardens, which had been ailing for some time, died in the latter part of last week. The skin has been consigned to Messrs. Rowland Ward, Ltd., by whom it will be mounted for the Natural History Museum. At the time of its death the animal, although about three years old, still retained the hairy coat of new-born Asiatic elephant calves.

In *The Field* of October 25 Mr. R. I. Pocock records the acquisition by the Zoological Society of the second known example of the South American short-eared dog, or fox (*Canis sclateri*). The first specimen was acquired by the society in 1882, and described by Dr. Sclater under the preoccupied name of *C. microtis*. In neither case is the precise habitat known, but Mr. Pocock, who also refers to the peculiarity of the association of short ears with small bodily size, considers that the species is probably a forest animal.

An exhibition of "Nature Photographs," organised by the Nature Photographic Society, is now being held at the house of the Royal Photographic Society, 35 Russell Square. It consists of 132 photographs of birds, animals, flowers, fungi, insects, &c., generally of a high order of merit, and many of them by workers who have earned a considerable reputation for work of this kind. Admission to the exhibition is by presentation of visiting card, between 11 and 5, until November 15. The photographs shown are just of the kind that must appeal to those interested in nature-study.

The annual dinner of the London School of Tropical Medicine was held at Prince's Restaurant on October 24, Dr. F. M. Sandwith presiding, and among those present were Lord Milner, Mr. Percival Nairne, Sir Charles Lukis, Sir J. West Ridgeway, Sir John Anderson, Surgeon-General May, Sir Patrick Manson, and many others. Mr. Austin Chamberlain, proposing the toast of the school, referred to the progress which tropical medicine has made during the last twenty-five years, and said that it is a matter of national pride that in so beneficent a movement our countrymen stand in the forefront in regard to the new learning which is being acquired. The London School has appealed for a sum of 100,000*l*. for endowment, research, and endowment of beds for certain tropical cases, of which about 70,000*l.* has been obtained. A pleasing event of the evening was the presentation to Sir Patrick Manson, the *doyen* of tropical research, of two portraits of himself on behalf of the subscribers, by Mr. Cantlie and Dr. Prout, representing the London and Liverpool Schools respectively.

A violent wind-storm passed over part of Wales on Monday night, October 27, causing damage roughly estimated at between 30,000*l.* and 50,000*l.*, and the loss of two lives, as well as injuries to many people. Two men named Woolford and Breeze were walking arm-in-arm when they were caught by the wind and blown a distance of thirty yards. Woolford fell on his head and was killed, and Breeze had two ribs fractured. From the position in which the dead body of a man named Harries was found in a field near Abercynon it is believed that the man must have been carried 300 or 400 yards by the force of the gale. Along the whole Taff Valley, from Treforest past Cilfynydd and by Quakers Yard to Treharris wrecked structures and up-rooted trees mark the path of the storm. It was first felt at Treforest, and it seemed to gather force as it entered the valley at Cilfynydd. Along the whole way the storm was confined to a path about 200 yards wide.

At the annual public meeting of the Five Academies, held last week at Paris, a paper on the subject of prehistoric trepanning was read, by the late Dr. Lucas Championnière; it dealt with instances of the operation, beginning with the first discovery of such a skull by M. Prunières under a dolmen in the Lozère, among the cave men, the ancient Gauls, and the pre-Columbian Americans. These people performed trepanning by means of flints, and the writer had succeeded in piercing the skull of an adult in the dissecting-room in thirty-five minutes by means of a flint, which was not specially sharpened. He attributed the skill of these early surgeons to the now lost art of rotating instruments in fire-making. The operation was performed in the case of serious skull wounds, and also to relieve headache and epilepsy, by releasing the spirit to which the attacks were attributed. He himself had seen a native at Biskra, in Algeria, whose head showed four perforations, and he and his brothers asserted that they had trepanned their own father twelve times. It is remarkable that the operation was not practised among highly civilised races, like Greeks, Egyptians, Arabs, Hindus, and Chinese, or among some peoples of low culture, like African negroes.

At the annual general meeting of the Royal Society of Edinburgh, held on October 27, the following office-bearers and councillors were elected:—*President:* Prof. James Geikie, F.R.S. *Vice-Presidents:* Dr. J. Burgess, Prof. T. Hudson Beare, Prof. F. O. Bower, F.R.S., Sir Thomas R. Fraser, F.R.S., Dr. B. N. Peach, F.R.S., and Sir E. A. Schäfer, F.R.S. *General Secretary:* Dr. C. G. Knott. *Secretaries to Ordinary Meetings:* Dr. R. Kidston, F.R.S., and Prof. A. Robinson. *Treasurer:* Mr. J. Currie. *Curator of Library and Museum:* Dr. J. S. Black. *Councillors:* Prof. T. H. Bryce, Mr. W. A. Carter, Mr. A. Watt, Dr. J. H. Ashworth, Dr. J. G. Gray, Prof. R. A. Sampson, F.R.S., Prof. D'Arcy W. Thompson, C.B., Prof. E. T. Whittaker, F.R.S., Principal A. P. Laurie, Prof. J. Graham Kerr, F.R.S., Dr. L. Dobbin, Mr. E. M. Wedderburn. It is worthy of note that the presidents of the Royal Societies of London and of Edinburgh are brothers, natives of Edinburgh, and both geologists.

At the annual general meeting of the Cambridge Philosophical Society, held on October 27, the following officers and council were elected:—*President:* The Master of Christ's. *Vice-Presidents:* Prof. Pope, Dr. Barnes, and Prof. Seward. *Treasurer:* Prof. Hobson. *Secretaries:* Mr. A. Wood, Mr. F. A. Potts, and Mr. G. H. Hardy. *Other Members of Council:* Sir J. J. Thomson, Mr. J. E. Purvis, Mr. R. P. Gregory, Dr. Cobbett, Mr. J. Mercer, Dr. Marshall, Mr. G. R. Mines, Mr. F. J. M. Stratton, Prof. Woodhead, Mr. C. Forster Cooper, Mr. C. E. Inglis, and Dr. Duckworth.

At the annual meeting of the Prehistoric Society of East Anglia, the honorary secretary made an announcement, which will be welcome to archæologists, that the society proposes to undertake a survey of Grime's Graves, at Weeting. A few of these constructions were superficially studied in 1852, and one was carefully examined by Canon Greenwell in 1870. But much still remains to be done, and the importance of flint implements of the Cissbury type found in the caves has been greatly increased by the suggestion of Mr. Reginald Smith that they are analogous to those of the Aurignacian age found on the Continent. Contributions are invited for the prosecution of this undertaking by Mr. W. G. Clarke, 12 St. Philip's Road, Norwich. The president, Mr. J. Reid Moir, discussed the fractured flints found in the Eocene "Bullhead" bed at Coe's Pit, Bramford, near Ipswich, with special reference to the views of M. Breuil, who is inclined to regard the fractures as the result of natural pressure. The Ipswich bed is now overlaid by some 40 ft. of deposits, partly sand, and it is difficult to imagine how pressure on the lower strata could have been exercised through such a medium. Mr. Reid Moir concludes, from experiments, that pressure may account for the fractures. If this be the case, it must have been exercised before the deposition of the present overlying strata. In later beds the "human touch" is sufficiently obvious, and it is thus possible to differentiate one type from the other with some confidence.

The Eugenics Review for October (v., No. 3) contains matter of much interest for the citizen. The Chancellor of Stanford University, U.S.A., writes on the eugenics of war, pointing out that it is the best part of the population that becomes the military, and that a country, therefore, by the ravages of war, suffers not only at the time but for generations afterwards. "Wars are not paid for in war-time; the bill comes later," as Benjamin Franklin said. Mr. Sören Hansen marshals evidence on the inferior quality of the first-born children, and a State not only loses citizens by the limitation of families, but is also penalised thereby by a deterioration in racial quality.

The monograph published by Prof. P. N. Ure, and issued by the Oxford University Press, on black glaze pottery from Rhitsona in Bœotia (pp. 63+xix plates, price 7*s.* 6*d.* net) is a useful contribution to our knowledge of Greek ceramics. Our information on the history of the Bœotian federation from literary sources is confined to Thebes; that of the minor members must be discovered by the spade. If this pottery could be accurately dated it would supply much useful evidence. The present monograph has established the leading facts, which must be supplemented by further excavation and examination of the material.

The Danysz rat virus, consisting of a cultivation of a microbe which produces a fatal infectious disease among rats, has been used with considerable success for the extermination of rats in many districts. The accompanying illustration shows the preparation of the "bait," made by impregnating crushed oats with the virus, for use in Kaltern, a village in the Austrian Tyrol, which had suffered severely from an invasion of field rats.

Saturating crushed oats with Danysz virus at Kaltern, Austrian Tyrol.

The age of the earth has long been a favourite topic for discussion, and conclusions have been arrived at from time to time remarkable mainly for their variety. This variety is likely to characterise for a long time to come other conclusions that may follow, for the simple reason that at present we lack the data for dealing with the subject in a comprehensive way. Estimates of geologic time, founded upon one set of facts and assumptions, are found to be difficult to square with those based upon other and equally trustworthy sets. Mr. H. S. Shelton considers some methods of attacking the problem in the October number of *Science Progress*. He points out the absence of sufficiently good data for the average rate of erosion of rocks, and suggests that further information could be obtained if we possessed fuller details concerning the extent of particular local formations. Of the geochemical methods he thinks the best is probably that based on calculations concerning the amount of limestone in the rocks of the earth; and from Mellard Reade's deductions he believes it is "possible to assess a probable minimum of the order of 500,000,000 of years." Respecting the estimates of Strutt, based on the study of helium and radioactive minerals, he says: "The most we can now infer is a moderate minimum of time, a result that is given equally well by other data if properly handled." Concerning biological evidence, he says: "The biologist has no independent standard of time. Vague as are the data of the geologist, those of the biologist are still more uncertain." Finally: "What we are entitled to say on the evidence before us—biological, geological, and physical—is this: It would be absurd to attempt, on very insufficient data, to give an estimate of the probable lapse of geologic time. But there is, at the present day, no reason whatever why it should not be a thousand million of years or a time even greater." This does not carry us very far, and Mr. Shelton's suggestions for further study of the problem are somewhat trite.

The October number of *The Entomologists' Monthly Magazine* contains a memoir and portrait of the late Dr. O. M. Reuter, the celebrated hemipterist, who died on September 2, in his native town of Abo, at the age of sixty-three.

The report of the Entomological Society of Ontario for 1912 mainly deals with the infestations of injurious insects in the Dominion and the best means of keeping them in check. Great aid in this work has been afforded by the establishment of field laboratories in various districts, which have enabled investigations to be carried on over much wider areas than was previously possible. Another feature of the year's work has been an increased importation of parasitic enemies of some of the most noxious insects, notably the introduction of cocoons of the larch-sawfly infected with an ichneumon-fly from the English Lake District.

The beautiful colours of thin films observable with Mr. C. V. Boys's scientific toy, "The Rainbow Cup," were referred to in a Note in our issue of January 23 of this year (vol. xc., p. 579). A cheap form of the instrument is now available from Messrs. J. J. Griffin and Sons, Ltd., the price being 2*s.* 6*d.* only instead of 25*s.* Though the new form is, of course, not so good as the more expensive instrument, it shows the changing colour patterns in a very pleasing way, and should interest a large section of the general public. An explanatory pamphlet is included in the box containing the instrument and the soap solution.

The Royal Meteorological Institute of the Netherlands has issued a useful paper on the rainfall of that country (*Mededeelingen en Verhandelingen*, 15), with maps and tables showing the annual and seasonal distribution. The work is a continuation prepared by Dr. Hartman of one published by Engelenburg in 1891, since which time the number of stations has greatly increased, and is the first instalment of a general climatology of the Netherlands. In addition to the annual means for the whole period, which differs for each station, all the means for the twenty-five years, 1881–1905, have been calculated, as this period has been adopted as a normal time for comparison by the Solar Commission of the International Meteorological Committee. The extreme annual values for this series vary from 828 mm. (32·6 in.)

at Leeghwater (South Holland) to 596 mm. (23·5 in.) at Kampen (E. Zuider Zee). The rainfall diminishes considerably near the coasts; at some distance from these it increases, and afterwards the diminution becomes progressive and general with distance from the sea. The maximum values occur in July, August, and October; the minimum values occur generally in February and April. In July the increased rainfall is due chiefly to thunderstorms.

THE present autumn has many meteorological features of especial interest. Only one-third of the autumn now remains, and although there is ample time for a thorough change to set in, there are at present no indications of generally colder conditions. The weekly reports issued by the Meteorological Office show an excess of temperature since the close of summer at the end of August, in all parts of the British Isles, and over England and Ireland the excess amounts to 3° for the period embraced by September and October. The absence of low temperatures is very pronounced, and at Greenwich the lowest shade temperature for October is 36°, while to October 28 there were nine nights with the thermometer above 50°. In October last year sharp frost was experienced on October 5 and 6, but it is not altogether uncommon to escape frost throughout the month, and in 1910 the lowest temperature at Greenwich for October was 39·6°. On twenty-one days out of the first twenty-eight days in October this year the shade temperature at Greenwich had exceeded 60°, and even towards the close of the month such high temperatures were fairly common. The autumn rains have so far been in excess of the average over the midland and eastern districts of England, but there is generally a deficiency in the western districts.

IN his remarks on Dr. Bohr's letter on the spectra of helium and hydrogen, in NATURE of October 23, p. 232, Prof. Fowler referred to certain corrections required in the wave-lengths calculated for the lines near $H\beta$, $H\gamma$, &c., as given in the original submitted to him. Dr. Bohr, however, corrected these wave-lengths in the proof, thus rendering Prof. Fowler's corrections unnecessary. We are asked to mention this in order to remove any ambiguity to which the reference to corrected wave-lengths may have given rise.

THE September number of *Terrestrial Magnetism and Atmospheric Electricity* devotes twenty pages to an account of the magnetic work of the Astronomer Royal, Edmund Halley. In 1698 he was placed in command of the *Paramour Pink* in order "to improve the knowledge of the longitude and the variations of the compasse." He spent two years taking observations in the Atlantic between latitudes 50° N. and 52° S., and published his results in a "General Chart of the Variations of the Compass" in 1701. The journal in which he entered all his observations is reprinted under the editorship of Messrs. Ault and Wallis, of the department of terrestrial magnetism, and Dr. Bauer has collected together the references to Halley's magnetic work in the journals of the Royal Society, and gives reprints of the letterpress which accompanied the sea charts of the western and southern oceans, and of the whole world.

SOME interesting results are recorded by Messrs. F. A. Sannino and A. Tosatti in the *Atti R. Accad. Lincei* (vol. xxii., ii., No. 5) of the effect of manuring grape vines with manganese sulphate. The result of the application is considerably to increase the yield of grapes per hectare, but the must obtained in the vintage is poorer in glucose, and higher in acidity than with the control, carried out on the same land, but without the addition of manganese. The wine obtained after fermentation shows a quite characteristic odour and flavour, and tends to resemble Marsala or Madeira. At the same time a tendency to develop turbidity is shown which is also found in wines when too rich in oxydases. The proportion of manganese present in the ash of the wine is at the same time markedly increased.

COMMENTING on the loss of the German naval airship *Zeppelin L2*, *The Engineer* for October 24 does not consider that present constructive methods will ever render available the tactical superiority of airships. No dirigible balloon has yet been constructed which has fulfilled its function otherwise than by dodging the forces of nature. It is held that both commercially and constructionally, the dirigible balloon of to-day appears to be an absurdity. Further, there is little reason to hope that conditions will change, and that new materials and methods of construction will be made available.

THE "James Forrest" lecture for 1913 was delivered by Mr. Alexander Gracie in the new buildings of the Institution of Civil Engineers on October 23, the subject being twenty years' progress in marine construction. Increase in size of vessel is undoubtedly the most valuable resource of the naval architect, as it leads directly towards the attainment of greater comfort, speed, and economy. Twenty years ago, the premier Atlantic vessel was the *Campania,* 600 ft. in length, 65 ft. in beam, and 41 ft. 6 in. in depth. To-day the largest vessel afloat is the *Imperator,* 880 ft. by 90 ft. by 63 ft. The Cunard liners *Lusitania* and *Mauretania* have been surpassed in size, but still hold their supremacy in speed unchallenged; these vessels maintain an ocean speed of between 25 and 26 knots. The advance has been greatly facilitated by the introduction and development of the steam turbine, which has provided the way to further progress in economy, lightness, and the construction of very large units, while at the same time eliminating vibration troubles and relieving the difficulties of engine-room management. Twenty years ago, the majority of cross-Channel vessels were paddle-steamers. Typical vessels were the paddle-steamer *Calais Douvres* and the twin-screw *Ibex*. The former vessel had a displacement of 1065 gross tons, and engines of 6000 indicated horse-power gave a speed of 20·64 knots. The corresponding dimensions of the latter vessel were 1062 gross tons, 4200 indicated horse-power, and 19·37 knots. The introduction in 1911 of geared-turbines in the *Normannia* and *Hantonia* has led to a great economy in fuel, these vessels using but 43 tons of coal per trip, as compared with 70 tons used by their immediate predecessors of the same capacity, but propelled by direct-driven three-screw turbines. Last summer, the Channel steamer *Paris*, fitted with geared turbines, attained the remarkable speed of 25·07 knots—a result which has only been surpassed by torpedo craft. Hydraulic transmission has lately been developed in Germany, and electrical transmission has also been applied to several vessels. Cargo steamers have advanced from 6400 to 9600 tons dead-weight, at practically constant speed of 11 knots. There are many attractive possibilities in the problem of producing a trustworthy internal-combustion engine able to compete successfully with the steam-engine and geared turbine.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences for November :—

Nov. 1. 16h. 0m. Mercury at greatest elongation east of the Sun.
2. 21h. 18m. Jupiter in conjunction with the Moon (Jupiter 4° 35′ N.).
4. 11h. 32m. Uranus in conjunction with the Moon (Uranus 3° 26′ N.).
5. 8h. 0m. Venus at greatest heliocentric latitude N.
12. 13h. 0m. Mercury stationary.
15. 12h. 25m. Saturn in conjunction with the Moon (Saturn 6° 49′ S.).
18. 7h. 6m. Mars in conjunction with the Moon (Mars 2° 23′ S.).
,, 13h. 21m. Neptune in conjunction with the Moon (Neptune 4° 40′ S.).
22. 18h. 0m. Mercury in inferior conjunction with the Sun.
26. 7h. 33m. Venus in conjunction with the Moon (Venus 5° 41′ N.).
,, 23h. 32m. Mercury in conjunction with the Moon (Mercury 6° 43′ N.).
27. 0h. 0m. Mars stationary.
30. 16h. 5m. Jupiter in conjunction with the Moon (Jupiter 4° 12′ N.).

A New Comet.—A Kiel telegram, dated October 24, distributes the information communicated by Prof. Hartwig that on October 23 Dr. Zinner discovered a comet of the 10th magnitude at 7h. 58·8m. M.T. Bamberg. Its position is given as R.A. 18h. 40m. 1s., and declination −4° 32′ 38″, and the object was observed to have a tail. The comet is thus situated in the constellation of Aquila, a little less than half-way between λ Aquilæ and η Serpentis.

Comet Metcalf 1913*b*.—The following is the ephemeris for Metcalf's comet as calculated by Herr A. Kobold, and published in *Astronomische Nachrichten*, No. 4686 :—

12h. M.T. Berlin.

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Oct. 30	20 46 53	+4 25·8	
31	46 31	3 13·9	
Nov. 1	46 13	2 6·1	
2	45 58	1 2·0	9·7
3	45 47	+0 1·5	
4	45 39	−0 55·9	
5	45 33	1 50·1	
6	45 31	2 41·4	9·9

This faint comet is now just moving into the constellation of Aquarius, and is only a suitable object for telescopes of large aperture.

Comet Westphal (1913*d*).—Comet Westphal is becoming a faint object, being now a little fainter than 8·5 magnitude. The following is a portion of the ephemeris published by Hermann Kobold in *Astronomische Nachrichten*, No. 4687 :—

12h. M.T. Berlin.

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Oct. 30	20 40 35	+23 16·8	
31	39 38	23 53·8	
Nov. 1	38 46	24 30·4	8·6
2	37 56	25 6·5	
3	37 11	25 42·3	
4	36 30	26 17·7	
5	35 51	26 52·8	8·6
6	35 17	27 27·5	

The comet is moving in the constellation of Vulpecula, and is in a good position for observation.

Elements and Numbers of Minor Planets.—The growth in the number of the minor planets discovered is clearly brought out in the two interesting communications by Dr. Cohn in *Astronomische Nachrichten*, No. 4688. In the first paper he refers to the elements and numbering of these bodies, and points out that in the interval, July 1, 1912, to June 30, 1913, sixty-seven objects have been given provisionary numbers. Five of these have been identified as old members of the group. Of the sixty-two remaining, nineteen hail from Heidelberg, seven from Johannesburg, nine from Neuchâtel, eleven from Simeïs, three from Vienna, and thirteen from Winchester. Of this number twenty-one have had their elliptical orbits checked and numbers assigned to them.

In the second communication Dr. Cohn points out the unsatisfactory state, and possibility of mistakes, in the present system of lettering the planets, owing to their great number, and suggests, with the help of other astronomers, a set of names for the planets from No. 570 to 727. As an example, it may be stated that 697 has been named "Galileo," as it was discovered on the day of the three hundredth anniversary of the discovery of Jupiter's satellites. 727 is termed "Nipponia," as the planet was discovered twice by Herr Hirayama in Tokio.

Theoretical Astronomical Research.—A circular regarding a plan for an institute for theoretical astronomical research has reached us from Lund, Sweden. It is a timely plea for financial support for a neglected part of astronomy. The work suggested as specially suitable to be undertaken by the institute is in the first place the investigations of the orbits of the asteroids, work which it is confidently anticipated will lead to the solution of "the problem of three bodies," and perhaps also solve the enigma of the evolution of the heavenly bodies. This work would be undertaken by three of a proposed staff of eight "theoretical astronomers." Two more would work at the problem of three bodies; to another couple would be assigned various cosmological problems, such as the figure of the heavenly bodies, tides, and related problems. The remaining astronomer would be required to deal with stellar statistics. These men would be of the standing of university professors, and have rather better pay. Each astronomer would have one algebraical computer and two numerical computers at his personal disposal, and should the necessity arise additional computers would be available. The project is conceived in a princely manner, the proposed yearly budget being 200,000 marks (German) (10,000*l*.), and the complete scheme requires a capital sum of 5,600,000 marks (280,000*l*.). Calculating machines, worked by lady computers, would be employed for the numerical calculations, and no fewer than 100,000 marks (5000*l*.) is proposed to be spent on machines.

COMMITTEES ON RADIO-TELEGRAPHIC INVESTIGATIONS.

Organisation of an International Commission.

A MEETING was held in Brussels at the commencement of last month at which the question of organising an international commission to carry out wireless experiments was further discussed. At the International Time Conference in Paris last October a series of resolutions was passed with reference to the formation of an international organisation for the scientific study of Hertzian waves and their relationship to the medium through which they travel. At this conference Mr. Goldschmidt, of Brussels, placed his high-power station at Brussels and the sum of 1000*l.* for preliminary studies at the disposal of the proposed international commission.

Arising out of these resolutions the representatives of the different countries who were present at Brussels last month drafted a provisional constitution for the international commission and a scheme for its work.

The objects of the commission are:—(1) To carry out experiments on the propagation of electric waves. (2) To make wireless telegraph measurements and the study of the problems related therto.

The provisional programme of the work of the commission will consist in making measurements in different countries and at different distances and in different directions of the strength of signals sent out from the station at Brussels. These measurements will be repeated from day to day or hour to hour as necessary in order to determine the variation of the strength of the signals both with time, with distance, and with direction, and later the effect of wave-length and decrement will be studied.

It is proposed to set up a receiving station near the transmitting station in Brussels in order accurately to control the strength of the waves sent out so that an allowance can be made for any unavoidable variation in reducing the final results.

The organisation consists of a number of national committees, one in each of the countries taking part. The national committees will send delegates to the international commission, and these delegates, together with the officers, will constitute the international commission. It is proposed that the international commission should meet once a year, or more often if the work is sufficiently advanced.

The Institution of Electrical Engineers has decided to undertake the formation of the national committee for Great Britain, under the scheme for the organisation and encouragement of electrical research which was announced at the institution meeting on December 12, 1912.

The British Association Committee.

The British Association Committee has now inaugurated an extensive scheme for the making of observations of natural electric waves by means of wireless telegraph receiving apparatus, and is addressing to wireless telegraph experimenters an invitation to cooperate in the making of observations. The records will be collected by the committee and compared and reduced by it.

These natural electric wave trains produce troublesome noises in the telephone receivers of wireless telegraph stations. Some proportion of them are due to lightning strokes within a few hundred miles of the receiving station; but even when there is no thunder weather recorded over the whole continent of Europe and the adjacent seas, they are received continuously by an antenna adjusted to a great wave-length. It has been suggested that some of these wave trains may be due to extraterrestrial causes, and it does not seen unreasonable to suppose that electrical discharges may occur in the sun and may be the source of a proportion of the natural electric wave trains we receive. There is little likelihood of our gaining a knowledge of the causes at work until organised observations are carried out simultaneously at numerous points of the globe and collated at a single centre, such as the committee now affords.

Another and distinct inquiry which urgently needs pursuing is the action of the earth's atmosphere in causing variations of the electric waves used in transmitting messages over long distances. The laws of these variations, especially in respect of their connection with weather conditions, with position on the earth's surface, and with the time of day would, if unravelled, probably throw light on the electrical conditions of the highest parts of our atmosphere. The committee has undertaken this inquiry also.

In carrying on the work the committee looks very largely to private experimenters for the collection of data. But it has been a matter of extreme gratification to find that the Imperial Navy and the British Post Office were willing to help. The Marconi Company also has, with commendable public spirit, promised to give its powerful assistance to the committee. Thus the committee can already make sure that data will be collected on its behalf in all parts of the world. Meanwhile private experimenters who are willing to assist the committee by making observations should communicate with the secretary, Dr. W. Eccles, University College, Gower Street, London, England.

APPLIED SCIENCE IN THE UNIVERSITY OF SHEFFIELD.

ON October 25 the completed buildings of the applied science department of Sheffield University were opened by Lord Haldane. These buildings have the largest frontage in Sheffield, being 350 ft. long, the architecture being of the Hampton Court Palace type. The cost of the additions has been approximately 45,000*l.* The central administrative block contains a very fine assembly-room, called the "Mappin Hall," after the late Sir Frederick Thorpe Mappin, first chairman of the applied science committee of Sheffield University, and a handsome departmental library which will house books having reference to applied science and pure science data more immediately bearing upon this subject. There are staff common-rooms, and the metallurgical record office included in this central block, and the department of pure geology is also housed here.

The south-east wing, a considerable portion of the cost of which was defrayed by the Drapers' Company of London, contains four floors; the two lower floors are devoted to non-ferrous metallurgy, the third floor to mining, and the fourth floor to applied chemistry which has particular reference to mining. The new non-ferrous department, which has been organised so as not in any way to overlap the metallurgy of the Royal School of Mines, has been designed to develop scientifically the silver industries of Sheffield. The course here is divided into two sections: first, the basis metal section, in which are produced on a works' scale ingots of German silver, Britannia metal, brass, and bronze, white metals, and other non-ferrous metals in use in Sheffield manufactures (for working these metals into the finished articles, the department has secured the friendly cooperation of silver manufacturers in Sheffield); secondly, the electroplating department, in which all classes of plating operations are carried on on a manufacturing scale. Each student's bench is fitted with a specially combined ammeter and voltmeter, so that the student may make his preliminary studies under exactly known conditions. There are two large laboratories for the preparatory and advanced stages of this special study of non-ferrous metals as used in the Sheffield trades. The lecture-rooms are two in number, one seating 150 and the other fifty students, both being provided with up-to-date electric lantern arrangements.

The micrographic laboratory has been made to a specially thought out design, each block of the polishing battery being run by a separate electric motor of one-seventh h.p., revolving at 1400 revolutions per minute. Adjacent to the polishing and etching-room is a photomicrographic department complete with dark-room. The photomicrographic apparatus is by Zeiss, and is fitted with the new arc lamp of this firm. There is a large staff and research laboratory, one side of which is devoted to calorimetric work.

From the point of view of pure science the most important installation in the new metallurgical wing is a specially devised recalescence laboratory for observing with great accuracy the critical points of iron and steel, the freezing points of metals, and the phenomena of solid solution in metals. There are coke-fired and electric vacuum furnaces in which a complete vacuum can be obtained in about one minute by means of the "Fleuss" pump. The recalescence apparatus comprises an astronomical clock by the Synchronome Company, a chronographic recorder reading to a quarter of a second, and a delicate galvanometer reading direct or in connection with a potentiometer. This installation, which has been made to specification by the Cambridge Scientific Instrument Co., has cost about 400*l.*, and is the most complete extant.

The melting-shop for non-ferrous metal will register the comparative melting efficiencies of coke, oil, gas, and electricity, each method being capable of making ingots of about 90 lb. weight. The static and dynamic testing of non-ferrous metals will be made in the ferrous department, which is provided with a single-lever Buckton machine on two centres, so that the machine may be arranged to read off the stress either in 3-in. ton moments or 12-in. ton moments. For more delicate work there is a two-ton static machine. The dynamic testing will be carried out on Arnold's standard stress-strain machine, on which it is hoped to obtain important results on the adherence of silverplating of different thicknesses on different basis metals.

In declaring the building open, Lord Haldane insisted most strongly that the industrial success of this country in the future depends upon the cordial cooperation of pure and applied science, which are practically indivisible. He said:—"Without a Kelvin or a Clerk Maxwell, or a Lister, or a man, to go further back, like Sir Isaac Newton, many of the things which we do to-day, and do so well, would not be done, but we have also to remember that unless other men of a similar type are produced in the future we cannot keep up to the level we are now at, but we should be at a disadvantage compared with other countries. You have done a very practical thing in founding this great new department of applied science; you have done the right thing in keeping applied science and pure science in close relation, and bringing both into intimate organic relation with the spirit of the University, that great permeating spirit without which they cannot be on a high level.

"What will be done in the department of applied science will be to go still further than has been possible in the past in bringing the application of science to bear on the problems of industry. It will not be practical work merely; it will be work in the course of which the student will be trained in the highest knowledge. He also will be told that he must not stop short at the conclusions to which science leads him, but must show his capacity to apply the conclusions at which he has arrived to the actual and practical solution of the difficulties which confront the industrial world. In the old days pure science appeared to be something no one was interested in from the point of view of practical education. Now the greatest commercial discoveries depend upon new ideas, new conceptions being developed by men who have genius which makes them devoted to their work, even though they have to starve to do it. It is only in universities and technical schools that we find these men, and if British industry is to hold its own in the future, we shall have to realise the necessity there is, not only to turn to science, but to see that pure science has an opportunity of developing itself and being brought in contact with daily work."

Lord Haldane went on to contrast the rapid strides that are being made in the development of universities in America with what is being done in this country. He has, he said, great faith in the capacity of the British nation, but unless we wake up thoroughly in the matter of education, and particularly higher education, he is a little nervous as to what we may find the state of things concerning our industrial supremacy some fifteen or twenty years hence.

"Nowadays not only Governments, but Government Departments are waking up about these things. For the last twelve months there has been a great deal of activity about the business of national education. Mr. Pease is carrying out what I believe to be a right line of policy. He is trusting the very highly expert officials at the Board of Education and consulting the education committees throughout the country. The local education committees have done splendid work, but the burden on them has been very heavy. The nation will have to make up its mind to give considerably more out of the taxes for this work. The plans are now fashioned. The Government knows exactly what to do to make advance if only it has the nation at its back. I hate any idea of increasing expenditure, whether it is out of local or national resources, if it can be avoided. This expenditure, however, cannot be avoided. Unless we spend it we shall go back as a nation. Our revenues, by which we keep up our fleets and armies, will shrink, because we shall not be holding our own with the industrial nations. What Sheffield has done will have to be done right through the country."

Lord Haldane also referred to the report of the Advisory Committee on University Grants, and mentioned that this Committee, amongst other matters, has practically decided recently to deal with a pension fund for professors (see Nature, March 6, 1913, p. 21), which, he said, "meant that instead of a man having to cling on to his post as the alternative to starving when he felt himself old, he could retire, and let a young man take his place, and go on with the development still further of the teaching which the professor had carried so far."

THE BRITISH ASSOCIATION AT BIRMINGHAM.

SECTION M.

AGRICULTURE.

Opening Address by Prof. T. B. Wood, President of the Section.

I propose to follow the example of my predecessor of last year, in that the remarks I wish to make to-day have to deal with the history of agriculture. Unlike Mr. Middleton, however, whose survey of the subject went back almost to prehistoric times, I propose to confine myself to the last quarter of a century—a period which covers what I may perhaps be permitted to call the revival of agricultural science.

Twenty-five years ago institutions concerned with the teaching of agriculture or the investigation of agricultural problems were few and far between. I do not propose to waste time in giving an exhaustive list, nor would such a list help me in developing the argument I wish to lay before the section. It will serve my purpose to mention that organised instruction in agriculture and the allied sciences was already at that date being given at the University of Edinburgh and at the Royal Agricultural College, whilst, in addition, one or more old endowments at other universities provided courses of lectures from time to time on subjects related to rural economy. Agricultural research had been in progress for fifty years at the Rothamsted Experimental Station, where the work of Lawes and Gilbert had settled for all time the fundamental principles of crop production. Investigations of a more practical nature had also been commenced by the leading agricultural societies and by more than one private landowner.

In these few sentences I have endeavoured to give a rough, but for my purpose sufficient, outline of the facilities for the study of agricultural science twenty-five years ago, at the time when the county councils were created. Their creation was followed almost immediately by what can only be called a stroke of luck for agriculture. The Chancellor of the Exchequer found himself with a considerable sum of money at his disposal, and this was voted by Parliament to the newly created county councils for the provision of technical instruction in agriculture and other industries.

Farmers were at that time struggling with the bad times following the wet seasons and low prices of the 'seventies and 'eighties, and some of the technical instruction grant was devoted to their assistance by the county councils, who provided technical instruction in agriculture. Thus, for the first time considerable sums provided by the Government were available for the furtherance of agricultural science; and, although at first there was no general plan of working and every county was a law unto itself, the result has been a great increase of facilities for agricultural education and research.

Almost every county has taken some part. The larger and richer counties have founded agricultural institutions of their own. In some cases groups of counties have joined together and federated themselves with established teaching institutions. For my purpose it suffices to state, without going into detail, that in practically every county, in one way or other, attempts have been made to carry out investigations of problems related to agriculture.

Twenty years after the voting of the technical instruction grant to the county councils, Parliament has again subsidised agriculture, in the shape of the Development Fund, by means of which large sums of money have been devoted to what may be broadly called agricultural science. It seems to me that the advent of this second subsidy is an occasion when this section may well pause to take stock of the results which have been achieved by the expenditure of the technical education grant. I do not propose to discuss the results achieved in the way of education, although most of the technical instruction grant has been spent in that direction. It will be more to the point in addressing the Agricultural Section to discuss the results obtained by research.

The subject, then, of my address is the result of the last twenty years of agricultural research, and I propose to discuss both successes and failures, in the hope of arriving at conclusions which may be of use in the future.

Agricultural science embraces a variety of subjects. I propose to consider first the results which have been obtained by the numerous practical field experiments which have been carried out in almost every county. I suppose that the most striking result of these during the last twenty years is the demonstration that in certain cases phosphates are capable of making a very great increase in the crop of hay, and a still greater increase in the feeding value of pastures. This increase is not yielded in all cases, but the subject has been widely investigated, and the advisory staffs of the colleges are in a position to give inquirers trustworthy information as to the probability of success in almost any case which may be submitted to them. This is a satisfactory state of things, and the question naturally arises: How has it come about?

On looking through the figures of the numerous reports which have been published on this subject, it appears at once that in many cases the increase in live-weight of sheep fed on plots manured with a suitable dressing of phosphate has been twice as great as the increase in weight of similar animals fed on plots to which phosphate has not been applied. Now about a difference of this magnitude between two plots there can be no mistake. It has been shown by more than one experimenter that two plots treated similarly in every way are as likely as not to differ in production from their mean by 5 per cent. of their produce, and this may be taken as the probable error of a single plot. Where, as in the case of many of the phosphate experiments, a difference of 100 per cent. is recorded, a difference of twenty times the probable error, the chances amount to a certainty that the difference is not an accidental variation, but a real effect of the different treatment of the two plots. The single-plot method of conducting field trials, which is the one most commonly used, is evidently a satisfactory method of measuring the effects of manures which are capable of producing 100 per cent. increases. It was good enough to demonstrate with certainty the effects of phosphatic manuring on many kinds of grass land, and it is to this fact that we owe one of the most notable achievements of agricultural science in recent years.

Another notable achievement is the discovery that in the case of most of the large-cropping varieties of potatoes the use of seed from certain districts in Scotland or the northern counties of Ireland is profitable. This is another instance of an increase large enough to be measured accurately by the single-plot method. Reports on the subject show that seed brought recently from Scotland or Ireland gives increased yields of from 30 to 50 per cent. over the yields produced by seed grown locally for three or more years.

That the single-plot method fails to give definite results in many cases where it has been used for manurial trials is a matter of common knowledge. Half the reports of such trials consist of explanations of the discrepancies between the results obtained and the results which ought to have been obtained. The moral is obvious. The single-plot method, which suffices to demonstrate results as striking as those given by phosphates on some kinds of pasture land, signally fails when the subject of investigation is concerned with differences of 10 per cent. or thereabouts.

Before suggesting a remedy for this state of things it will be well to consider the allied subject of variety testing, which has been brought into great prominence recently by the introduction of new varieties of many kinds of farm crops. In testing a new variety it is necessary to measure two properties—its quality and its yielding capacity—for money-return per acre is obviously determined by the product of yielding capacity and quality as expressed by market price. I propose here to deal only with the determination of yielding capacity. The determination of quality is not allied to manurial trials.

In attempting to determine yielding capacity there has always been a strong temptation to rely on the measurement of obvious structural characters. For instance, in the case of cereals many farmers like large ears, no doubt with the idea that they are an indication of high-yielding capacity. Many very elaborate series of selections have been carried out, on the assumption that large grains, or large ears, or many ears per plant implied high yield.

We may take it as definitely settled that none of these characters is trustworthy, and that the determination of yielding capacity resolves itself into the measurement of the yield given by a definite area. The actual measurement, therefore, is the same as that made in manurial trials, and is, of course, subject to the same probable error of about 5 per cent.

It follows, therefore, that it is subject to the same limitations. Variety trials on single plots, and that is the method commonly used, will serve to measure variations in yielding capacity of 30 per cent., or more, but are totally inadequate to distinguish between varieties the yielding capacities of which are within 10 per cent. of each other.

Numbers of such single-plot trials have been carried out, with the result that many varieties with yielding capacities much below normal have almost disappeared from cultivation, and those commonly grown do not differ greatly from one another—probably not more than 10 per cent.

Ten per cent. in yielding capacity, however, in cereals means a return of something like 15*s.* to 20*s.* per acre—a sum which may make the difference between profit and loss; and if progress is to be made in manuring and variety testing, some method must be adopted which is capable of measuring accurately differences in yield per unit area of the order of 10 per cent.

The only way of decreasing the probable error is to increase the number of plots, and to arrange them so that plots between which direct comparison is necessary are placed side by side, so as to reduce as much as possible variations due to differences in soil. Thus it has been shown that with ten plots in five pairs the probable error on the average can be reduced to about 1 per cent., in which case a difference of from 5 to 10 per cent. can be measured with considerable certainty.

Such a method involves, of course, a great deal of trouble; but agricultural science has now reached that stage of development at which the obvious facts which can be demonstrated without considerable effort have been demonstrated, and further knowledge can only be acquired by the expenditure of continually increasing effort. In fact, the law of diminishing return holds here, as elsewhere.

It appears, then, that for questions involving measurements of yield per unit area, such, for instance, as manurial or variety trials, further advance is not likely to be made without the expenditure of much more care than has been given to such work in the past. The question naturally arises: Is it worth while? I think the following instance shows that it is:—

Some years ago an extensive series of variety trials was carried out in Norfolk, in which several of the more popular varieties of barley were grown side by side at several stations for several seasons. In all, the trial was repeated eleven times. As a final result it was found that Archer's stiff-straw barley gave 10 per cent. greater yield than any other variety included in the trials, and by repetition of the experiment the probable error was reduced to 1½ per cent. The greater yield of 10 per cent., being over six times the probable error of the experiment, indicates practical certainty that Archer barley may be relied on to give a larger crop than any of the other varieties with which it was compared. One difficulty still remained. It was almost impossible to obtain anything like a pure strain of Archer barley. Samples of Archer sold for seed commonly contained 25 per cent. of other varieties. This difficulty was removed by Mr. Beaven, who selected, again with enormous trouble, a pure high-yielding strain of Archer barley. Since this strain was introduced into the Eastern Counties the demand for it has always exceeded the supply which could be grown at Cambridge and at the Norfolk Agricultural Station, and it is regarded by farmers generally as a very great success.

The conclusion, therefore, is that a 10 per cent. difference is well worth measuring, that it cannot be measured with certainty by the single-plot method, and that it behoves those of us who are concerned with field trials to look to our methods, and to avoid printing figures for single-plot experiments which may very well be misleading. Almost everyone thinks himself competent to criticise the farmer, who is commonly described as too self-satisfied to acquaint himself with new discoveries, and too conservative to try them when they are brought to his notice. Let us examine the real facts of the case. Does the farmer ignore new discoveries? The largely increasing practice of consulting the staffs of the agricultural colleges, which has arisen among farmers during the last few years, conclusively shows that he does not; that he is, in fact, perfectly ready to avail himself of sound advice whenever he can. Is he too conservative to try new discoveries when brought to his notice? The extraordinary demand for seed of the new Archer barley quoted above, and for seed of new varieties generally, the continuous advance in the prices of phosphatic manures, as the result of increased demand by farmers, the trade in Scotch and Irish seed potatoes, all show how ready the farmer is to try new things. The chief danger seems to be that he tries new things simply because they are new, and he may be disappointed if those who are responsible for the new things in question have not taken pains to ascertain with certainty that they are not only new but good. Farmers are nowadays in what may be called a very receptive condition. Witness the avidity with which they paid extravagant prices for single tubers of so-called new, but inadequately tested, varieties of potatoes some years ago, and in a less degree the extraordinary demand for seed of the much-boomed French wheats, and the excitement about nitragin for soil or seed inoculation. Witness, too, the almost universal failure of the new potatoes and French wheats introduced during the boom, and the few cases in which nitragin gave any appreciable result. The farmer who was disappointed with his ten-guinea tuber, his expensive French wheat, or his culture of nitragin cannot but be disillusioned. Once bitten, twice shy. He does not readily take advice again.

Let us, therefore, recognise that the farmers of the country are ready to listen to us, and to try our recommendations, and let that very fact bring home to us a sense of our responsibility. All that is new is not, therefore, necessarily good. Before we recommend a new thing let us take pains to assure ourselves of its goodness. To do so we must find not only that the new thing produces a greater return per acre, but that the increased return is worth more than it costs to produce, and we must also define the area or the type of soil to which this result is applicable. This implies in practice that each field trial should confine itself to the investigation of only one, or, at most, two, definite points, since five pairs of plots will be required to settle each point; that the experimental results should be reviewed in the light of a thorough knowledge of farm book-keeping, and that accurate notes should be taken of the type of the soil, and the area to which it extends, and of the various meteorological factors which make up the local climate. At present we are not in possession of a sufficient knowledge of farm accountancy, but there is hope that this deficiency will be removed by the work of the Institute for Research in Agricultural Economics, which has recently been founded at Oxford by the Board of Agriculture and the Development Commission. The excellent example set by Hall and Russell in their "Survey of the Soils and Agriculture of the South-Eastern Counties," an example which is being followed in Cambridge and elsewhere, seems likely to result in the near future in a complete survey of the soils of England which will make a sound scientific basis for delimiting the areas over which the results of manurial or variety trials are applicable.

Reviewing this branch of agricultural science, the outlook is distinctly hopeful. New fertilisers are coming into the market, as, for instance, the various products made from atmospheric nitrogen. New varieties of farm crops are being produced by the Plant-breeding Institute at Cambridge, and elsewhere. It is to be hoped that the work of the Agricultural Economics Institute at Oxford will throw new light on the interpretation of experimental results from the accountancy standpoint. Finally, the soil surveys on which the colleges have seriously embarked will assist in defining the areas over which such results are applicable. It only remains for those of us who are responsible for the conduct of field trials to increase the accuracy of our results, and the steady accumulation of a mass of systematic and scientific knowledge is assured. It will be the business of the advisory staffs with which the colleges have recently been equipped by the Board of Agriculture and the Development Commission to disseminate this knowledge in practicable form to the farmers of this country.

One more point, and I have finished this section of my address. I have perhaps inveighed rather strongly against the publication of the results of single-plot trials. I quite recognise that the publication of such results was to a great extent forced upon those experimenters who were financed by annually renewed grants of public money. Nowadays, however, agricultural science is in a stronger position, and I venture to hope that most public authorities which subsidise such work are sufficiently alive to the evils attendant on the publication of inconclusive results to agree to continue their grants for such periods as may suffice for the complete working out of the problem under investigation, and to allow the final conclusions to be published in some properly accredited agricultural journal, where they would be readily and permanently available to all concerned. This would in no wise prevent their subsequent incorporation in bulletins specially written for the use of the practical farmer.

So far I have confined my remarks to subjects of which I presume that every member of the section has practical experience, subjects which depend on the measurement of the yield per unit area. These subjects, however, although they have received far more general attention than anything else, by no means comprise the whole of agricultural science. Certain scientific workers have confined their efforts to the thorough solution of specific and circumscribed problems. I propose now to ask the section to direct its attention to some typical results which have been thus achieved during the last twenty years.

The first of these is the development of what I may call soil science. Twenty years ago the bacteriology of nitrification had just been worked out by Warington and by Winogradski. The phenomena of ammoniacal fermentation of organic matter in the soil were also fairly well established. The fixation of atmospheric nitrogen by organisms symbiotic on the leguminosæ had been definitely demonstrated. Fixation of nitrogen by free-living organisms had been suggested, but was still strenuously denied by most soil investigators. No suggestion had yet been made of the presence in normal soils of any factor which inhibited crop production. The last twenty years have seen a wonderful advance in soil science. Our knowledge of nitrification and ammoniacal fermentation has been much extended. The part played by the nodule organisms of the leguminosæ has been well worked out, has seen a newspaper boom, and a subsequent collapse, from which it has not yet recovered. But the greatest advance has been the discovery of the part played by protozoa in the inhibition of fertility.

The suggestion that ordinary soils contained a factor which limited their fertility emanated in the first instance from the American Bureau of Soils. The factor was at first thought to be chemical, and its presence was tentatively attributed to root excretion. Certain organic substances, presumably having this origin, have been isolated from sterile soils, and found to retard plant growth in water-culture. It is claimed, too, that the retardation they cause is prevented by the presence of many ordinary manurial salts with which they are supposed to form some kind of combination.

Contributions to the subject have come from several quarters, but whilst the suggested presence of an inhibitory factor has been generally confirmed, its origin as a root-excretion and its prevention by manurial salts has not received general confirmation outside American official circles. The matter has been strikingly cleared up by the work of Russell and Hutchinson at Rothamsted, who observed that the fertility of certain soils which had become sterile was at once restored by partial sterilisation, either by heating to a temperature below 100° C., or by the use of volatile antiseptics such as toluene. This observation suggested that the factor causing sterility in these cases was biological in nature, that it consisted, in fact, of some kind of organism inimical to the useful fermentation bacteria, and more easily killed than they by heat or antiseptics. After a long series of admirable scientific investigations these workers and their colleagues have shown that soils contain many species of protozoa, which prey upon the soil bacteria, whose numbers they keep within definite limits. In certain circumstances, such, for instance, as those existing in the soil of sewage farms, and in the artificial soils used for the cultivation of cucumbers, tomatoes, &c., under glass, the protozoa increase so that the bacteria are reduced below the numbers requisite to decompose the organic matter in the soil into substances suitable for absorption by the roots of the crop. Practical trials of heating such soils, or subjecting them to the action of toluene, or other volatile antiseptics, have shown that their lost efficiency can thus be easily restored, and the method is now rapidly spreading among the market gardeners of the Lea Valley.

I have attempted to sketch the chief points of this subject with some detail in order to show that strictly scientific work, quite outside the scope of what some people still regard as "practical," may result in discoveries which, apart from their great academic interest, may at once be turned to account by the cultivator. The constant renewal of expensively prepared soil which becomes "sick" in the course of a year or so is a serious item in the cost of growing cucumbers and tomatoes. It can now be restored to fertility by partial sterilisation at a fraction of the cost of renewal, and considerable sums are thus saved by the Lea Valley growers.

For my second instance of scientific work which has given results of direct value to farmers, I must ask to be allowed to give a short outline of the wheat-breeding investigations of my colleague Prof. Biffen. Even as late as fifteen years ago plant-breeding was in the purely empirical haphazard stage. Then came the rediscovery of Mendel's laws of heredity, which put in the hands of breeders an entirely new weapon. About the same time the Millers' Association created the Home-grown Wheat Committee, of which Biffen was a member. Through this committee he was able to define his problem as far as the improvement of English wheat was concerned. There appeared to be two desiderata: (1) The production of a wheat which would crop as well as the best standard home-grown varieties, at the same time yielding strong grain, *i.e.* grain of good milling and baking quality; and (2) the production of varieties of wheat resistant to yellow rust, a disease which has been computed to decrease the wheat crop of the world by about one-third.

The problem having been defined, samples of wheat were collected from every part of the world and sown on small plots. From the first year's crop single ears were picked out and grown on again. Thus several hundred pure strains were obtained. Many were obviously worthless. A few possessed one or more valuable characteristics: strong grain, freedom from rust, sturdy straw, and so on. These were used as parents for crossing, and from the progeny two new varieties have been grown on, thoroughly tested, and finally put on the market. Both have succeeded, but both have their limitations. Burgoyne's Fife, which came from a cross between strains isolated respectively from Canadian Red Fife and Rough Chaff, was distributed by the Millers' Association after a series of about forty tests, in which it gave an average crop of forty bushels per acre of grain, which milled and baked practically as well as the best imported Canadian wheat. It is an early-ripening variety which may even be sown as a spring wheat. It has repeatedly been awarded prizes for the best sample of wheat at shows, but it only succeeds in certain districts. It is widely and successfully grown in Bedfordshire and Dorset, but has not done well in Norfolk. The other variety, Little Joss, succeeds much more generally. In a series of twenty-nine trials scattered between Norfolk and Shropshire, Kent and Scotland, it gave an average of forty-four bushels per acre, as compared with forty bushels given by adjoining plots of Square Head's Master. It originated from a cross between Square Head's Master and a strain isolated from a Russian graded wheat known as Ghirka. Its grain is the quality of ordinary English wheat. It tillers exceptionally well in spring, and is practically rust-proof. Its one drawback is its slow growth during the winter if sown at all late. It has met with its greatest success in the Fen districts, where rust is more than usually virulent.

The importance of this work is not to be measured only by the readiness with which the seed of the new varieties has been tried by farmers and the extent to which it has succeeded. The demonstration of the inheritance of immunity to the disease known as yellow rust, the first really accurate contribution to the inheritance of resistance to any kind of disease, inspires hope that a new method has appeared for the prevention of diseases in general.

Biffen's work too shows the enormous value of co-operation between the investigator and the buyer in defining problems connected with the improvement of agricultural produce. It is open to doubt if a committee of farmers would have been able to define the problems of English wheat production as was done by the Millers' Committee, and in the solution of any problem its exact definition is half the battle. Mackenzie and Marshall in their work on the "Pigmentation of Bacon Fat" and on the spaying of sows for fattening, have found the great value of consultation with the staffs of several large bacon factories. There seems to be in this a general lesson that before taking up any problem one should get into touch not only with the producers but with the buyers, from whom much useful information can be obtained.

I feel that Biffen's work has borne fruit in still another direction, for which perhaps he is not alone responsible. Twenty years ago agricultural botany took a very subsidiary position in such agricultural examinations as then existed. In some of the agricultural teaching institutions there was no botanist, in others the botanist was only a junior assistant. It is largely due to the work of Biffen and the botanists at other agricultural centres that botany is now regarded as perhaps the most important science allied to agriculture.

I must here repeat that I am not attempting to make a complete survey of all the results obtained in the last twenty years. My object is only to pick out some of the typical successes and failures and to endeavour to draw from their consideration useful lessons for the future. So far I have not referred to the work which has been done in the nutrition of animals, and I now propose to conclude with a short discussion of that subject. The work on that subject which has been carried out in Great Britain during the last twenty years has been almost entirely confined to practical feeding trials of various foods or mixtures of foods, trials which have been for the most part inconclusive.

It has been shown recently that if a number of animals in store condition are put on a fattening diet, at the end of a feeding period of twelve to twenty weeks about half of them will show live-weight increases differing by about 14 per cent. from the average live-weight increase of the whole lot. In other words, the probable error of the live-weight increase of a single fattening ox or sheep is 14 per cent. of the live-weight increase. This being so, it is obvious that very large numbers of animals must be employed in any feeding experiment which is designed to compare the feeding value of two rations with reasonable accuracy. For instance, to measure a difference of 10 per cent. it is necessary to reduce the probable error to 3 per cent. in order that the 10 per cent. difference may have a certainty of thirty to one. To achieve this, twenty-five animals must be fed on each ration. Those conversant with the numerous reports of feeding trials which have been published in the last twenty years will agree that in very few cases have such numbers been used. We must admit then that many of the feeding trials which have been carried out can lay no claim to accuracy. Nevertheless, they have served a very useful purpose. From time to time new articles of food come on the market, and are viewed with suspicion by the farmers. These have been included in feeding trials and found to be safe or otherwise, a piece of most useful information. Thus, for instance, Bombay cotton cake, when first put on the market, was thought to be dangerous on account of its woolly appearance. It was tried, however, by several of the agricultural colleges and found to be quite harmless to cattle. Its composition is practically the same as that of Egyptian cotton cake, and it now makes on the market practically the same price.

Soya-bean cake is another instance of a new food which has been similarly tested, and found to be safe for cattle if used in rather small quantities and mixed with cotton cake. The price is now rapidly rising to that indicated by its analysis. Work of this kind is, and always will be, most useful. Trials with few animals, whilst they cannot measure accurately the feeding value of a new food, are quite good enough to demonstrate its general properties, and its price will then gradually settle itself as the food gets known.

Turning to the more strictly scientific aspects of animal nutrition, entirely new ideas have arisen during the last twenty years. I propose to discuss these shortly, beginning with the proteins. Twenty years ago the generally accepted view of the *rôle* of proteins in nutrition was that the proteins ingested were transformed in the stomach and gut into peptones, and absorbed as such without further change. Splitting into crystalline products, such as leucin and tyrosin, was thought only to take place when the supply of ingested protein exceeded the demand, and peptones remained in the gut for some time unabsorbed. It is now generally agreed that ingested protein is normally split into crystalline products which are separately absorbed from the gut, and built up again into the various proteins required by the animal. If the ingested protein does not yield a mixture of crystalline products in the right proportions to build up the proteins required, those crystalline products which are in excess are further changed and excreted. If the mixture contains none of one of the products required by the animal, then life cannot be maintained. This has been actually demonstrated in the case of zein, one of the proteins of maize, which contains no tryptophane. The addition of a trace of tryptophane to a diet, in which zein was the only protein, markedly increased the survival period of mice.

The adoption of this view emphasises the importance of a knowledge of the composition of the proteins, and especially of a quantitative knowledge of their splitting products, and much work is being directed to this subject in Germany, in America, and more recently in Cambridge as a result of the creation there of an institute for research in animal nutrition by the Board of Agriculture and the Development Commission. This work is expected ultimately to provide a scientific basis for the compounding of rations, the idea being to combine foods the proteins of which are, so to speak, complementary to each other, one giving on digestion much of the products of which the other gives little. Meantime, it is desirable that information should be collected as to mixtures of foods which are particularly successful or the reverse.

Here the question arises, for what purpose does the animal require a peculiarly complicated substance like tryptophane? The natural suggestion seems to be that the tryptophane grouping is required for the building up of animal proteins. It has also been suggested that such substances are required for the formation of hormones, the active principles of the internal secretions the importance of which in the animal economy has received such ample demonstration in recent years. The importance of even mere traces of various substances in the animal economy is another quite recent conception. Thus it has been shown, both in Cambridge and in America, that young animals fail to grow on a diet of carefully purified casein, starch, fat, and ash, although they will remain alive for long periods. In animals on such a diet, however, normal growth is at once started by the addition of a few drops of milk or meat juice, or a trace of yeast, or other fresh animal or vegetable matter. The amount added is far too small to affect the actual nutritive value of the diet. Its effect can only be due to the presence of a trace of some substance which acts, so to speak, as the hormone of growth. The search for such a substance is now being actively prosecuted. Its discovery will be of the greatest scientific and practical interest.

Evidently new ideas are not lacking amongst those who are engaged in investigating the *rôle* of the proteins and their splitting products in the animal economy. But of more immediate practical interest is the question of the amount of protein required by animals under various conditions. It is obviously impossible to fix this amount with any great accuracy, since proteins differ so widely in composition, but from many experiments, in which a nitrogen balance between the ingesta and the excreta was made, it appears that oxen remain in nitrogenous equilibrium on a ration containing about one pound of protein per 1000 lb. live-weight per day. All the British experiments of a more practical nature have been recalculated on a systematic basis by Ingle, and tabulated in the Journal of the Highland and Agricultural Society. From them it appears that increase of protein in the ration, beyond somewhere between one and a half and two pounds per 1000 lb. live-weight per day of digestible protein, ceases to have any direct influence on increase in live-weight.

We may fairly conclude, then, that about two pounds of proteins per 1000 lb. live-weight per day is sufficient for a fattening ox. This amount is repeatedly exceeded in most of the districts where beef production is a staple industry, the idea being to produce farmyard manure rich in nitrogen. The economy of this method of augmenting the fertility of the land is very doubtful. The question is one of those for the solution of which a combination of accurate experiment and modern accountancy is required. Protein is the most expensive constituent of an animal's dietary. If the scientific investigator, from a study of the quantitative composition of the proteins of the common farm foods, and the economist, from careful dissection of farm accounts, can fix an authoritative standard for the amounts of protein required per 1000 lb. live-weight per day for various types of animals, a great step will have been made towards making mutton and beef production profitable apart from corn-growing.

For many years it has been recognised that an animal requires not only so much protein per day, but a certain quota of energy, and many attempts have been made to express this fact in intelligible terms. Most of them have taken as basis the expression of the value of all the constituents of the diet in terms of starch, the sum of all the values being called the starch equivalent. This term is used by various writers in so many different senses that confusion has often arisen, and this has militated against its general acceptance. Perhaps the most usual sense in which the term is used is that in which it means the sum of the digestible protein multiplied by a factor (usually 0·94) plus the digestible fat multiplied by a factor (usually 2·3), plus the digestible carbohydrates. This, however, gives misleading values which are too high in concentrated foods and too low in bulky foods, the discrepancy being due to the larger proportion of the energy of the bulky foods which is used up in the much greater work of digestion which they require. Kellner and his school have devised a method which measures the starch equivalent by experiment, a much more satisfactory and practical method than any system which depends purely on calculation.

An animal or a number of animals are kept on a maintenance diet so that their weight remains constant. To this diet is added a known weight of starch, and the increase in weight observed. The animal or animals are then placed again on the same maintenance diet for some time, and then a known weight of the food to be tested is added, and the increase in weight again observed. The data thus obtained indicate that so many pounds of starch produce as much increase in live-weight as so many pounds of the food under experiment, from which it is easy to calculate how many pounds of starch are actually required to produce as much increase in live-weight as 100 lb. of the food under experiment. The starch equivalent thus found expresses an experimentally determined fact which is of immediate practical value in arranging a dietary, its value, however, depending on the accuracy with which it has been determined. Kellner and his colleagues have thus determined the starch equivalents of all the commonly used foods. Their values for concentrated foods, and other foods commonly used in Germany, have been determined with considerable accuracy, and with the method which has also been devised for defining the relation between the experimentally determined equivalent and the equivalent calculated from the analysis by means of a formula, they form by far the most trustworthy basis for arranging a feeding ration including such kinds of foods.

But roots, which form the staple of the diet of fattening animals in Great Britain, are not used on the same scale in Germany, and Kellner's starch equivalents for roots have not been determined with sufficient accuracy or under suitable conditions to warrant their use for arranging diets under our conditions.

This, and the fact that the term starch equivalent is so widely misunderstood, is no doubt the reason why the Kellner equivalent has not been more generally accepted in Great Britain. An advance will be made in the practice of feeding as soon as the starch equivalent of roots has been accurately determined under our conditions, when the Kellner equivalents will no doubt come into general use.

I have now reached the end of my survey. I recognise that it is very incomplete, and that I have been compelled to neglect whole subjects in which important work has been done. I venture to hope, however, that my words have not been altogether unprofitable. It is somewhat difficult to summarise what is in itself really nothing but a summary. Perhaps, however, I may be allowed to point out once more what appears to me to be the moral of the last twenty years of work in agricultural science.

The many practical field and feeding tests carried out all over the country have demonstrated several very striking results; but, if they are to be continued with profit, more trouble must be taken to insure accuracy. Farmers are ready to listen. It behoves us more than ever to found what we tell them on accurate results.

Besides such practical trials, however, much has been done in the way of individual scientific work. The results thus obtained, as, for instance, Russell and Hutchinson's partial sterilisation of soils, Biffen's new wheats, and Beaven's pure Archer barley, are of practical value to the farmer as immediate as the most practical field trial, and of far wider application.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The Herbert Spencer lecture will be delivered by Prof. C. Lloyd Morgan, F.R.S., professor of psychology in the University of Bristol, on Friday, November 7. The subject of the lecture will be:—"Spencer's Philosophy of Science."

Dr. O. W. Richardson, F.R.S., professor of physics in Princeton University, New Jersey, has been appointed as from January 1 next to the Wheatstone chair of physics at King's College, London, in succession to Prof. C. G. Barkla, F.R.S.

Mrs. W. Bayard Cutting and her children have (says *Science*) given 40,000*l.* to Columbia University for a fund in memory of the late W. Bayard Cutting, who served as trustee of the University from 1880 until his death, in 1912. The income of this fund is to be applied to the maintenance of travelling fellowships, open to graduate students of distinction in letters, science, law, and medicine or engineering.

Students who are working privately with the object of graduating in the University of London will welcome the "London University Guide and University Correspondence College Calendar, 1914," published by the University Correspondence College, London, and distributed gratuitously. The first part of the volume constitutes the guide, and contains the regulations for the examinations leading to the various degrees to be held by the University of London in 1914 and 1915. The calendar, 1913–14, which completes the volume, gives particulars of the facilities offered by the University Correspondence College to students who desire assistance in their work through the post.

A very useful form of pocket diary, which covers the academic year beginning with October, 1913, instead of commencing with January in the usual way, has been published by the Cambridge University Press. Though concerned more particularly with events in the work of the University of Cambridge, the diary will appeal to all whose work is in connection with colleges or schools. The diary is published in three forms, at 1*s.* net, 2*s.* net, and 2*s.* 6*d.* net respectively. From the same source we have received "The Cambridge Diary for the Academical Year 1913–14," in block form. Each sheet contains seven days, and ample space is provided for manuscript notes of engagements. The price of this diary is 1*s.* net.

The establishment of new universities in Germany was one of the chief topics of discussion at the recent congress of German university teachers held at Strasburg. The movement was strongly opposed in a report presented by Prof. Bücher, of Leipzig. According to this, many corporations, with the encouragement of the Ministry are endeavouring to raise the status of existing institutions to that of university rank. The preponderance of government in such institutions would be municipal, and consequently university independence would be endangered, and, in addition, a high academic standard would not be maintained. Overcrowding of the existing universities was advanced as an argument in favour of the creation of new institutions, but the organisation of such universities as those of Berlin and Leipzig enabled them to deal with large numbers without any detriment to the teaching. Prof. Kaufmann, of Breslau, remarked that quite 40 per cent. of the students were unsuited for an academic training, and the creation of new institutions would in no way relieve overcrowding at the older universities, but simply increase the total number of students. Many teachers, however, were strongly in favour of the movement, contending that the establishment of universities in the large industrial and commercial centres was an essential and necessary element in modern conditions of life. It was a movement which should be strenuously supported. Side by side with this question arose that of the standard required for the doctorate. The congress considered it should be made imperative for all universities to demand a thesis embodying independent and original research work from the candidate.

THE second annual report of the King Edward VII. British-German Foundation states that there is an increase in the expenditure, due to a larger number of cases assisted, and to the fact that several of the permanent allowances have been raised. We learn from *The Times* that in accordance with the terms of the trust deed, which provides for an annual joint sitting of the two sections of the foundation, alternately in England and Germany, the first joint conference was held last September, at Sir Ernest Cassel's residence in London. The question of the best way of employing the surplus funds was discussed, and it was agreed finally to adopt the following resolution:—"That a certain proportion of the surplus funds of the German section be employed in enabling British subjects to attend or visit universities, schools, institutes, or business establishments in Germany, or to reside in Germany, and that a certain proportion of the surplus funds of the British section be employed in enabling Germans to attend or visit universities, schools, institutes, or business establishments in the United Kingdom, or to reside in the United Kingdom." It is hoped that this scheme will serve to assist students who are not possessed of the necessary means in pursuing a course of studies abroad, and give them an insight into the customs and character of the German people, affording them an opportunity of making lasting friendships with Germans, and thus help in promoting a good understanding between the two nations. The second joint conference of the two sections was held in Berlin on October 25. Its main object was to discuss the merits of the scheme of studentships and the desirability of continuing it.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 20.—M. F. Guyon in the chair.—Pierre **Termier**: The A1 excursion of the twelfth International Geological Congress: the Appalachian region of Canada.—R. **Lépine** and M. **Boulud**: The presence, in the vascular walls, of a ferment setting free a reducing sugar at the expense of the virtual sugar of the blood, and capable of hydrolysing phloridzin. These experiments show that the vascular walls possess a new function, hitherto ascribed to the liver alone.—Léon **Lichtenstein**: Some applications of the notions of functions of an infinity of variables in the calculus of variations.—François **Lukács**: Laplace's series.—Pierre **Idrac**: Experimental researches on the *vol plané*. Photographic experiments with small balloons show that in places where birds are capable of hovering flight there is an ascending current of air with velocities of the order of 3 to 4 metres per second. This corresponds to the magnitude of the velocity of air currents in the *vol plané* of an aëroplane.—R. **Fortrat**: An abnormal Zeeman phenomenon with the sodium doublet, $\lambda = 2853$. The use of a ferro-cobalt electromagnet, made according to the indications of P. Weiss, enabled the author to place an ordinary spark in a field of 49400 Gauss. The experimental results obtained agree closely with the theory of Voigt.—Raoul **Dupuy**: Functional arterial hypertensions. Pseudo-arterio-sclerosis. A discussion of the means of differentiating arterio-sclerosis from functional hypertension.—P. **Chaussé**: The path of penetration of the tuberculous virus in the calf and the tuberculigenic power of cow's milk. Inhalation is the usual mode of tuberculous infection in the young calf; intra-uterine infection must also be taken into consideration, since the latter furnishes an important proportion of the graver cases. Although the calf is much more exposed than the adult animal to infection through the alimentary canal, this is relatively the least important mode of infection. The milk of the cow is not the cause of infection of the calf to any great extent.—J. **Danysz**: The use of some new medicinal combinations in the treatment of trypanosomiasis. A compound obtained by the action of silver nitrate upon arsenobenzene, was found capable of sterilising the blood of rabbits infected with Surra by a single injection. *Trypanosoma rhodesiense* was more resistant but succumbed to a mixture of the above reagent with trypan red.—Jules **Amar**: The physiological effects of work and the degree of fatigue.—R. **Anthony**: The experimental study of the factors determining the cranial morphology of mammals deprived of teeth.—J. **Chaine**: The *îlots* of the Termites.—M. **Lemoigne**: The butylene-glycollic fermentation of glucose by staphylococci.—Lucien **Mayet** and Jean **Pissot**: The discovery of the engraved bone of a mammoth showing a human figure, in the upper Aurignacian layer of La Colombière, near Poncin. The drawing described would appear to be the first engraving of man of the middle Quaternary epoch.—Jean **Boussac**: The geological constitution of Haute-Tarentaise.—F. **Dienert**: Remarks concerning some experiments with fluorescin.

GERMAN SCHOOL CHEMISTRY.

Methodik des chemischen Unterrichts. By Dr. Karl Scheid. Pp. xv+448. (Leipzig: Quelle und Meyer, 1913.) Price 20 marks.

EDUCATIONAL restlessness, so characteristic of the times in England, prevails to a scarcely less degree in the country to which we are so often directed to turn for pedagogic inspiration; and the agitation about methods of teaching science is not the least remarkable example of the contemporary stir in the educational world of Germany.

The present volume is the fourth of a series constituting a handbook of scientific and mathematical instruction issued under the editorship of Dr. J. Norrenburg, and is written by a professor of the Realgymnasium mit Oberrealschule at Freiburg in Breisgau. "Knapp und einfach in der Form," it is declared to be by the editor; "Knapp" it may be by Teutonic standards, but it extends to about 450 large pages, and it "grinds exceeding small," as books on Methodik are apt to do in every language. However, the work is of much interest, and to a large degree readable. It refers to German boys' schools, and the terminology of the German system, with its slight and subtle variations, presents some difficulty to the English reader.

The first or general part of the book gives an account of the history of chemistry teaching in German schools, a description of its present condition, and of the various recommendations and criticisms that have been made by scientific, medical, or industrial authorities. The general educational principles involved in science teaching are discussed at considerable length with a great deal of division and sub-division. The second or special part of the book gives the outline of a suggested course of school chemistry.

The chief impression produced by reading this account of German school science is the comfortable one that we in England are well in advance of Germany in our attempts to make science worthy of its place in the school curriculum. It is somewhat remarkable that a German writer should have paid such little attention to what has been going on in other countries. There is a eulogistic reference to Faraday's "Chemistry of a Candle," but no allusion to the very great work that has been done in England during the last twenty-five years towards improving school science.

The difficulties recounted by Dr. Scheid, the unsatisfactoriness of the traditional methods, and the obstacles to reform, are very much the same as we have known here. There has been a strong academic prejudice against the intrusion of science into the school curriculum; the science that has been taught has been diluted university science administered dogmatically; sciences have been artificially severed; they have been detached from living nature and from human interests; they have resulted in a thing of shreds and patches that has been of no account for any terrestrial or celestial purpose. Against all this a rebellion has been fermenting; the demonstration is condemned; the pupils are to work in laboratories; they are to be put into the position of discovering rather than of being told; things, in fact, are moving as they have moved here, but they have not moved so fast.

There are many wise things said in the book, which, if they are not new, are the things that need to be said again and again. Dr. Scheid insists, for example, that the school teacher must remember that he has not got a collection of prospective chemists before him; that the method of teaching is more important than the range of matter; that every occasion must be taken to connect school teaching with the realities of life and industry; that the artificial tendency, not imposed by nature, between natural history and the exact sciences must disappear, if the realistic (*i.e.* modern) schools are to be true educational institutions in a thorough cultural sense. Only then will the Ober-realschulen and Realgymnasien be in a position to give a scientific education equivalent to the humanistic one. The distribution of different branches of science to different teachers, the severance of physics from chemistry, are deprecated. Chemistry dissociated from physics, says the author, is resolved into a mosaic of details. Boyle, Dalton, and Davy were chemists and physicists in one person.

The course of chemistry outlined by Dr. Scheid is not quite like those which have supplanted the old academic courses that prevailed in this country. He begins with limestone, and makes it the object of some fundamental observations, partly quantitative, passing then to air and combustion. Sulphur and sulphuric acid lead to hydrogen, and then comes water. Flame, salt, and hydrochloric acid, quantitative experiments on the laws of combination, carbon and carbon dioxide, carbonates, nitrogen compounds, phosphorus, silicon, and the heavy metals—these complete the topics of the lower course. The higher is more like the traditional systematic course. Proposals for the treatment of organic chemistry begin with alcohol, and include a restricted list of the substances and topics related more especially to everyday life.

L

Whilst the course suggested is in many respects interesting, and no doubt a great improvement on much that has prevailed, it does not seem to be better than many that are now being followed in this country.

It is well known that the prominent position taken by Germany in chemical science is in no degree due to the quantity or quality of the chemistry in its schools. We still hear, indeed, from time to time, of the pronouncement made a score of years ago by a group of eminent German chemists to the effect that a classical education was to be preferred above all else as a preparation for the serious study of science. This pronouncement is akin to many that are heard in the world of education, and is of the nature of those half-truths which are so particularly mischievous. Just as in this country, so long as modern studies were disdained and were the resort of the less intellectually gifted, and so long as modern studies were being taught on a vicious model, ancient studies might well seem to be the best preparation for every kind of higher training.

It will be interesting to see the face of German education when Dr. Scheid and his coadjutors have achieved their reform of its school science. Meanwhile it matters much less in Germany than here whether school science is good or bad, for in Germany there is plenty of education, and of good education, of some kind; there is a sincere belief in it; there is a sincere belief in science; and there are plenty of men sufficiently well trained to keep the country eminent in science and pre-eminent in the application of scientific knowledge to the welfare of the State.

ARTHUR SMITHELLS.

ZOOLOGICAL BIBLIOGRAPHIES AND CATALOGUES.

(1) *Catalogue of the Books, Manuscripts, Maps, and Drawings in the British Museum (Natural History)*. Vol. iv., P—SN. Pp. 1495–1956. (London: British Museum (Natural History); Longmans, Green and Co., 1913.)

(2) *A Bibliography of the Tunicata*, 1469–1910. By John Hopkinson. Pp. xii + 288. (London: The Ray Society; Dulau and Co., Ltd., 1913.) Price 15*s*. net.

(3) *Catalogue of the Noctuidæ in the Collection of the British Museum*. By Sir G. F. Hampson. Plates cxcii–ccxxi. (London: British Museum (Natural History); Longmans, Green and Co., 1913.)

(4) *Catalogue of the Ungulate Mammals in the British Museum (Natural History)*. Vol. 1, Artiodactyla. Family Bovidæ, Subfamilies Bovinæ to Ovibovinæ. By R. Lydekker, F.R.S. Pp. xvii + 249. (London: British Museum (Natural History); Longmans, Green and Co., 1913.)

(1) THE British Museum of Natural History continues to issue at frequent intervals a series of extremely useful catalogues, guides to the collections, or other valuable volumes. Not the least welcome of these to workers in the museum, although probably not of general interest to the public, is the "Catalogue of the Books, Manuscripts, Maps, and Drawings." This, under the superintendence of Mr. B. B. Woodward, the librarian, is still in course of completion, and vol. iv. now lies before us. Starting at P, it brings the entries under authors' names down to SN. We learn from the director's preface that the first sheet was passed for press in October, 1910, and the issue of this volume marks a distinct advance in cataloguing a library, the value and richness of which is probably known to very few of the public.

(2) A catalogue of a very different nature is Mr. John Hopkinson's "Bibliography of the Tunicata," from 1469–1910, compiled for the Ray Society. This was commenced for the private use of its author in connection with the publication by the Ray Society of the late Messrs. Alder and Hancock's "British Tunicata." During the course of its completion it was found to contain so many references not in any previous bibliography that it appeared to Mr. Hopkinson that if printed it might be useful to others—a surmise which we expect will prove correct, as the bibliography, which must have involved immense labour, has been very carefully prepared.

(3) A second volume issued by the British Museum contains plates 192–221 of Sir George Hampson's "Catalogue of the Noctuidæ." In this a large number of species are illustrated, the work having been carefully executed by Messrs. West, Newman and Co. The colours have been very well reproduced; each species is named, and a reference given to its habitat and the page on which it is described.

(4) The first volume of Mr. R. Lydekker's "Catalogue of the Ungulate Mammals" deals with the cattle, sheep, goats, chamois, takin, and musk-oxen. Owing to the large size of most of the species and the relatively small number of specimens available, the work is written on lines different from those governing other catalogues. Real systematic detail and thorough conciseness of description cannot be attained until a much larger series of specimens can be accumulated. Instead, although the principle of priority in scientific nomenclature has been adhered to, an

attempt has been made to render the descriptions as little obtuse as possible, so that they may be of interest to sportsmen as well as to scientific naturalists, to the former of whom the Ungulates are of special interest.

Recent minute study and careful comparison of specimens has led to such multiplication of species that new arrangements of them are unavoidable. In most modern works an attempt is made to group the known forms by instituting new and narrower genera which are often identical with old-time species. Mr. Lydekker attempts to attain the same end by classing nearly-related forms as races of a single species. We are not sure that we approve of this method, which involves a greater use of trinomials, where binomials would often suffice, and is, we think, a hopeless struggle against modern tendencies. In the case of the musk-oxen this practice gains nothing; nor does it seem a great advantage to grade all the sheep inhabiting the North American continent as subspecies of *Ovis canadensis*. In other respects we have nothing but praise for a work which will certainly be valued by those for whom it is intended.

THE SCIENCE OF FORESTRY.

(1) *The Theory and Practice of Working Plans* (*Forest Organisation*). By Prof. A. B. Recknagel. Pp. xii + 235 + 6 plates. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 8*s*. 6*d*. net.

(2) *The Important Timber Trees of the United States: A Manual of Practical Forestry*. By S. B. Elliott. Pp. xix + 382 + plates. (London: Constable and Co., Ltd., 1913.) Price 10*s*. 6*d*. net.

(3) *A Handbook of Forestry*. By W. F. A. Hudson. Pp. ix + 82. (Watford: The Cooper Laboratory, n.d.) Price 2*s*. 6*d*. net.

THE output of forestry literature in America is becoming remarkable. In addition to several admirable periodical publications like the *Forest Quarterly* and the Proceedings of the Society of American Foresters, as well as the numerous bulletins, circulars, and miscellaneous works issued by the Forest Service at Washington, there are constantly appearing now useful text-books on the different branches of the science of forestry. These are especially valuable to us, as, with the exception of the standard works of Nisbet and Schlich, which are necessarily limited and stereotyped in scope, scarcely any serious books on forestry have appeared of late years in England. In arboriculture, which is the study of individual trees, on the contrary, English writers still keep up the tradition of Loudon and are in the first rank.

(1) Forest organisation is the subject of an excellent book by Prof. Recknagel, of Cornell University. The works in English on this important branch of forestry hitherto available have been practically two only, Schlich's "Manual," vol. iii., somewhat limited in scope, and D'Arcy's "Working Plans," confessedly confined to Indian practice. We have had no treatise which gave a general discussion of the subject. The merit of Prof. Recknagel's work is the clear and concise way in which he treats of the different methods of estimating the yield of the forest, and the ample details which he gives concerning the modes of management in Germany, Austria, France, and the United States. The author agrees with Schlich in considering that Judeich's method is the most rational of the seventeen methods described for determining the yield, *i.e.*, of calculating the actual amount of timber that should be cut annually in a forest, which is worked so as to give a constant annual return. This method, with obvious simplifications, can be adapted to ordinary estates in England, on which there is a considerable area of woods of different ages. On p. 53, line 9, there is an obvious error: 49,000 should read 24,500.

(2) It is significant of the depletion of the timber supplies of the United States that numerous books are now being published there which deal with the formation of new woods by planting methods. The latest of these, by Mr. Elliott, is designed for the use of private landowners in America. The first part (pp. 1–129) deals with the ordinary details of sylviculture, and contains nothing novel, though the account of nursery work, as it is carried on in Pennsylvania, with illustrations of the State Forest Nursery, is of considerable interest.

The second part of the book (pp. 130–357) is a description of the important timber trees which are suitable for planting for profit in North America. There is scarcely any information in this which will be of much service to English foresters, as the author's experience is mostly drawn from the eastern part of the United States, while for us it is the Pacific Coast trees that are of value. His knowledge of the latter is limited, as evidenced by the perfunctory way in which the Douglas fir is treated, and the omission of the Sitka spruce. The statement that "one who purchases Western hemlock believing it to be Oregon pine is not much wronged" is quite erroneous. The latter tree (*Pseudotsuga Douglasii*) is, of course, much superior to the hemlock, both in rate of growth and in the quality of the timber produced. The account of the cultivation in America of Scots pine, European larch, and Norway spruce is of considerable interest. All three grow well for a time, but never make good trees in the eastern parts of the United States.

(3) The "Handbook of Forestry," which has been issued by the Cooper Laboratory at Watford, is inconvenient to handle, being a thin folio of 82 pages, with 25 illustrations of very unequal merit. While generally sound in regard to practice, it contains nothing that has not been said before in several small, handy text-books, and is startling in its omissions. While the London plane is included as a forest tree, the Corsican pine, which is the most valuable of its genus for many soils and situations, is omitted. In the chapter entitled "conditions affecting growth" nothing is said about the important questions of altitude, exposure to wind, situation near the sea or inland, and latitude, all important factors influencing the choice of species and the formation of new plantations. The "Black Poplar" (*Populus nigra*) is correctly drawn; but in the description it is confused with the "Black Italian Poplar" (*Populus serotina*), the fast-growing hybrid tree, which should always be planted in preference to the former, when timber is required.

Such statements as (p. 64) that the lime is not indigenous, and names like *Tilia magnifolia*, show that the author is not well acquainted with forest botany. The two native birches are distinguished by drawings, but nothing is said of their very different soil-requirements.

OUR BOOKSHELF.

Practical Stone Quarrying: a Manual for Managers, Inspectors, and Owners of Quarries, and for Students. By A. Greenwell and Dr. J. Vincent Elsden. Pp. xx + 564. (London: Crosby Lockwood and Son. 1913.) Price 12*s*. 6*d*. net.

WHEN our hard-headed forbears were roving Piltdown, the art of the quarryman could scarcely have been in its infancy; yet we have far to travel in the mazes of the past if we must find its beginnings, and the work of some of the early masters of the craft still remains to excite our wonder. From the nature of the material ancient methods were very like our own, and probably differed mainly in speed.

Old though the art may be we are still in doubt as to what a quarry is; most likely the ancient quarryman was not troubled with this question, but now, what with Acts of Parliament, judicial embellishments, and the sanction of custom, it has become impossible to define "quarry." The authors of this volume have made a brave effort to clear up the confusion; it is very interesting, but scarcely successful. They have had almost as much difficulty with "stone"; however, by including some "mines" among the quarries and omitting to take account of some materials which would come under their own definition of stone, they have succeeded in producing an eminently satisfactory book on the subject, one for which there was a real need.

After an adequate discussion of the occurrence of stone, the distribution of quarries in the United Kingdom, and divisional planes in rocks, there follows some excellent advice on the location of quarries and their proper development, a subject of the greatest importance.

A large amount of space is devoted to methods of extraction, tools, blasting, cableways, and haulage systems. The table, p. 300, giving the amounts of different explosives used in the United Kingdom, would have been more valuable if the explosives had been classified according to the kind of rock and the uses of the stone.

A short chapter treats of the preparation of stone for the market, another with the dangers of quarrying, and the book concludes with some remarks on quarry legislation which may be commended to the notice of those in authority. The volume is very well illustrated, and there is a fair index.

The Microtomist's Vade-Mecum. A Handbook of the Methods of Microscopic Anatomy. By A. B. Lee. Seventh edition. Pp. x + 526. (London: J. and A. Churchill, 1913.) Price 15*s*. net.

WE gladly welcome the new edition of this work which has become indispensable in all laboratories of biology. The general plan and the size of the book remain unaltered, but the author has managed by judicious "pruning," and some exclusion of out-of-date matter, to introduce much new matter, more than seven hundred additonal entries appearing in the index.

Goldmann's *intra-vitam* staining methods, and improvements in the silver fibril stains of Bielschowsky and Ramón y Cajal are detailed. Gibson's new mounting media, which dispense with the use of clearing agents, and confer on unstained or feebly stained objects just the required degree of visibility, are described. The sections relating to the blood and blood parasites have been rewritten. Not the least useful part of the contents are the full references given to the literature of the subject. Those who have worked with former editions will find that the present one maintains in all respects the high standard of its predecessors. R. T. H.

Astronomy Simplified. By Rev. Alex. C. Henderson. (London: James Clarke and Co., 1913.)

THE object of this book is, as the author states, "to extend a knowledge of the sublimest of the sciences," and he intentionally reminds the reader many times throughout the pages that while man is striving to find out the laws which govern the behaviour of matter in space, there is a greater

Power who not only created the laws, but formed matter and space.

The book consists of three chapters, covering seventy-five pages, followed by a series of subsidiary chapters, which are termed notes, which extend another seventy-one pages. The three chapters deal with general information about the sun, moon, and stars, diurnal motions of the heavenly bodies and comets. The treatment is quite elementary, clear, and brief, and the information accurate. The notes, which are twenty-six in number, treat of a miscellaneous set of subjects relating to astronomy, and may be considered in some cases as brief essays. The headings of some of these notes are as follows:—Auroræ, magnetic storms, sun-spots, and prominences; seven methods of obtaining accurate time; eclipses; proofs of the earth's rotundity, &c.

The book is neatly produced, contains numerous illustrations, and will no doubt serve a useful purpose in drawing youthful minds to the subject of astronomy.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Philosophy of Vitalism.

I think that I voice the feelings of all London zoologists when I say how grateful we all are both to the Zoological Board of the University of London and to the governing body of King's College for the opportunity which they have afforded us of hearing the new philosophy of vitalism so brilliantly expounded by Prof. Hans Driesch.

Perhaps you would spare me a little space if I try to set forth some reasons why Prof. Driesch's conceptions do not appear to me to be of much service in assisting the progress of zoology.

At the outset, one or two preliminary remarks may be made. The question whether for any consistent system of philosophy, or attempt to explain the universe, an idealistic attitude must be adopted, and the question whether at the present juncture idealistic conceptions ought to be imported into zoological science are two entirely different things.

The task of zoologists is not to explain the universe; it is the much humbler one of endeavouring to compare together zoological phenomena and to ascertain the rules governing them. All "explanation" is merely comparison; we endeavour so far as we can to express the more complex phenomena in terms of the simpler, and so to find uniformity and order beneath an apparent welter of unconnected details.

Now Prof. Driesch offers us an "entelechy," *i.e.* a non-material, non-mechanical "*arranging*" power, a rudimentary "psychoid" which knows its purpose and uses the materials at its disposal in order to effect that purpose. Does the conception of entelechy help us to collate zoological facts or not?

It was invented to account for the remarkable fact that when the first two blastomeres of the egg of a sea-urchin are separated from one another each will give rise to a perfect larva of diminished size. Driesch argued that since in normal circumstances one of these blastomeres would have given rise to half a larva, therefore when it is separated from its fellow some innate power must be at hand to rearrange the materials of the blastomere so as to give rise to a whole larva. But if the conception of an entelechy will cut the Gordian knot of this difficulty, there are a great many cases where the facts seem to be totally inconsistent with the existence of an entelechy.

If the tail of a lizard be broken off a little bud is formed at the injured surface, from which in due time a new tail is developed. But if this bud be slightly indented by a prick from a knife *two* tails and not one are developed from the bud.

What is the entelechy doing in this case? Is its purpose altered, and has it decided to use the materials to make two tails? Are we not justified in saying that if an entelechy was invented to explain why one blastomere of a sea-urchin's egg forms a whole larva, it must be rejected because it utterly fails to explain why the injured bud on a lizard's tail makes two tails?

Again, if, when the egg of a frog has divided into two blastomeres it be tightly clipped between two glass slides in order to prevent its rotating, and if the whole preparation be inverted, then there will often result a ghastly two-headed tadpole. Why does the entelechy allow its purpose to be upset by so small a thing as the inversion of the egg? Is this not a much less violent change than cutting the egg in two? Instances of this kind might be multiplied indefinitely, and they show that at the best the conception of an entelechy is of quite limited application. There is another conception which is far more helpful in binding together phenomena, and that is the idea of "organ-forming substance." In the egg of Cynthia, an Ascidean, the development of which has been worked out by Conklin, these organ-forming substances can be seen in the living egg. This case was not alluded to by Prof. Driesch, as it is one which is almost impossible to reconcile with his theory. In the egg of Cynthia there is a yellow substance in the outer layer of the protoplasm. This collects round the entering spermatozoon when the egg is fertilised, and eventually forms a crescent in one quadrant of the egg. As development proceeds it is relegated to certain cells in the segmenting egg, and is eventually used up in forming the longitudinal muscles of the tail of the Ascidean tadpole. Now it is possible to kill the cells containing this substance on one or both sides of the segmenting egg. If the cells on one side be killed then there results a larva devoid of muscles on one side of its tail.

Now if we assume that normal development depends on the juxtaposition of certain organ-forming substances in certain spatial relations to one another, then when the two-cell stage of the egg of a frog is inverted these substances can partially or totally rearrange themselves, not under the influence of an entelechy, but under the influence of gravity. So also in the regenerating lizard's tail, the spatial relations of the organ-forming materials with respect to one another are altered by the indentation produced by the knife, and so two tails and not one develop.

Whence do these organ-forming substances come? The development of the egg of Cynthia teaches us that they arise from the nucleus of the ripe egg, and that they are definitely arranged (in some cases at least) under the influence of the spermatozoon. The ectoderm-forming substance of the egg of Cynthia is contained in the nuclear sap of the unripe egg and is emitted when the nuclear membrane breaks down. "But," Driesch will reply, "I have shown that the nuclei of a segmenting egg can be displaced from their normal positions without altering the result." Granted. When once fertilisation has been effected and the arrangement of materials in the cytoplasm fixed, the nuclei which result from the division of the zygote nucleus enter on a period of inactivity so far as influence on the cytoplasm is concerned. But this inactivity does not last for ever, for though the Cynthia tadpole is incapable of regenerating anything, that same tadpole metamorphosed into an adult Ascidian will regenerate any part that is cut off—even its head. In the same way Roux showed that when one blastomere of a frog's egg is killed the surviving blastomere will give rise to half a tadpole; but that half-tadpole, if it lives, will *post-generate* the missing half, and this belated regeneration is accompanied by a migration of nuclei into the injured half.

It may be objected that it is difficult to imagine what kind of chemical composition an "organ-forming substance" possesses. This is true; it may be difficult to compare it with chemical substances found in dead matter, but our knowledge of the possible complications of organic substance in living matter is as yet small. This at least may be said, the active agent in development and regeneration can be displaced from its original position, and can be divided into two, and such attributes are much more easily connected in our minds with a substance than with a non-material entity, which, Prof. Driesch assures us, is not in space.

The Piltdown Skull and Brain Cast.

IN suggesting that a reconstruction of the Piltdown skull, made by the use of casts of the actual fragments, is not trustworthy (NATURE, October 30, p. 267), Prof. Elliot Smith does Dr. Smith Woodward and Mr. F. O. Barlow less than justice. The casts now in circulation are most accurate representations of the originals, and reflect the greatest credit on the modeller, Mr. Barlow. Anatomists have had no difficulty in gaining the freest access to the actual specimens; even those who, like myself, regard the original reconstruction of the skull and brain cast as fundamentally erroneous, have had every privilege granted to them on repeated visits to see the Piltdown fragments in Dr. Smith Woodward's keeping. A reconstruction made from casts is then just as trustworthy as one made from the original fragments.

You have already (NATURE, October 16, p. 197) permitted me, by the use of a diagram, to demonstrate the errors in the original reconstruction; I also availed myself of that opportunity to show diagrammatically the only reconstruction which gives an approximate symmetry to the right and left sides of the head, and, at the same time, places the parts in their proper anatomical positions. It is clear, from his letter (NATURE, October 30, p. 267) that Prof. Elliot Smith knows of another method, one which fulfils the same conditions, but gives a much smaller brain-capacity. All that is necessary to convince me that he is right and I am wrong is a drawing of that reconstruction: one comparable with the drawings in my previous letter. I have articulated the fragments in the manner suggested in his letter, and find that the degree of asymmetry in his suggested reconstruction is as great as in the original. It is possible that I have misinterpreted some of the indications given in his letter. Any error of this kind would be cleared up by a drawing.

Pianoforte Touch.

PRESSURE of other work has prevented me from replying earlier to Prof. Pickering's letter in NATURE for July 31. It is, of course, difficult to express any definite opinion about an experiment without fuller knowledge of the circumstances than can be acquired from a mere written description; at the same time it appears to me very easy to suggest explanations for the failure of the experiment. To strike the same note a hundred times in succession is certainly a very severe test to impose on a person's powers of discrimination. In this connection it would be interesting to perform, for the sake of comparison, one hundred tests of a totally different character, say the well-known tests of blindfolding a person and making him taste tea and coffee, according to a prearranged succession. It would be giving the hearer a fairer chance if the experiment were performed by playing over a short sequence of notes, say a simple melody a number of times in succession. I have always performed the test in this manner, and it has generally been successful.

Then, again, there is evidently a certain knack about producing these touch effects, and though one may try to strike a note sometimes in a pressing or caressing manner, and sometimes sharply, it is quite easy to fail to produce the desired effects, especially if the note is struck by the fingers. The best results I have been able to get in this way have usually been produced by holding the wrists high above the keyboard for a brilliant tone and right below the keyboard (so as almost to pull the keys down) for a soft tone. In producing the same effects with a pneumatic player, variation of the load on the regulating bellows by means of my sliding weight or some equivalent method produces sufficient differences, but the action of the feet in pedalling has so much effect on the touch that even here it is easy to fail, especially in experimenting where the performer consciously attempts to produce a particular effect and thinks of what he is doing. In the course of playing a composition the touch control is easier, as the necessary movements of the hands and feet are performed unconsciously, the performer only being conscious of the effect produced and not thinking of why or how he moves his levers and pedals to produce that effect.

Another point which has been overlooked in this discussion is that different makes of piano respond in very different degrees to small differences of touch. I recently tested a number of different pianos, and found that the make which I always use was by far the most sensitive, while one of the least sensitive was similar to the piano used by our local musical society, thus accounting for the comparative harshness of some of the professional performances compared with my pneumatic effects.

It is, of course, necessary to distinguish carefully between variations in quality of individual notes and variations in the quality of *chords*. The possibility of producing the latter variations in the pneumatic player is proved beyond doubt, and, to my mind, it is very largely the failure of either the instrument or the performer to produce a pleasing balance between the various components of a chord that renders the playing so mechanical and uninteresting. The usual effect is to produce with soft playing a heavy bass drowning a dull treble, and with loud playing a shrill treble drowning a weak bass. This effect is probably due to a large extent to the action of the regulating bellows, which in the ordinary players are controlled by springs. In playing a chord a number of different striking hammers of unequal mass have to be set in motion by means of the air pressure, or rather tension, acting on the "playing pneumatics" or small bellows which operate the fingers, and the duration of the impulse necessary to produce the maximum effect is greater for the bass than the treble hammers. Now the regulating bellows are in a continual state of vibration, producing rapid fluctuations of tension every time a note is played. If these fluctuations synchronise with the impulses required to produce the maximum effect in a particular part of the scale, it is evident that the corresponding part of the chord will predominate. Now, in playing softly the regulating bellows are only slightly compressed, and they open and shut slowly; in playing loudly they are much more highly compressed, and they collapse and open sharply. Thus the unpleasing want of balance in the quality of chords is easily accounted for. This difficulty I get over by varying the load on the regulating bellows, and also the inertia by means of a sliding weight, as well as by controlling its vibrations by hand. I have seen a patent in which it is sought to control the regulating bellows by enclosing it in an air chamber in which the tension can be varied by means of valves, and attempts have also been made to vary the tension in a spring controlling the bellows; but this can only be done by compressing the spring by a corresponding amount, and the time required to produce this compression appears to be too long to render the method efficacious.

The usual method of concealing this want of balance is to operate the two halves of the keyboard with separate controls. This system produces effects which are pleasing at first, but are very artificial and limited in character, and a person who is accustomed to this method of "faking" his chords is scarcely likely ever to learn how to balance their different parts with due regard to the effects required. Possibly this explanation may clear up some of the obscure points in my descriptions referred to by Prof. Morton. At the same time, I have heard professional pianists of considerable reputation whose range of control did not extend beyond that obtainable by damping down the halves of the keyboard or accenting notes by means of punch-holes.

Prof. Pickering's references to the sustaining pedal or lever are calculated to suggest the inference that Prof. Pickering may not have had much experience in manipulating his piano-player. If he finds it necessary to listen for each note before he knows when to operate his sustaining lever it would appear that he has not yet learnt *to play each note at the exact instant that he wishes it played,* and in this case it is not easy to see how it would be possible to play accompaniments in which it is necessary to listen to and keep in time with the soloist. Personally, I have always considered that the sustaining lever played a far more important part in pneumatic playing than in hand playing, one reason being that the necessary movements can be regulated with much greater rapidity and precision by hand than by foot. The right hand operating the speed regulator fixes the exact instant at which each note is going to be played, the left hand operates the sustaining levers and other controls at the correct predetermined instant. Probably, as Prof. Pickering says, an experienced pianist can also work hand and foot together, and I have known one musician who could operate the sustaining pedal of the piano three times in succession in holding down a single chord. This would be quite easy with a piano-player, and I certainly often use the lever twice if not three times in playing a chord. But it must be much more difficult to do the same in playing with fingers, and with the majority of amateurs the main use of the loud pedal appears to be to compensate for the loss of resonance caused by boxing up the piano and covering it with rugs, vases, and photograph frames.

The slight sound of suction through the air-holes is, of course, an inevitable defect, but one soon ceases to notice it. As regards "thud," well, fingers as well as pneumatics sometimes produce this.

G. H. Bryan.

The Light Energy Required to Produce the Photographic Latent Image.

The amount of light energy required to produce a latent image on a modern high-speed photographic plate is known to be extremely small. The energy per silver grain may be roughly calculated without difficulty, and the calculation leads to some interesting conclusions regarding the nature of the latent image.

Consider an exposure sufficient to produce a deposit of unit density, that is, one which will transmit but one-tenth of the incident light. A negative has unit density when the silver deposit is 10 milligrams per square decimetre, or 0·1 mg. per sq. cm. (Sheppard and Mees, "Investigations of the Theory of the Photographic Process," p. 41). This amount of silver represents roughly 10^{12} molecules, or 10^7 grains 3 μ in diameter. Now the amount of light energy required to produce an exposure giving unit density is of the order of 10^7 watt-sec (erg) per sq. cm., and therefore 10^{-11} erg per grain, or 10^{-26} erg per molecule. The probable uncertainty in these values is not greater than a factor of 10.

The effect of the light on the plate is to permit the chemical reduction of silver halide to metallic silver with an additional expenditure of energy less than that required to reduce the unexposed silver bromide. Development we know to proceed by whole-grain units, hence we reason that one molecule in a grain (10^{12} molecules) is so affected by exposure that the whole grain is developable.

The simplest assumption to be made is that one electron per grain is detached from one molecule; such a liberation would require (Davis, *Phys. Rev.*, xx., p. 145, and others) 5×10^{-12} erg, or less (*Astroph. Journ.*, xxi., p. 404), a quantity consistent with that calculated above from the known exposure and mass of silver. Hence the hypothesis is reasonable that the latent image consists of halide salt in each grain of which one electron has been liberated by exposure to light.

An Aural Illusion.

Mr. Alliston refers in Nature of September 18 (p. 61) to a certain aural illusion, and wonders if anyone has thought of it before.

Two or three years ago, in a letter to *Knowledge*, I commented on the fact that if a flash of lightning 2 or 3 miles long happened to occur "head on" to an observer, the result of the flash travelling so far quicker than the sound would be that he would hear first the thunder caused by the part of the flash nearest to him, which arose last, and then in succession the earlier sounds, until finally he would hear the opening crash, like a phonographic record reversed. Sometimes I have noticed that a thunder peal ends up with a sudden and more violent crash, and I wonder if this is owing to the explosion which begins a peal of thunder being louder and more abrupt than the after noise

Cape Town, October 10.

NATURAL HISTORY AND TRAVEL.[1]

THE latest addition to Messrs. Witherby's well got-up series of volumes on the life-histories of British birds, four of which, dealing with the golden eagle, the osprey, the spoonbill, the stork, and some herons, have already been issued, is quite equal to its predecessors as a contribution to ornithology. The four species of terns (1) are its subject-matter; and the author, Mr Bickerton, is to be congratulated for the excellence of his photographs showing the eggs, the young and adult birds, and the nesting-sites, as well as for the time and labour devoted to securing them, and to compiling the voluminous notes embodied in the text. To the ordinary reader the text is naturally somewhat tedious on account of its prolixity and repetitions, unavoidably due to the similarity in mode of life of the species described; and the value of the volume would have been increased by the addition of a short chapter summarising the results, and pointing out briefly the differences in habit between the several species. This is the only criticism, however, we have to offer of an admirable and painstaking piece of work; and we trust Mr. Bickerton will be able to find the leisure to observe and record the habits of other groups of British birds in a similar way.

"The Charm of the Hills" (2) is mainly a collection of reprints of articles already published in various periodicals, such as the *Scotsman* and *Country Life*. The book is divided into two parts, chapters i. to xxxi. being a miscellaneous series of disconnected chapters dealing mostly with certain aspects of bird-life in the Scotch highlands, while the second part, entitled, "The Year on the Hills," also devoted mainly to birds, recounts observations upon their habits in the Cairngorm mountains in spring, summer, autumn, and winter. Mr. Seton Gordon is an enthusiastic and trustworthy field-naturalist, and while he writes feelingly and well about his own personal experiences, his book contains a great deal that is interesting and instructive to those for whom wild life in the mountains has a fascination.

"The Flowing Road" (3) is full of facts of interest both to the naturalist and the geographer. It is an account of five expeditions, mostly by canoe, along the rivers and streams of the northern countries of South America. Two of these were undertaken with the object of visiting a native people in the south-eastern corner of Venezuela, reported to be savage and unknown. The others, however, as the author tells us, were instigated "neither by a wish to hunt the beasts of the jungle . . . nor to report on the social or industrial conditions of the land, nor even to add to the sum of knowledge of the 'scientific' world—but solely to satisfy the hunger which incites me every now and again to go and 'see things'—the curiosity which Prof. Shale has called the primal instinct." Despite this modest disclaimer, nevertheless Mr. Whitney's narrative, setting forth the true nature of the areas traversed, and of the inhabitants found there, is a really valuable contribution to many branches of knowledge; because there are certainly few districts in the world lying beyond the beaten tracks of travel less accurately known than those drained by the Amazon and the Orinoco and their tributaries, and probably none, according to the author's experience, which have been so frequently and persistently misrepresented in printed accounts inspired by self-interest or based on the superficial observations of casual tourists.

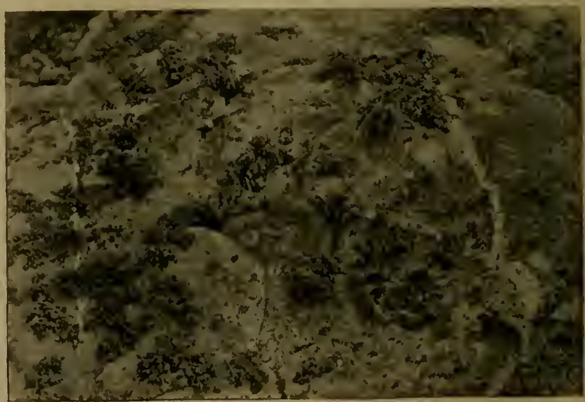

FIG. 1.—The Arctic tern—admirably protected by the surroundings on which it has settled. From "The Home life of the Terns or Sea Swallows," by W. Bickerton.

Those who have heard Mr. Dugmore lecture would expect him to write entertainingly and well about the habits and characteristics of the animals with which he has had personal experience; and those who have read his "Camera Adventures in the African Wilds," will find "Wild Life and the Camera" (4) equally readable and trustworthy, although widely different in its subject-matter, which is confined to North American species.

The greater number of the chapters are given

[1] (1) "The Home-life of the Terns or Sea Swallows." Photographed and Described by W. Bickerton. Pp. 88+xxxii mounted plates. (London: Witherby and Co., 1912.) Price 6*s*. net.
(2) "The Charm of the Hills." By S. Gordon. Pp. xiv+248. (London: Cassell and Co., Ltd., 1912.) Price 10*s*. 6*d*. net.
(3) "The Flowing Road." Adventuring on the Great Rivers of South America. By C. Whitney. Pp. 319. (London: W. Heinemann, 1912.) Price 12*s*. 6*d*. net.
(4) "Wild Life and the Camera." By A. R. Dugmore. Pp. xi+332. (London: W. Heinemann, 1912.) Price 6*s*. net.
(5) "The Feet of the Furtive." By C. G. D. Roberts. Pp. 277. (London: Ward, Lock, and Co., Ltd., 1912.) Price 6*s*.
(6) "Insect Workers." By W. J. Claxton. Pp. xii+62. (London: Cassell and Co., Ltd., 1912.) Price 1*s*. net.
(7) "Letters from Nature's Workshop." By W. J. Claxton. Pp. 192. (London: G. G. Harrap and Co., 1912.) Price 1*s*. 6*d*. net.

up to birds; but there is much to interest anglers in those devoted to salmon- and trout-fishing. Mammals are in a minority; but perhaps the chapter describing caribou migration in Newfoundland is the most valuable in the book from the naturalist's point of view. A few chapters containing instructions and hints on bird and mammal photography, and on camping out, will be most helpful to those who wish to follow in Mr. Dugmore's steps and attempt to do what he has done under similar physical conditions.

"The Feet of the Furtive" (5) contains several well-written stories of a kind much in vogue at the present time, wherein the author weaves interesting facts in natural history into an attractive fabric of fiction. The habits of familiar North American mammals are the theme Mr. Roberts presents so cleverly in this guise; but while giving full play to his imagination and to his powers of linguistic expression, he never oversteps the bounds of probability, and carefully avoids that pitfall authors too frequently dig for themselves and their readers, by attempting to humanise the species whose mode of life they wish to portray. Many of the stories recall others that have already been published by American authors; but there is a distinct air of novelty about the one called "The World of Ghost Lights," which gives a vivid picture of one aspect of life in the ocean depths.

In his little book for children, called "Insect Workers" (6), Mr. Claxton tells once again the story of the burying beetle, trapdoor spider, ants and aphides, wasps, and other common and familiar species of articulated animals the industries of which never fail to appeal to the imagination of children and to arouse their interest in creatures they are mostly taught by their elders to fear and destroy.

The purpose of awakening and fostering a taste for nature-study also underlies "Lessons from Nature's Workshop" (7), by the same author. This book, however, is rather more pretentious in scope than the last, and is written for readers of maturer mind, many of the chapters being devoted to more or less abstract questions in natural history, such as the struggle for existence in plants, assimilative coloration, scenery, and so forth.

R. I. P.

FIG. 2.—The Newfoundland caribou in migration. Going at a quick walk, or swinging trot, or at times a gallop, they usually travel in single file along the well-worn leads or paths that have been used for centuries. In nearly all cases a doe leads the herd. From "Wild Life and the Camera."

PROF. NOGUCHI'S RESEARCHES ON INFECTIVE DISEASES.

THE Royal Society of Medicine mostly limits the record of its work to its own Proceedings and the medical journals; and it does well to observe this wise rule. But from time to time it receives some communication of the highest importance to the general welfare, and on such occasions it is mindful of its immediate duty to the public. It lately held a special meeting, at which Prof. Noguchi, of the Rockefeller Institute, demonstrated the results of his researches into syphilis, general paralysis of the insane, epidemic infantile paralysis, and rabies. None who heard Prof. Noguchi and saw the great crowd of physicians and surgeons listening to him could fail to recognise the profound significance of this occasion.

No man of science works alone or in isolation: and a vast amount of cooperative work is being done in diverse parts of the world on what may be called the "higher types" of germs. Let us note the development of the work. Let us go back half a century, to the earliest methods of Pasteur. We may take 1855 as an approximate date for the beginning of the founding of "the germ-theory." For many years the only method which Pasteur had for the growth of germs in pure culture was the use of fluid media, such as broth; and, under the conditions of bacteriology fifty years ago, the use of these fluid media was full of difficulties. He had to wait until 1872 for the discovery that germs could be grown on solid media, such as gelatine or slices of potato. He had to wait until 1875 for the discovery that germs could be stained with aniline dyes so as to distinguish them, under the microscope, from their surroundings.

Pasteur lived until 1895—that is, ten years after the first use of his protective treatment against rabies, and two years after the first use in practice of diphtheria antitoxin—but he did not live to see more than the beginning of the study of the higher types of germs. At the time when he died, many of the lower types—the bacilli and the micrococci—had been discovered, isolated, grown in pure culture on solid media, and proven, by the inoculation of test animals, to be the very cause of this or that infective disease. But the higher types, such as the *plasmodium* of malaria, were still waiting to be worked out. Then, after Pasteur's death, came Ross's fine work on malaria; and then came two discoveries of no less importance—the discovery (Schaudinn, Hoffmann) of *Spirochaeta pallida* in cases of syphilis, and the discovery (Forde, Dutton) of *Trypanosoma gambiense* in a case of sleeping sickness. These two discoveries brought syphilis and sleeping sickness, at last, within the range of practical bacteriology. Long ago, Moxon had said of syphilis that it was "a fever cooled and slowed by time"; but the cause of that fever was unknown until the *Spirochaeta pallida* was discovered.

But to prove that it does not merely accompany, but actually causes the disease, it had to be grown in pure culture, and inoculated into test animals, producing in them some characteristic sign. Syphilis must be studied as diphtheria, tetanus, typhoid fever, and tubercle had been studied. That is the meaning of all the work done by Ehrlich and his school upon salvarsan—that, in particles of tissue from a rabbit in which the disease has been produced, the *Spirochaeta pallida* is present, under the microscope, before a dose of salvarsan, and is absent after it.

The work has been of immeasurable complexity, and there is much still to be done. There are many species of spirochætes discoverable in this or that condition of bodily life, besides *Spirochaeta pallida*; indeed, Prof. Noguchi demonstrated seven species. But he has cleared the way in this field of bacteriology. He has distinguished those which need some air for their growth from those which cannot grow in air; he has discovered the method of adding a fragment of sterilised animal substance to each tube of pure culture: and these methods are of great value.

But that is not all. For he has detected *Spirochaeta pallida* in the brain, in general paralysis of the insane. He has found it in twelve out of seventy specimens. There is no need to underline the importance of that statement.

Also, Prof. Noguchi has obtained in pure culture the germs of anterior polio-myelitis (epidemic infantile paralysis). Of all the many diseases of childhood in which the art of medicine, apart from its science, is of no great use, few are more unkind than infantile paralysis. It is the Rockefeller Institute that we must thank here. First came Flexner's magnificent work on epidemic cerebrospinal meningitis, and his discovery (1908) of the special antitoxin for that disease; then came the study of epidemic infantile paralysis. To have in one's hands, in a test-tube, infantile paralysis, is a grand experience for a man who has attended a children's Hospital, year in year out, long before the Rockefeller Institute was born or thought of. It is enough to make him believe that the doctors some years hence may be able to stop the disease before it can inflict irremediable injury on the nerve cells of the spinal cord.

Finally, Prof. Noguchi spoke of rabies (hydrophobia). He has been able to obtain, in pure culture, the microscopic bodies which Negri discovered in the brain in that disease. He demonstrated to the Royal Society of Medicine, on the lantern-screen, photographs showing the cycle—not unlike that of the *plasmodium malariae*—through which these bodies pass until, like miniature shrapnell, they break, setting free their constituent granules; and each granule becomes a "Negri body," and starts the cycle again. Happily, the protective treatment against rabies did not have to wait for the discovery of these Negri bodies. Pasteur worked at rabies, as Reed and Lazear worked at yellow fever, knowing that the virus was there, and able to control, fight, and beat it, without seeing it under the microscope.

The Royal Society of Medicine deserves the thanks of the public for inviting Prof. Noguchi to give this demonstration in London. He is indeed, in width and originality of work, equal to his fellow-countryman, Prof. Kitasato. He has helped to make it possible for men of science to extend to other diseases those methods of study which brought about the discovery of diphtheria antitoxin, and the protective treatments against cholera, typhoid fever, and plague.

STEPHEN PAGET.

EDWARD NETTLESHIP, F.R.S.

Mr. E. Nettleship, whose death on October 30 we have to deplore, was well known to the public as a distinguished ophthalmic surgeon, and to men of science as an enthusiastic worker on the subject of heredity. He was one of the six sons of Henry John Nettleship, solicitor, of Kettering. Three of his brothers became noted. The eldest, Henry, held the Corpus professorship of Latin at Oxford with great distinction. The second, John Trivett, was well known for his accurate and realistic pictures of wild animals, and was the author of the first serious study of Browning. The youngest, Richard Lewis, was a Fellow of Balliol College, Oxford.

Edward Nettleship was born in 1845, and after a preliminary education at Kettering became a student of the Royal Agricultural College at Cirencester, and of the Royal Veterinary College. Though he qualified as a veterinary surgeon, he soon relinquished that branch, and studied at King's College and the London Hospital Medical Schools, taking the Fellowship of the Royal College of Surgeons of England in 1870. He specialised in ophthalmic surgery at a time when most ophthalmic surgeons still practised general surgery. He was appointed surgeon to the South London Eye Hospital, but his real life-work was carried out at St. Thomas's Hospital and the Moorfields Eye Hospital.

At St. Thomas's Hospital that remarkable personality, Liebreich, who still lives an artistic life in Paris, had laid the foundation of an ophthalmic clinic. Nettleship continued his work, and brought it to a state of perfection previously unequalled in England. At Moorfields he had been assistant to the late Sir Jonathan Hutchinson, where he rivalled his teacher and life-long friend in his enthusiasm for clinical work, and in his abounding inquisitiveness into the mysteries of eye diseases.

Papers full of acute observation and accurately authenticated facts came rapidly and continuously from Nettleship's pen. He thus built up a reputation which ranks with that of the greatest ophthalmic clinicians of the past—Mackenzie of Glasgow, von Graefe of Berlin, and Sir William Bowman of London, the founders of modern clinical ophthalmology. His magnetic personality attracted many of the best students to his side, and he thus founded a tradition for careful observation and accuracy of detail which is being carried on by his successors. He did not suffer fools gladly, and his somewhat brusque manner towards them kept his little band select, whilst it unfortunately aroused some enmity in those who had not the opportunity of testing intimately his sterling character and warm friendliness. He built up a very large private practice, one of his most distinguished patients being Mr. Gladstone, on whom he operated successfully for cataract.

About fifteen years ago Nettleship retired from practice and settled down in his country house at Hindhead. It was not a retirement to ease and luxury, but merely a deviation into scientific work little less laborious than his earlier work. He devoted himself especially to the study of heredity, and his painstaking and illuminating researches in this subject require no other testimonial than that they were rewarded by the Fellowship of the Royal Society in 1912.

These are his greatest works, but he was full of lively interest in all that pertained to ophthalmology. Much of his time and energy was given up to colour-vision, and he did most valuable service as a member of the departmental committee of the Board of Trade on sight tests for the mercantile marine.

Mr. Nettleship was somewhat reserved, and only those who gained his confidence and learnt to know him well succeeded in penetrating to the fires of friendship which glowed within him. He has passed away, leaving behind him a record of work which lives and will continue to live.

J. Herbert Parsons.

NOTES.

At the meeting of the Royal Society of Edinburgh, held on November 3, 1913, the following were elected honorary fellows:—Prof. Horace Lamb, F.R.S., professor of mathematics in the University of Manchester; Sir W. T. Thiselton-Dyer, K.C.M.G., F.R.S., formerly director of the Royal Botanic Gardens, Kew; Dr. G. E. Hale, director of the Mount Wilson Solar Observatory (Carnegie Institution of Washington); Prof. Emil C. Jungfleisch, Mem.Inst.Fr., professor of organic chemistry in the College of France, Paris; Prof. S. Ramón y Cajal, professor of histology and pathological anatomy in the University of Madrid; Prof. V. Volterra, professor of mathematics and physics in the University of Rome; Prof. C. R. Zeiller, Mem.Inst.Fr., professor of plant palæontology in the National Superior School of Mines, Paris.

The Physical Society's Annual Exhibition will be held on Tuesday, December 16, at the Imperial College of Science, and will be open both in the afternoon and evening.

Announcement is made from Paris that Prof. Charles Richet, professor of physiology in the University of Paris, and member of the Academy of Medicine, has been awarded the Nobel Prize for science.

The eighty-eighth Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Prof. H. H. Turner, F.R.S., his title being "A Voyage in Space."

The brain of the late Prince Katsura, which, according to his wishes, has been removed to the Imperial University Museum in Tokio, was found to weigh 1600 grams—the same as that of Kant.

The death is reported, in his seventy-ninth year, of Dr. P. R. Uhler, an American entomologist and geologist of repute. For three years he was an assistant to Prof. Louis Agassiz, at Harvard, and afterward explored parts of the island of Hayti for him. Since

1862 he had been officially connected with the Peabody Institute, Baltimore. Dr. Uhler was the author of many contributions to scientific journals, and his collection of locusts, presented several years ago to the U.S. Government, was considered one of the best ever made.

THE death is announced, at sixty-seven years of age, of Dr. H. F. Parsons, formerly of the Medical Department of the Local Government Board. An obituary notice in *The Times* reminds us that Dr. Parsons served on many Departmental Committees, including those on water, gas, regulations as to cremation, the work of the Geological Survey, and the medical inspection and feeding of children in public elementary schools. He contributed papers to the Transactions of the Epidemiological Society, of which he became president, and to those of other scientific bodies. He was a fellow of the Geological Society, and among his works were memoranda on the sanitary requirements of cemeteries, disinfection by heat, a report on the influenza epidemic of 1899–90, and an examination of the comparative mortality of English districts.

THE jubilee of the practical realisation of the ammonia-soda process by the chemist, Ernest Solvay, was recently celebrated in Brussels, and was marked by munificent gifts of five million francs for scientific purposes by the veteran inventor, who on the same occasion celebrated his seventy-fifth birthday. The Institute of Applied Chemistry of the faculty of sciences at Paris received 500,000 francs, and the same sum was allotted to the University of Nancy to create a chair of electrotechnics. A fund of 500,000 francs was also put aside for a quadrennial prize to be awarded by the International Congress of Hygiene for researches in transmissible disease. On the occasion of the jubilee, M. Solvay delivered an enthusiastic eulogy of pure science and its results, and made the interesting avowal that the pursuit of science was the *rêve doré de toute sa vie,* and had it not been for the necessity of providing for a family he would probably have taken it up as his profession. On the occasion of this jubilee King Albert honoured M. Solvay by naming him a grand officer of the Order of Leopold.

IMPORTANT proposals for another British Antarctic Expedition, to start next year, are made public by a letter to the Press from Sir Clements Markham, and by Mr. J. F. Stackhouse, who is to lead the expedition. The completion of work in the McMurdo Sound region by the expeditions under Shackleton and Scott directs attention elsewhere in the British section of Antarctica, and Sir Clements Markham regards as one of the next most important problems the investigation of the connection between King Edward VII. Land and Graham Land. It is proposed by Mr. Stackhouse to begin his work at the eastern or Graham Land end of the British quadrant, and to follow the coast, hoping to prove or disprove its continuity, and thus to solve a leading question regarding the physiography of Antarctica in outline. The scheme depends largely upon the incidence of an open season, when the ice-pack leaves a passage along the coast; Scott himself held the chances of such an opportunity to be good. Financial support is invited, and headquarters for the expedition have been established at Sardinia House, Kingsway, W.C.

THE National Council of Public Morals has established a private commission to inquire into the extent and character of the decline in the birth-rate, its causes, its effects, and its economic and national aspects. This commission is both a strong and representative one, and the fact that Dr. Stevenson, the Superintendent of Statistics for the Registrar-General, and Dr. Newsholme, Medical Officer to the Local Government Board, have joined it gives one confidence that it will be able to obtain and use in an effective manner the best statistical data available to anyone. It will be remembered that these two authorities published in 1906 a paper on the decline in human fertility, which attracted considerable attention. The commission is also to be congratulated on obtaining as members several well-known lady doctors, including Dr. Mary Scharlieb and Dr. Ettie Sayer, who through their professional work have had special opportunity for studying fertility and its absence from the woman's point of view. Economic science, medicine, law, and journalism are all well represented, and the biological aspects of the questions to be discussed will not be forgotten with Mr. Walter Heape to stand for this branch of science. As might perhaps have been expected, the clerical element somewhat predominates. Bishop Boyd-Carpenter is the chairman of the commission, and the Rev. James Marchant the secretary, and there is besides a galaxy of bishops, deans, and well-known preachers. Among these we are glad to find the Dean of St. Paul's, whose sane and broad-minded treatment of such subjects as eugenics has done so much to focus the attention of serious people on them.

The Falmouth Packet of September 17 contains an account of the recent visit of the surveying ship *Carnegie,* of the Carnegie Institution of Washington, in charge of Capt. W. J. Peters. This is the second visit paid by the vessel to Falmouth for the purpose of magnetic observations, the first having been paid four years ago. From Falmouth the *Carnegie* left for New York, whence she set out in June, 1910. The cruise has extended over a large part of the world, calls having been made at, amongst other places, Rio de Janeiro, Cape Town, Colombo, Mauritius, Manila, Fiji, Falkland Islands, and St. Helena. Its geographical position and the presence of a magnetic observatory have in the past rendered Falmouth a specially favourable port for linking up observations on the Atlantic with land observations in western Europe. The discontinuance of magnetic work at Falmouth has been so recent that its usefulness as a base has scarcely as yet been impaired, but in future years unfortunately greater uncertainty will prevail as to the secular change there of the magnetic elements.

THE opening meeting of the Institution of Electrical Engineers for the present session will be held on November 13, when the premiums awarded for papers read or published during the session 1912–13 will be presented, and an address on pressure rises will be given by Mr. W. Duddell, F.R.S., the president of the institution. In the list of papers to be read at meetings during the first half of the session we notice one by Mr. H. R. Speyer on the development of electric power for industrial purposes in India. The papers in preparation for the second half of the session are to deal largely with electric traction, and great prominence is to be given to the general question of the electrification of railways. The fifth Kelvin lecture is to be delivered by Sir Oliver Lodge on January 22, 1914. Much of the good work accomplished by the institution is done by the local sections, which meet regularly. The local branches which have been inaugurated up to the present are the Birmingham, Dublin, Manchester, Newcastle, Scottish, Western, and Yorkshire Sections. The Newcastle Section sometimes meets at Newcastle, and sometimes at Middlesbrough; the Scottish alternately at Glasgow and Edinburgh; the Western alternately at Bristol and Cardiff, and the Yorkshire Section at Leeds.

THE Natal Sugar Growers' Association has for some time past been in communcation with the Durban Technical Institute with the view of establishing a sugar school, the aim of which would be to prepare young men for the technical control and investigation of the manufacture of cane-sugar. The original scheme was to establish three lectureships—in chemistry, bacteriology, and entomology respectively. These, together with the lectureships already in existence, would supply a good technical training. The three specialists appointed would also conduct research in connection with the processes of manufacture and growth of cane-sugar. A wide field is open in this direction. There are problems in the sugar-house awaiting solution which are of great interest in themselves, and the solution of which will be of prime importance to the sugar industry, as something like 20 per cent. of the available sugar is at present lost. In this field it is hoped that the specialists will do pioneer work. Two lecturers—one in the chemistry and one in the bacteriology of cane-sugar—are soon to be appointed, the appointments in the first instance to be for three years at a salary of 400*l.* per annum in each case. Applications should be sent to Mr. B. M. Narbeth, principal of the Durban Technical Institute, Durban, Natal.

GUSTAF ISAK KOLTHOFF, who died on October 26, in his sixty-eighth year, had considerable reputation as a scientific hunter and as a pioneer in the realistic methods of exhibiting natural groups of animals in Museums. His chief monument is the large cyclorama at Stockholm, known as the Biological Museum, in which, with the assistance of the Swedish artist, Bruno Liljefors, he has presented the Swedish vertebrate fauna under the successive conditions of spring, summer, autumn, and winter. A small, but perhaps more genuinely instructive example of his work in this direction is the Biological Museum at the University of Upsala, in which University he was appointed zoological curator so long ago as 1878. In addition to these and to the museum which, about 1865, he created in the boys' school at Skara, near his own home, Kolthoff was responsible for the installation of six other collections of Swedish mammals and birds in various places in Sweden. He was without scientific training of the academic kind, and picked up the technique of his profession while still a youth in the workshops of the State Zoological Museum. By his own study, however, he became a skilled practical ornithologist and entomologist, and in that capacity accompanied Baron A. E. Nordenskjöld's expeditions to Greenland in 1883 and 1887. He also joined Prof. A. G. Nathorst on his voyages to Beeren Island, Spitsbergen, and King Karl's Land. In 1890 he himself led an expedition to Spitsbergen and north-east Greenland. In addition to many popular accounts of his travels, he was responsible, together with Dr. L. Jägerskiöld, for a work entitled "Birds of the North," which appeared during the years 1895 to 1899. In 1907, at the Linnean festival, he received from the University of Upsala the honorary degree of doctor of philosophy.

IN the Transactions of the Hull Scientific Field Naturalists' Club (vol. iv., Part 5), Mr. T. Sheppard describes the excavation of an Anglo-Saxon cemetery at Hornsea, the objects obtained having been deposited in the Hull Museum. Some of the corpses were buried in the crouched position, which seems to be a not unusual feature in Anglo-Saxon interments in east Yorkshire. Among the "finds" is a series of bronze brooches, similar to examples found in Norway, with very naturalistic representations of horse heads. A bell formed of very thin metal is, from comparison with an example from Papcastle, Cumberland, now in the British Museum, assigned to the Roman period. The "food vases" found are interesting because they are unlike the typical Anglo-Saxon cinerary urns, being quite plain, without any trace of ornamentation, and very similar to ordinary domestic utensils. They evidently contained food when placed with the burials.

IN the October number of *Science Progress* Mr. A. G. Thacker contributes an interesting article on the significance of the Piltdown discovery. The era of *Homo sapiens*, he states, should include the Aurignacian epoch and all that comes after; before that epoch we are among kindred but unfamiliar creatures. He suggests, therefore, that the Aurignacian and three subsequent ages should be classed as Deutolithic, and the previous epochs grouped as Protolithic. A discussion follows of the possible relationships of *Pithecanthropus erectus*, the Java ape-man; *Homo heidelbergensis*, the Heidelberg man; *Eoanthropus dawsoni*, the Piltdown woman; *Homo neandertalensis* or *Homo primigenius*, the Neanderthal man of Acheulian and Mousterian times; and *Homo sapiens*, garrulous man. "The power of speech was a crying need of the advancing primates . . . it was language that transformed the horde into the tribe. The creatures were probably widely dispersed on the earth, whilst they were yet speechless . . . rudimentary powers of speech may thus have been acquired independently by more than one species; and this, not blood-relationship, may have been the explanation of the man-like symphysis of the Heidelberg jaw." On this hypothesis the common ancestor is conceived as possessing a simian mandibular symphysis, a massive jaw, large teeth, and probably a low forehead. From this ancestor the Heidelberg and Piltdown types may have come along diverging branches; the former leading up to Neanderthal man, the latter to *H. sapiens*. The author is strongly inclined to think that both the apes and Pithecanthropus have a low forehead, not because they are degenerate, but because they are immediately descended from monkeys. And even in its more plausible application to Neanderthal man, he views the degeneracy theory with considerable suspicion.

UNTIL quite recently holothurians (sea-cucumbers) were known from the older rocks merely by their hard spicules and plates, which were long ago identified in the Scottish Carboniferous. From certain very fine-grained Middle Cambrian beds in British Columbia there have, however, been obtained impressions of soft-bodied organisms which Dr. C. H. Walcott (Smithson. Miscell. Collect., vol. lvii., No. 3) identified as holothurians, under the generic names of Eldonia, Loggania, Louisella, and Mackenzia. But his determination was not suffered to pass without criticism, and in *Science* of February 16, 1912, Dr. Lyman Clark expressed very strong doubts as to whether any of these genera are really holothurian, stating confidently that Eldonia is not. These criticisms are discussed in the August number of *The American Naturalist* by Mr. Austin Clark, who arrives at the conclusion that, with the exception of Mackenzia, which is regarded as a zoantharian, the original identification is correct, two of the genera being assigned to the existing deep-sea family Elpidiidæ, while the third (Eldonia) represents an allied pelagic family. In bodily form the last-named type recalls a medusa, but the resemblance may probably be regarded as a parallel adaptation to a free-swimming existence.

IN the October number of *Bedrock*, Prof. Poulton replies to Prof. Punnett's criticism of the theory of mimicry in the July number of the same review. After pointing out that de Vries himself holds that small variations may be inherited and selected, he brings instances to show that such transmission does actually occur. The case of *Acraea alciope* is adduced as demonstrating that an incipient mimetic feature may arise as an occasional variation in one part of the area inhabited by a given species, which feature may be further developed in distinctness, and in the relative number of individuals possessing it, in the presence of a distasteful model occupying another part of the range of the mimicking species. These facts, it is contended, support the conclusion that "the mimetic pattern was attained by steps and not suddenly." A more elaborate instance is afforded by *Papilio polytes*, with its two mimetic females. Here, apparently, the pigments of mimic and model have different genetic antecedents. By a detailed analysis of the patterns of the forms in question, and by a comparison of their numerical relation with the non-mimetic form in regions where the respective models are present, rare, or absent, Prof. Poulton arrives at the conclusion that these forms have been derived from the ancestral condition by gradual stages, and that his opponent is not justified in the statement that natural selection is non-existent in so far as concerns the comparative numbers of the mimetic and non-mimetic females of this species.

The Scientific American for October 18 contains an article on earthquakes and the Panama Canal, by Mr. D. F. MacDonald, geologist to the Isthmian Canal Commission. The recent occurrence of two earthquakes in the Isthmian zone has directed attention to a subject that might be of considerable importance with regard to the safety of the canal works. Mr. MacDonald, however, concludes that little danger is to be feared from earthquake disturbances (see NATURE, vol. xcii., p. 174), and he gives two main reasons for his view. The first is connected with the geological structure of the isthmus. Though numerous small faults along the course traversed show that readjustments of the crust have taken place in times past, the district is one from which high mountains and all evidences of recent displacement are alike absent. Again, though a large number of tremors are recorded every month by the Bosch-Omori seismograph at Ancon, the isthmus is entirely free from serious earthquakes. The seismic record of the isthmus dates from the Spanish conquest, and during more than three centuries there have been only two earthquakes of any consequence. One in 1621 destroyed many buildings in Panama, while another in 1882 damaged several buildings and bridges, and in places threw the railway track out of alignment. But neither of these shocks, it is probable, would have damaged seriously even the most delicate parts of the canal.

To *Symons's Meteorological Magazine* for October Mr. R. C. Mossman contributes an article on correlations at St. Helena, the fifth of these interesting investigations. The results are not considered as conclusive, but some suggestive resemblances and contrasts have been disclosed. During the years 1893–1903 there was an undoubted relation between the rainfall in the vicinity of Fort William from January to March, and the mean temperature at St. Helena for the months May to August following, but from 1904–11 the correlation breaks down. A relation could also be traced between the mean temperature at St. Helena during January to April and the mean barometric pressure at Punta Arenas (Magellan Straits) during the four months following, but during the last six years (1906–11) the results, for reasons given, were not very conclusive. With respect to temperature at St. Helena and rainfall at Mexico City, the curves pursued the same course from 1892 to 1898, while from 1899 to 1909 they were the reverse of each other. It will probably be remembered that Dr. W. N. Shaw pointed out (NATURE, December 21, 1905, "The Pulse of the Atmospheric Circulation") an apparent connection between the seasonal variation of wind-force at St. Helena and the rainfall in the south of England.

Vol. x. of "Contributions from the Jefferson Physical Laboratory of Harvard University" consists of reprints of eleven papers on physical subjects which appeared during 1912 in the Proceedings of the American Academy, *The Philosophical Magazine, The Astrophysical Journal,* and our own columns. The researches described have been aided by the Rumford fund of the American Academy, the Bache fund of the National Academy, and the Thomas Jefferson Coolidge fund of the University. More than half the volume is occupied by the researches of Dr. P. W. Bridgman on the thermodynamic properties of liquids at high pressures. To this work, which takes its place as one of the classics in this field, we have directed our readers' attention, as it has been published. Other important papers are those by Profs. Pierce and Evans showing that carborundum crystals possess electrostatic capacity owing to the alternation of insulating and conducting strata within them, by Profs. Kennelly and Pierce, showing how the motion of the diaphragms of telephone receivers affect the impedances of the instruments, and by Prof. Peirce on the maximum magnetisation in iron, to which we referred in our issue for July 24. From this list of first-class work it will be seen that Harvard is not one of those universities which overlooks its duty of increasing knowledge in its anxiety to impart knowledge and test it by examination.

The enzymic activity of the sap of a number of vegetables such as cabbage, onions, ginger, and radishes has been investigated by T. Tadokoro, and the results published in a contribution to the Journal of the College of Agriculture, Tohoku University, vol. v., part 2. The capacity of the sap to induce certain enzymic changes appears to vary widely with the plant, peptolytic action being more pronounced in the case of onions and ginger than in the other six plants studied. Diastase was detected in every case with the exception of onions, and urease was present in ginger and yam-roots, although not to any great extent. Catalase and oxydase action was obtained with each sap, but the power to hydrolyse amygdalin and salicin was confined to that of the yam and cabbages.

At a meeting of the Institute of Chemistry on October 29, the first of two lectures was delivered by Mr. W. P. Dreaper on the research chemist in the works, with special reference to the textile industry. The total gross value in 1907 of the textile materials and fabrics manufactured in the United Kingdom amounted to 333,000,000*l.*, and 1,253,000 persons were employed in their manipulation. On a basis of one chemist for every 2000 persons employed, no fewer than 600 chemists should be utilised in this industry alone, each of whom would deal with an annual gross output valued at more than 500,000*l.* One large aniline dye combine on the Continent already employs 700 chemists. The lecturer insisted that the industrial chemist who remains in his laboratory is lost. Knowledge of chemistry alone is an insufficient equipment; modern research requires a knowledge of physics and the power to apply it. The work of the textile chemist was considered in detail, and specially illustrated by reference to the developments in mercerising and schreinering. The chemist working under industrial conditions at once realises the success achieved by the "rule-of-thumb" man in the past; by systematically studying his methods and seeking to discover points he has not fully realised the chemist may often be able to improve upon them. The nature of the methods and machinery used for producing artificial fibres, and more recently artificial fabrics were reviewed. In conclusion the lecturer dealt with the influence of theory and the chemist's work on actual industrial operations.

Messrs. A. Gallenkamp and Co.'s new catalogue (section 1, part iii.), recently issued, deals mainly with the requirements of engineering chemistry. Fuel calorimeters of all descriptions are dealt with very fully, a special feature being a full description of the method of using each of the better known types of instrument. Gas calorimeters are also well represented, including two self-recording types. Five types of CO_2 recorders are illustrated, including all the instruments in common use, and this is supplemented by apparatus for draught measurement and flue gas analysis. The section dealing with oil testing includes viscosimeters, both the flow and friction types, flash-point and distillation apparatus. Apparatus for iron and steel analysis includes an electric tube furnace, apparatus for the determination of carbon by the wet combustion process, and for the estimation of arsenic, phosphorus, and sulphur. The last quarter of the catalogue is devoted to pyrometers; this includes instruments of every type. The principles utilised in the various instruments and their mode of use are briefly but accurately summarised.

We learn from *The Builder* for October 31 that the Liverpool Corporation has held recently a competition for a sanatorium of phthisis patients. This is one of the first municipal sanatoriums to be tackled by the architectural profession, and it was extraordinary to note the great diversity of planning shown by the thirty-one sets of designs submitted. Tuberculosis sanatorium planning is as yet in its infancy, and this fact accounts for these differences in treatment. It is probable that we shall not arrive at anything like a standard type until several have been built and their actual working arrangements tested. The first premium was awarded to Messrs. T. R. and V. Hooper, of Redhill. In their design, nearly all the blocks are isolated, with the exception of the actual wards; these are combined into one long wing. The children's wards are separate, and comprise practically a small self-contained sanatorium; this block is particularly good, and forms a one-storey bungalow. There is a good deal to be said in favour of aiming at a cheerful collegiate-like character in such a building, rather than going on the lines of the regular and somewhat dreary infirmary type, and this is perhaps the best feature in favour of Messrs. Hooper's design.

Three new volumes in Messrs. T. C. and E. C. Jack's compact little series, "The People's Books," have recently reached us; and they merit a word or two of description in addition to the announcement of their publication, in our weekly list of books received. Mr. E. W. Maunder contributes a popular account of astrophysics in a volume having the title, "Sir William Huggins and Spectroscopic Astronomy." Dr. W. D. Henderson has written a volume on "Biology," in which he gives in language as free from technicalities as possible, a broad account of the main facts of the science of life; and Mr. J. Arthur Hill writes with dignity and philosophic power upon the subject of "Spiritualism and Psychical Research." Each volume contains about 96 pp., and is published at the price of 6*d.* net.

OUR ASTRONOMICAL COLUMN.

Comet News.—The latest comet discovered, namely 1913*e*, (Zinner), has been identified as a return of 1900 III. (Giacobini), so that it has made two revolutions since its original discovery, the period being 6·435 years. Being of about the tenth magnitude and its declination a large southerly one, namely, greater than 19°, it is not a favourable object for observers in high northern latitudes. An ephemeris extending to November 14 is given in *Astronomische Nachrichten*, No. 4690.

Herr T. Banachiewicz, as *Astronomische Nachrichten*, No. 4689, states, reported a light change in comet 1913*c* (Neujmin) on October 6, while on October 8 the comet could no longer be seen. Dr. Graff also looked for the comet in vain.

Writing to the *Astronomische Nachrichten*, No. 4690, on September 11, Prof. Barnard describes an unusual appearance of this comet on September 9. He at first thought that a small star was involved in the north preceding side of the comet, but further observation indicated that the star was travelling with the comet; in fact, it was the nucleus. Using the 40-in. and a power of 460 the nucleus was still stellar, but with 700 it became ill-defined and not so readily taken for a star. He concludes in the following words:—"The nucleus was estimated to be 11·5 magnitude. It was so clear cut and distinctly star-like that one would not for a moment have suspected any real connection with the faint nebulosity apparently attached to it south following. I have not before seen such a striking case of a comet being essentially all nucleus."

Comet 1913*d* (Westphal) does not gain in brightness, as was anticipated, in spite of its distance from the sun being reduced. The following is a continuation of the ephemeris printed in *Astronomische Nachrichten*, No. 4687:—

12*h.* *M.T.* *Berlin.*

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
Nov. 6	20 35 17	+27 27·5	8·6
7	34 46	28 2·0	
8	34 18	28 36·1	
9	33 54	29 9·9	8·6
10	33 32	29 43·4	
11	33 14	30 16·7	
12	33 0	30 49·8	
13	20 32 48	+31 22·6	8·7

According to Miss S. M. Levy, of Berkeley, California, the above ephemeris reads about 23 seconds too great in R.A., and about 3·4′ too small in declination for November 13. During the current week the comet passes from Vulpecula into Cygnus, and is in a good position for observation.

Spectra Obtained by Means of the Tube-arc.—Another important spectroscopic research has just been published by Prof. A. S. King (Contributions from the Mount Wilson Solar Observatory, No. 73), who has been studying the relation of the arc and spark lines by means of a tube-arc. In this paper he presents in some detail the leading features of the spectrum of this form of arc, and by a comparison with other sources he infers the probable character of the radiation involved. The results discussed and finely illustrated are based on fifty plates taken with instruments of different degrees of dispersion. This paper follows the one described in this journal in July last (Vol. xci., p. 541), and the main results of the inquiry may be briefly summarised as follows:—In the study of the tube-arc spectrum a region near the centre of the tube's cross-section was found to give the hydrogen spectrum and the enhanced lines of metals most strongly, with some variation among different elements as to how rapidly their enhanced lines diminish in intensity towards the wall. The arc lines of two groups of elements, represented by iron and calcium, show different degrees of response to the conditions most favourable for enhanced lines. The arc lines of titanium and vanadium differ from those of the other elements studied, as they show their greatest strength close to the wall. On the question of dissymmetry of lines produced in the central part of the tube, the dissymmetry is usually towards the red, but some lines show little or no effect. In the cases of λ4481 (Mg.) and λ4267 (C.) the dissymmetry is explained by the observation that both these lines are double. Tests on the ionisation of the vapour and on its conductivity compared to that of the tube material, together with the spectroscopic phenomena of the tube arc, indicate that the effects may largely be due to the impact of electrons emitted by the highly heated carbon, the resultant effect of these impacts becoming stronger near the centre of the tube.

Kodaikanal Prominence Observations and Discussions.—Two bulletins, Nos. 31 and 33, of the Kodaikanal Observatory, have come to hand dealing with the routine observations of prominences and a discussion of past data. No. 31, by the director, Mr. J. Evershed, is confined to the summary of prominence observations for the first half of the present year. Compared with the previous six months the mean frequency remained practically unaltered, while the mean height slightly increased, and the mean extent somewhat diminished. The eastern limb showed a slight preponderance in numbers and areas over the western. Only five metallic prominences were observed. Other observations recorded include the displacements of the hydrogen lines, prominences projected on the disc as absorption markings, &c.

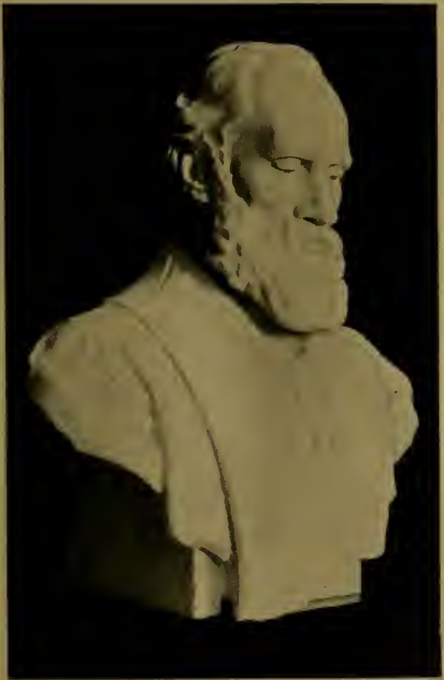
Bulletin No. 33 is written by the assistant-director, Mr. T. Royds, and deals with prominence periodicities, the investigation being a construction of the periodograms of prominences in the same way as Schuster investigated the sun-spot data. Mr. Royds confined the Kodaikanal data to the years 1905–1912, and determined the mean daily areas by dividing the total prominence areas for each month by the effective number of days of observation in each month. The prominence periodogram finally obtained displayed the presence of three periods of large intensity, two nearly homogeneous, of $6\frac{1}{3}$ and $7\frac{1}{2}$ months, and the third, provisionally fixed at $13\frac{1}{3}$ months, the highest of the band. The mean daily frequencies for each month from the year 1881 to 1912, deduced from observations at Palermo and Catania, were similarly analysed, as a check, and they indicate distinct peaks at the same points as the Kodaikanal curve. The amplitudes of these short periods in terms of a percentage of the average of mean daily areas are given as follows:—

Period	$13\frac{1}{3}$ months.	Percentage	13·6
"	$7\frac{1}{2}$ "	"	9·1
"	$6\frac{1}{3}$ "	"	10·1

Mr. Royds concludes by adding that other independent prominence data which are sufficiently complete and continuous are, however, highly desirable in order to establish firmly the reality of these periods.

PRESENTATION OF BUST OF LORD KELVIN.

At the general statutory meeting of the Royal Society of Edinburgh, held on October 27, a marble bust of the late Lord Kelvin, by Mr. A. M'Farlane Shannan, which had been given by Lady Kelvin



Marble bust of Lord Kelvin.

to the society, was formally presented and received. Sir William Turner, the retiring president, occupied the chair, and there was a large and representative gathering of the fellows and the general public. Prof. Crum Brown made the presentation in the name of Lady Kelvin. After referring to Lady Kelvin's thoughtful kindness in giving this beautiful bust as a permanent possession of the Royal Society of Edinburgh, and to his own lifelong friendship with Lord Kelvin, Prof. Crum Brown referred especially to Lord Kelvin's "supreme love of truth and of his intense interest in everything, however apparently trivial, connected with the constitution or with the working of the physical universe. These were the prime motives to his work, and he carried it out in the same spirit. Having formulated a problem, he followed the straightest course to its solution. Of course, he encountered difficulties; these he did not evade, he surmounted them. To do so he had often to invent and construct special instruments of wholly novel type. . . Lord Kelvin was a great mathematician. He was never at a loss to find the mathematical key. . . . Lord Kelvin was no intellectual miser. When in the course of his scientific work he came across something which could be so applied as to be of practical use, he developed this application, and thus became the inventor of instruments, truly scientific instruments, differing in character from those he made for purely scientific purposes only in this, that they were also used and very highly prized by those who were not necessarily scientific, who perhaps did not care about the dissipation of energy or vortex motion. These practical men, by using Lord Kelvin's inventions, came to see that pure science was not vain; they came to know something of the tree from its fruit. Lord Kelvin was quite free from selfishness or jealousy. He rejoiced in his own work and discoveries; he also rejoiced in the discoveries of others. In questions of first importance to man, where science gave no help, Lord Kelvin was a humble and devout disciple. In Lady Kelvin's name I hand over to the Royal Society of Edinburgh, through you, sir, as president, this beautiful work of art and striking likeness of Lord Kelvin, one of the greatest discoverers in pure science, a true benefactor of mankind, our honoured president and dear friend."

In accepting the bust in the name of the society, Sir William Turner referred more particularly to Lord Kelvin as a fellow of the Royal Society of Edinburgh. He joined the society in 1847, and continued so to be for the remaining sixty years of his life. His early communications were on the theory of heat, and their Transactions contained a valuable record of that brilliant work. Numerous communications followed, and his last paper was communicated in 1906, just a year before his death. This was upon the initiation of deep-sea waves, and, as all knew, the sea and the deep-sea formed important features in his practical career. Lord Kelvin occupied the presidential chair for three different periods, from 1873 to 1878, from 1886 to 1890, and from 1895 to his death in 1907. The second period was only for four years, the council of the society relieving him from the full five years at that time in order that he might be able to accept the invitation of the Royal Society of London to act as their president, an arrangement which was carried out by mutual understanding between the two councils. He asked Prof. Crum Brown to be good enough to convey to Lady Kelvin their most devoted and hearty thanks for that admirable bust of her late husband, which would be one of their precious possessions.

ORNITHOLOGICAL NOTES.

To the *Bull. Soc. Imp. Nat. Moscou* for 1912 Prof. P. P. Suschkin contributes an article of more than 200 pages on the bird-fauna of the Minussinsk district of the Upper Yenisei, the Sahan Mountains, and the Urhanchen country, an area of special interest on account of being the meeting-place of several sections of the Eastern Holarctic fauna. To the north and east, for instance, is the realm of the East Siberian fauna, while on the west we enter the great plain of western Siberia, with a fauna differing but slightly from that of Europe. To the southward is the fauna of Central Asia, and, finally, to the south-west that of Turkestan.

The local distribution of the large number of species of birds found in this vast tract is shown in elaborate tables, which indicate not only the area visited by each, but likewise whether this includes steppe, wooded steppe, or alpine country. The paper should be of great value to students of zoological distribution.

In this connection may be noticed a paper by Mr. T. Iredale in the Transactions of the New Zealand Institute for 1912 (vol. xlv.) on the bird-fauna of the Kermadec Islands, in which stress is laid on the affinity between the birds of New Zealand on one hand, and those of New Caledonia on the other. It is suggested that the Kermadec Islands should be regarded as one province of the Australian region, exhibiting marked Polynesian affinities, Norfolk and Lord Howe Islands as a second, and New Caledonia as a third.

Turning to Australia, reference may be made to a coloured plate in the July number of *The Emu*, illustrating the remarkable variation in shape, size, colour, and marking displayed by the eggs of the piping-crow, or Australian magpie (*Gymnorhina tibicen*), which, it is claimed, exceeds that in any other bird. Nine specimens are figured, each from a different clutch, and each more or less unlike the rest, the variation in colour ranging from greenish-blue to reddish and sandy, and the markings from blackish spots to reddish scribblings. In an accompanying note Mr. A. F. B. Hall states that, unlike those of many sea-birds, all the eggs of any particular clutch are practically similar, and this similarity extends to all the clutches laid by each individual bird. This, it may be added, has an important bearing on the theory of "wagtail-cuckoos," "reed-warbler-cuckoos," &c.

Footprints of the larger species of moas are, it appears, but very rarely found, the two chief, if not only, recorded instances of their discovery having taken place at Turangui, Poverty Bay, in 1871, and on the Manawater River, Palmerston North, in 1894. At the latter locality four other footprints were exposed in 1911 by a flood, which washed away a bank 15 ft. high, revealing at its base a bed of clay containing four prints. These are described and figured by Mr. K. Wilson in the aforesaid volume of the Transactions of the New Zealand Institute. The tracks measure 18 in. across the foot, 12 in. from point of middle toe to heel, and 30 in. from heel to heel. Plaster casts have been taken.

In the first number of vol. ii. of *The Austral Avian Record* Mr. J. B. Cleland directs attention to abnormal coloration in the palate and pharynx of certain Australian birds, the variation taking the form of black and grey tints in some groups, and of yellow or orange in others. No suggestion as to the reason for this departure from the normal flesh-colour is suggested.

The autumn number (vol. v., No. 7) of *Bird Notes and News* is illustrated by a reproduction in black and white of an exquisite painting by Mr. H. Grönvold of the white heron, or egret, with the legend, "Where are my companions? Save me." The issue includes a chronological sketch of the movement against the plumage trade, from its rise in 1869 to the present day, with the text of the Government Plumage Bill. Reference is also made to the protection of birds at lighthouses, the slaughter of swallows in France, and bird-catching in this country.

In the October number of *British Birds*, Mr. H. F. Witherby records the results of a series of careful observations made by himself with the object of ascertaining the cause of the baldness of the area round the base of the beak in adult rooks. The investigation also included the moults undergone by the plumage generally. In rooks of the year the area which is bare in their parents is fully feathered; but Mr. Witherby records that a number of hair-like "filoplumes" grow amid the narial bristles, and that larger filoplumes, as well as down-like plumules, are hidden among the contour-feathers of the chin and throat. In the first—July and August—moult the feathers are renewed all over the head in the normal manner, although those on the area which eventually becomes bare are of a somewhat abnormal type. In the following January, however, or somewhat later, the feathers of this area are gradually shed, and not replaced—although most of the filoplumes and plumules persist—while the feather-papillæ undergo an abnormal development into curious pin-like growths over the now permanently bare area. R. L.

THE SYNTHESIS OF GLUCOSIDES BY MEANS OF FERMENTS.

AT the closing session of the eleventh International Congress of Pharmacy, recently held at the Hague, Prof. Emile Bourquelot, of Paris, delivered a lecture on the synthesis of glucosides by means of ferments, in which he described the results of his recent researches on this subject.

Hitherto it has not been proved that enzymes have anything but an analytical action; Prof. Bourquelot, who has been working on the ferments for something like twenty years, has, however, obtained results which justify the conclusion that the decomposing action continues up to a certain point only, and that at this point a synthetic action begins. He gives as an example the action of emulsion on arbutin; one of the products of decomposition is hydroquinone, but the action ceases before the whole of the arbutin is decomposed. This he shows to be due to the presence of the products of decomposition, for when hydroquinone is added to a solution of the enzyme and the glucoside, the decomposing action of the enzyme is greatly retarded.

Having established this fact, Prof. Bourquelot allowed ferments to act upon methyl alcohol in the presence of glucose, and succeeded in forming methylglucoside β. He next dealt with other alcohols, and succeeded in synthesising a series of glucosides, and determined the conditions under which synthesis could be effected. By combining different sugars with the same alcohol, a number of hitherto unknown glucosides was synthesised, and the synthesis of many others is possible.

PHYSICS AT THE BRITISH ASSOCIATION.

THE meetings of Section A of the British Association at Birmingham were of great interest to the general scientific public and of considerable value to those more specially interested in the particular problems discussed and the papers read at the sectional meetings. English physicists, astronomers, and mathematicians attended the meeting in force. Among those who were present may be mentioned Lord Rayleigh, Sir J. J. Thomson, Sir Joseph Larmor, Prof. Rutherford, Prof. Bragg, Prof. Poynting, Prof. Hobson, Prof. H. H. Turner, Sir D. Gill, Dr. Glazebrook, Principal E. H. Griffiths, Prof. Lamb, Prof. Love, Prof. S. P. Thompson, and Mr. J. H. Jeans. A distinguished company of foreigners also attended, amongst whom were Madame Curie, Prof. H. A. Lorentz, Prof. E. Pringsheim, Prof. Arrhenius, Prof. R. W. Wood, and Dr. Bohr. With the president of the association a physicist, and Dr. H. F. Baker as sectional president, the *personnel* of the meeting was of great interest in itself, and in consequence the papers and discussions were of a very high order of excellence.

The address of Sir Oliver Lodge was of special interest, as in it he touched on the main subjects of discussion in the section. The address has been published in full in an earlier number of NATURE, so that there is no need for further remark here. The sectional president's address has also appeared in full in NATURE, and there is similarly no call to deal with it further in this place. It was listened to by a crowded audience, and formed a fitting opening to a meeting that proved itself of great importance, and in which the interest was kept up till the last day.

The address of Dr. Baker, after a vote of thanks proposed by Sir Oliver Lodge and seconded by Lord Rayleigh, was followed by a paper by Prof. Barkla on the nature of X-rays. This subject has practically ceased to be controversial except as it has passed over into the general subject of radiation. Prof. Barkla gave an outline of the evidence in favour of the undulatory theory, of which he has always been a keen exponent, and which is now accepted by all physicists. Sir J. J. Thomson and Prof. Rutherford spoke in the following discussion, the former paying a well-deserved compliment to Prof. Barkla on the large amount of our knowledge of X-rays which is due to him. Prof. Rutherford laid stress on some of the still outstanding difficulties in the subject. The discussion was not so interesting as it would have been a year ago, when the supporters of the corpuscular theory would have been in force. This paper was followed by one from Sir J. J. Thomson on the structure of the atom. This was a brilliant attempt to construct an atom which would account for some of the evidence for the quantum theory of energy. The paper was delivered with the clearness and boldness now always expected from Sir J. J. Thomson, and it will be long before his illustration of the quantum theory by pint-pots is forgotten.

The next paper was by Prof. H. A. Lorentz. Prof. Lorentz is known to all physicists as the leading exponent of all questions involving the interactions of æther and matter. His presence at the Birmingham meeting added greatly to the interest and value of the discussions. His command of English, his extraordinary capacity for exposition, and his quiet humour made his paper and his speeches in discussion one of the most enjoyable features of the proceedings of Section A. The subject of the paper was, "The Relation between Entropy and Probability." The entropy of a body in a certain state is intimately connected with the probability of that state. Boltzmann has deduced the expression of the relation in his well-known formula, in which the entropy is proportional to the logarithm of the probability of the state. Prof Lorentz's paper was to investigate how the probability is to be evaluated. The method of calculation, closely connected with Gibbs's microcosmical ensembles, gives the entropy of Boltzmann's formula as the thermodynamical entropy. On account of the enormous number of molecules contained in a body, Boltzmann's formula has the remarkable property that great changes in the value assigned to the probability have no appreciable effect on the entropy.

A special case considered was that of a monatomic gas. If the number of molecules is n, P the probability $= Cv^n e^{\frac{3n}{2}-1}$. C being a determinate constant factor; hence if we omit the corresponding term in the entropy S, this $= n\frac{R}{N}\log\left(ve^{\frac{3}{2}-\frac{1}{n}}\right)$, which since n is very large $= n\frac{R}{N}\log\left(ve^{\frac{3}{2}}\right)$, an expression which is neither very large nor very small when the mass of the gas is comparable with a gram-molecule. Now it is clear if P be multiplied by n, or even a high power of n, say n^{100}, this produces no appreciable effect on S, for $\log n$ is very small compared with n for large numbers. Boltzmann's formula is therefore insensible to such factors as n^{100} in the value of P. Again, if the n molecules be supposed distributed at random over a volume v, the probability that they all lie in one half of it is $\frac{1}{2^n}$, whereas it is 1 if all possible distributions are considered. The corresponding difference in the entropy is no more than $n\frac{R}{N}\log 2$. The result of this property is that we are to a large extent free in the choice of a value of P. Thus, in order to calculate the entropy, we may as well take the probability of the most probable state of things as the much higher value that is obtained if all possible states are included.

After Prof. Lorentz, another paper on the structure of the atom was read by Prof. Rutherford. The author took the opposite view to that represented by Sir J. J. Thomson's atom. The Rutherford atom consists of a charged nucleus of minute dimensions, in which most of the mass is concentrated. This nucleus is surrounded by a distribution of electrons. The evidence for this structure of atom lies in the large angle scattering of high-speed particles like the α and β particles from radio-active matter. New experiments were described by Prof. Rutherford on the scattering of α particles by the simple gases. It was unfortunate that there was no time for a fuller discussion of the interesting points raised by this paper and that of Sir J. J. Thomson.

The last communication, taken on Thursday, was one by Dr. Swann—who has just left Sheffield for America—on the resistances of thin metallic films. Some of the hitherto unexplained facts in connection with the conductivity of thin films were explained on the hypothesis that the film deposited by the electric discharge does not consist of a continuous and homogeneous distribution of molecules, but of patches or groups of molecules more or less definitely separated from each other. This distribution was taken account of in the paper, and a formula calculated to allow for the resulting alteration in the mean free path of electrons concerned in conduction. The agreement of the theory with experimental results is as close as could be hoped for.

On Friday morning the most important discussion of Section A, if not of the whole meeting, took place. The subject was radiation, and it was opened by Mr. J. H. Jeans in a masterly and concise manner. The discussion turned on the question of the validity of the laws which have hitherto been believed to be the ultimate laws of nature. The problem at its simplest occurs in the case of black body radiation. Mr. Jeans regarded the work of Poincaré as conclusive when starting with the mean energy of each vibration of specified wave-length he deduces the quite definite result that the exchange of energy must take place by finite jumps. This leads directly to the quantum hypothesis which the opener assumed in its entirety. He went on to consider what other phenomena bear witness to its truth. The most important is the photoelectric effect: the energy imparted to an electron appears to be exactly the right amount required by the quantum hypothesis. Mr. Jeans quoted in this connection the recent work of Dr. Bohr, who has arrived at a convincing and brilliant explanation of the laws of spectral series.

Against the quantum theory seem to be arranged most of the well-established results of the undulatory theory of light. The great difficulty is the reconciliation of the two sets of facts. The boldest and simplest attempt lies in abandoning altogether present conceptions of the æther, and relying on some purely descriptive principle, such as relativity. But the attempt at a dynamical explanation should be made, and Mr. Jeans concluded by a suggestion as to the meaning of the Planck constant h. This constant is connected with e, the charge of an electron. We may, perhaps, imagine that the equations of the æther involve e or h as well as the Maxwell terms. These terms may be eliminated in forming the equations for wave propagation for certain cases, and in that event there will be no discrepancy between the quantum theory and the undulatory theory. But where the equations are applied to interactions between matter and æther, the older theory will not apply, and the terms involving h must remain in.

The second speaker was Prof. Lorentz. He accepted the quantum theory, and sought a method of accounting for it. Some kind of discontinuity in the transfer of energy is experimentally proved, but the individual existence of quanta in the æther is impossible. He considered the scheme of transference of energy from matter to resonators and to the æther. The transfer from a resonator to the æther of a quantum can be easily conceived, but it is difficult to understand how the quantum can be transferred back to the resonator from the æther, for once in the æther it becomes distributed indefinitely. Prof. Lorentz suggested that the quanta are necessary in some transference, and that perhaps the solution was to be found in assuming them operative in transferences from matter to the resonator and *vice versa*, and not in the interchange between resonators and the æther. The difficulty in this view is to distinguish clearly the two classes, matter and resonator. Prof. Lorentz was again clear and very interesting. His humour again appeared, as when referring to Sir J. J. Thomson's atom he remarked that "it was highly ingenious—as it could not otherwise be—but the point was, did it represent the truth?"

Prof. Pringsheim followed, and confined his remarks to the experimental bearing of the problems raised. The constants of radiation are not accurately enough known—for example, Stefan's and Planck's constants. He also referred to the question of the radiation from other sources than the black body. Dr. Bohr, of Copenhagen, was the next speaker. His work had been referred to by previous speakers, and he gave a short explanation of his atom. His scheme for the hydrogen atom assumes several stationary states for the atom, and the passage from one state to another involves the yielding of one quantum. Dr. Bohr also emphasised the difficulty of Lorentz's scheme for distinguishing between matter and the radiator. Planck's resonator has all the ordinary properties of matter, and it is difficult to keep up the distinction. Prof. Lorentz intervened to ask how the Bohr atom was mechanically accounted for. Dr. Bohr acknowledged that this part of his theory was not complete, but the quantum theory being accepted, some sort of scheme of the kind suggested was necessary.

Prof. Love represented the older views, and maintained the possibility of explaining facts about radiation without adopting the theory of quanta. He criticised the application of the equi-partition of energy theory, on which part of the quantum theory rests. The evidence for the quantum theory of most weight is the agreement with experiment of Planck's formula for the emissivity of a black body. From the mathematical point of view, there may be many more formulæ which would agree equally well with the experiments. A formula due to A. Korn was dealt with, which gave results over a wide range, showing just about as good agreement with experiment as the Planck formula. In further contention that the resources of ordinary theory are not exhausted, he pointed out that it may be possible to extend the calculation for the emissivity of a thin plate due to Lorentz to other cases. For this calculation no simple analytical expression represents the results over the whole range of wave-lengths, and it may well be that in the general case no simple formula exists which is applicable to all wave-lengths. Planck's formula may, in fact, be nothing more than an empirical formula. Lord Rayleigh spoke next. He did not attempt to discuss the question, but welcomed the discussion. It was interesting to see Lord Rayleigh at the meeting, and references to his historic work on the subject of radiation were made by several of the speakers.

Sir J. Larmor spoke about the theory of the equipartition of energy. In an isolated region of the æther there is no way open for the interchange of energy at all between one type of radiation and another, so that the assumption of "other things being indifferent" is not applicable. The structure of an electron and the mechanism by which it reacts with the æther is totally unknown. In the very intense kinetic phenomena which occur when transferences of energy take place, the energy may not be expressible as a sum of squares, as the equipartition theory requires. A transfer may be even discontinuous. Sir J. Larmor went on to show that equi-partition need not therefore be necessary as regards free radiation, and atomic vibrations which are set up by its agency and must be in equilibrium with it need not come under the equi-partition theory. The new knowledge we have of specific heats at very low temperatures has also led to further speculations and extension of theoretical schemes, but it can be held that there is nothing destructive of older principles of physics. He looked to a reconciliation between the older and newer views from further knowledge of the interactions between free æther and electrons.

Sir J. J. Thomson further discussed the equipartition theory, and was prepared to give it up if it was the cause of all the difficulty. Referring to statistical methods, he recalled De Morgan's saying that if a calculation in probability required more than half a sheet of notepaper, its result should not be received without further independent evidence.

Sir Oliver Lodge spoke also, and pointed out that the ordinary laws could not apply in the interior of an electron or a positive charge, for if they did the charge would fly to pieces because of the mutual repulsion of its parts.

Prof. Lorentz again spoke, and remarked that a theory that explained both the phenomena of specific heat and the absorption spectrum was not to be disposed of on purely mathematical grounds. He emphasised the fact that the Planck constant was there, and that it had some very definite meaning which had to be interpreted.

Dr. S. D. Chalmers gave an account of an atom model which agreed with the results of the quantum theory, and also with the magneton hypothesis. Mr. Jeans closed the discussion with replies to some criticisms, and again pointed out that from the experimental point of view Prof. Lorentz's discrimination of matter and radiators was impossible. No distinction between them could be made.

This discussion went on from ten o'clock to one, and the interest was kept up till the end. It was of great value, as all points of view were represented, and gave a much clearer notion of the trend of thought on this fundamental subject to those who have not been able to follow the literature very carefully. We understand that the discussion is to be published in full in the reports. This will be a valuable addition to the literature of the subject.

Sir Joseph Larmor gave a short account of a paper on lightning and protection from it. He discussed the relation of the field of force near a lightning conductor and the mechanism of the discharge. It was unfortunate that there was only a few minutes for the subject, as there was no discussion, and the views brought forward were of great practical importance. It is to be hoped the paper will appear in full and will have the attention it deserves.

Prof. W. H. Bragg spoke on X-rays and crystals, which was of great interest and importance. The paper was discussed at a special meeting of the section on Tuesday afternoon. It was unfortunate that some of those most interested—Profs. Pope, Barlow, and Armstrong, for example—were unable to be present at the discussion. Prof. Bragg gave an account of the new method of using characteristic Röntgen rays and crystals. With his son, Mr. W. L. Bragg, he had obtained as many as five orders of spectra by reflection at certain planes of the crystals. If in a crystal there are planes specially rich in atoms, these planes, spaced at definite distances, act somewhat in the manner of an echelon grating, and spectra are produced. From the characters of the spectra of different orders—absence, diminished intensity, and so on—the spacing of the planes can be determined, and so we have a new method of determining the arrangement of atoms in crystals. The diamond has been thoroughly examined, and a model of its structure was shown. The method is a singularly beautiful one, and apparently not open to criticism. The method also provides, in the words of Prof. Bragg, a spectroscope for X-rays, and measurements could be made without doubt to an accuracy of 1 part in 1000. For the discussion of the paper Prof. Bragg specially came back to Birmingham and gave further details of the method. Prof. Arrhenius congratulated the authors, and remarked that it was the beginning of a new crystallography. Reference was made to the work of Pope and Barlow, and Prof. Bragg explained that in his view the differences between the structures obtained by the new method and by the old might be reconciled. He made no claim to have contradicted the work resting on the theory of close packing. The paper and discussion were listened to by large audiences, and formed one of the most interesting parts of a successful meeting.

On Friday, after the radiation discussion, the department of mathematics met separately, when two papers on mathematical physics were read. Prof. Eddington spoke on the dynamics of a globular stellar system. The problem attacked is that of the determination of different possible distributions of velocity which correspond to a steady state. In the paper a number of simpler cases are worked out. It is of special interest to find a system in which there is a strong preference for motion to and from the centre (following Prof. Turner's suggestion for explanation of the two star streams). Systems satisfying this kind of motion, and also requiring only a finite density at the centre of the system, have been found. The other paper at this meeting was by Dr. Swann on the expression for the electrical conductivity of a metal deduced from the electron theory.

On Monday the department of general physics held a joint discussion with Section G (engineering) on the investigation of complex stress distribution. This discussion was more on the engineering side than the physical, and will be dealt with in the special article on the proceedings in Section G. The department of cosmical physics met at the same time, and several important papers were contributed. Mr. C. E. St. John, of Mount Wilson Observatory, gave an important account of some late results of solar work at Mount Wilson. He made out a clear connection between the radial velocity of gases in the solar atmosphere and the intensity of the lines which are used in the velocity determinations. That is to say, a connection has been demonstrated between radial velocity and the level in the solar atmosphere. The displacements of Fraunhofer lines in the penumbræ of sun-spots thus is shown to give a means of sounding the solar atmosphere and of assigning relative levels to the sources of the lines. The results obtained clearly open a wide field for further solar research.

Dr. S. Chapman gave an interesting paper on the lunar influence on terrestrial magnetism and its dependence on solar periodicity. On Schuster's theory of the variation of magnetic force Dr. Chapman considered the effect of the lunar tide in the earth's atmosphere. This effect can be detected in the observations. The solar effect is due to the ionisation and conductivity in the upper atmosphere depending on the sun's hour angle. The study of the lunar period is valuable, as it enables us to separate the two effects, periodicity in the atmosphere and periodicity in the conductivity. No apparent relation has been detected between the conductivity and the eleven-year solar cycle. A paper on solar and terrestrial magnetic disturbances was read by the Rev. A. L. Cortie, S.J.

Two interesting papers on meteorology were read—Mr. J. I. Craig on a temperature see-saw between England and Egypt, and on temperature frequency curves by Mr. Gold and Mr. F. J. W. Whipple. There were two papers on seismology: "The Distribution of Earthquakes in Space and Time," by the Rev. H. V. Gill, S.J.; and "Notes on the Construction of Seismometers," by the Rev. W. O'Leary, S.J. A communication of general interest was read by Dr. J. S. Owens, dealing with methods for measuring the amount of atmospheric pollution by suspended matter, such as smoke and dust. Prof. H. H. Turner gave a paper on the Fourier sequence as a substitute for the periodogram. Mr. J. H. Reynolds's communication on arrangements for a reflecting telescope was taken as read. After the joint discussion, the department of general physics met for another important session. Prof. Pringsheim gave his paper on a theory of luminescence and the relation between luminescence and pure temperature radiation. It was interesting to the section to hear in Prof. Pringsheim another distinguished foreign visitor, and one whose name is intimately connected with the experimental results that form the foundation of the new theories of radiation.

The next paper was by Prof. R. W. Wood, of Baltimore, who is well known as one of the most brilliant experimentalists of our day. He described some experiments on resonance spectra under high dispersion. As is expected of Prof. Wood, most interesting and amusing details of experiments were related. The method of removing spider-webs from the long buried tube of the spectrograph by sending "the household pussy cat" through is an original and effective method of attaining the desired end. Amongst the many interesting details of the work, which will be fully described elsewhere, may be mentioned the method of exciting the resonance spectrum of iodine by monochromatic illumination filtered through bromine vapour to supply light of a small enough range of wave-length to include only one line of the iodine spectrum. The paper was full of the kind of experimental perfection that is to be found in so much of Prof. Wood's work.

Prof. S. B. Maclaren gave a paper on a theory of magnets. This paper dealt with some of the difficulties of magnetic theory, and pointed out how an explanation of paramagnetism and diamagnetism may be arrived at. Magnetic induction is explained by means of tensions in the field acting on matter, and the molecular magnetic field is not explained as due to the circulation of electric current sheets. Prof. Coker gave a demonstration of large polarising apparatus for lantern projection. Beautiful pictures result, but the apparatus has been described before, and there is no need for details in this place.

In the middle of the same morning the department of pure mathematics met, when communications were read by Prof. J. C. Fields, Prof. Hilton, Lieut.-Col. Allan Cunningham, Prof. A. C. Dixon, and Mr. M. D. Hersey. A paper by Prof. A. W. Conway was taken as read.

On Tuesday morning there was a joint meeting with Section E (geography), when four papers on geodetic subjects were read. An account of this joint meeting will appear in the article describing the work of the geographical section, which will shortly be published in NATURE. At the same time the department of general physics met and had another series of important papers and discussions. Dr. W. H. Eccles read an account of some experiments on contacts between electrical conductors. The paper explained the absence of a linear relation between current and electromotive force when the current passes across a "loose contact." The behaviour of the contact was explained by purely thermal actions in the matter near the point of contact. The Joule, Peltier, and Thomson effects all play a part.

Prof. Poynting read a paper on the twisting of indiarubber. By means of an exceedingly delicate piece of apparatus he had measured the changes in length and cross section of steel and copper wires under torsion, and had tried the same with indiarubber. Indiarubber showed no observable change in volume when twisted, but a very large increase in length when compared with steel. Sir J. J. Thomson, in discussing the subject, suggested a connection in the behaviour of these materials under magnetic influence.

Two papers—one by Sir J. J. Thomson on X_3 and the evolution of helium, the other by Mr. F. W. Aston on a new elementary constituent of the atmosphere—created great interest. A number of chemists came to hear of this fresh invasion of their territory by Sir J. J. Thomson. The gas X_3, which has been described before, is now considered by Sir J. J. Thomson to be H_3. Evidence was given in the paper which though in detail perhaps not convincing, yet has great cumulative weight. The chemists present were prepared to accept the possibility of an H_3 molecule. As to the evolution of helium, there seems little doubt that it comes from the material bombarded by the kathode rays in the tube. Here there is a divergence between the views recently put forth that such helium results from a transformation of the gas in the discharge tube. In the discussion Sir Oliver Lodge emphasised the importance of these experiments, as in his opinion it was the first case of the artificial production of atomic disintegration. Mr. Aston dealt with an investigation of the existence of an element with atomic weight about 22. Sir J. J. Thomson's positive ray method had detected such an element, and the paper was an account of the partial separation of neon into two gases of approximate atomic weights, 19·9 and 22·1. The method was one of diffusion attested by a change of density. The method of determining the density was by means of a specially constructed quartz balance of small size hung inside the tube containing the gas. By adjustment of the gas pressure the quartz beam could be balanced and the density of the gas determined with great accuracy. The smallness and compactness of the apparatus enabled very small quantities of gases to be dealt with. No physical differences except in density had been discovered between the two gases.

Dr. E. E. Fournier D'Albe gave an account of the minimum quantity of light discoverable by selenium. Very faint illuminations can be detected, and it was suggested that there might be a possibility of direct measurement of the Planck quantum of energy. A paper by Mr. H. B. Keene on the transmission of X-rays through metals was of interest, especially as it was allied to Prof. Bragg's paper on X-rays and crystals. Other papers were by Mr. J. F. Forrest on the electric arc as a standard of light, and by Dr. G. A. Shakespear on the resistance of air to falling spheres and on a method of increasing the sensitiveness of measuring instruments. The method was to throw the image of a Nernst filament lamp from the mirror of any deflected instrument on to a radio-micrometer strip; any change in the direction of the original reflected beam of very small amount results in a large deflection of the radio-micrometer. The method can be repeated, and any increase in sensitiveness obtained except for the difficulty of keeping steady conditions. Mr. J. S. Anderson described a new method of starting mercury lamps. Papers by Mr. W. H. F. Murdoch on a magnetic susceptibility meter, Mr. A. J. Lotka on a new process for enlarging photographs, and Prof. H. Stansfield on the sensitiveness of the human skin as a detector of low-voltage alternating electrostatic fields were taken as read. The discussion on Tuesday afternoon of Prof. Bragg's paper has already been referred to.
